We have developed two baselines inspired by the current lexical/syntactic pattern-based approaches in the literature, which combine speech verbs and hand-crafted rules.

B_{lex} Lexical: cue verb + the longest of the spans before or after it until the sentence boundary.

B_{syn} Syntactic: cue verb + verb syntactic object. B_{syn} is close to the model in de La Clergerie et al. (2011).

Instead of relying on a lexicon of verbs, our baselines use those identified by the verb-cue classifier. As direct quotations are not always explicitly introduced by a cue-verb, we defined a separate baseline with a rule-based approach (B_{rule}) that returns text between quotation marks that has at least 3 tokens, and where the non-stopword and non-proper noun tokens are not all title cased. In our full results we apply each method along with B_{rule} and greedily take the longest predicted spans that do not overlap.

5 Supervised Approaches

We present two supervised approaches to quotation extraction, which operate over the tokens and the phrase-structure parse nodes respectively. Despite the difference in the item being classified, these approaches have some common features:

Lexical: unigram and bigram versions of the token, lemma, and POS tags within a window of 5 tokens either side of the target, all indexed by position.

Sentence: features indicating whether the sentence contains a quotation mark, a NE, a verb-cue, a pronoun, or any combination of these. There is also a sentence length feature.

Dependency: relation with parent, relations with any dependants, as well as versions of these that include the head and dependent tokens.

External knowledge: position-indexed features for whether any of the tokens in the sentence match a known role, organisation, or title. The titles come from a small hand-built list, while the role and organisation lists were built by recursively following the WordNet (Fellbaum, 1998) hyponyms of person and organization respectively.

Other: features for whether the target is within quotation marks, and whether there is a verb-cue near the end of the sentence.

		Strict			Partial		
		P	R	F	P	R	F
PARC	B_{rule}	75	94	83	96	94	95
	Token	97	91	94	98	97	97
SMHC	B_{rule}	87	93	90	98	94	96
	Token	94	90	92	99	97	98

Table 4: PARC and SMHC results on direct quotations. The token based approach is trained and tested on all quotations.

5.1 Token-based Approach

The token-based approach treats quotation extraction as analogous to NE tagging, where there are a sequence of tokens that need to be individually labelled. Each token is given either an I, an O, or a B label, where B denotes the first token in a quotation, I denotes the token is inside a quotation, and O indicates that the token is not part of a quotation. For NE tagging it is common to use a sentence as a single sequence, as NEs do not cross sentence boundaries. This does not work for quotations, as they can cross sentence and even paragraph boundaries. As such, we treat the entire document as a single sequence, which allows the predicted quotations to span both sentence and paragraph bounds.

We use a linear chain Conditional Random Field (CRF)[2] as the learning algorithm, with the common features listed above, as well as the following features:

Verb: features indicating whether the current token is a (possibly indirect) dependent of a verb-cue, and another for whether the token is at the start of a constituent that is a dependent of a verb-cue.

Ancestor: the labels of all constituents that contain the current token in their span, indexed by their depth in the parse tree.

Syntactic: the label, depth, and token span size of the highest constituent where the current token is the left-most token in the constituent, as well as its parent, and whether either of those contains a verb-cue.

Table 5: Results on PARC. [1]*All* reports the results over all quotations (direct, indirect and mixed). For the baselines, this is a combination of the strategy in B_{lex} or B_{syn} with the rules for direct quotations. Constituent$_G$ shows the results for the constituent model using the gold parse.

5.2 Constituent-based Approach

The constituent approach classifies whole phrase structure nodes as either *quotation* or *not a quotation*. Ideally each quotation would match exactly one constituent, however this is not always the case in our data. In cases without an exact match we label every constituent that is a subspan of the quotation as a *quotation* as long as it has a parent that is not a subspan of the quotation. In these cases multiple nodes will be labelled *quotation*, so a post-processing step is introduced that rebuilds quotations by merging predicted spans that are adjacent or overlapping within a sentence. Restricting the merging process this way loses the ability to predict quotations that cover more than a sentence, but without this restriction too many predicted quotations are erroneously merged.

This approach uses a maximum entropy classifier[3] with $L1$ regularisation. In early experiments we found that the constituent-based approach performed poorly when trained on all quotations, so for these experiments the constituent classifier is trained only on indirect and mixed quotations. The classifier uses the common features listed above as well as the following features:

Span: length of the span, features for whether there is a verb or a NE.

Node: the label, number of descendants, number of ancestors, and number of children of the target.

Context: dependency, node, and span features for the parent and siblings of the target.

In addition the lexical features described earlier are applied to both the start and end tokens of the node's span, as well as the highest token in the dependency parse that is within the span.

6 Results

6.1 Direct Quotations

Table 4 shows the results for predicting direct quotations on PARC and SMHC. In both corpora and with both metrics the token-based approach outperforms B_{rule}. Although direct quotations should be trivial to extract, and a simple system that returns the content between quotation marks should be hard to beat, there are two main factors that confound the rule-based system.

The first is the presence of mixed quotations, which is most clearly demonstrated in the difference between the strict precision scores and the partial precision scores for B_{rule}. B_{rule} will find all of the directly-quoted portions of mixed quotes, which do not exactly match a quotation, and so will receive a low precision score with the strict metric. However the partial overlap score will reward these

B_{lex}	52	68	59	87	77	82	77	84	81
B_{syn}	75	59	66	89	66	76	91	80	85
Token	82	67	74	88	84	86	92	86	89
Constituent	77	63	69	91	75	82	91	82	86

Table 6: Results on SMHC. [1]*All* reports the results over all quotations (direct, indirect and mixed). For the baselines, this is a combination of the strategy in B_{lex} or B_{syn} with the rules for direct quotations.

predictions, as they do partially match a quote, so there is a large difference in those scores. Note that the reduced strict score does not occur for the token method, which correctly identifies mixed quotations.

The other main issue is the presence of quotation marks around items such as book titles and scare quotes (i.e. text that is in quotation marks to distance the author from a particular wording or claim). In Section 4.5 we described the methods that we use to avoid scare quotes and titles, which are rule-based and imperfect. While these methods increase the overall F-score of B_{rule}, they do have a negative impact on recall, which is why the recall is lower than might be expected. These results demonstrate that although direct quotations can be accurately extracted with rules, the accuracy will be lower than might be anticipated and the returned spans will include a number of mixed quotations, which will be missing some content.

6.2 Indirect and Mixed Quotations

The token approach was also the most effective method for extracting indirect and mixed quotations as Tables 5 and 6 show. Indirect quotations were extracted with strict F-scores of 59% and 60% and partial F-scores of 76% and 74% in PARC and SMHC respectively, while mixed quotes were found with strict F-scores of 56% and 85% and partial F-scores of 87% and 86%.

Although there is a strong interconnection between syntax and attribution, results for B_{syn} show that merely considering attribution as a syntactic relation (Skadhauge and Hardt, 2005) has a large impact on recall: only a subset of inter-sentential quotations can be effectively matched by verb complement boundaries.

The constituent model yielded lower results than the token one, and in particular it greatly lowered the recall of mixed quotations in both corpora. Since the model heavily relies on syntax, it is particularly affected by errors made by the parser. The conjunction *and* in Example 3 is incorrectly attached by the parser to the cue *said*, leading the classifier to identify two separate spans. In order to verify the impact of incorrect parsing on the model, we ran the constituent model using gold standard parses for PARC. This resulted in an increase in strict P and increased the F-score for mixed quotations to 57%, similarly to the score achieved by the token model. However, it surprisingly negatively affected R for indirect quotations.

(3) Graeme Hugo, said *strong links between Australia's 700,000 ethnic Chinese and China could benefit both countries* ***and*** *were unlikely to pose a threat*.

The tables also report results for the extraction of all quotations, irrespective of their type. For this score, the baseline models for indirect and mixed quotations are combined with B_{rule} for direct quotations.

6.3 Model Comparison

We designed the features for the token and constituent models to be largely similar. This al-

lows us to conclude that the difference in performance between the token and constituent models is largely driven by the class labelling and learning method. Overall, the token-based approach outperformed both the baselines and the constituent method. Qualitatively we found that the token-based approach was making reasonable predictions most of the time, but would often fail when a quotation was attributed to a speaker through a parenthetical clause, as in Example 4.

(4) *Finding lunar ice*, said Tidbinbilla's spokesman, Glen Nagle, *would give a major boost to NASA's hopes of returning humans to the moon by 2020.*

The token-based approach has a reasonable balance of the various label types, and benefits from a decoding step that allows it to make trade-offs between good local decisions and a good overall solution. By comparison, the constituent-based approach has a large class imbalance, as there are many more negative (i.e. not quotation) parse nodes than there are positive, which makes finding a good decision boundary difficult. We experimented with reducing the number of negative nodes to consider, but found that the overall F-score was equivalent or worse, largely driven by a drop in recall. We also found that in many cases the constituent-approach predicted quotes that were too short, or that were only the second half of a conjunction, without the first half being labelled. We expect that these issues would be corrected with the addition of a decoding step, that forces the classifier to make a good global decision.

7 Speaker Attribution

While the focus of this paper is on extracting quotations, we also present results on finding the speaker of each quotation. As discussed in Section 2, quotation attribution has been addressed in the literature before, including some work that includes large-scale data (Elson and McKeown, 2010). However, the large-scale evaluations that exist cover only direct quotations, whereas we present results for direct, indirect, and mixed quotations.

For this evaluation we use four of the methods that were introduced in O'Keefe et al. (2012). The first is a simple rule-based approach (Rule) that returns the entity closest to the speech verb nearest the quotation, or if there is no such speech verb then the entity nearest the end of the quotation. The second method uses a CRF which is able to choose between up to 15 entities that are in the paragraph containing the quotation or any preceding it. The third method (No seq.) is a binary MaxEnt classifier that predicts whether each entity is the speaker or not the speaker, with the entity achieving the highest speaker probability predicted. In O'Keefe et al. (2012) this model achieved the best results on the direct quotations in SMHC, despite not using the sequence features or decoding methods that were available to other models. The final method that we evaluate (Gold) is the approach that uses sequence features that use the gold-standard labels from previous decisions. As noted by O'Keefe et al., this method is not realisable in practise, however we include these results so that we can reassess the claims of O'Keefe et al. when direct, indirect, and mixed quotations are included. For our results to be comparable we use the list of speech verbs that was presented in Elson and McKeown (2010) and used in O'Keefe et al. (2012).

Table 7 shows the accuracy of the two methods on both PARC and SMHC, broken down by the type of the quotation. The first observation that we make about these results in comparison to the O'Keefe et al. results, is that the accuracy is generally lower, even for direct quotations. This discrepancy is caused by differences in our data compared to theirs, notably that the sequence of quotations is altered in ours by the introduction of indirect quotations, and that some of the direct quotations that they evaluated would be considered mixed quotations in our corpora. The rule based method performs particularly poorly on PARC, which is likely caused by the relative scarcity of direct quotations and the fact that it was designed for direct quotations only. Direct quotations are much more frequent in SMHC, so the rules that rely on the sequence of speakers would likely perform relatively better than on PARC.

While the approach using gold-standard sequence features unsurprisingly performed the best, the most straightforward learned model (No seq.), trained without any sequence information, equalled or outperformed the two other non-gold approaches for all quotation types on both corpora. This indicates that the CRF model evaluated here was not able to effec-

Corpus	Method	Dir.	Ind.	Mix.	All
PARC	Rule	70	60	47	62
	CRF	82	68	65	73
	No seq.	85	74	65	77
	Gold	88	79	74	82
SMHC	Rule	89	76	78	84
	CRF	83	72	71	78
	No seq.	91	79	81	87
	Gold	93	81	83	89

Table 7: Speaker attribution accuracy results for both corpora over gold standard quotations.

tively use the sequence information that is present.

8 Conclusion

In this work we have presented the first large-scale experiments on the entire quotation extraction and attribution task: evaluating the extraction and attribution of direct, indirect and mixed quotations over two large news corpora. One of these corpora (SMHC) is a novel contribution of this work, while our results are the first presented for the other corpus (PARC). This work has shown that while rule-based approaches that return the object of a speech verb are indeed effective, they are outperformed by supervised systems that can take advantage of additional evidence. We also show that state-of-the-art quotation attribution methods are less accurate on indirect and mixed quotations than they are on direct quotations.

Future work will include extending these methods to extract all attributions, i.e. beliefs, eventualities, and facts, as well as the source spans. We will also evaluate the effect of adding a decoding step to the constituent approach. This work provides an accurate and complete quotation extraction and attribution system that can be used for a wide range of tasks in information extraction and opinion mining.

Identifying Web Search Query Reformulation using Concept based Matching

Ahmed Hassan
Microsoft Research

hassanam@microsoft.com

Abstract

Web search users frequently modify their queries in hope of receiving better results. This process is referred to as "*Query Reformulation*". Previous research has mainly focused on proposing query reformulations in the form of suggested queries for users. Some research has studied the problem of predicting whether the current query is a reformulation of the previous query or not. However, this work has been limited to bag-of-words models where the main signals being used are word overlap, character level edit distance and word level edit distance. In this work, we show that relying solely on surface level text similarity results in many false positives where queries with different intents yet similar topics are mistakenly predicted as query reformulations. We propose a new representation for Web search queries based on identifying the concepts in queries and show that we can significantly improve query reformulation performance using features of query concepts.

1 Introduction

Web search is a process of querying, learning and reformulating queries to satisfy certain information needs. When a user submits a search query, the search engine attempts to return the best results to that query. Oftentimes, users modify their search queries in hope of getting better results. Typical search users have low tolerance to viewing lowly ranked search results and they prefer to reformulate the query rather than wade through result listings (Jansen and Spink, 2006). Previous studies have also shown that 37% of search queries are reformulations to previous queries (Jansen et al., 2007) and that 52% of users reformulate their queries (Jansen et al., 2005).

Understanding query reformulation behavior and being able to accurately identify reformulation queries have several benefits. One of these benefits is learning from user behavior to better suggest automatic query refinements or query alterations. Another benefit is using query reformulation prediction to identify boundaries between search tasks and hence segmenting user activities into topically coherent units. Also, if we are able to accurately identify query reformulations, then we will be in a better position to evaluate the satisfaction of users with query results. For example, search satisfaction is typically evaluated using clickthrough information by assuming that if a user clicks on a result, and possibly dwells for a certain amount of time, then the user is satisfied. Identifying query reformulation can be very useful for finding cases where the users are not satisfied even after a click on a result that may have seemed relevant given its title and summary but then turned out to be not relevant to the user's information need.

Previous work on query reformulation has either focused on automatic query refinement by the search system, e.g. (Jones et al., 2006; Boldi et al., 2008) or on defining taxonomies for query reformulation strategies, e.g. (Lau and Horvitz, 1999; Anick, 2003). Other work has proposed solutions for the query reformulation prediction problem or for the similar problem of task boundary identification (Radlinski and Joachims, 2005; Jones and Klinkner, 2008). These solutions have adopted the

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1000–1010,
Seattle, Washington, USA, 18-21 October 2013.

bag-of-words approach for representing queries and mostly used features of word overlap or character and word level edit distances. Take the queries "hotels in New York City" and "weather in New York City" as an example. The two queries are very likely to have been issued by a user who is planning to travel to New York City. The two queries have 5 words each, 4 of them are shared by the two queries. Hence, most of the solutions proposed in previous work for this problem will incorrectly assume that the second query is a reformulation of the first due to the high word overlap ratio and the small edit distance. In this work, we propose a method that goes beyond the bag-of-words method by identifying the concepts underlying these queries. In the previous example, we would like our method to realize that in the first query, the user is searching for "hotels" while for in the second query, she is searching for the "weather" in New York City. Hence, despite similar in terms of shared terms, the two queries have different intents and are not reformulations of one another.

To this end, we conducted a study where we collected thousands of consecutive queries and trained judges to label them as either reformulations or not. We then built a classifier to identify query reformulation pairs and showed that the proposed classifier outperforms the state-of-the-art methods on identifying query reformulations. The proposed method significantly reduces false positives (non-reformulation pairs incorrectly classified as reformulation) while achieving high recall and precision.

2 Related Work

There are three areas of work related to the research presented in this paper: (i) query reformulation taxonomies, (ii) automatic query refinement, and (iii) search tasks boundary identification. We cover each of these areas in turn.

2.1 Query Reformulation Taxonomies

Existing research has studied how web search engines can propose reformulations, but has given less attention to how people perform query reformulations. Most of the research on manual query reformulation has focused on building taxonomies of query reformulation. These taxonomies are generally constructed by examining a small set of query logs. Anick (2003) classified a random sample of 100 reformulations by hand into eleven categories. Jensen et al. (2007) identified 6 different kinds of reformulation states (New, Assistance, Content Change, Generalization, Reformulation, and Specialization) and provided heuristics for identifying them. They also used them to predict when a user is most receptive to automatic query suggestions. The same categories were used in several other studies (Guo et al., 2008; Lau and Horvitz, 1999). Huang and Efthimis (2010) proposed another reformulation taxonomy. Their taxonomy was lexical in nature (e.g., word reorder, adding words, removing words, etc.). They also proposed the use of regular expressions to identify them. While studying re-finding behavior, Teevan et al. (2006) constructed a taxonomy of query re-finding by manually examining query logs, and implemented algorithms to identify repeat queries, equal click queries and overlapping click queries. None of this work has built an automatic classifier distinguishing reformulation queries from other queries. Heuristics and regular expressions have been used in (Huang et al., 2010) and (Jansen et al., 2007) to identify different types of reformulations. This line of work is relevant to our work because it studies query reformulation strategies. Our work is different because we build a machine-learned predictive model to identify query reformulation while this line of work mainly focuses on defining taxonomies for reformulation strategies.

2.2 Automatic Query Refinement

A close problem that has received most of the research attention in this area is the problem of automatically generating query refinements. These refinements are typically offered as query suggestions to the users or used to alter the user query before submitting it to the search engine.

Boldi et al. (2008) introduced the concept of the query-flow graph where every query is represented by a node and edges connect queries if it is likely for users to move from one query to another. Mei et al. (2008) used random walks over a bipartite graph of queries and URLs to find query refinements. Query logs were used to suggest query refinements in (Baeza-Yates et al., 2005). Hierarchical agglomerative clustering was used to group similar queries that can be used as suggestions for one

another. Other research has adopted methods based on query expansion (Mitra et al., 1998) or query substitution (Jones et al., 2006). This line of work is different from our work because it focuses on automatically generating query refinements while this work focuses on identifying cases of manual query reformulations.

2.3 Search Task Boundary Identification

The problem of classifying the boundaries of the user search tasks within sessions in web search logs has been widely addressed before. This problem is closely related to the problem of identifying query reformulation. A search task has been defined in (Jones and Klinkner, 2008) as a single information need that may result in one or more queries. Similarly , Jansen et al. (2007) defined a session as a series of interactions by the user toward addressing a single information need. On the other hand, a query reformulation is intended to modify a previous query in hope of getting better results to satisfy the same information need. From these definitions, it is clear how query reformulation and task boundary detection are two sides of the same problem.

Boldi et al. (2008) presented the concept of the query-flow graph. A query-flow graph represents chains of related queries in query logs. They use this model for finding logical session boundaries and query recommendation. Ozmutlu (2006) proposed a method for identifying new topics in search logs. He demonstrated that time interval, search pattern and position of a query in a user session, are effective for shifting to a new topic. Radlinski and Joachims (2005) study sequences of related queries (query chains). They used that to generate new types of preference judgments from search engine logs to learn better ranked retrieval functions.

Arlitt (2000) found session boundaries using a calculated timeout threshold. Murray et al. (2006) extended this work by using hierarchical clustering to find better timeout values to detect session boundaries. Jones and Klinkner (2008) also addressed the problem of classifying the boundaries of the goals and missions in search logs. They showed that using features like edit distance and common words achieves considerably better results compared to timeouts. Lucchese et al. (Lucchese et al., 20011) uses a similar set of features as (Jones and Klinkner, 2008), but uses clustering to group queries in the same task together as opposed to identifying task boundary as in (Jones and Klinkner, 2008). This line of work is perhaps the closest to our work. Our work is different because it goes beyond the bag of words approach and tries to assess query similarity based on the concepts represented in each query. We compare our work to the state-of-the-art work in this area later in this paper.

3 Problem Definition

We start by defining some terms that will be used throughout the paper:

Definition: *Query Reformulation* is the act of submitting a query Q_2 to modify a previous search query Q_1 in hope of retrieving better results to satisfy the same information need.

Definition: A *Search Session* is group of queries and clicks demarcated with a 30-minute inactivity timeout, such as that used in previous work (Downey et al., 2007; Radlinski and Joachims, 2005).

Search engines receive streams of queries from users. In response to each query, the engine returns a set of search results. Depending on these results, the user may decide to click on one or more results, submit another query, or end the search session. In this work, we focus on cases where the user submits another query. Our objective is to solve the following problem: Given a query Q_1, and the following query Q_2, predict whether Q_2 is reformulation of Q_1.

4 Approach

In this section, we propose methods for predicting whether the current query has been issued by the user to reformulate the previous query.

4.1 Query Normalization

We perform standard normalization where we replace all letters with their corresponding lower case representation. We also replace all runs of whitespace characters with a single space and remove any leading or trailing spaces. In addition to the standard normalization, we also break queries that do not respect word boundaries into words. Word breaking is a well-studied topic that has proved to be

Table 1 : Examples of queries, the corresponding segmentation, and the concept representation. Phrases are separated by "|" and different tokens in a keyword are separated by "_"

Query	Phrases and Keywords	Concept Representation
hotels in new york city	hotels in new_york_city	Concept1 {head="hotels", modifiers = "new york city"}
hyundai roadside assistance phone number	hyundai roadside_assistance | phone_number	Concept1 {head = "roadside _assistance", modifiers = "hyundai"}, Concept2{"phone_number"}
kodak easyshare recharger chord	kodak_easyshare recharger_cord	Concept1{head ="recharger_cord", modifiers ="kodak easyshare"}
user reviews for apple iphone	user_reviews for apple_iphone	Concept1{head="user_reviews" , modifiers = "apple iphone"}
user reviews for apple ipad	user_reviews for apple_ipad	Concept1{head ="user_reviews", modifiers = "apple ipad"}
tommy bhama rug	tommy_bhama rug	Concept1{head ="rug", modifiers ="tommy bhama"}
tommy bhama perfume	tommy_bhama perfume	Concept1{head ="perfume", modifiers ="tommy bhama"}

useful for many natural language processing applications. This becomes a frequent problems with queries when users do not observe the correct word boundaries (for example: "southjerseycraigslist" for "south jersey craiglist") or when users are searching for a part of a URL (for example "quincycollege" for "quincy college"). We used a freely available word breaker Web service that has been described at (Wang et al., 2011).

4.2 Queries to Concepts

Lexical similarity between queries has been often used to identify related queries (Jansen et al., 2007). The problem with lexical similarity is that it introduces many false negatives (e.g. synonyms) , but this can be handled by other features as we will describe later. More seriously, it introduces many false positives. Take the following query pair as an example Q_1: weather in new york city and Q_2: "hotels in new york city". Out of 5 words, 4 words are shared between Q_1 and Q_2. Hence, any lexical similarity feature would predict that the user submitted Q_2 as a reformulation of Q_1. What we would like to do is to have a query representation that recognizes the difference between Q_1 and Q_2.

If we look closely at the two queries, we will notice that in the first query, the user is looking for the "weather", while in the second query the user is looking for "hotels". We would like to recognize "weather", and "hotels" as the head keywords of Q_1 and Q_2 respectively, while "new york city" is a modifier of the head keyword in both cases. To build such a representation, we start by segmenting each query into phrases. Query segmentation is the process of taking a users search query and dividing the tokens into individual phrases or semantic units (Bergsma and Wang, 2007). Many approaches to query segmentation have been presented in recent research. Some of them pose the problem as a supervised learning problem (Bergsma and Wang, 2007; Yu and Shi, 2009). Many of the supervised methods though use expensive features that are difficult to reimplement.

On the other hand, many unsupervised methods for query segmentation have also been proposed (Hagen et al., 2011; Hagen et al., 2010). Most of these methods use only raw web n-gram frequencies and are very easy to re-implement. Additionally, Hagen et al. (2010) have shown that these methods can achieve segmentation accuracy comparable to current state-of-the-art techniques using supervised learning. We opt for the unsupervised techniques to perform query segmentation. More specifically, we adopt the mutual information

method (MI) used throughout the literature. A segmentation for a query is obtained by computing the pointwise mutual information score for each pair of consecutive words. More formally, for a query $x = \{x_1, x_2, ..., x_n\}$

$$PMI(x_i, x_{i+1}) = log \frac{p(x_i, x_{i+1})}{p(x_i)p(x_{i+1})} \quad (1)$$

where $p(x_i, x_{i+1})$ is the joint probability of occurrence of the bigram (x_i, x_{i+1}) and $p(x_i)$ and $p(x_{i+1})$ are the individual occurrence probabilities of the two tokens x_i and x_{i+1} .

A segment break is introduced whenever the point wise mutual information between two consecutive words drops below a certain threshold τ. The threshold we used, $\tau = 0.895$, was selected to maximize the break accuracy (Jones et al., 2006) on the Bergsma-Wang-Corpus (Bergsma and Wang, 2007). Furthermore, we do not allow a break to happen between a noun and a proposition (e.g. no break can be introduced between "hotels" and "in" or "in" and "new York" in the query "hotels in new york city"). We will shorty explain how we obtained the part-of-speech tags.

In addition to breaking the query into phrases, we were also interested in grouping multi-word keywords together (e.g. "new york", "Michael Jackson", etc.). The intuition behind that is that a query containing the keyword "new york" and another containing the keyword "new mexico" should not be awarded because they share the word "new". We do that by adopting a hierarchical segmentation technique where the same segmentation method described above is reapplied to every resulting phrase with a new threshold $\tau_s < \tau$. We selected the new threshold, $\tau = 1.91$, to maximize the break accuracy over a set of a random sample of 10,000 Wikipedia title of persons, cities, countries and organizations and a random sample of bigrams and trigrams from Wikipedia text.

In our implementation, the probabilities for all words and n-grams have been computed using the freely available Microsoft Web N-Gram Service (Huang et al., 2010).

Now that we have the phrases and keywords in each query, we assume that every phrase corresponds to a semantic unit. Every semantic unit has a head and a zero or more modifiers. Dependency parsing could be used to identify the head and modifiers from every phrase. However, because queries are typical short and not always well-formed sentences, this may pose a challenge to the dependency parser. But as we are mainly interested in short noun phrases, we can apply a simple set of rules to identify the head keyword of each phrase using the part of speech tags of the words in the phrase. A part-of-speech (POS) tagger assigns parts of speech to each word in an input text, such as noun, verb, adjective, etc. We used the Stanford POS tagger, using Stanford CoreNLP, to assign POS tags to queries (Toutanova et al., 2003). To identify the head and attributes of every noun phrase, we use the following rules:

- For phrases with of the form: "NNX+" (i.e. one more nouns, where NNX could be NN: noun, singular, NNS: noun, plural, NNP: proper noun, singular or NNPS: proper noun, plural), the head is the last noun keyword and all other keywords are treated as attributes/modifiers.

- For the phrases of the form "NNX+ IN NNX+", where IN denotes a preposition or a subordinating conjunction (e.g. "in", "of", etc.), the head is the last noun keyword before the preposition.

Table 1 shows different examples of queries, the corresponding phrases, keywords, and concepts. For example the query "kodak easyshare recharger chord" consists of a single semantic unit (phrase) and two keywords "Kodak easyshare" and "recharger cord". The head of this semantic unit is the keyword "recharger cord" and "kodak easyshare" is regarded as an attribute/modifier. Another example is the two queries "tommy bhama rug" and "tommy bhama perfume". The head of the former is "rug", while the head of the latter is "perfume". Both share the attribute "tommy bhama". This shows that the user had two different intents even though most of the words in the two queries are shared.

4.3 Matching Concepts

Phrases in two concepts may have full term overlap, partial term overlap, or no direct overlap yet are semantically similar. To capture concept similarity,

we define four different ways of matching concepts ranked from the most to the least strict:

- Exact Match: The head and the attributes of the two concepts match exactly.
- Approximate Match: To capture spelling variants and misspelling, we allow two keywords to match if the Levenshtein edit distance between them is less than 2.
- Lemma Match: Lemmatization is the process of reducing an inflected spelling to its lexical root or lemma form. We match two concepts if the lemmas of their keywords can be matched.
- Semantic Match: We compute the concept similarity by measuring the semantic similarity between the two phrases from which the concepts where extracted. Let $Q = \{q_1, ..., q_I\}$ be one phrase and $S = \{s_1, ..., s_J\}$ be another, the semantic similarity between these two phrases can be measured by estimating the probability of one of them being a translation of another. The translation probabilities can be estimated using the IBM Model 1 (Brown et al., 1993; Berger and Lafferty, 1999). The model was originally proposed to model the probability of translating from one sequence of words in one language to another. It has been also used in different IR applications to estimate the probability of translating from one sequence of words to another sequence in the same language (e.g. (Gao et al., 2012), (Gao et al., 2010) and (White et al., 2013)). More formally, the similarity between two sequences of words, $Q = \{q_1, ..., q_I\}$ and $S = \{s_1, ..., s_J\}$, can be defined as:

$$P(S|Q) = \prod_{i=1}^{I} \sum_{j=1}^{J} P(s_i|q_j) P(q_j|Q) \quad (2)$$

where $P(q|Q)$ is the unigram probability of word q in query Q. The word translation probabilities $P(s|q)$ are estimated using the query-title pairs derived from the clickthrough search logs, assuming that the title terms are likely to be the desired alternation of the paired query. The word translation probabilities $P(s|q)$ (i.e. the model parameters θ) are optimized by maximizing the probability of generating document titles from queries over the entire training corpus:

$$\theta^* = argmax_\theta \prod_{i=1}^{M} P(S|Q, \theta) \quad (3)$$

where $P(S|Q, \theta)$ is defined as:

$$P(S|Q, \theta) = \frac{\epsilon}{(J+!)^I} \prod_{i=1}^{I} \sum_{j=1}^{J} P(s_i|q_j) \quad (4)$$

where ϵ is a constant, I is the token length of S, and J is the token length of Q. The query-title pairs used for model training are sampled from one year worth of search logs from a commercial search engine. The search logs do not intersect with the search logs where the data described in Section5.1 has been sampled from. S and Q are considered a match if $P(S|Q, \theta) > 0.5$.

4.4 Features

4.4.1 Textual Features

Jones and Klinkner (2008) showed that word and character edit features are very useful for identifying same task queries. The intuition behind this is that consecutive queries which have many words and/or characters in common tend to be related. The features they used are:

- normalized Levenshtein edit distance
- 1 if $lev > 2$, 0 otherwise
- Number of characters in common starting from the left
- Number of characters in common starting from the right
- Number of words in common starting from the left
- Number of words in common starting from the right
- Number of words in common
- Jaccard distance between sets of words

4.4.2 Concept Features

As we explained earlier the word and character edit features capture similarity between many pairs of queries. However, they also tend to mis-classify many other pairs especially when the two queries share many words yet have different intents. We used the conceptual representation of queries described in the previous subsection to compute the following set of features, notice that every feature has two variants one at the concept level and the other at the keyword (head or attribute) level:

- Number of "exact match" concepts in common
- Number of "approximate match" concepts in common
- Number of "lemma match" concepts in common
- Number of "semantic match" concepts in common
- Number of concepts in Q_1
- Number of concepts in Q_2
- Number of concepts in Q_1 but not in Q_2
- Number of concepts in Q_1 but not in Q_2
- 1 if Q_1 contains all Q_2s concepts
- 1 if Q_2 contains all Q_1s concepts
- all above features recomputed for keywords instead of concepts

4.4.3 Other Features

Other features, that have been also used in (Jones and Klinkner, 2008), include temporal features:

- time between queries in seconds
- time between queries as a binary feature (5 mins, 10 mins, 20 mins, 30 mins, 60 mins, 120 mins)

and search results feature:

- cosine distance between vectors derived from the first 10 search results for the query terms.

4.5 Predicting Reformulation Type

There are different strategies users use to reformulate a query which results in different types of query reformulations:

- Generalization: A *generalization* reformulation occurs when the second query is intended to seek more general information compared to the first query
- Specification: A *specification* reformulation occurs when the second query is intended to seek more specific information compared to the first query
- Spelling: A *spelling* reformulation occurs when the second query is intended to correct one or more misspelled words in the first query
- Same Intent: A *same intent* reformulation occurs when the second query is intended to express the same intent as the first query. This can be the result of word substitution or word reorder.

We used the following features to predict the query reformulation type:

- Length (num. characters and num. words) of Q_1, Q_2 and difference between them
- Number of out-of-vocabulary words in Q_1, Q_2 and the difference between them
- num. of "exact match" concepts in common
- num. of "approximate match" concepts in common
- num. of "lemma match" concepts in common
- num. of "semantic match" concepts in common
- num. of concepts in Q_1, Q_2 and the difference between them
- num. of concepts in Q_1 but not in Q_2
- num. of concepts in Q_1 but not in Q_2
- 1 if Q_1 contains all Q_2s concepts
- 1 if Q_2 contains all Q_1s concepts
- all concept features above recomputed for keywords instead of concepts

5 Experiments and Results

5.1 Data

Our data consists of query pairs randomly sampled from the queries submitted to a commercial search engine during a week in mid-2012. Every record in our data consisted of a consecutive query pair (Q_i,Q_{i+1}) submitted to the search engine by the same user and in the same session (i.e. within less than 30 minutes of idle time, the 30 minutes threshold has been frequently used in previous work, e.g. (White and Drucker, 2007)). Identical queries were excluded from the data because they are always labeled as reformulation and their label is very easy to predict. Hence, when included, they result in unrealistically high estimates of the performance of the proposed methods. All data in the session to which the sampled query pair belongs were recorded. In addition to queries, the data contained a timestamp for each page view, all elements shown in response to that query (e.g. Web results, answers, etc.), and visited Web page or clicked answers. Intranet and secure URL visits were excluded. Any personally identifiable information was removed from the data prior to analysis.

Annotators were instructed to exhaustively examine each session and "re-enact" the user's experience. The annotators inspected the entire search results page for each of Q_i and Q_{i+1}, including URLs, page titles, relevant snippets, and other features. They were also shown clicks to aid them in their judgments. Additionally, they were also shown queries and clicks before and after the query pair of interest. They were asked to then use their assessment of the user's objectives to determine whether Q_{i+1} is a reformulation of Q_i. Each query pair was labeled by three judges and the majority vote among judges was used. Because the number of positive instances is much smaller than the number of negative instances, we used all positive instances and an equal number of randomly selected negative instances leaving us with approximately 6000 query pairs.

Judges were also asked to classify reformulations into one of four different categories: Generalization (second query is intended to seek more general information), Specification (second query is intended to seek more specific information), Spelling (second query is intended to correct spelling mistakes), and Same Intent (second query is intended to express the same intent in a different way).

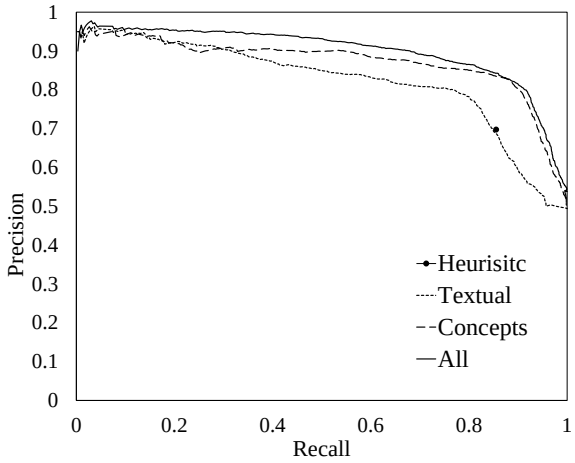

Figure 1 Precision-Recall Curves for the Reformulation Prediction Methods

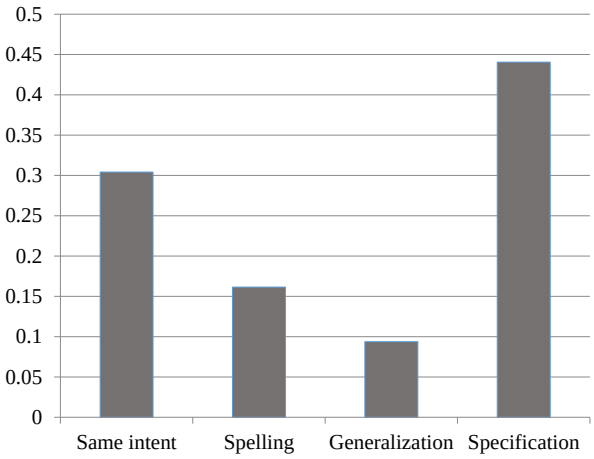

Figure 2 Distribution of Query Reformulation Types

5.2 Predicting Query Reformulation

In this section we describe the experiments we conducted to evaluate the reformulation prediction classifier. We perform experiments using the data described in the previous section. We compare the performance of four different systems:

- The first one, *Heuristic*, simply computes the similarity between two queries as the percentage of common words to the length of the longer query in terms of the number of words.

Table 2 : Heuristics vs. Textual vs. Concept Features for Reformulation Prediction

	Accuracy	Reform. F1	No-Reform. F1
Heuristics	77.10%	75.60%	69.07%
Textual	82.90%	71.75%	87.75%
Concepts	87.60%	81.20%	90.78%
All	89.02%	83.63%	91.75%

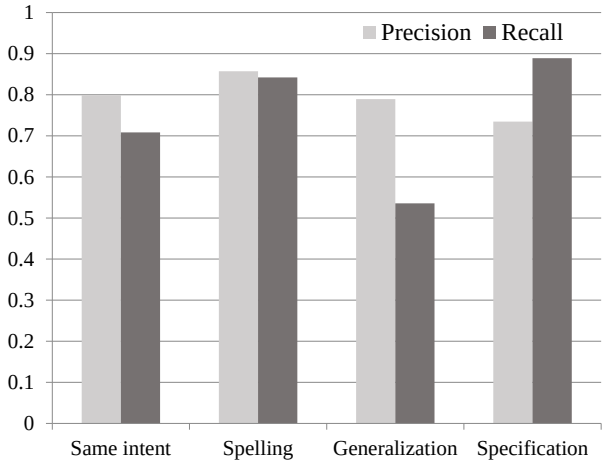

Figure 3 Precision and Recall for Query Reformulation Type Prediction

When finding common words, it allows two words to be matched if their Levenshtein edit distance is less than or equals 2. The second query is predicted to be a reformulation of the first if similarity $\geq \tau_{sim}$ and the time difference $\leq \tau_{time}$ minutes. The two thresholds were set to 0.35 and 5 minutes respectively using grid search to maximize accuracy over the training data.

- The second system, *Textual*, uses the textual features from previous work that have been described in Section 4.4.1 and the temporal and results features described in Section 4.4.3.

- The third system, *Concepts*, uses the concept features that we presented in Section 4.4.2 and the temporal and results features described in Section 4.4.3.

- Finally, the last system, *All*, uses both the textual features, the conceptual features and the temporal and results features.

For all methods, we used gradient boosted regression trees as a classifier with 10-fold cross validation. We also tried other classifiers like SVM and logistic regression but we got the best performance using the gradient boosted regression trees. All reported differences are statistically significant at the 0.05 level according to a two-tailed student t-test.

The accuracy, positive (reformulation) F1, and negative (non-reformulation) F1 for the four methods are shown in Table 2. The precision recall curves for all methods are shown in Figure 1; the heuristic method uses fixed thresholds resulting in a single operating point. The results show that the concept features outperform the textual features. Combining them together results in a small gain over using the concept features only. The concept features were able to achieve higher precision rates while not sacrificing recall because they were more effective in eliminating false reformulation cases.

We examined the cases where the classifier failed to predict the correct label to understand when the classifier fails to work properly. We identified several cases where this happens. For example, the classifier failed to match some terms that have the same semantic meaning. Many of these cases were acronyms (e.g. “AR” and “Accelerated Reader”, ”GE” and ”General Electric”). These cases can be handled by using a semantic matching method that yields higher coverage especially in cases of acronyms.

The classifier also failed in cases where the keyword extractor and/or the POS tagger failed to correctly parse the queries (e.g. “last to know”was not recognized as a song name). These cases can be handled by identifying named entities as a preprocessing step and treating them accordingly when identifying keywords or assigning POS tags to keywords.

Another dominant class of cases where the classifier failed were cases where the dependency rules failed to correctly identify the head keyword in a query. In many such cases, the query was a non well-formed sequence of words (e.g. "dresses Christmas toddler"). This is the hardest class to handle. Since it is hard to correctly parse short text and it is even harder when the text it is not well-formed.

5.3 Predicting Reformulation Type

We conducted another experiment to evaluate the performance of the reformulation type classifier. We performed experiments using the data described earlier where judges were asked to select the type of reformulation for every reformulation query. The distribution of reformulations across types is shown in Figure 2. The figure shows that most popular reformulations types are those where users move to a more specific intent or express the same intent in a different way. Reformulations with spelling suggestions and query generalizations are less popular. We conducted a one-vs-all experiment using gradient boosted regression trees with 10-fold cross validation. The precision and recall of every type are shown in Figure 3. The micro-averaged and macro-averaged accuracy was 78.13% and 72.52% respectively.

6 Conclusions

Identifying query reformulations is an interesting and useful application in Information Retrieval. Reformulation identification is useful for automatic query refinements, task boundary identification and satisfaction prediction. Previous work on this problem has adopted a bag-of-words approach where lexical similarity and word overlap are the key features for identifying query reformulation. We proposed a method for identifying concepts in search queries and using them to identify query reformulations. The proposed method outperforms previous work because it can better represent the information intent underlying the query and hence can better assess query similarity. We showed that the proposed method significantly outperforms the other methods. We also showed that we can reliably predict the type of the reformulation with high accuracy.

Abstract

Passage retrieval is a crucial first step of automatic Question Answering (QA). While existing passage retrieval algorithms are effective at selecting document passages most similar to the question, or those that contain the expected answer types, they do not take into account which parts of the document the searchers actually found useful. We propose, to the best of our knowledge, the first successful attempt to incorporate searcher examination data into passage retrieval for question answering. Specifically, we exploit detailed examination data, such as mouse cursor movements and scrolling, to infer the parts of the document the searcher found interesting, and then incorporate this signal into passage retrieval for QA. Our extensive experiments and analysis demonstrate that our method significantly improves passage retrieval, compared to using textual features alone. As an additional contribution, we make available to the research community the code and the search behavior data used in this study, with the hope of encouraging further research in this area.

1 Introduction

Automated Question Answering (QA), is an attractive variation of search where the QA system automatically returns an *answer* to a user's question, instead of a list of document results. Passage retrieval is a first critical step of QA system, where candidate passages are identified and scored as likely to contain an answer. While significant progress has been made recently on incorporating syntactic and semantic analysis for improving the QA system performance, this analysis is typically applied only on the (limited) set of candidate passages retrieved. The main reason is that it is generally not practical to perform deep analysis on all documents in a large collection, and not yet feasible for the Web at large.

In the web search setting, automated question answering presents additional challenges and opportunities. On the downside, the questions and queries from real users are often not grammatical or well-formed, differing from the questions used in the traditional TREC Question Answering evaluations (Kelly and Lin, 2007; Sun et al., 2005). On the upside, by interacting with a search engine, the millions of searchers implicitly provide additional clues about usefulness of documents, result ranking, and other aspects of the search process. In this paper, we explore making use of the search behavior data to improve passage retrieval for automated Question Answering on the web.

Our basic observation is that when a user is attempting to answer a question, he or she will more carefully examine the parts of the document that contain an answer. This observation is intuitive, and is strongly supported by numerous eye tracking studies (e.g., Buscher et al. (2008) and Buscher et al. (2009a)). Based on this, we hypothesize that the passages containing the answers can be *automatically identified* from the naturalistic searcher behavior, and this prediction can be subsequently used to improve passage ranking. To the best of our knowledge, our work is the first to successfully incorporate searcher examination into passage ranking for Question Answering.

Our approach is primarily aimed at recurring (repeated) questions, which comprise a large fraction of the search volume (while the exact statistics vary, over 50% of search queries are submitted by multiple users). For such questions, a system would track the clicked result URLs, as well as the user interactions on the landing pages. Then the system would use this information to present the improved results to new users who ask the same (or similar) question. Intuitively, our method uses the same general idea of result click data mining, used by the major search engines to improve result ranking, but takes

*Work done at Emory University.

Seattle, Washington, USA, 18-21 October 2013.

it a step further to exploit user interactions on the actual landing pages. A key point to emphasize is that our approach exploits the *natural browsing behavior* of the users, not requiring any additional effort from the searchers.

Specifically, our contributions include:

- A novel approach to passage retrieval for question answering, that naturally integrates textual and behavioral evidence.
- A robust infrastructure for connecting fine-grained searcher behavior to precise page contents.
- Thorough experiments over hundreds of search sessions and thousands of page views, demonstrating significant improvements to passage retrieval by harnessing the user's page examination data.

Next we describe related work, to place our contribution in context.

2 Related Work

Our work brings together two areas of research: passage retrieval for question answering, and mining searcher behavior data.

Passage retrieval has long been recognized as the first crucial step of automatic question answering. In some cases, passage retrieval can even serve as the final product of a Question Answering system (Clarke et al., 2000). As another example, redundancy in the retrieved passages has been used by the AskMSR system (Brill et al., 2002) to select answers. Tellex et al. (2003) report a thorough comparison of passage retrieval methods for QA, up to 2003. Additional improvements have been achieved by using deeper analysis of the text. For example, Cui et al. (2005) exploited dependency relations between the question terms, Aktolga et al. (2011) incorporated syntactic structure and answer typing, while Harabagiu et al. (2005) used semantic analysis at all stages of the question answering process. In this paper, we pursue a complementary direction, by exploiting searcher examination behavior, with the assumption that human searchers can easily zoom in on relevant passages as part of normal searching.

It has been previously recognized that searcher interactions could be valuable for question answering, and a task on Complex Interactive QA has been ran as part of TREC 2007 (Kelly and Lin, 2007). Our work goes much further by considering not only explicit interactions, but also the searcher examination behavior (i.e., detailed information on which text passages were examined) – which, as we show, provides additional valuable information for passage retrieval. Furthermore, it has been recognized that the questions used in traditional TREC QA evaluation may not be reflective of the "real" questions, posed by users (Bernardi and Kirschner, 2010). Our paper uses a subset of the real questions posted by users on Community Question Answering (CQA) sites, and searches and interactions from real users – which makes our task unique and more challenging than the previous settings.

In particular, our work builds on the rich history of using eye tracking technology to identify areas of interest and attention, and to study reading behavior. In the context of web search document examination, Buscher et al. (2008) extracted sub-documents by tracking eye movements as implicit feedback and expanded search queries to improve the search result ranking. Buscher et al. also studied the prediction of salient Web page regions using eye-tracking (Buscher et al., 2009a). This work, and others, have shown that user attention can help identify regions of documents of particular relevance or usefulness for the query. While eye tracking equipment limits the applicability of these findings to lab studies, these studies served as inspiration to our work to detect the *inferred* areas of interest. Specifically, we use mouse cursor tracking as a natural proxy for user's attention, to replace the requirement for eye tracking equipment. As originally reported by Rodden et al. (2008), the authors discovered the coordination between a user's eye movements and mouse movements when scanning a web search results page. This work was further extended by Huang et al. (2012) to predict the gaze position from mouse cursor movement, with mean error of about 150 px. In summary, there is mounting evidence that the user's attention in web search can be approximated using mouse cursor, scrolling, and other interaction data. In particular, Hijikata (2004) proposed a method to extract text passages of Web pages based on the user's mouse activity and found that extracted passages based on mouse ac-

tivity such as *text tracing, link pointing, link clicking and text selection* enable more accurate extraction of key words of interest than using the whole text of the page. Recently, White and Buscher (2012) proposed a method that uses text selections as implicit feedback for document ranking. Most closely related to this work is a contemporaneous effort on improving web search result summaries, or snippets, by exploiting searcher behavior on the examined documents, described by Ageev et al. (2013). However, to the best of our knowledge, there has been no prior work on modeling searcher interaction on result documents to improve Question Answering performance, and in particular the passage retrieval step.

3 Problem Statement and Approach

This section first states the problem we are addressing more precisely. Then, we describe the key parts of our approach (Section 3.2), and the required infrastructure we had to develop to accomplish the required data collection (Section 3.4).

3.1 Problem Statement

Our goal is to incorporate the searcher behavior (in particular, page examination) into passage retrieval. That is, by analyzing the searcher behavior data, we aim to identify the parts of the page that contain relevant passages for answering a question. Specifically, given a question, a set of queries generated by searchers attempting to answer this question, and a set of documents retrieved by a search engine for each of the queries, our goal to retrieve a set of *passages* that contain correct answers for the question.

That is, our goal is to identify, from searcher behavior, the passages in the documents most likely to contain correct answers to a question, which could then be incorporated into a fully automated question answering system, or returned to the user directly, for example, by incorporating these passages into the result abstracts or "snippets".

3.2 Approach

Our approach accomplishes the goal above by incorporating both textual and behavioral evidence. Specifically, we combine together traditional text-based passage retrieval features, and the inferred user interest in specific parts of a document based on searcher behavior.

First, a passage score is obtained from the QA-SYS system (Ng and Kan, 2010), resulting in a strong text-only baseline that generates *candidate passages*. Separately, examination behavior data is collected over the landing pages, using our logging infrastructure described in the next section. Then, a behavior model is trained to identify the passages of interest to the user, based on user examination data (Section 4.2). Finally, the behavior-based prediction of interest in each candidate passage is combined with the original (text-based) passage score, in order to generate the final *behavior-biased* passage ranking (Section 4.3). Note that by decoupling the behavior modeling from the candidate generation method, our approach can be used with any other passage retrieval approach that provides scores for the candidate passages (that could be combined with the behavior scores for the final ranking step).

While general and flexible, our approach makes two key assumptions, resulting in potential limitations. First, our approach is primarily targeted (and evaluated for) informational questions – that is, questions for which the user expects to find an answer in the text of the page. For other question classes (e.g., opinion), passage retrieval might have to be optimized differently. We also assume that the user interactions on landing pages can be collected by a search engine or a third party. This is not far-fetched: already, browser plug-ins and toolbars collect some form of user interactions on web pages, major organizations can (and sometimes do) use proxies, and common page widgets like banner ads and visit counters commonly inject JavaScript to monitor basic user interactions – and can be easily extended to collect the examination data described in this paper. The privacy and security of these methods are beyond the scope of this paper, we merely point out that these behavior gathering tools, assumed by our approach, already exist and are already widely deployed. The interested reader can obtain an overview of the relevant privacy issues and proposed solutions in references (Mayer and Mitchell, 2012; Krishnamurthy and Wills, 2009).

3.3 Acquiring Search Behavior Data

Our infrastructure for acquiring search behavior was developed with two goals in mind: (1) to obtain behavior data similar to real-world search, with the ability to track fine-grained search behavior such as

a mouse cursor movement (as there are no publicly available data of this kind); (2) to create a controlled and clean ground truth set, to train our system and evaluate the effectiveness of our approach.

To collect sufficient amount of search behavior data, we adapted for our task the publicly available UFindIt architecture, described in reference Ageev et al. (2011). The participants played several search contests, or "games", each consisting of 12 search tasks (questions) to solve. The stated goal of the game was to submit the highest possible number of correct answers within the allotted time. After the searcher decided that they found the answer, they were instructed to type the answer together with the supporting URL into the corresponding fields in the game interface. Each search session (for one question) was completed by either submitting an answer or clicking the "skip question" button to pass to the next question.

Participants were recruited through the Amazon Mechanical Turk (MTurk) service. As a first step, the workers had to solve a ReCaptcha puzzle to verify that they are human and not an automated "bot". A browser verification check was performed to confirm that the browser was compatible with our JavaScript tracking code. During the data postprocessing stage, we filtered out the users who did not answer even the easy, trivial questions, as it indicated either poor understanding of the game rules, or an attempt to make a quick buck without effort.

In order to capture all of the participants' search actions, they were instructed to use only our search interface (and not a separate browser window). The search interface performed the web searches using the public API of a popular web search engine, and showed result pages to the users using the original page design, layout and stylesheets, so the user's search experience is not affected.

3.4 Page Examination Behavior Logging

A key part of our system is a mechanism for collecting searcher interactions on web pages, and tying them precisely to the page content at the word level. As the HTML page passed through the proxy, a JavaScript code is embedded to track the user's interactions, including mouse movements and scrolling, as well as the properties of the visited page. The behavioral (interaction) events are logged by the search interface proxy and written to the server log.

To connect the tracked mouse cursor positions to exact text passages we employed the following trick. After the HTML page is rendered in the browser window, our JavaScript code modifies the page DOM tree so that each word is wrapped by a separate DOM Element. Then for each DOM Element, the window coordinates of that element are evaluated and saved in an Element's attribute. The processed HTML page is then saved to the server by an asynchronous request. The saved coordinates are updated if the page layout is changed due to *resize* window event or AJAX action.

As a result of this instrumentation, for each page visit we know the searcher's intent (question), a search engine query that the user issued, a URL and HTML page, the bounding boxes of each word in the HTML text, and all of the searcher actions, e.g., mouse movement coordinates, mouse clicks, and scrolling.

4 Behavior-Biased Passage Retrieval

We now present the details of our behavior-biased passage retrieval algorithm (BePR). First, we describe the text-only retrieval system. Then, we introduce our method for inferring the most interesting or useful parts of the document from user behavior (Section 4.2).

4.1 Text-Based Passage Retrieval

We adopt an open-source question answering framework QANUS (Ng and Kan, 2010) (version v29Nov2012). The QANUS distribution contains the fully functional factoid QA system QA-SYS that we use as a baseline for our experiments. QA-SYS implements many of the state-of-the-art question answering techniques, and is similar to a top-performing QA system from TREC (Sun et al., 2005). The QA-SYS distribution is configured for processing documents and questions in TREC QA format, and we adopted QA-SYS for answer extraction from web documents. QA-SYS takes a set of documents and a question as an input, and processes the input in three stages: (1) information source preparation, (2) question processing, and (3) answer retrieval.

In the first stage, the downloaded HTML pages are pre-processed with Natural Language Tool Kit (NLTK, Bird (2006)). Extracted text is divided into sentences using *Punkt* unsupervised sentence split-

ter (Kiss and Strunk, 2006). The QA-SYS performs Part of Speech tagging using Stanford POS tagger (Toutanova et al., 2003), and Named Entity Recognition using Stanford NER (Finkel et al., 2005), and then builds a Lucene index over the set of input documents. In the second stage the QA-SYS performs POS tagging, NE recognition, and question type classification for an input question.

To answer a question, QA-SYS creates a query from the question, performs the search over the indexed text collection, and retrieves top 50 documents. Each document is split by sentences, and for each sentence a *QA-SYS Passage Retrieval Score* ($TextScore$) is computed as a linear combination of term frequency score, proximity score, and term coverage score. After that 40 passages with the highest $TextScore$ are retrieved, for each passage QA-SYS performs pattern based answer extraction based on the identified expected answer type of the question.

As the focus of this paper is to improve Passage Retrieval performance, we use the $TextScore$ sentence ranking as a baseline, and improve on it by adding the new search behavioral features indicating the passage relevance, as described next.

4.2 Inferring Relevant Passages from Search Behavior

To rank passages by their "interestingness" – that is, to identify the passages that have been carefully examined by the searcher, we use a learning-to-rank approach, and apply regression algorithms to predict the probability that a specific passage is interesting for a user. A passage is labeled as "interesting", if the user submitted an answer in the current session, and both the passage and the answer have at least one common word, after stemming and stop-word removal.

For each passage, a set of behavior features that could represent passage interestingness is created. To associate behavioral features with a given document passage, we match the sequence of behavior events and the set of bounding boxes for each word and DOM Element of a page. For efficiency, we build a spatial R-Tree index of these bounding boxes, which allows us to quickly find the matching DOM Elements for each event.

One key feature is the duration of the time interval when a mouse cursor was hovering over the specific text passage, or very close to the passage. We also take a scrollbar and event count features from papers (Buscher et al., 2009b), and (Guo and Agichtein, 2012) to detect evidence of "reading" vs. "skimming" behavior, and adopt those features to represent the behavior near the specific location of a page. The full set of our passage behavior features are reported in Table 1.

Feature	Description
MouseOverTime	Time duration when the mouse cursor was over the text passage
MouseNearTime	Time duration when the mouse cursor was close to the text passage in the window $(x \pm 100px,\ y \pm 70px)$
MouseOverEvents	The number of mouse events during *MouseOverTime*
MouseNearEvents	The number of mouse events during *MouseNearTime*
DispTime	Time duration when the text passage has been visible in the browser window (depends on scrollbar position)
DispMiddleTime	Time duration when the text passage was visible in the middle part of the browser window

Table 1: Behavior features for text passages

To implement the passage ranker, we experimented with a variety of learning-to-rank (LTR) algorithms, and chose two implementations of Regression Trees, due to their strong performance for general web search ranking tasks. The first algorithm is Regression Tree (Friedman et al., 2001), and the second is Gradient Boosting Regression Tree algorithm (Friedman, 2001). They are named *BePR-BTree*, and *BePR-GBM* respectively.

The dataset consists of a set of questions, with associated search behavior data collected from all the users who tried to find an answer to this question, the answers submitted by the users, and a set of validated answers. These sets are divided into training, validation, and test, so that the training and validation set URLs are disjoint, and the test set have no intersection with training and validation set by URLs, questions, and users. The training set is created from only those page visits where the document text has non-empty intersection with the user's answer, and the answer is correct. The trained regres-

sion algorithm is applied to all page visits in the test set. When the trained model is applied at test time, it has no information about the user's intent, the correct answer, or the current query, but rather uses only the behavioral features of the current page visit to identify the "interesting" passages.

The predicted probability of passage interestingness is averaged over all the users and page visits, and the resulting passage interestingness is then used as the $BScore$ of the passage. Note that $BScore$ is defined for only *visited* pages; to incorporate the overall clickthrough information (i.e., the fraction of the time a page was visited, indicating relevance), we introduce a generalized version, designated as $BSscore_{All}$, defined as: $\gamma \cdot CTR + (1-\gamma) \cdot BScore$, where CTR is the clickthrough rate for the page, defined as the fraction of time the result was clicked for all searches. Intuitively, this version reduces the weight of the behavior score for the pages with insufficient behavior data by "backing off" to the document clickthrough rate, according to the parameter γ. For the cases where only the visited pages are considered (ignoring the searches when the page was not visited), γ is set to 0, reverting the score to the original $BScore$ definition. The resulting behavior-based passage score is then used as the aggregate value of searcher interest in the passage for the combined passage retrieval step, described next.

4.3 Combining Textual and Behavioral Evidence

The final step in our approach is to *combine* the text-based score $TextScore(f)$ for a sentence (Section 4.1) with the interestingness score $BScore(f)$ (Section 4.2), inferred from the examination data. In our current implementation we combine these scores by linear combination:

$$FScore(f) = \lambda \cdot BScore(f) + (1 - \lambda) \cdot TextScore(f)$$

Other more sophisticated ways to combine text and behavior evidence are possible, such as jointly learning over both text and behavior features. However, we chose to follow the simpler linear approach for interpretability of the results (e.g., by varying the λ parameter).

5 Data Collection and Experimental Setup

This section presents the methodology used for selecting the questions (Section 5.1), the corresponding search behavior data (Section 5.2), and the experimental collections and metrics (Section 5.3).

5.1 Questions

The search tasks were selected from community question answering sites such as wiki.answers.com and Yahoo! Answers by the researchers. The criteria used were that the question should be clearly stated, had a clear answer, and that finding this answer was not a trivial task, that is, the answer was not retrieved simply by submitting the question verbatim to Google, Bing, or Yahoo! Search engines. Overall, 36 such questions were selected, posing (as it turned out) greatly varying levels of difficulty for participants. These questions were randomly split into three game rounds of 12 questions each.

5.2 Browsing Behavior Dataset

The search behavior data for each of the questions above was acquired as described in Section 3.3. A total of 270 participants finished the game. After filtering out users who did not follow the game rules, we have 3047 search sessions performed by 265 users. Our data for these users consists of 7800 queries, 3910 unique queries, 8574 SERP clicks on 1544 distinct URLs. For 5683 page visits (66%) and 883 distinct URLs the on-page behavioral data is collected. For the rest 34% of page visits the behavioral data were not collected due to conflicts between our JavaScript tracking code and other code presented on the page. For each page view there are about 400 atomic browsing events (mouse movements, scrolling, key pressing) on average. All the source and derived data are available at `http://ir.mathcs.emory.edu/intent`.

The dataset is divided into training, validation, and test set in the following way. The behavior dataset for the first game is divided randomly into equal-sized training and validation sets that are disjoint by URLs. The training set was used to train the regression algorithm for predicting passage attractiveness, and the validation set was used to explore the influence of behavior weight λ on passage retrieval performance, and to select the parameter λ for using on a test set. The validation set consists of 254 different URLs spread over 11 questions, and

for each of them there is a collected browsing behavior.

The test set consists of 441 URLs spread over 24 questions, and the test set has no intersection with training and validation set by URLs, questions, and users.

5.3 Candidate Document Selection Strategies

The first step for question answering is a selection of a candidate document set. In our settings, we may select a subset of web documents in a different way. We explore passage retrieval effectiveness using three different strategies of document set selection.

- For each question select *All* documents that are in top 10 documents returned by a search engine for any query that was issued during search for the specific question. For our dataset this gives around 500 candidate documents per question on average.

- For each question select only documents that were *Clicked* by a user. This restricts a candidate document set to set of most promising documents. For our dataset this gives around 25 candidate documents per question on average.

- For each pair of question and *Relevant* document apply passage retrieval to the specific document. In this experiment we label a document "Relevant" if a correct answer was extracted from it. In a real-world scenario, while document relevance could be estimated by a variety of click-based methods, we address the challenge of how to actually extract the correct answer from the document, automatically, with the help of the natural behavior data. We perform this experiment to estimate the performance of passage retrieval for the case when relevant documents are known with high confidence.

Evaluation Metrics: We evaluate passage retrieval performance by standard Mean Reciprocal Rank (MRR), and Mean Average Precision (MAP) metrics for top 20 retrieved sentences (Voorhees and Tice, 1999). We also evaluate ROUGE-1 metric (Lin, 2004) for the first retrieved passage.

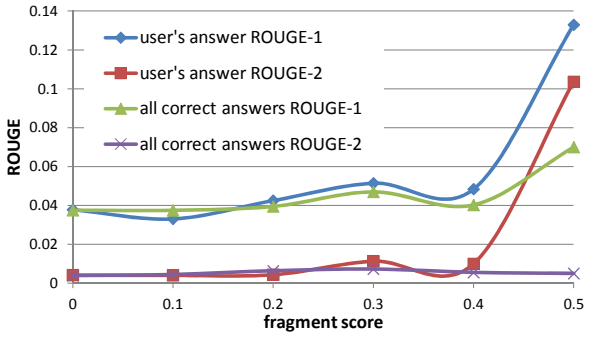

Figure 1: The actual passage interestingness, measured by intersection with user's answer, vs. the passage relevance score $BScore$ predicted from behavior data

6 Results

We now present the empirical results. First, we report the intermediate result of using behavior data to infer the interesting (useful) passages in the document. Then, we report the main results of the paper where the quality of the generated snippets with and without using behavior data is compared using human judgments.

6.1 Prediction of Passage Interestingness

This experiment evaluates how well we can predict interesting passages by observing a user's on-page behavior. We suppose that the passage is interesting if it is related to the answer for the question. For each visited page, we collect the user's answer (if submitted), and all correct answers from all users who answered this question. Then, we compare those answers to each text passage in the document using ROUGE metrics (Lin, 2004).

Figure 1 shows the relationship between the interestingness of a passage and behavior score. The graph shows that when the score is high ($\geq$ 0.5), then average intersection between the passage and user's answer is much higher than those when the passage score is low. All ROUGE-N metrics significantly grow when the behavior score grows, although ROUGE-2 over all correct answers are always very small (it grows from 0.003 to 0.007). ROUGE-1 is much greater than ROUGE-2 for high scores, as the interesting passage might contain useful information for the answer, but the user reformulates the obtained information and submits reformulated answer. The ROUGE-N metrics for a user's answer are much greater than those for all correct

Feature	Feature Importance
DispMiddleTime	0.51
MouseOverTime	0.34
DispTime	0.12
MouseNearTime	0.02
MouseOverEvents	0.01
MouseNearEvents	0.01

Table 2: Feature importance for behavioral features, as measured by Gini coefficient

answers, as other users might obtain valuable information from other documents, and some questions have distinct correct answers.

Behavior Feature Importance Analysis: To estimate relative importance of behavior features we evaluated the Gini importance index (Breiman, 1996) for each behavior feature from the Table 1. The Table 2 shows that the most important features are the time duration when the text passage was visible in the middle part of the scrolling window, and the time duration when the mouse cursor was over the text passage. The first feature has been shown to be a good feature for re-ranking search results in reference (Buscher et al., 2009b), and we have shown that it is also useful for passage retrieval. The *MouseOverTime* feature has been previously shown to be correlated with examination time, measured by eye-tracking experiments (Guo and Agichtein, 2010), and it helps us detect local behavior in the neighborhood of a specific text passage.

Analysis of Searcher Attention: In order to better understand what characteristics of the textual passages attract the searcher's attention, we explored 21 linguistic features for each sentence. Our features were designed to estimate text readability, and the overlap of a passage with the query that was used to find the document. We implemented the readability features from (Kanungo and Orr, 2009), and query matching features from (Metzler and Kanungo, 2008). Table 3 reports the top 10 features with the highest absolute value of the correlation coefficient with passage interestingness score $BScore$. Interestingly, the most highly correlated features are related to readability, while query matching features are less important.

Feature description	*corr*
Number of distinct words in the passage	0.31
Total number of words in the passage	0.28
Number of letter ([a-zA-z]) characters	0.27
Relative location of the passage in the document	-0.25
Number of unique words in the passage divided by total number of words	-0.24
Number of punctuation characters	-0.20
Number of words with first letter capitalized	-0.17
Overlap of query terms expanded with synonyms and the passage	0.15
Absolute count of query terms matched in the passage	0.15
Average position of query term within the passage	-0.14

Table 3: Correlation of passage interestingness $BScore$ with linguistic properties of a sentence

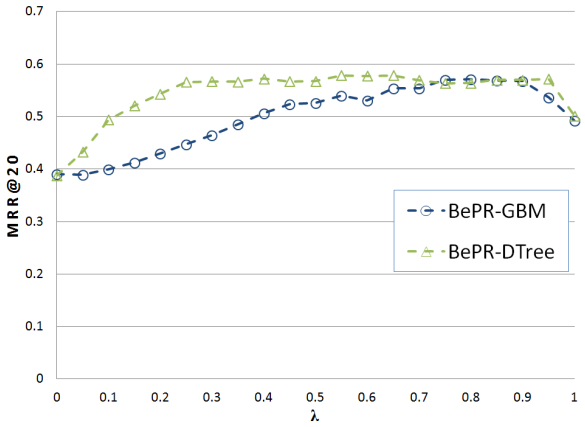

Figure 2: MRR for passage retrieval for varying behavior weight λ and interestingness prediction algorithms *BePR-DTree*, and *BePR-GBM*

6.2 Passage Retrieval with Behavior Data

This section reports the main results of the paper. First, we describe the parameter tuning, followed by the main performance results.

Parameter Tuning: To tune the passage retrieval performance, we use the validation set to find the optimal value for λ. Figure 2 reports the passage retrieval MRR for varying λ, for two learning algorithms BePR-GBM and BePR-DTree. The figure shows that both BePR-GBM and BePR-BTree improve over the QA-SYS baseline. BePR-GBM algorithm achieves the best performance with $\lambda = 0.8$, and also exhibits more robust behavior compared to BePR-BTree, so we use BePR-GBM with $\lambda = 0.8$ for the main experiments described next. Similarly, using the training and validation sets, we optimized

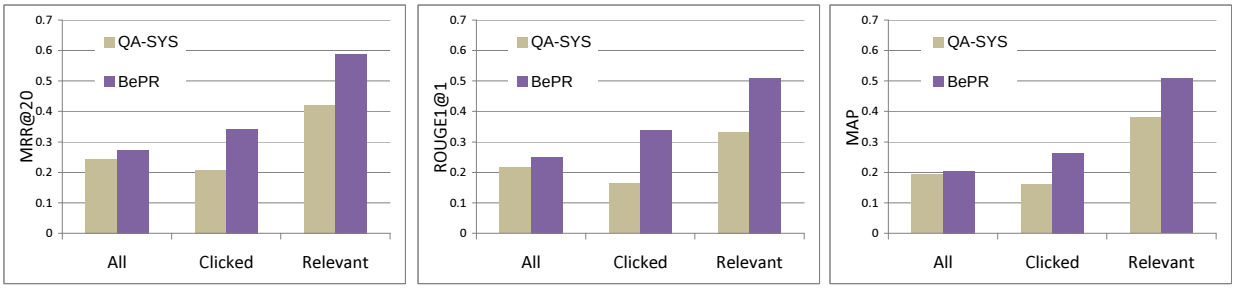

Figure 3: Passage retrieval MRR (a), ROUGE1 (b), and MAP (c) for the BePR and QA-SYS systems, on the test set.

the value of the clickthrough rate weight $\gamma = 0.05$ (used for the $BScore_{All}$ score) for the *All* document set only (as for the *Clicked* and *Relevant* document sets, γ is always set to 0 by construction).

Main retrieval results: We now compare the baseline algorithm for passage retrieval implemented in QA-SYS system and described in section 4.1 with the BePR algorithm (section 4.2-4.3) that combines the textual passage score and the behavior score using the λ parameter for the relative weight of the behavior evidence.

Figure 3 reports the main results of the paper, namely the MRR, ROUGE-1@1 and MAP passage retrieval metrics for the baseline QA-SYS algorithm, and BePR-GBM, on the test set. As the figure shows, BePR achieves higher performance on all metrics, and for all document sets. The improvements are statistically significant ($p < 0.01$) for experiments with Clicked and Relevant document sets. Not surprisingly, the improvements are smallest when *All* documents are considered, as unclicked documents do not provide any associated behavior data. As the results show, our simple back-off strategy (using the document clickthrough rate with the γ parameter) is moderately successful, but could be further refined in the future.

Finally, we illustrate how behavior features affect passage ranking. Let's consider a question "*How many Swedes speak English as a percentage?*". The perfect relevant page for this question is a Wikipedia page "Languages of Sweden". A sentence "Main foreign language(s): English 89%, German 30%, French 11%." contains an answer to the question, but it has only a small intersection with question terms, and QA-SYS ranks this question in the 13th place. Other sentences that contain a country name, a number, or have more terms that match the question are ranked higher. In contrast, as searchers examined this sentence carefully to find the answer, BePR is able to promote this sentence to the second place in the ranking.

7 Resources and Data

All the code and the collected data used in this research are available at `http://ir.mathcs.emory.edu/intent/`. The dataset contains the set of questions used for the experiments, and user's behavior: queries submitted by users to search engine, result pages, visited URLs, downloaded landing pages, on-page browsing behavior (mouse movements, scrollbar events, resize actions, clicks). By sharing our code and data, we hope to encourage further research in this area.

8 Conclusions and Future Work

We presented the first successful approach to incorporating naturalistic searcher behavior data into passage retrieval for question answering. Specifically, we developed a robust method to infer searcher interest in specific parts of the document, which could then be combined with more traditional textual features used for passage retrieval. Our results show significant improvements over a strong baseline, derived from a competitive Question Answering system.

To implement the proposed method in a real-world search engine for Web QA, the proposed infrastructure and/or the released data could be used as a training set for the algorithm that predicts fragment interestingness from user behavior. Such a system would need to track document examination data. This can already be done by incorporating our released tracking code or a similar method into a

browser toolbar, banner ad system, visit counters or other JavaScript widgets that already track user visits. While we acknowledge user privacy as an important concern, it is beyond the scope of this work.

In the future, we plan to extend this work to more precisely pinpoint the answer location on a page, and consequently incorporate searcher behavior into subsequent answer extraction and ranking stages of question answering. We also plan to further investigate the examination data to better understand how searchers find correct (and incorrect) answers using both general web search engines and QA systems – in order to inform and further improve query suggestion, result snippet generation, and result ranking algorithms.

Abstract

This paper presents the Kazakh Language Corpus (KLC), which is one of the first attempts made within a local research community to assemble a Kazakh corpus. KLC is designed to be a large scale corpus containing over 135 million words and conveying five stylistic genres: literary, publicistic, official, scientific and informal. Along with its primary part KLC comprises such parts as: (i) annotated sub-corpus, containing segmented documents encoded in the eXtensible Markup Language (XML) that marks complete morphological, syntactic, and structural characteristics of texts; (ii) as well as a sub-corpus with the annotated speech data. KLC has a web-based corpus management system that helps to navigate the data and retrieve necessary information. KLC is also open for contributors, who are willing to make suggestions, donate texts and help with annotation of existing materials.

1 Introduction

This article describes theoretical and practical issues experienced during the construction of the Kazakh Language Corpus. Kazakh is an agglutinative and highly inflected language which belongs to the Turkic group. It is official state language of Kazakhstan and a mother tongue for more than 10 million people all around the world. However, up until the early 90's of 20th century, due to historical reasons of the Soviet era, Russian language was the predominant language in spoken and written communication in Kazakhstan. This fact in turn caused the problem of underrepresentation of Kazakh language in various fields such as science, entertainment, official documentation, etc. For this reason, while assembling the corpus, we had to group categories that are generally presented as separate in other corpora into five stylistic genres. Also, in contrast to other corpora (Aksan et al., 2012; Chen, 1996), we included texts as they were available, i.e we did not try to fill a predefined set of categories. Substantial part of materials was collected using source-customized web crawlers and donated texts.

KLC also contains a manually annotated sub-corpus with morpho-syntactic and structural markups encoded in XML following general notions outlined in CES (Ide, 1998). Our syntactic tagset comprises a set of syntactic categories well-defined in a classical Kazakh grammar, and the part of speech (POS) tagset is based on a positional system in which the tags are formed by concatenation of POS of a word form and a chain of encoded linguistic properties, such as number, case, voice etc. The annotations have been carried out manually by philology students specializing in morphology and syntax. Trying to make the annotation process as comfortable as possible, we have designed a web-based annotation tool with a user-friendly interface. We took a great care for the annotation quality, and to do that we (i) arranged the validation process, and (ii) equipped the tool with a recommendation system that, as we will show, improves the inter-annotator agreement.

As a part of KLC we have also compiled the annotated read-speech corpus (RSC), which includes audio recordings of words, phrases, sentences (from all genres), news articles and excerpts from books, that were carefully chosen from the primary part of the corpus. All text materials were read by volunteers who represented different age, gender, region and education backgrounds in a balanced way. Each audio file is accompanied with a label file and a corresponding text transcript. Moreover, some of the transcripts have been grammatically annotated, i.e. in addition to a word-level segmentation of audio information a portion of our data has lexical, and morpho-syntactic annotations. In total RSC contains 10GB or more than 40 hours of speech.

This paper is organized as follows. Section 2 reviews the existing work. Section 3 provides detailed information about the primary corpus. Sections 4 and 5 thoroughly describe annotated text and speech sub-corpora respectively. Finally, we draw conclusions and discuss future work in Section 6.

2 Related Work

Since the pioneering corpus of Brown University was completed in 1964 by Francis and Kučera (1979), corpus linguistics has become a thriving research field. Over the past two decades researchers all around the world released many corpora, including well known British National Corpus (BNC) (Burnard, 2007) developed between 1991 and 1994, and containing more than 100 million words of written and spoken language from a wide range of sources (Ide and Macleod, 2001; Al-Sulaiti and Atwell, 2006). All materials were selected on a basis of three independent criteria (medium, domain and time), where each criterion had predefined target proportions. The spoken part (remaining 10%) consists of orthographic transcriptions of unscripted informal conversations and spoken language collected in different contexts. BNC is tagged for part of speech (POS) using the CLAWS4 (Constituent Likelihood Automatic Word-tagging System) (Leech et al., 1994) tagging system developed at Lancaster University. BNC is generally accepted as a balanced corpus, and many researchers, such as the creators of Turkish National Corpus (Aksan et al., 2012), Korean National Corpus (Kim, 2006) etc., adopted it as a model for compiling their own corpora.

The Russian National Corpus (RNC) has been released by the group of specialists from different organizations led by the Institute of Russian language, Russian Academy of Sciences (Ruscorpora, 2003). The corpus covers primarily a period from the middle of the XVIII to the early XXI centuries. It includes both written texts (fiction, memoirs, science, religious literature and others) and recorded spoken data (public speeches and private conversations). Currently RNC contains over 350 million word forms that are automatically POS-tagged and lemmatized. The corpus also includes semantic tags for words and texts (Apresjan et al., 2006). Along with its main part, RNC contains such subcorpora as: Deeply Annotated Corpus, that contains sentences with a complete morphological and syntax structure markup, where the syntax structure is largely based on the Meaning-Text Theory introduced by Aleksandr Žolkovskij and Igor Mel'čuk; English – Russian, German – Russian, Ukrainian – Russian, Belorussian – Russian parallel corpora; Dialect corpus; Poetry corpus and others.

Unfortunately, up until now, not too much work has been accomplished in developing a corpus that will represent Kazakh language. To the best of our knowledge there has been a limited number of attempts to compile one, but resulting corpora are too small in size and scope, or not available to the public. A Kazakh corpus has been initiated by the Committee on Languages of the Ministry of Culture of the Republic of Kazakhstan (CLMCRK, 2009). This corpus is small in size and not annotated, as it remains in its very early stage of development. The new sub-corpus for Kazakh has been recently built by Baisa et al. as a part of larger corpus of Turkic languages (Baisa and Suchomel, 2012). This corpus was compiled using a web crawler that selected texts based on a language model trained on Wikipedia texts. Although the obtained corpus is relatively large in size, the data was not categorized by genres. Also, since a crawler was not source-customized, the corpus may contain some noise coming in the form of text in Russian or other languages. We also could not find enough information about a Kazakh corpus that has been developed at Xinjiang University and used in their research (Altenbek and Xiao-long, 2010). The absence of an available corpus that will be large enough to represent Kazakh language decelerates many research activities (Mukan, 2012). We believe that building an open Kazakh corpus will have a significant impact and it will be very useful tool in the analysis of Kazakh.

3 KLC Primary Corpus

KLC is one of the first attempts to build a large scale, general purpose corpus that represents the present state of Kazakh language. Currently, the size of the primary corpus is more than 135 million words and it contains approximately more than 400 000 documents classified by genres into the following five sections: (1) *literary* section contains Kazakh literary texts that were published in the range from the beginning of the XX century till present; (2) *official* section includes mainly official statutes, orders, acts and other materials produced by the governmental organizations within the period of 2009-2012; (3) *scientific* section includes books, research monographs, dissertations, articles and essays from various fields (informatics, biology, chemistry, etc.); (4) *publicistic* section contains periodicals and articles from online sources, i.e. newspapers and magazines published over the last ten years; (5) *informal language* section includes documents with colloquial Kazakh texts extracted from the popular blog platforms starting from 2009. We have to note that while compiling this corpus we intentionally relaxed the document selection criteria by not restricting the collected data to particular domains, media, and time. This was mainly dictated by the lack of materials, and partially due to the reasons mentioned in the introduction.

Our main sources of data were Internet websites as well as digitized forms of books, dissertations and articles from public and personal libraries. For each website we designed a source-specific crawler, thereby increasing the precision of the meta data (e.g. authors, news categories, etc.) extraction. Additionally, we filtered out documents with a high consistency of Russian texts by aligning them to a language model trained on pure Russian texts. We also filtered out all documents with the size

less than 1kB. It took about 7 months to grow the corpus to its current size. Table 1 provides a general quantitative description of the corpus.

We release the data under a license that in accordance with Kazakhstan's law allows distribution of some materials in whole (official documents, news articles) and some only in part (literature, scientific texts, analytics) provided that sources are properly cited. This license does not allow printed or electronic publications or similar use of substantial portions of text drawn from the corpus without the permission of its original publisher(s) or copyright holder(s).

3.1 Text Documents Description

Each document is stored in a plain text format in the UTF-8 encoding. Documents contain both the content and the meta-data in a single file, and have the following simple structure:

- TITLE – the title of a document;
- SOURCE – the source of a document
- AUTHOR – the author(s) of a document;
- DATE – the date when a document was published;
- META – additional information;
- TEXT – the content of a document.

Provided that the corresponding information is present in a source, the <META> tag contains both the name of the section of the corpus to which a document belongs and a further categorical sub-division, such as the type of a literary work, e.g. a poem. That is, whenever possible such categories are assigned automatically, e.g. some websites provide this information. For sources that lack meta data, such as the digitized books, dissertations and scientific papers, the corresponding categories (informatics, biology, chemistry, etc.) are assigned manually.

3.2 Writing System of Kazakh language

Kazakh adopts different writing systems depending on the regions where it is spoken (Cyrillic alphabet in Kazakhstan, Arabic and Latin graphics in other countries). Recently the government of Kazakhstan has decided to adopt Kazakh alphabet to a Latin graphic. In this regard we believe that KLC could become a valuable tool. Indeed, we have already provided a group working on this problem with statistical information about letter distributions in Kazakh texts. This information could also aid in designing various speech corpora as well as a proper Kazakh keyboard layout. It can be stated that the latter was done rather carelessly just as a simple adjustment to a Russian keyboard (Wikipedia, 2012). Current Kazakh Cyrillic alphabet consists of 42 letters, whereas 9 of them are pure Kazakh letters and the others adopt the Russian symbolic. Figure 1 shows the distribution of Kazakh letters in the corpus. It can be seen that there is a small non-zero distribution of pure Russian letters (underlined). This can be explained by the ineluctable use of Russian words due to the lack of a proper translation or inheritance of Russian vocabulary.

4 The Annotated Sub-corpus

In order to enhance the effectiveness of the corpus as a research tool, we have annotated a portion of the data for syntactic and POS tags, lemmata, and for morpheme types and boundaries. Table 2 provides net amount and the percentages (with respect to the current size of the corpus) of the annotated data in terms of documents, words, unique words, and lemmata.

The annotation process has been carried out completely manually. We favored a manual annotation over a semi-automatic one, for the following two reasons: (i) finding language independent tools (not to mention Kazakh-specific) which support a fine grained level of annotation that we employ turned out to be rather challenging; (ii) though we refused and partially could not afford a semi-automatic annotation we provided the annotators with a *semi-automatic-like annotation* experience by equipping our annotation tool with a fairly advanced recommendation system. The annotation was performed mainly by the undergraduate students majoring in Kazakh philology. As a quality control measure, two validators (a graduate student majoring in Kazakh philology and one of the authors) were assigned to check a random sample of about 10% of the annotated data. Validators did not just fix errors, we also held regular "work-through-errors" sessions in an attempt to synchronize annotations. Our analysis of validated data suggest that the annotation

7	Tense	T	3
8	Mood	M	4
9	Voice	V	5

Table 4: Linguistic properties considered in the POS tagset design

quality was fairly high, as roughly only 6% of annotated tokens were fixed.

To the best of our knowledge this is the first attempt to annotate Kazakh texts with various linguistic markups. Given this, in the following subsections we would like to describe the tagsets (syntactic and POS), the annotation scheme (the format in which the annotated data is stored and distributed), and the annotation tool itself.

4.1 Designing the Tagsets

The syntactic tagset. At the initial stage of the corpus development we did not plan to build a detailed treebank, leaving this task for the future work. Therefore, our syntactic tagset comprises a compact set of syntactic categories well-defined in a classical grammar. Table 3 contains the tagset description along with the equivalent tags defined in a widely used Penn Treebank (Marcus et al., 1993) tagset[1]. In addition to that, we also label proverbials which are rather common elements of Kazakh language. We do not treat them as a separate syntactic category, for they typically serve as a single syntactic unit (e.g. predicate, adverbial, clause, etc.) Instead each syntactic tag has a corresponding binary property that marks the proverbial case.

The POS tagset. Kazakh is an agglutinative Turkic language, in which word forms are generated by means of the affix inflection. Different affix types mark different linguistic properties. For instance, consider a translation of a simple Kazakh sentence:

Mektepke bardym. - school.Dat go.Past.1sg - I went to school.

In this example pronoun *"I"* and preposition *"to"* are "hidden" in the affixes of case and person, i.e.:

Mektep(NN = *a school*) + *ke* (dative case = *to school*)

bar(VB, imperative = *go*) + *dy* (past tense = *he/she went*) + *m* (1st person = *I went*)

As the example shows, inflected affix chains contain important information that is not always present in the context, hence a tagset should be designed in a way to capture this information to the extent possible. For this reason, we design a positional tagset (Oflazer et al., 2003; Hajič and Hladká, 1998; Hana and Feldman, 2010), in which the final tags are constructed by the concatenation of the basic tag (often POS of a word form) and the en-

[1]For ease of presentation we used bracketing instead of listing, i.e. SBAR(Q) should be read as SBARQ, SBAR; (WH)NP as WHNP, NP; etc.

Table 5: The POS tagset description

coded chains of linguistic properties (LPs). Table 4 contains main LPs defined in Kazakh grammar along with their codes and *cardinalities*, i.e. a number of values they accept. Although integrating a rich set of LPs may considerably enlarge the size of a tagset, we tried to consider as many LPs as possible for the following two reasons: (i) previous research shows that increasing the size of a tagset does not necessarily decrease the tagging accuracy (Elworthy, 1995) and that for agglutinative languages omitting grammatical aspects may hurt the accuracy of *n*-gram tagging (Feldman, 2008); (ii) it is easier to reduce a detailed tagset than to re-annotate data for the missed information. Table 5 provides a detailed description of the designed tagset (not including punctuation) both qualitatively and quantitatively. The table contains a list of tags grouped by the ten major POS (in bold). For each tag we provide a set of LPs it accepts and *generative capacities*, i.e. the upper bound on a number of possible tags that can be generated from a given basic tag and the different combinations of the corresponding LPs[2]. The list of 36 basic tags was compiled following the best practices of Penn tagset design (Marcus et al., 1993), and bearing in mind the specifics of Kazakh grammar. Particularly, we broke down the major POS categories in sub-categories, in order to capture semantic distinctions and various usage patterns. For instance, negative (tag #6) and desiderative (tag #7) auxiliary verbs in conjunction with main verbs are used to mark uninflected negation (via *no* and *not*) and desiderative mood construction (via usage of *to come* in the meaning of *to want*) respectively. Similarly, auxiliary nominals (tag #27) are used as prepositional phrases such as, *in front of*, *at the top of*, etc. Also, apart from the ordinal and cardinal numerals we distinguish *collectives* (tag #15), that are used to emphasize completeness of quantities as in *both*, *all three*, etc.; and *fractions* (tag #16) as in *half*, *quarter*, etc. Finally, following classical Kazakh grammar, we treat onomatopoeias (tag #34), i.e. sound imitations as in *tic-tac* or *knock-knock*, as a distinct part of speech.

The *maximum* size of the tagset equals to the total generative capacity, or 3844 tags. However, depending on the

[2]The multiplication of cardinalities of LPs does not always give the exact number of possible tags, for there are rules that restrict certain combinations of LPs. Moreover, some LP combinations may be technically valid but semantically incorrect as they would make no sense, e.g. *bala + m + myn - I am a son of my son*. Where possible we tried to account for such exceptions, checking the combinations and providing exact numbers.

[3]Unlike any other part of speech that accepts the NSPC LP chain and must be in the third person (singular or plural) to be in any case other than nominative, personal pronouns can be in any case for any person, thus having a larger capacity.

morpheme → *token*	*direct speech* → *sentence*

chapter → *document*	*sentence* → *dialog*

Figure 2: Structural markup hierarchy

level of granularity required for an application, some or even all LPs may be dropped or added back in, providing additional flexibility. Even the minimal tagset of 36 basic tags can be further reduced to a universal tagset (Petrov et al., 2011) that consists of 11 tags, with the first seven major POS groups being mapped to their direct equivalents, and the latter four (Interjection through Foreign word) being mapped to the *catch all* category.

Lastly, given the designed tagset the aforementioned Kazakh sentence can be tagged as follows:

Mektepke/ZEP_A0N0S0P3C3 (ZEP - non-personal noun; A0 - inanimate; N0 - singular; S0 - no possessor; P3 - 3rd person; C3 - dative case) ***bardym***/ET_G0T3M1V0P1 (ET - regular verb; G0 - not negated; T3 - past tense; M1 - indicative mood; V0 - active voice; P1 - 1st person) **./.**

4.2 The Annotation Scheme

We have developed an XML-based annotation scheme that follows paradigms of the CES (Ide, 1998) and is convertible into the XCES standard (Ide et al., 2000). The main difference with the latter is that in our scheme the raw text and all markup types (i.e. lexical, syntactic and structural annotation; cf. Section 4) are stored in a single document. For the morpho-lexical and syntactic markups we have corresponding tags, i.e. <TOK> - *token* and <SU> - *syntactic unit*, respectively. Main linguistic characteristics, such as POS, lemmata, morpheme segmentation and syntactic labels are marked through the corresponding sub-tags and properties. All the aforementioned tags have their place in the global hierarchy of the structural markup. In turn, this hierarchy is integrated into the structure of an XML document itself. Figure 2 shows the schematic representation of the developed structural markup. A statement *A* → *B* represents *"A is contained by B"* relation.

4.3 The Annotation Tool

To ease the process of annotation we have developed a special tool that was designed as a web application with a logging and a document management system. The tool allows for (auto)saving current work and reviewing and revising the already annotated documents.

Functionality-wise the tool consists of the following three modules: (1) the syntactic module is designed to parse sentences using the syntactic tagset described in subsection 4.1, and to simultaneously mark sentence boundaries; (2) the morpho-lexical module is designed to perform a morphological analysis, and to comprise such functionalities as morpheme segmentation, POS tagging and lemma identification; (3) finally, the structural module is designed to mark up the logical structure of a document, i.e. paragraphs, dialogues, direct speech, lists, etc. Annotation of a given document is performed in the order in which we described the modules. The decision on such an order, as many other major design decisions, was made accounting for the annotators' feedback, suggestions and requests, thus making the annotation experience as convenient as possible. The validators have almost identical interface with additional functionality, such as a quick look up and correction of word-level (morphology) and sentence-level (syntax) markups. Also, both the validators and the annotators have means to correct orthography and punctuation. However, the originals of each and every annotated document are kept. In fact we have already collected data on misspellings to use in our ongoing research in spelling correction.

	Before	After
inter-annotator agreement	0.81	0.84
average MAE	0.08	0.07
average speed, words/hour	212.1	322.6

Table 6: Various characteristics of the annotation process before and after introducing the recommendation system

We have also developed a recommendation system for morphological analysis based on the already annotated data. For a given word or a given morpheme, the system generates a list of recommended markups ordered by the decreasing frequency of the previous usage. While this approach arguably has a potential to propagate errors, our experiments suggest the opposite. We have measured the inter-annotator agreement, average mean absolute error (MAE), and the annotation speed with and without the recommendation system. All measurements were taken for five annotators, who had been working with the tool for two weeks. For the experiments the annotators were given a randomly chosen news article containing about 300 words. The agreement was calculated using Fleiss' kappa (Fleiss and others, 1971). The average MAE was calculated as

$$\Delta MAE = \frac{1}{|A|}\sum_{a \in A}\frac{W - C_a}{W}$$

where A is a set of annotators, W is a number of words in a test document, and C_a is a number of words correctly annotated by the annotator a. The golden truth annotation was provided by the validators. The comparison of the measurements is given in Table 6. As we can see

Age group	I		II		III		IV		
Region	F1	M1	F2	M2	F3	M3	F4	M4	**Sum**
1	3	3	2	1	2	1	2	1	**15**
2	2	3	2	1			2	1	**11**
3	1	1	2	3	2	1	1		**11**
4	3	2		1		1			**7**
5	2	2	2	1	2	2	2	1	**14**
6	2	2	2	2	2		1	2	**13**
7	2	2	1	2	2		2	1	**12**
8	2	1	1	2	1	1	2	1	**11**
9	3	2	2	1	3	1	1	1	**14**
10	1	1	2	2	1	1	2	1	**11**
11	2	1	2	1	1		2		**9**
12	2	2	2		2	1	2	1	**12**
13	2	2	2	1	1	1	1	1	**11**
14	2	1	1	1	1	2	1	2	**11**
15	1	3		1	2				**7**
Total	**30**	**28**	**23**	**20**	**22**	**12**	**21**	**13**	**169**
Age group, %	**35%**		**25%**		**20%**		**20%**		

Table 7: The distribution of the speakers.

the inter-annotator agreement improves with the incorporation of the recommendations, while, in contrast to the error propagation assumption, the error rate slightly decreases. Moreover, we get more than 100 words/hour increase in the labeling speed. Thus, we conclude that as long as the quality of the already annotated data is high, the recommendation system will help to produce quality annotations at a higher speed. One can argue that we used a rather small sample of data to evaluate our recommendation system. However, we drew conclusions not only from the experimental results but also from opinions of validators, who confirmed that they noticed that after integrating the recommendation system annotations grew more coherent and synchronized.

Finally, let us provide a brief technical description of the tool. The design and structure of the front end is based on HTML5 and CSS3. We also use JQuery for HTML elements manipulation and various event handling. The tool can be tried out at `http://kazcorpus.kz/klcweb/annotated/#annotsample`, and the detailed information about it can be found at `http://kazcorpus.kz/klcweb/annotated/#annotdemo`.

5 Read Speech Corpus

Most of the modern speech processing systems require a large amount of audio and text data for training acoustic and language models. Depending on the type of an application required data varies from high quality microphone read speech (Garofalo et al., 2007) to conversational telephone speech (Godfrey and Holliman, 1997; Canavan and Zipperlen, 1996), from continuous speech (Garofolo et al., 1993) to connected (Leonard and Doddington, 1993) and isolated words (Pitrelli et al., 1995). In our current work, we collected a corpus of more than 40 hours of high quality microphone read Kazakh speech of 169 native speakers for the large vocabulary continuous speech recognition tasks.

5.1 Text Materials

The text materials to be uttered were carefully selected from the primary section of the corpus and divided into two parts: *sentences* and *stories*. The "sentences" part has more than 12 000 different sentences randomly and equally extracted from all of the five genre specific sections of the corpus. The sentences are chosen so that in total they contain more than 120 000 words which belong to the set of the most frequent words that cover the 95% of all the texts in the corpus. Additionally, the sentences were grouped according to their length in words. Thus, we have ten groups of sentences, so that the first group contains the sentences of length six, the second – of length seven, and so on up until the length of 15.

The "stories" part contains short online news extracted from publicistic genre section of the corpus. Each story consists of up to 300 words. All the materials were subdivided into non-intersecting sets of texts and distributed among the speakers in the following manner. Each speaker was assigned exactly 75 sentences and one story. Of the 75 sentences 50 belonged to the first five

"short-sentenced" groups (10 sentences per each group), and the remaining 25 belonged to the last five "long-sentenced" groups (5 sentences per each group).

5.2 Speakers

The main criteria of a speaker selection were the following: a region where (s)he learned Kazakh or spent most of his/her life; age; gender; and the ability to read Kazakh.

The first criterion helped us to capture various accents attributed to speakers' settlement both local and external. From the regional perspective we divide the speakers into 15 groups: 14 domestic (one per each administrative region, i.e. "oblast", of Kazakhstan) and one abroad (all foreign countries). Furthermore, the speakers are divided into the following four age groups (not including children and school students): (i) 18-27 years, (ii) 28-37 years, (iii) 38-47 years, (iv) 48 years and above. We did not strictly balance the speakers by their gender due to the difficulties in finding the volunteers, but still tried to choose no more than three speakers of the same gender per one age-regional group. A female-to-male distribution of speakers is 57% to 43%, respectively.

The other important criterion is the ability to read Kazakh, since not all of the interviewees could read in Kazakh sufficiently fluent, which is a common issue in a bilingual country such as Kazakhstan. Additionally, we kept a record of the speakers' education, i.e. whether they attended and graduated from a university, or graduated from a school or a college without attending any universities.

The speakers were encoded using the following scheme: <Region><Gender><Year of birth><Initials><Education>, where "Region" holds the values in the range of [1-15], "Gender" – F or M, "Year of birth" – the last two digits of a year of birth, "Initials" – initials of a name followed by a surname, "Education" – 1 for school, 2 for college, and 3 for university, e.g. 06F70ZK3.

In total, we have recorded 169 speakers. Table 7 presents a distribution of the speakers across the age, gender and regional groups. The blank spots show the speaker profiles that we could not recruit. Mostly, these cases correspond to the distant regions and elder male groups.

5.3 Recording Setup

The actual recording sessions took place in a sound-proof studio of the university with the assistance of a sound operator. Before the recordings, the speakers were instructed, documented and given some time to prepare, as well as asked to fill in the copyright transfer form for the audio data with their voice. They were not constrained on the manner, speed or time except for the correctness of reading. The average time for a recording session per speaker was about 40-45 minutes, though there were cases that lasted for two hours. Audio data was captured using a professional vocal microphone Neumann TLM 49 and digitized by LEXICON I-ONIX U82S sound card. The format of the recorded audio files is 44.1 kHz 16-bit PCM-encoded mono WAVE file format. All the recorded audio files were manually post-processed to have each utterance (sentences and stories) in a separate file and in the corresponding directories. The size of the speech corpus is about 8.5 GB on disk. A collective duration of the audio files is more than 40 hours long.

Letter	ASCII version	Letter	ASCII version
А	a	П	p
Ә	Ae	Р	r
Б	b	С	s
В	v	Т	t
Г	g	У	u

Н	n	Ь	'
Ң	Ng	Э	3
О	o	Ю	Ju
Ө	Oe	Я	Ja
#	pause		

Figure 3: ASCII version of the Kazakh letters.

5.4 Transcription and Annotation

Each audio file is provided with its corresponding orthographic transcription and TIMIT-style word-level segmentation, as well as morpho-syntactic annotation files. Both the transcript generation and the annotation were performed manually by trained linguists. The transcription files contain the exact orthographic transcriptions of the utterances, which may differ from the original text. For example, the numbers, abbreviation, foreign words and dates are expanded depending on how they were uttered by the speakers. In addition, the transcription of the stories have the sentence boundaries labeled with <s> and </s> tags. For the segmentation we used WaveSurfer (2013), an open-source tool for sound

visualization and manipulation, which supports TIMIT word-level transcription format. Although, it supports Unicode, it does provide a proper support for Kazakh symbols. Therefore, we used an ASCII version of the Kazakh letters depicted on Figure 3. Also, we used the # symbol for the pauses and silence, and ^ symbol for other non-speech events.

6 Conclusion and Future Work

In this work we have described the design and compilation process of the Kazakh Language Corpus. KLC is oriented for a wide range of users and we believe that it will be a valuable tool for research communities, especially given that a portion of the data has been labeled with multiple levels of annotation, including word-level segmentation of audio information. We are already using the annotated data in our initial experiments in morpheme segmentation and error correction.

One can explore the corpus through the website (`http://kazcorpus.kz`) that was designed to provide the best experience in the analysis of data.

For the future work we plan to use the corpus as a research tool to tackle the following problems: (i) automatic part of speech tagging, (ii) morphological disambiguation, (iii) statistical machine translation. For the latter we have already started collecting parallel text in Russian and English.

Acknowledgments

We would like to thank the Ministry of Education and Science of the Republic of Kazakhstan for supporting this work through a grant under the 055 research program.

We express our gratitude to Dr. A. Sharipbayev for his valuable advice on methodology of constructing the read-speech corpus.

We also would like to sincerely thank our validators and annotators: Bobek A., Asemgul R., Aidana Zh., Nazerke G., Nazym K., Ainur N., Sandughash A., Zhuldyzai S., Dinara O., Aigerim Zh. The annotation and validation work they have done helped a great deal in designing tagsets. This work would not be possible without their contribution.

Automatic Extraction of Morphological Lexicons from Morphologically Annotated Corpora

Ramy Eskander, Nizar Habash, Owen Rambow
Center for Computational Learning Systems
Columbia University
{reskander,habash,rambow}@ccls.columbia.edu

Abstract

We present a method for automatically learning inflectional classes and associated lemmas from morphologically annotated corpora. The method consists of a core language-independent algorithm, which can be optimized for specific languages. The method is demonstrated on Egyptian Arabic and German, two morphologically rich languages. Our best method for Egyptian Arabic provides an error reduction of 55.6% over a simple baseline; our best method for German achieves a 66.7% error reduction.

1 Introduction

Morphological lexicons specify all inflected forms for each lexeme; in a language with rich morphology, such a resource can be important for natural language processing (NLP) tasks in order to limit data sparseness. For example, a morphological lexicon is an important component of a morphological tagger or of a part-of-speech (POS) tagger for languages with rich morphology.[1] Traditionally, a morphological lexicon has been created through painstaking lexicographic and morphological analysis of the language, drawing on unannotated corpora. Recently, new approaches have emerged. Fully or largely unsupervised approaches cannot link surface forms to morphosyntactic features and are thus not suited for building morphological lexicons. This problem is overcome by approaches that use explicit linguistic knowledge. In this paper, we investigate using existing morphologically annotated corpora. In a morphologically annotated corpus, the words in naturally occurring texts or transcribed speech are annotated for the correct morphological analysis (including, of course, core POS) in context. While there has been much work on computational morphology, to our knowledge this is the first paper to study the question of how to extract morphological lexicons from morphologically annotated corpora, and how to determine how much annotation is needed. In this paper, we assume a corpus with each word annotated with morphosyntactic features and with a lemma which tells us what lexeme the word form is part of. The task is to predict the correspondence between a word form and its lemma and morphological features.

This paper makes two contributions. First, we introduce an algorithm that learns unseen forms by analogy. This algorithm is language-independent. It incrementally merges complementary paradigm information about different lexemes into more abstract and more informative inflectional classes. Second, we explore how to model stems, and we propose a generalization of the Semitic root-and-template modeling. We use Egyptian Arabic (EGY), and German (GER) as our test languages. We test on corpus data, in order to simulate a standard real-world application. The baseline just uses the word forms seen in training and does not predict any unseen forms. Our language-independent algorithm improves the performance for both EGY and GER, with error reductions over the baseline of 44.4% for EGY and of 66.7% for GER. By adding language-specific modeling of the stem using templates, we obtain further error reductions for EGY (up to 55.6%) but not for GER.

Next, we review related work (Section 2) and introduce the key linguistic concepts we use (Section 3). We present our basic language-independent method in Section 4, and our language-specific modeling of stem variation in Section 5.

[1] Note that a full-form morphological lexicon is functionally equivalent to a morphological analyzer-generator, since one can be used to create the other.

Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Approaches to Morphological Modeling Much work has been done in the area of computational morphology ranging from systems painstakingly designed by hand (Koskenniemi, 1983; Buckwalter, 2004; Habash and Rambow, 2006; Détrez and Ranta, 2012) to unsupervised methods that learn morphology models from unannotated data (Creutz and Lagus, 2007; Monson et al., 2008; Hammarström and Borin, 2011; Dreyer and Eisner, 2011). There is a large continuum between these two approaches. Closer to one end, we find work on minimally supervised methods for morphology learning that make use of available resources such as parallel data, dictionaries or some additional morphological annotations (Yarowsky and Wicentowski, 2000; Cucerzan and Yarowsky, 2002; Neuvel and Fulop, 2002; Snyder and Barzilay, 2008). Closer to the other end, we find work that focuses on defining morphological models with limited lexicons that are then extended using raw text (Clément et al., 2004; Forsberg et al., 2006). The work presented in this paper falls in the middle of this continuum: we are interested in learning complete morphological models using rich morphological annotations and, optionally, limited linguistic knowledge. We compare the value of different amounts of annotation and how they relate to additional linguistic knowledge.

Morphological Paradigms Many traditional and modern theories of inflectional morphology organize natural language morphology by paradigms (Stump, 2001; Walther, 2011; Camilleri, 2011). Within the continuum we discussed above, we find hierarchical representations of paradigm knowledge that have been used in manually constructed morphological models (Finkel and Stump, 2002; Habash et al., 2005). Furthermore, Détrez and Ranta (2012) introduce an implementation of Smart Paradigms – heuristically organized paradigms minimizing the number of forms needed to predict the full paradigm of a particular lexeme.

Both Forsberg et al. (2006) and Clément et al. (2004) describe methods for automatically populating a lexicon from raw data given a set of morphological inflectional classes in a language. Our work differs in that we use annotated data, but do not start with a complete set of inflectional classes; thus, our work is exactly complementary to this work.

The concept of a paradigm is also used in many published efforts on unsupervised learning of morphology, although not always in a way consistent with its use in linguistics. For instance, Snover et al. (2002) (and later on Can and Manandhar (2012)) define a paradigm as "a set of suffixes and the stems that attach to those suffixes and no others". This definition is quite limited since it is not modeling the notion of lexeme. Chan (2006) defines a simpler concept of paradigms in his *probabilistic paradigm* model, which has many limitations, such as not handling syncretism or irregular morphology, nor distinguishing inflection and derivation.

Dreyer and Eisner (2011) learn complete German verb paradigms from a small set of complete seed paradigms (50 or 100), which they choose randomly from all verbs in the language. They model stem changes using letter-based models, and use a large unannotated corpus in addition to the seed paradigms. Durrett and DeNero (2013) attack the same problem as Dreyer and Eisner (2011). Instead of using unannotated text, they model explicit rules for affixes and stem changes. The major difference between these two efforts and our work is that the problem is defined differently: we assume that the training and test data is defined by a corpus, not by complete paradigms. Our methods therefore are more sensitive to frequency effects of tokens. We believe that our way of stating the problem is more relevant to actual computational challenges for languages with limited morphological resources. We empirically compare our approach to that of Durrett and DeNero (2013) in Section 5.

None of the unsupervised approaches mentioned model inflectional classes, i.e., meta-paradigmatic representation that cluster the various paradigms of different lexemes into a set of general classes of paradigms. There is no explicit notion of morphosyntactic features. In this paper we target the learning and completion of inflectional classes from morphologically annotated data. Our approach does not sacrifice details of what paradigms should include: we handle syncretism and stem changes, and allow for the prediction of new word forms from morphosyntactic features and lemmas, unlike the largely unsupervised work. Our work also differs from most previous work in that we investigate how to model stem change explicitly. Whereas other approaches model stem syncretism through letter-

based models (Yarowsky and Wicentowski, 2000; Neuvel and Fulop, 2002; Dreyer and Eisner, 2011), we explore the use of abstract stems.

In our previous work on the EGY morphological analyzer CALIMA, we similarly used a lexicon of annotated morphological forms and extended it automatically using a simpler approach to paradigm completion (Habash et al., 2012).

3 Linguistic Terminology

In this section, we review key concepts from morphology, and introduce the terminology we will use in this paper.[2] We then introduce our own formalization of stems using vocalic templates.

Morphology is the study of word forms and their decomposition into elementary morphemes, which are the smallest meaning-bearing units of a language. There are two types of morphological processes: inflectional and derivational morphology. In inflectional morphology, a core meaning is retained and different word forms reflect different types of morphosyntactic features such as person, number, or tense. In derivational morphology, the core meaning of a word is changed, and perhaps even its part-of-speech (POS). In this paper, we restrict our interest to inflectional morphology. Furthermore, we take the written form of the word to be primary, and base all morphological analyses on the written form.

We will refer to the set of all word forms that are related through inflectional morphology alone as **lexeme**. We can refer to a lexeme with a **lemma**, which we take to be a language-specific and conventionalized choice of one of the inflected forms. For example, in English the verb is conventionally cited in the infinitive (often with *to*, which can be omitted), while in Arabic it is conventionally cited in perfective third person masculine singular. The lemma is sometimes referred to as a "citation form". A **paradigm** of a lexeme is a list of **cells**, where a cell is a combination of a complete set of morphosyntactic features (properties) and the corresponding inflected form of the lexeme. A paradigm is **complete** if there are cells for all possible morphosyntactic features (the list of possible morphosyntactic features is of course language-dependent).

We can divide the word forms into **affixes** (i.e., prefixes and suffixes) and the **stem**. There is no single correct way to do this for the words of a language. Each lexeme has its own paradigm. We can abstract from paradigms by grouping together paradigms which share the same affixes in corresponding cells, and where stems in corresponding cells differ in some restricted manner. We can define the **inflectional class** (IC) more formally as a set of **abstract cells**, where an abstract cell is a combination of a complete set of morphosyntactic features (properties) and an abstract representation of a stem (an **abstract stem**) along with fully specified affixes. The abstract stems (and thus the abstract cells) must have the property that, given a single instantiated word form of a lexeme along with its associated IC, we can derive the *complete* paradigm of the lexeme deterministically. In the first results we present, we simply assume that the stem is either shared entirely with other abstract cells, or it is entirely lexically instantiated. We explore language-specific approaches to defining an abstract stem in Section 5, where we also discuss relevant morphological facts of EGY and GER.

Prefixes, suffixes, and stems can be the same for different cells of a single paradigm or IC. This is called **syncretism**. We will refer to the cells which share a stem as a **stem syncretism zone** or "zone" for short.

4 Language-Independent Inflectional Class Construction Algorithm

In this section, we present our language-independent IC construction algorithm (LICA). LICA consists of a core algorithm for building ICs from seen data and models of soft-stem syncretism and affix prediction.

4.1 Problem Definition

Starting with a corpus of words annotated as triples of ⟨*prefix*+*stem*+*suffix*, *lemma*, *features*⟩, we want to create a lexicon of complete ICs, with each IC having an associated set of lemmas. The following is an input example specifying the inflected form of the 3rd person plural imperfective inflection for the EGY lemma **katab**[3] 'write': ⟨y+iktib+uwA, **katab**, I3UP⟩.

[2] We (roughly) base our terminology and our conceptualization on the inferential-realizational theory of Stump (2001).

[3] Arabic transliteration throughout the paper is presented in the Habash-Soudi-Buckwalter scheme (Habash et al., 2007).

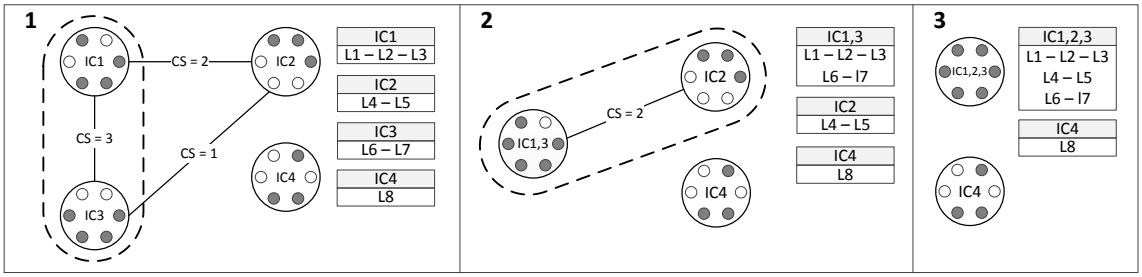

Figure 1: This graph illustrates two merges that result in combining three ICs in two steps. The IC cells are represented as solid (filled cells) or blank (empty cells) circles. CS is the compatibility score marking the number of matching filled cells in an IC. The boxes to the right of the graph represent the lexicon which associates lemmas (L*) with ICs. IC4 is not connected with any of the other ICs, because it has cell values that are incompatible with them.

4.2 Core Algorithm

Building the Initial Inflectional Classes An initial IC is constructed for each lemma found in the input corpus using all the triplets involving said lemma. Since the lemma itself is an inflected form with an *a priori* fixed feature combination, we also use the lemma to construct the initial IC, even if it did not occur as a word form in the corpus. If all inflected forms of a lemma appear in the training data, the IC will be complete. However, typically there are many unseen forms. If all seen forms related to one lexeme have the same stem, the abstract stem chosen for the IC is a single stem variable; the abstract cells of the new IC can of course differ in terms of affixes (which are always fully specified rather than represented as variables). In cases when the seen forms of one lemma have more than one stem, the IC created will simply be the same as the paradigm, i.e., we have fully instantiated stems as our abstract stems. We call such ICs **suppletive ICs**. At this point, we have a repository of numerous incomplete ICs and a lexicon consisting of a one-to-one mapping between lemmas and these new ICs. We then identify all ICs that are exactly the same (by definition, these are not suppletive ICs), and merge the associated sets of lemmas. We now have a new lexicon in which some ICs are associated with more than one lemma.

Constructing the Inflectional Class Graph We construct an IC graph that connects all *mergeable* ICs. Two ICs are mergeable if neither of the ICs is suppletive, if they share at least one abstract cell for some morphological feature, and if no morphological features are associated with different abstract cells, i.e., there are no incompatibilities. Each point in the graph represents a specific IC, while the edges carry the following four scores that we use to determine mergeability order:

- The **compatibility score** is the number of non-empty intersections between the two ICs.
- The **originality score** is the larger number of previous merges of the two ICs. At the beginning, this number is 0 for all edges.
- The **completeness score** is the size of the union of non-empty rows from the two ICs
- The **lexical size score** is the sum of the number of lemmas associated with the two ICs.

The edges of the graph are ranked according to the compatibility score first (more is better). Any ties are broken using the originality score (lower is better), any remaining ties by the completeness score (more is better) and then by the lexical size score (more is better). We explored all possible orders of tie breaking using EGY data, and determined the order of the listing above to be best. We use it in all experiments reported in this paper.

Merging the Inflectional Classes While the IC graph is still connected, we repeat the following merging procedure. Starting with the highest ranked edge in the graph, we merge the two ICs connected by the edge. In case of multiple edges that are equally highly ranked (after tie breaking), we select randomly among them. The merge creates a new IC that has the union of the cells in the two ICs. The lexicon is adjusted accordingly by associating with the new IC the union of all the lemmas originally associated with the two ICs. The new IC inherits the union of all the IC graph connections of its predecessors. The IC graph edge scores between the new

IC and other ICs are recalculated. Graph edges that become incompatible after the merge are removed. The two original ICs are removed from the graph and lexicon. See Figure 1 for an illustration of the merge process.

4.3 Completing Stems and Affixes

Soft Stem Syncretism Zones We extend the concept of stem-syncretism zones into a statistical model that computes the probability that the abstract stems in two abstract cells are the same given their feature combinations, i.e., that they belong to the same syncretism zone. We refer to this approach as "soft" stem-syncretism zones or "soft zones" for short. The probabilities are computed for each feature-combination pair as the ratio of the times the abstract stem for the feature-combination pair are equal divided by the times the abstract stem for the feature-combination pair are not empty. The probabilities can be computed after the initial IC graph construction or after the merging process has concluded; they can also be based on IC type counts or weighted by the number of associated lemmas. Applying soft zones to fully complete the ICs can only be done after merging is completed. We try all the possible alternatives for learning the SZs on the EGY data, including experiments with small training data sizes. The best accuracy is obtained using IC type weights learned after the merge. We use this setting for all experiments.

When applying the soft zones to determine the abstract stems of empty cells, we consider all filled cells in the same IC and select the abstract stem from the cell of the feature combination that has the highest soft-zone probability with the feature combination of the empty cell. Note that the copied abstract stem can be either a stem variable, or, for a suppletive IC, a lexical form.

Predicting Affixes In building the ICs mentioned above, some feature combinations and their corresponding affixes (prefixes and suffixes) are missing since they were not in the training data. We fill the missing affixes in a particular IC i by copying them from other ICs that we rank by overall seen affix similarity to IC i. ICs with conflicting affixes for any feature combinations are excluded completely. For any remaining missing affix-feature combination, we use the most common affix for that feature combination over all ICs.

4.4 Model Application

The complete ICs produced by the completion algorithm, associated with their lemmas in the lexicon, can now be used to predict the surface form of a given lemma and morphological features. We use the following procedure: If the given features are the same as those used to define the lemma, then the surface form is the same as the lemma form. If the lemma was seen in training, we select its IC from the model and generate the inflection associated with the features. This may require instantiating a stem variable (in case the IC is not suppletive), but this can be done deterministically from the lemma.

If the lemma has not been seen, then we build an IC on the fly using the lemma, i.e., an IC with a single cell. We then pick an IC from the model that does not conflict with that IC. The priority is given to the IC with the largest lexicon size, which is likely to be a result of several merges. If such an IC does not exist, a backup mode returns the stem of the lemma associated with the most frequent affixes of the queried features.

4.5 Results on Egyptian Arabic

Data and Metrics We use a morphologically annotated EGY corpus based on the CALLHOME EGY (CHE) corpus (Gadalla et al., 1997).[4] We divide the corpus into three parts: training, development and test, of about 75K, 36K and 41K words, respectively. We conduct our experiments on verbs only since they have a large number of possible morphosyntactic feature combinations. The verbs in these experiments are uncliticized. Clitics are easily handled using a few orthographic rules (El Kholy and Habash, 2010). On average, uncliticized verbs are about 12% of all words in our corpus. The data is represented in triplets as described in Section 4.1. There is a total of 19 feature combinations of aspect/mood (perfective,imperfective and imperative), person (first, second and third), gender (masculine, feminine and neutral) and number (singular and plural). Some combinations are invalid such as the first and third persons with the imperative form. The lemma we use is the Arabic citation form for verbs, which is the perfective third person masculine sin-

[4]The corpus was automatically annotated using information from the CHE transcripts (Gadalla et al., 1997) and the Egyptian Colloquial Arabic Lexicon (Kilany et al., 2002). For more details, see Habash et al. (2012) and Eskander et al. (2013).

gular (P3MS) inflection. We use this fact to fill the P3MS cells when building the initial ICs.

We evaluate the accuracy of the automatically generated bidirectional lexicon by generating surface forms from lemmas and morphosyntactic features. We use the model application method described in Section 4.4.

Baseline Our baseline system consists of two steps. First, we check the features. All cases of citation form features (in the case of EGY, P3MS) return the lemma as the inflected form. Otherwise, we look up the lemma and feature pair among all triplets in the training data and return the inflected form if such a triplet was found. If not, the baseline does not return an answer.

Results The results on tokens are summarized in Table 2 under the column heading BL (baseline) and NOTMP (LICA with no stem template). Our system consistently improves over the baseline for all training data sizes explored.

Error Analysis We performed an error analysis using the best settings found on the development set. We found that in 46% of the error types the lemma is unseen. Additional 35% of the cases are due to stem templates that are unseen in the complete ICs although their corresponding lemmas are seen. About one tenth of the cases are because of the existence of multiple forms of the same lemma and feature combinations, where our system assigns a form that is different from the gold form. Finally, gold errors contribute to about 9% of all errors.

4.6 Results on German

Data and Metrics For our experiments, we use the TIGER corpus (Brants and Hansen, 2002). We divide the corpus into three parts: training, development and test, of about 709K, 143K and 37K words, respectively. However, we use the first 75K words in training and the first 36K words in development to have the results comparable to EGY. We conduct our experiments on verbs only. We disregard any verbs with separable prefixes (as is common in work in morphology learning). On average, verbs without separable prefixes are about 9% of all words in our corpus. The data is represented in triplets as described in Section 4.1. There are 28 feature combinations of tense (present, past), person (first, second and third), number (singular, plural), and mood (indicative, subjunctive, imperative, past participle, infinitive). Some combinations are invalid such as any tense with the non-tensed participle or infinitive. The infinitive is the lemma. We use the same metrics as for EGY (Section 4.5).

Results The results are summarized in Table 5, with the relevant results in the column NOTMP. We see that our algorithm performs substantially better than the baseline at all training set sizes, with greater relative error reductions at smaller training sizes.

Error Analysis We inspected all error types in the development set and found that nearly 8% of all error types are errors in the gold annotation of the development set, and in 4% of cases, our predicted form is correct because a lemma is shared by two verbal paradigms (for example, *werden* has different past participles depending on whether it is the passive auxiliary or the verb for 'become').

5 Language-Specific Modeling of Stems

5.1 General Approach

We model the abstract stems using the notions of **orthographic template** and **orthographic root**. To meet our definition of IC given above, we define these two notions so that the root and template can always be extracted deterministically. We define them simply in terms of sets of letters: the set of letters of the alphabet used to write the language we are modeling is partitioned into the **root letters** and the **pattern letters**. The orthographic template is a string that specifies the template letters and that has placeholders for the root letters, which we write as '□'. The orthographic root is a sequence of strings that specifies the root letters that can fill a vocalic template's placeholders, in the order specified. Note that an IC along with a root is equivalent to a paradigm, since the root can be inserted deterministically into the abstract stem. This gives us another way to specify a lexeme: since a complete paradigm enumerates all inflected forms of a lexeme, and since a complete IC along with a root defines a complete paradigm, we can specify a lexeme to be a pair consisting of an IC along with a root. This pair determines a complete mapping from morphosyntactic features to surface word forms for the lexeme.

The basic algorithm discussed earlier is modified as follows: when we read in the training data, the

EGY Inflectional Class (IC) Repository			
	IC-1	IC-2	IC-3
P1US	□a□a□+t	□a□∼+ayt	□u□+t

root of the lemma is used to decompose the stem of the inflected form into a root and a template.

5.2 Choosing Root and Pattern Letters

Determining which letters count as root letters and which count as pattern letters is language-specific. In this paper, we use three approaches to choosing root and pattern letters.

No Template (NOTMP) In this approach, we do not model the stem at all, i.e., there are no pattern letters. As a result, the ICs cannot express stem changes; any verb with a stem change will be an irregular verb and it will be modeled with a suppletive IC. Note that in EGY, *every* verb manifests a stem change between the perfective and imperfective forms, while in GER many verbs in fact do have the same stem for all inflected forms. The results of the NOTMP approach are the same basic approach results already presented in Section 4.

Scholar (SCHLR) In this approach, we use linguistic scholarship and intuition to choose a set of letters to be the pattern letters. These are letters which we know can change in stems within the same IC. We discuss this approach for EGY in Section 5.3.1 and for GER Section 5.4.1.

Empirical (EMPR) In this approach, we obtain the set of pattern letters empirically. We align the letters of all the stems in the development corpus with the stem letters of their corresponding lemmas. This allows us to identify which letters change between lemma stem and inflected stem. We order the letters by the probability that a letter changes given all occurrences of that letter, and by the probability that a letter changes given all changes that occur. This gives us two rankings. For both rankings and for each letter that changes, we construct a set of letters by including all letters from the most highly ranked letter down to the letter under consideration. This gives us per ranking as many sets as there are letters that change. We then choose the best performing set among all sets generated by both rankings. We present the results of this approach for EGY in Section 5.3.1 and for GER in Section 5.4.1.

5.3 Egyptian Arabic

5.3.1 Choice of Pattern Letters

Scholar-based Pattern Letters For the EGY SCHLR approach, we selected the following pattern letters: اأإآوؤيىئءـُـِـّ *AÂĂĀwŵyýŷ’aui∼*. These letters cover all the so-called weak root radicals, Hamzated forms and diacritics that are often used to discuss different verbal paradigms in Arabic (Gadalla, 2000). Table 1 shows three EGY inflectional classes. We follow the standard practice in modeling Arabic morphology of assuming that each placeholder in an orthographic template corresponds to exactly one letter from the orthographic root (i.e., the root is a sequence of strings each of length one). We would like to stress that our orthographic template and root differ from the notions of pattern and root in Semitic morphology (for an overview, see (Habash, 2010)): while for **katab** ‘write’ the orthographic root as well as the “real” root is ‖k,t,b‖, the orthographic root for **xal∼aý** ‘let’ is ‖x,l‖ (as opposed to the real root ‖x,l,y‖). Henceforth, we will omit the adjective “orthographic”, since we will not talk about the “real” root. To inflect a lemma for a particular set of features, we combine the root with the □ slots in the corresponding inflectional class feature row, e.g., Hal∼ + P2FS ⇒ ‖H,l‖ +

□a□∼+aytiy ⇒ Hal∼aytiy. Note that in this paper, we do not use any rules; all regular phonological and orthographic variation is "compiled" into the ICs. We also see examples of stem syncretism zones in Table 1; they are marked with horizontal lines. The stems associated with P3MS, P3FS and P3UP happen to be the same within each IC (although different across ICs). Different ICs have different zones: e.g., IC-1 has one zone for the P*** features, while IC-2 and IC-3 have two identical zones for P3** and P[12]**.

Empirically Determined Pattern Letters For EGY, the EMPR approach, using the algorithm described in Section 5.2, yields the following optimal set of pattern letters: اأإويىيئءثـّـُـِ *AÂĂwyýŷ'θaui*. This set is very similar to the SCHLR set except in that it omits the lexically constant (per lexeme) Shadda diacrtic ّ ∼ (orthographic gemination marker), and some very infrequent Hamzated forms; and it also adds one letter ث θ as a result of orthographic inconsistency in the training data.

Corpus Size	Verb Count	BL	NOTMP	SCHLR	EMPR	EMPR IIC+HZ
0K	0	19.3	20.0	20.0	20.0	58.8
1K	95	51.8	64.2	68.3	68.1	83.3
5K	630	64.2	77.0	83.9	83.9	91.1
10K	1,201	70.4	84.3	89.4	89.1	92.4
25K	2,994	79.6	91.5	94.4	94.8	95.6
50K	5,966	84.5	94.2	96.9	96.7	97.2
75K	8,690	85.6	94.9	97.5	97.6	97.2

Table 2: Learning curve comparing system performance for EGY on **tokens** (development set).

Results The template approaches SCHLR and EMPR consistently beat NOTMP which does not make use of any templatic stem modeling (see Table 2). However, SCHLR and EMPR perform about equally. This is not surprising since the two sets of pattern letters are quite similar.

Error Analysis We conducted an error analysis of EMPR using the best settings found on the development set. About 86% of the error types in NOTMP where the lemma is unseen are solved after introducing EMPR. Additionally, 71% of the cases in NOTMP where the stem template is unseen and the lemma is seen are solved. However, 7% of the error types in EMPR are not present in NOTMP, and they are all cases where the stem template is unseen while the lemma is seen. Errors due to multiple stem forms and gold errors remain the same in both NOTMP and EMPR, contributing to 26% and 23%, respectively, of all the error types in EMPR.

5.3.2 Other Enhancements with Linguistic Knowledge

Other linguistic knowledge can also help enrich the process of IC learning, especially under limited annotation conditions. We use the following two types of linguistic knowledge, which seamlessly integrate into the core merging algorithm described above.

Iconic Inflectional Classes (IICs) are ICs that are manually fully annotated, i.e., they have all the template cells for all morphosyntactic features specified. IICs are treated like any other ICs when constructing the initial IC graph. They are different from other ICs in that they initially have no lemmas associated with them in the lexicon.

Hard Stem-Syncretism Zones (HZ) are stem-syncretism zones determined manually by linguists to hold for all ICs. As such they can be more fine-grained than is needed to describe individual ICs. A hard zone is not applied in case of any partial disagreement within it. Unlike soft zones, they could be applied before or after the merge process, and they do not guarantee that the ICs will be completely filled.

We conducted experiments where we added external linguistic knowledge to our training data. We added 112 IICs which are extracted from all EGY verb inflections listed in a reference grammar of EGY (Gadalla, 2000). Also we added the following eight HZs for EGY (with reference to features $<tense, person, gender, number>$): (P1US-P1UP-P2MS-P2FS-P2UP), (I1UP-I2MS-I3MS-I3FS), (I2FS-I2UP-I3UP), (P3FS-P3UP), (C2FS-C2UP), (P3MS), (I1US), and (C2MS). Applying the HZs on the completed ICs (before soft zone application) gives higher results than applying them on initial ICs. We only report below on the setting of applying HZs after IC merge completion. We present the accuracies of IC learning for the baseline, and for the best setup with and without IICs and HZs, for different training sizes in Table 2. The baseline with no training data is at 19.3%

because of all the cases with verbs appearing in the citation form. As expected, IICs always help improve accuracy, especially under limited (and no) data conditions. However the benefits diminish rapidly for larger training sets. When evaluating on types only (results not presented in this paper), we find that using IICs in our system with no data is better than using the baseline with 75K words.

5.3.3 Blind Test Set

Table 3 shows the accuracies the different systems on our blind test set. The results for the test set are lower than those of the development set, but the trends are the same. We also compare our results to those obtained using the system of Durrett and DeNero (2013) on the same test data. Note that we apply their system to our problem – predicting unseen forms from annotated corpora (i.e., incomplete paradigms), not to the problem for which they created their system – predicting unseen forms from complete paradigms. Our best system outperforms theirs by 2.8% absolute in accuracy.

System	Accuracy	Error Reduction
Baseline	84.7	
NOTMP	91.5	44.4
SCHLR	93.2	55.6
EMPR	93.2	55.6
Durrett & DeNero	90.4	37.3

5.4 German

5.4.1 Choice of Pattern Letters

Scholar-based Pattern Letters We now discuss our scholarship-based choice of pattern letters for German. Like Arabic, German verb paradigms can show stem changes which are typically vowel changes. Furthermore, like Arabic, German has prefixes, suffixes, and circumfixes. However, unlike Arabic, German has many verbs (called "weak verbs") which are regular in the sense that they show no stem change at all. The irregular verbs, or "strong verbs", show many different patterns of stem changes. Another difference to Arabic is that the affixes are not the same for all verb paradigms. In particular, the weak verbs form several inflectional classes (which, of course, differ only in affixes). Finally, unlike Arabic, in the strong verbs the orthographic root does not necessarily consist

Table 4: Example of three inflectional classes (some cells omitted in the interest of space economy) and associated lemmas with their roots in German ("X" stands for past tense). The different blocks in the IC table specify different stem syncretism zones.

of sequences of single letters: the strong verbs have monosyllabic stems (plus perhaps derivational morphology), with the vowel in this stem potentially undergoing changes. However, the onset and coda of the stem syllable can be any consonant cluster allowed by German phonology. Thus, in German, we model roots as pairs of strings of any length (which represent the onset and coda of the stem syllable). Table 4 shows a weak IC and two strong ICs.

Since German strong verbs can have any stem vowel, we assume that all eight vowel letters of German (*aeiouäöü*) are pattern letters, and all other consonant letters are root letters. German weak verbs show no stem changes at all; if we tailored our templates to them, we would define all letters to be root letters, and there would be no pattern letters at all. This is in fact the experiment we reported on in Section 4.6, and whose results are shown as NOTMP in Table 5. However, since we do not know during training time whether a verb is weak or strong, all verbs will be modeled with an orthographic template, even though there is no stem change at all.

Empirically Determined Pattern Letters For GER, the EMPR approach, using the algorithm described in Section 5.2, yields *oaäß* as the optimal

set of pattern letters. The EMPR pattern letters differ from the SCHLR pattern letters by omitting five vowels, but including the *ß* variant of the *s*.

Results In table 5 we see that using all eight vowels as pattern letters (SCHLR column) in fact decreases performance at every training size (and relatively more at smaller training sizes). However, if we use the empirically obtained pattern letter set *oaäß*, we see that we perform better than SCHLR at almost all training sizes, and slightly better than NOTMP at larger training sizes.

Error Analysis A manual inspection of all development error types again revealed 8% development set annotation errors and 4% acceptable variations. To investigate why NOTMP outperforms SCHLR for German on the development set, we performed an oracle experiment: we assumed we knew for each seen verb in training whether it is a weak or a strong verb. If it is weak, we model it using NOTMP, and if it is strong, using SCHLR. We observe as expected that the performance on weak verbs is very similar to that obtained using NOTMP on all verbs. However, for the strong verbs, it is only when we have more than 75,000 words of training data that the oracle outperforms NOTMP. We assume that the reason is that the highly frequent verbs are strong, but occur frequently enough so that their IC can be learned directly from the training data. Using SCHLR simply adds noise for these very frequent verbs. It is only for the less frequent strong verbs that SCHLR can contribute, and then only when a large amount of training data is available.

5.4.2 Blind Test Set

Table 6 shows the accuracies the different systems on our blind test set. The results for the test set are lower than those of the development set, and NOTMP, SCHLR,and EMPR produce very similar accuracy results. We also compare our results to those obtained by running the system of Durrett and DeNero (2013) on the same training and test data. Our system outperforms Durrett and DeNero (2013)'s system reducing the error of by 5%.[5]

[5]We also tested our system on Durrett and DeNero (2013)'s problem definition and data, training on 200 GER paradigms, and testing on 200 unseen paradigms. This is the case of testing for unseen lemmas in our system. Our system gives an accuracy of 88.4% as opposed to 91.8% as reported by Durrett and DeNero (2013). Our system was not designed for this task.

Corpus Size	Verb Count	BL	NOTMP	SCHLR	EMPR

6 Conclusion and Future Work

We presented a method for automatically learning inflectional classes and associated lemmas from morphologically annotated corpora. In the future, we plan to improve several aspects of our models, in particular, using more powerful language-independent template transformations to automatically optimize for stem and affix modeling. We plan to take the insights from this paper and apply them to new dialects and languages with limited resources. We are interested in extending our approach to languages with different morphological systems, e.g., agglutinative or reduplicative. We will explore ideas from unsupervised morphology learning to minimize the need for morphological annotations.

Joint Language and Translation Modeling with Recurrent Neural Networks

Abstract

We present a joint language and translation model based on a recurrent neural network which predicts target words based on an unbounded history of both source and target words. The weaker independence assumptions of this model result in a vastly larger search space compared to related feed-forward-based language or translation models. We tackle this issue with a new lattice rescoring algorithm and demonstrate its effectiveness empirically. Our joint model builds on a well known recurrent neural network language model (Mikolov, 2012) augmented by a layer of additional inputs from the source language. We show competitive accuracy compared to the traditional channel model features. Our best results improve the output of a system trained on WMT 2012 French-English data by up to 1.5 BLEU, and by 1.1 BLEU on average across several test sets.

1 Introduction

Recently, several feed-forward neural network-based language and translation models have achieved impressive accuracy improvements on statistical machine translation tasks (Allauzen et al., 2011; Le et al., 2012b; Schwenk et al., 2012). In this paper we focus on recurrent neural network architectures, which have recently advanced the state of the art in language modeling (Mikolov et al., 2010; Mikolov et al., 2011a; Mikolov, 2012), outperforming multi-layer feed-forward based networks in both perplexity and word error rate in speech recognition (Arisoy et al., 2012; Sundermeyer et al., 2013). The major attraction of recurrent architectures is their potential to capture long-span dependencies since predictions are based on an *unbounded history* of previous words. This is in contrast to feed-forward networks as well as conventional n-gram models, both of which are limited to fixed-length contexts. Building on the success of recurrent architectures, we base our joint language and translation model on an extension of the recurrent neural network language model (Mikolov and Zweig, 2012) that introduces a layer of additional inputs (§2).

Most previous work on neural networks for speech recognition or machine translation used a rescoring setup based on n-best lists (Arisoy et al., 2012; Mikolov, 2012) for evaluation, thereby side stepping the algorithmic and engineering challenges of direct decoder-integration.[1] Instead, we exploit *lattices*, which offer a much richer representation of the decoder output, since they compactly encode an exponential number of translation hypotheses in polynomial space. In contrast, n-best lists are typically very redundant, representing only a few combinations of top scoring arcs in the lattice. A major challenge in lattice rescoring with a recurrent neural network model is the effect of the unbounded history on search since the usual dynamic programming assumptions which are exploited for efficiency do not hold up anymore. We apply a novel algorithm to the task of rescoring with an unbounded language model and empirically demonstrate its effectiveness (§3).

The algorithm proves robust, leading to significant improvements with the recurrent neural network language model over a competitive n-gram baseline across several language pairs. We even observe consistent gains when pairing the model with a large n-gram model trained on up to 575 times more

[1] One notable exception is Le et al. (2012a) who rescore reordering lattices with a feed-forward network-based model.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1044–1054,
Seattle, Washington, USA, 18-21 October 2013.

data, demonstrating that the model provides complementary information (§4).

Our joint modeling approach is based on adding a *continuous space representation* of the foreign sentence as an additional input to the recurrent neural network language model. With this extension, the language model can measure the consistency between the source and target words in a context-sensitive way. The model effectively combines the functionality of both the traditional channel and language model features. We test the power of this new model by using it as the only source of traditional channel information. Overall, we find that the model achieves accuracy competitive with the older channel model features and that it can improve over the gains observed with the recurrent neural network language model (§5).

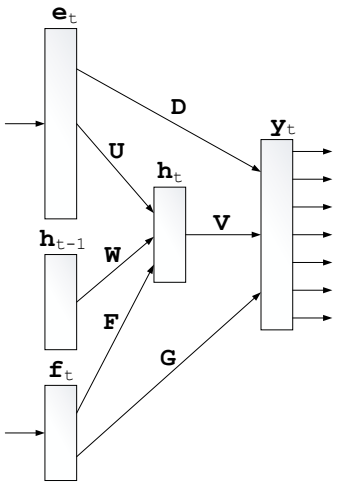

Figure 1: Structure of the recurrent neural network model, including the auxiliary input layer $\mathbf{f}_t$.

2 Model Structure

We base our model on the recurrent neural network language model of Mikolov et al. (2010) which is factored into an input layer, a hidden layer with recurrent connections, and an output layer (Figure 1). The input layer encodes the target language word at time t as a 1-of-N vector $\mathbf{e}_t$, where $|V|$ is the size of the vocabulary, and the output layer $\mathbf{y}_t$ represents a probability distribution over target words; both of size $|V|$. The hidden layer state $\mathbf{h}_t$ encodes the history of all words observed in the sequence up to time step t. This model is extended by an *auxiliary input layer* $\mathbf{f}_t$ which provides complementary information to the input layer (Mikolov and Zweig, 2012). While the auxiliary input layer can be used to feed in arbitrary additional information, we focus on encodings of the foreign sentence (§5).

The state of the hidden layer is determined by the input layer, the auxiliary input layer and the hidden layer configuration of the previous time step $\mathbf{h}_{t-1}$. The weights of the connections between the layers are summarized in a number of matrices: $\mathbf{U}$, $\mathbf{F}$ and $\mathbf{W}$, represent weights from the input layer to the hidden layer, from the auxiliary input layer to the hidden layer, and from the previous hidden layer to the current hidden layer, respectively. Matrix $\mathbf{V}$ represents connections between the current hidden layer and the output layer; $\mathbf{G}$ represents direct weights between the auxiliary input and output layers.

The hidden and output layers are computed via a series of matrix-vector products and non-linearities:

$$\mathbf{h}_t = s(\mathbf{U}\mathbf{e}_t + \mathbf{W}\mathbf{h}_{t-1} + \mathbf{F}\mathbf{f}_t)$$
$$\mathbf{y}_t = g(\mathbf{V}\mathbf{h}_t + \mathbf{G}\mathbf{f}_t)$$

where

$$s(z) = \frac{1}{1+\exp\{-z\}}, \quad g(z_m) = \frac{\exp\{z_m\}}{\sum_k \exp\{z_k\}}$$

are sigmoid and softmax functions, respectively. Additionally, the network is interpolated with a maximum entropy model of sparse n-gram features over input words (Mikolov et al., 2011a).[2] The maximum entropy weights are added to the output activations before computing the softmax.

The model is optimized via a maximum likelihood objective function using stochastic gradient descent. Training is based on the back propagation through time algorithm, which unrolls the network and then computes error gradients over multiple time steps (Rumelhart et al., 1986). After training, the output layer represents posteriors $p(e_{t+1}|e_{t-n+1}^t, \mathbf{h}_t, \mathbf{f}_t)$; the probabilities of words in the output vocabulary given the n previous input words e_{t-n+1}^t, the hidden layer configuration $\mathbf{h}_t$ as well as the auxiliary input layer configuration $\mathbf{f}_t$.

[2]While these features depend on multiple input words, we depicted them for simplicity as a connection between the current input word vector $\mathbf{e}_t$ and the output layer ($\mathbf{D}$).

Naïve computation of the probability distribution over the next word is very expensive for large vocabularies. A well established efficiency trick uses word-classing to create a more efficient two-step process (Goodman, 2001; Emami and Jelinek, 2005; Mikolov et al., 2011b) where each word is assigned a unique class. To compute the probability of a word, we first compute the probability of its class, and then multiply it by the probability of the word conditioned on the class:

$$p(e_{t+1}|e_{t-n+1}^{t}, \mathbf{h}_t, \mathbf{f}_t) = \\ p(c_i|e_{t-n+1}^{t}, \mathbf{h}_t, \mathbf{f}_t) \times p(e_{t+1}|c_i, e_{t-n+1}^{t}, \mathbf{h}_t, \mathbf{f}_t)$$

This factorization reduces the complexity of computing the output probabilities from $\mathcal{O}(|V|)$ to $\mathcal{O}(|C| + \max_i |c_i|)$ where $|C|$ is the number of classes and $|c_i|$ is the number of words in class c_i. The best case complexity $\mathcal{O}(\sqrt{|V|})$ requires the number of classes and words to be evenly balanced, i.e., each class contains exactly as many words as there are classes.

3 Lattice Rescoring with an Unbounded Language Model

We evaluate our joint language and translation model in a lattice rescoring setup, allowing us to search over a much larger space of translations than would be possible with n-best lists. While very space efficient, lattices also impose restrictions on the context available to features, a particularly challenging setting for our model which depends on the entire prefix of a translation. In the ensuing description we introduce a new algorithm to efficiently tackle this issue.

Phrase-based decoders operate by maintaining a set of *states* representing competing translations, either partial or complete. Each state is scored by a number of features including the n-gram language model. The independence assumptions of the features determine the amount of *context* each state needs to maintain in order for it to be possible to assign a score to it. For example, a trigram language model is indifferent to any context other than the two immediately preceding words. Assuming the trigram model dominates the Markov assumptions of all other features, which is typically the case, then we have to maintain at least two words at each state, also known as the *n-gram context*.

```
1: function RescoreLattice(k, V, E, s, T)
2:   Q ← topologically-sort(V)
3:   for all v in V do                    ▷ Heaps of split-states
4:     H_v ← minHeap()
5:   end for
6:   h_0 ← 0⃗                              ▷ Initialize start-state
7:   H_s.add(h_0)
8:   for all v in Q do                    ▷ Examine outgoing arcs
9:     for ⟨v, x⟩ in E do
10:      for h in H_v do                  ▷ Extend LM states
11:        h' ← scoreRNN(h, phrase(h))
12:        parent(h') ← h                 ▷ Backpointers
13:        if H_x.size() ≥ k∧             ▷ Beam width
14:          H_x.min()<score(h') then
15:            H_x.removeMin()
16:        if H_x.size()<k then
17:            H_x.add(h')
18:      end for
19:    end for
20:  end for
21:  I = maxHeap()
22:  for all t in T do                    ▷ Find best final split-state
23:    I.merge(H_t)
24:  end for
25:  return I.max()
26: end function
```

Figure 2: Push-forward rescoring with a recurrent neural network language model given a beam-width for language model split-states k, decoder states V, edges E, a start state s and final states T.

However, a recurrent neural network language model makes much weaker independence assumptions. In fact, the predictions of such a model depend on *all* previous words in the sentence, which would imply a potentially very large context. But storing all words is an inefficient solution from a dynamic programming point of view. Fortunately, we do not need to maintain entire translations as context in the states: the recurrent model compactly encodes the entire history of previous words in the hidden layer configuration $\mathbf{h}_i$. It is therefore sufficient to add $\mathbf{h}_i$ as context, instead of the entire translation. The language model can then simply score any new words

based on $\mathbf{h}_i$ from the previous state when a new state is created.

A much larger problem is that items, that were previously equivalent from a dynamic programming perspective, may now be different. Standard phrase-based decoders (Koehn et al., 2007) *recombine* decoder states with the same context into a single state because they are equivalent to the model features; usually recombination retains only the highest scoring candidate.[3] However, if the context is large, then the amount of recombination will decrease significantly, leading to less variety in the decoder beam. This was confirmed in preliminary experiments where we simulated context sizes of up to 100 words but found that accuracy dropped by between 0.5-1.0 BLEU.

Integrating a long-span language model naïvely requires to keep context equivalent to the entire left prefix of the translation, a setting which would permit very little recombination. Instead of using inefficient long-span contexts, we propose to maintain the usual n-gram context and to keep a fixed number of hidden layer configurations k at each decoder state. This leads to a new split-state dynamic program which splits each decoder state into at most k new items, each with a separate hidden layer configuration representing an unbounded history (Figure 2). This maintains diversity in the explored translation hypothesis space and preserves high-scoring hidden layer configurations.

What is the effect of this strategy? To answer this question we measured translation accuracy for various settings of k on our lattice rescoring setup (see §4 for details). In the same experiment, we compare lattices to n-best lists in terms of accuracy, model score and wall time impact.[4] The results (Table 1 and Figure 3) show that reranking accuracy on lattices is not significantly better, however, rescoring lattices with $k = 1$ is much faster than n-best lists. Similar observations have been made in previous work on minimum error-rate training (Macherey et al., 2008). The recurrent language model adds an overhead of about 54% at $k = 1$ on top of the time to produce the baseline 1-best output, a considerable but not necessarily prohibitive overhead. Larger values of k return higher probability solutions, but there is little impact on accuracy: the BLEU score is nearly identical when retaining up to 100 histories compared to keeping only the highest scoring.

While surprising at first, we believe that this effect is due to the high similarity of the translations represented by the histories in the beam. Each history represents a different translation but all translation hypothesis share the same n-gram context, and, more importantly, they are translations of the *same foreign words*, since they have exactly the same coverage vector. These commonalities are likely to result in similar recurrent histories, which in turn reduces the effect of aggressive pruning.

	BLEU	oracle	sec/sent
Baseline	28.25	-	0.173
100-best	28.90	37.22	0.470
1000-best	28.99	40.06	3.920
lattice ($k = 1$)	29.00	43.50	0.093
lattice ($k = 10$)	29.04	43.50	0.599
lattice ($k = 100$)	29.03	43.50	4.531

4 Language Model Experiments

Recurrent neural network language models have previously only been used in n-best rescoring

[3] Assuming a max-translation decision rule. In a minimum-risk setting, we may assign the sum of the scores of all candidates to the retained item.

[4] We measured running times on an HP z800 workstation equipped with 24 GB main memory and two Xeon E5640 CPUs with four cores each, clocked at 2.66 GHz. All experiments were run single-threaded.

settings and on small-scale tasks with baseline language models trained on only 17.5m words (Mikolov, 2012). We extend this work by experimenting on lattices using strong baselines with n-gram models trained on over one billion words and by evaluating on a number of language pairs.

4.1 Experimental Setup

Baseline. We experiment with an in-house phrase-based system similar to Moses (Koehn et al., 2003), scoring translations by a set of common features including maximum likelihood estimates of source given target mappings $p_{MLE}(e|f)$ and vice versa $p_{MLE}(f|e)$, as well as lexical weighting estimates $p_{LW}(e|f)$ and $p_{LW}(f|e)$, word and phrase-penalties, a linear distortion feature and a lexicalized reordering feature. Log-linear weights are estimated with minimum error rate training (Och, 2003).

Evaluation. We use training and test data from the WMT 2012 campaign and report results on French-English, German-English and English-German. Translation models are estimated on 102m words of parallel data for French-English, 91m words for German-English and English-German; between 3.5-5m words are newswire, depending on the language pair, and the remainder are parliamentary proceedings. The baseline systems use two 5-gram modified Kneser-Ney language models; the first is estimated on the target-side of the parallel data, while the second is based on a large newswire corpus released as part of the WMT campaign. For French-English and German-English we use a language model based on 1.15bn words, and for English-German we train a model on 327m words. We evaluate on the newswire test sets from 2010-2011 containing between 2034-3003 sentences. Log-linear weights are estimated on the 2009 data set comprising 2525 sentences. We rescore the lattices produced by the baseline systems with an aggressive but effective context beam of $k = 1$ that did not harm accuracy in preliminary experiments (§3).

Neural Network Language Model. The vocabularies of the language models are comprised of the words in the training set after removing singletons. We obtain word-classes using a version of Brown-Clustering with an additional regularization term to optimize the runtime of the language model (Brown et al., 1992; Zweig and Makarychev, 2013). Direct connections use maximum entropy features over unigrams, bigrams and trigrams (Mikolov et al., 2011a). We use the standard settings for the model with the default learning rate $\alpha = 0.1$ that decays exponentially if the validation set entropy does not increase after each epoch. Back propagation through time computes error gradients over the past twenty time steps. Training is stopped after 20 epochs or when the validation entropy does not decrease over two epochs. We experiment with varying training data sizes and randomly draw the data from the same corpora used for the baseline systems. Throughout, we use a hidden layer size of 100 which provided a good trade-off between time and accuracy in initial experiments.

4.2 Results

Training times for neural networks can be a major bottleneck. Recurrent architectures are particularly hard to parallelize due to their inherent dependence on the previous hidden layer configuration. One straightforward way to influence training time is to change the size of the training corpus.

Our results (Table 2, Table 3 and Table 4) show that even small models trained on only two million words significantly improve over the 1-best decoder output (Baseline); this represents only 0.6 percent of the data available to the n-gram model used by the baseline. Models of this size can be trained in only about 3.5 hours. A model trained on 50m words took 63 hours to train. When paired with an n-gram model trained on 25 times more data, accuracy improved by up to 0.7 BLEU on French-English.

5 Joint Model Experiments

In the next set of experiments, we turn to the joint language and translation model, an extension of the recurrent neural network language model with additional inputs for the foreign sentence. We first introduce two continuous space representations of the foreign sentence (§5.1). Using these representations we evaluate the accuracy of the joint model in the lattice rescoring setup and compare against the traditional translation channel model features (§5.2). Next, we establish an upper bound on accuracy for the joint model via an oracle experiment (§5.3). Inspired by the results of the oracle experiment we

train a transform between the source words and the reference representations. This leads to the best results improving 1.5 BLEU over the 1-best decoder output and adding 0.2 BLEU on average to the gains achieved by the recurrent language model (§5.4).

Setup. Conventional language models can be trained on monolingual or bilingual data; however, the joint model can only be trained on the latter. In order to control for data size effects, we restrict training of all models, including the baseline n-gram model, to the target side of the parallel corpus, about 102m words for French-English. Furthermore we train recurrent models only on the newswire portion (about 3.5m words for training and 250k words for validation) since initial experiments showed comparable results to using the full parallel corpus, available to the baseline. This is reasonable since the test data is newswire. Also, it allows for more rapid experimentation.

5.1 Foreign Sentence Representations

We represent foreign sentences either by latent semantic analysis (LSA; Deerwester et al. 1990) or by word encodings produced as a by-product of training the recurrent neural network language model on the source words.

LSA is widely used for representing words and documents in low-dimensional vector space. The method applies reduced singular value decomposition (SVD) to a matrix M of word counts; in our setting, rows represent sentences and columns represent foreign words. SVD reduces the number of columns while preserving similarity among the rows, effectively mapping from a high-dimensional representation of a sentence, as a set of words, to a low-dimensional set of *concepts*. The output of SVD is an approximation of M by three matrices: T contains single word representations, R represents full sentences, and S is a diagonal scaling matrix:

$$M \approx TSR^T$$

Given vocabulary V and n sentences, we construct M as a matrix of size $|V \times n|$. The ij-th entry is the number of times word i occurs in sentence j, also known as the term frequency value; the entry is also weighted by the inverse document frequency, the relative importance of word i among all sentences, expressed as the negative logarithm of the fraction of sentences in which word i occurs.

As a second representation we use single *word*

embeddings implicitly learned by the input layer weights $\mathbf{U}$ of the recurrent neural network language model (§2), denoted as **RNN**. Each word is represented by a vector of size $|\mathbf{h}_i|$, the number of neurons in the hidden layer; in our experiments, we consider concatenations of individual word vectors to represent foreign word contexts. These encodings have previously been found to capture syntactic and semantic regularities (Mikolov et al., 2013) and are readily available in our experimental framework via training a recurrent neural network language model on the source-side of the parallel corpus.

5.2 Results

We first experiment with the two previously introduced representations of the source-side sentence. Table 5 shows the results compared to the 1-best decoder output and an RNN language model (target-only). We first try LSA encodings of the entire foreign sentence as 80 or 240 dimensional vectors (sent-lsa-dim80, sent-lsa-dim240). Next, we experiment with single-word RNN representations of sliding word-windows in the hope of representing relevant context more precisely. Word-windows are constructed relative to the source words aligned to the current target word, and individual word vectors are concatenated into a single vector. We first try contexts which do not include the aligned source words, in the hope of capturing information not already modeled by the channel models, starting with the next five words (ww-rnn-dim50.n5), the five previous and the next five words (ww-rnn-dim50.p5n5) as well as the previous three words (ww-rnn-dim50.p3). Next, we experiment with word-windows of up to five aligned source words (ww-rnn-dim50.c5). Finally, we try contexts based on LSA word vectors (ww-lsa-dim50.n5, ww-lsa-dim50.p3).[5]

While all models improve over the baseline, none significantly outperforms the recurrent neural network language model in terms of BLEU. However, the perplexity results suggest that the models utilize the foreign representations since all joint models improve vastly over the target-only language model. The lowest perplexity is achieved by the context covering the aligned source words (ww-rnn-dim50.c5) since the source words are a better predictor of the target words than outside context.

[5]We ignore the coverage vector when determining word-windows which risks including already translated words. Building word-windows based on the coverage vector requires additional state in a rescoring setting meant to be light-weight.

	$-p(e\|f)$	$-p(f\|e)$ $-p(e\|f)$
Baseline without CM	24.0	22.5

Table 6: Comparison of the joint model and the channel model features (CM) by removing channel features corresponding to $-p(e|f)$ from the lattices, or both directions $-p(e|f), -p(f|e)$ and replacing them by various joint models. We re-tuned the log-linear weights for different feature-sets. Accuracy is based on the average BLEU over news2010, newssyscomb2010, news2011.

The experiments so far measured if the joint model can improve *in addition* to the four channel model features used by the baseline, that is, the maximum likelihood and lexical translation features in both translation directions. The joint model clearly overlaps with these features, but how well does the recurrent model perform compared *against* the channel model features? To answer this question, we removed channel model features corresponding to the same translation direction as the joint model, specifically $p_{MLE}(e|f)$ and $p_{LW}(e|f)$, from the lattices and measured the effect of adding the joint models.

The results (Table 6, column $-p(e|f)$) clearly show that our joint models are competitive with the channel model features by outperforming the original baseline with all channel model features (24.7 BLEU) by 0.2 BLEU (ww-rnn-dim50.n5, ww-rnn-dim50.c5). As a second experiment, we removed all channel model features (column $-p(e|f), p(f|e)$), diminishing baseline accuracy to 22.5 BLEU. In this setting, the best joint model is able to make up 1.5 of the 2.2 BLEU lost due to removal of the channel

model features, while modeling only a single translation direction. This setup also shows the negligible effect of the target-only language model in the absence of translation scores, whereas the joint models are much more effective since they do model translation. Overall, the best joint models prove very competitive to the traditional channel features.

5.3 Oracle Experiment

The previous section examined the effect of a set of basic foreign sentence representations. Although we find some benefit from these representations, the differences are not large. One might naturally ask whether there is greater potential upside from this channel model. Therefore we turn to measuring the upper bound on accuracy for the joint approach as a whole.

Specifically, we would like to find a bound on accuracy given an *ideal representation* of the source sentence. To answer this question, we conducted an experiment where the joint model has access to an LSA representation of the reference translation.

Table 7 shows that the joint approach has an oracle accuracy of up to 4.3 BLEU above the baseline. This clearly confirms that the joint approach can exploit the additional information to improve BLEU, given a good enough representation of the foreign sentence. In terms of perplexity, we see an improvement of up to 65% over the target-only model. It should be noted that since LSA representations are computed on reference words, perplexity no longer has its standard meaning.

	BLEU	PPL
Baseline	25.2	341
target-only	26.4	218
oracle (sent-lsa-dim40)	27.7	124
oracle (sent-lsa-dim80)	28.5	103

5.4 Target Language Projections

Our experiments so far showed that joint models based on direct representations of the source words are very competitive to the traditional channel models (§5.2). However, these experiments have not shown any improvements over the normal recurrent neural network language model. The previous section demonstrated that good representations can lead to substantial gains (§5.3). In order to bridge the gap, we propose to learn a separate transform from the foreign words to an encoding of the reference target words, thus making the source-side representations look more like the target-side encodings used in the oracle experiment.

Specifically, we learn a linear transform $d_\theta : \mathbf{x} \rightarrow \mathbf{r}$ mapping directly from a vector encoding of the foreign sentence $\mathbf{x}$ to an l-dimensional LSA representation $\mathbf{r}$ of the reference sentence. At test and training time we apply d_θ to the foreign words and use the transformation instead of a direct

source-side representation.

The transform models all foreign words in the parallel corpus except singletons, which are collapsed into a unique class, similar to the recurrent neural network language model. We train the transform to minimize the *squared error* with respect to the reference LSA vector using an SGD online learner:

$$\theta^* = \arg\min_{\theta} \sum_{i=1}^{n} \Big(\mathbf{r}_i - d_\theta(\mathbf{x}_i) \Big)^2 \qquad (1)$$

We found a simple constant learning rate, tuned on the validation data, to be as effective as schedules based on constant decay, or reducing the learning rate when the validation error increased. Our feature-set includes unigram and bigram word features. The value of unigram features is simply the unigram count in that sentence; bigram features receive a weight of the bigram count divided by two to help prevent overfitting. Then the vector for each sentence was divided by its L2 norm. Both weighting and normalization led to substantial improvements in test set error. More complex features such as skip-bigrams, trigrams and character n-grams did not yield any significant improvements. Even this representation of sentences is composed of a large number of instances, and so we resorted to feature hashing by computing feature ids as the least significant 20 bits of each feature name. Our best transform achieved a cosine similarity of 0.816 on the training data, 0.757 on the validation data, and 0.749 on news2011.

The results (Table 8) show that the transform improves over the recurrent neural network language model on all test sets and by 0.2 BLEU on average. We verified significance over the target-only model using paired bootstrap resampling (Koehn, 2004) over all test sets (7526 sentences) at the $p < 0.001$ level. Overall, we improve accuracy by up to 1.5 BLEU and by 1.1 BLEU on average across all test sets over the decoder 1-best with our joint language and translation model.

6 Related Work

Our approach of combining language and translation modeling is very much in line with recent work on n-gram-based translation models (Crego and Yvon, 2010), and more recently continuous space-based translation models (Le et al., 2012a; Gao et al., 2013). The joint model presented in this paper differs in a number of key aspects: we use a recurrent architecture representing an unbounded history of both source and target words, rather than a feed-forward style network. Feed-forward networks and n-gram models have a finite history which makes predictions independent of anything but a small history of words. Furthermore, we only model the target-side which is different to previous work modeling both sides.

We introduced a new algorithm to tackle lattice rescoring with an unbounded model. The automatic speech recognition community has previously addressed this issue by either approximating long-span language models via simpler but more tractable models (Deoras et al., 2011b), or by identifying confusable subsets of the lattice from which n-best lists are constructed and rescored (Deoras et al., 2011a). We extend their work by directly mapping a recurrent neural network model onto the structure of the lattice, rescoring all states instead of focusing only on subsets.

7 Conclusion and Future Work

Joint language and translation modeling with recurrent neural networks leads to substantial gains over the 1-best decoder output, raising accuracy by up to 1.5 BLEU and by 1.1 BLEU on average across

several test sets. The joint approach also improves over the gains of the recurrent neural network language model, adding 0.2 BLEU on average across several test sets. Our models are competitive to the traditional channel models, outperforming them in a head-to-head comparison.

Furthermore, we tackled the issue of lattice rescoring with an unbounded recurrent model by means of a novel algorithm that keeps a beam of recurrent histories. Finally, we have shown that the recurrent neural network language model can significantly improve over n-gram baselines across a range of language-pairs, even when the baselines were trained on 575 times more data.

In future work we plan to directly learn representations of the source-side during training of the joint model. Thus, the model itself can decide which encoding is best for the task. We also plan to change the cross entropy objective to a BLEU-inspired objective in a discriminative training regime, which we hope to be more effective. We would also like to apply recent advances in tackling the vanishing gradient problem (Pascanu et al., 2013) using a regularization term to maintain the magnitude of the gradients during back propagation through time. Finally, we would like to integrate the recurrent model directly into first-pass decoding, a straightforward extension of lattice rescoring using the algorithm we developed.

Abstract

Domain adaptation for SMT usually adapts models to an individual specific domain. However, it often lacks some correlation among different domains where common knowledge could be shared to improve the overall translation quality. In this paper, we propose a novel multi-domain adaptation approach for SMT using Multi-Task Learning (MTL), with in-domain models tailored for each specific domain and a general-domain model shared by different domains. The parameters of these models are tuned jointly via MTL so that they can learn general knowledge more accurately and exploit domain knowledge better. Our experiments on a large-scale English-to-Chinese translation task validate that the MTL-based adaptation approach significantly and consistently improves the translation quality compared to a non-adapted baseline. Furthermore, it also outperforms the individual adaptation of each specific domain.

1 Introduction

Domain adaptation is an active topic in statistical machine learning and aims to alleviate the domain mismatch between training and testing data. Like many machine learning tasks, Statistical Machine Translation (SMT) assumes that the data distributions of training and testing domains are similar. However, this assumption does not hold for real world SMT systems since training data for SMT models may come from a variety of domains. The translation quality is often unsatisfactory when translating texts from a specific domain using a general model that is trained over a hotchpotch of bilingual corpora. Therefore, domain adaptation is crucial for SMT systems to achieve better performance.

Previous research on domain adaptation for SMT includes data selection and weighting (Eck et al., 2004; Lü et al., 2007; Foster et al., 2010; Moore and Lewis, 2010; Axelrod et al., 2011), mixture models (Foster and Kuhn, 2007; Koehn and Schroeder, 2007; Sennrich, 2012; Razmara et al., 2012), and semi-supervised transductive learning (Ueffing et al., 2007), etc. Most of these methods adapt SMT models to a specific domain according to testing data and have achieved good performance. It is natural that real world SMT systems should adapt the models to multiple domains because the input may be heterogeneous, so that the overall translation quality can be improved. Although we can easily apply these methods to multiple domains individually, it is difficult to use the common knowledge across different domains. To leverage the common knowledge, we need to devise a multi-domain adaptation approach that jointly adapts the SMT models.

Multi-domain adaptation has been proved quite effective in sentiment analysis (Dredze and Crammer, 2008) and web ranking (Chapelle et al., 2011), where the commonalities and differences across multiple domains are explicitly addressed by Multi-task Learning (MTL). MTL is an approach that learns one target problem with other related problems at the same time, using a shared feature representation. The key advantage of MTL is to enable implicit data sharing and regularization. Therefore, it often leads to a better model for each task. Analogously, we expect that the overall translation quality can be further improved by using an MTL-based

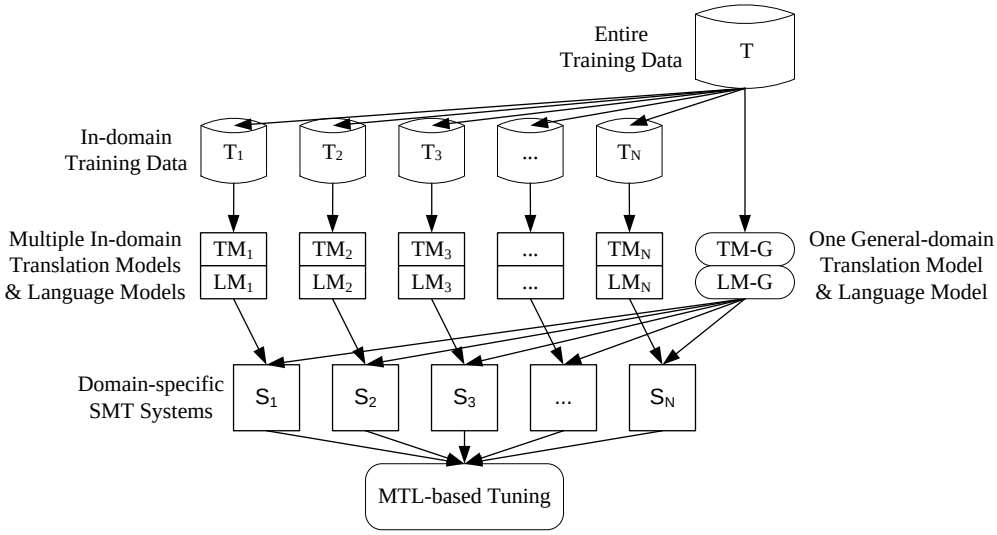

Figure 1: An example with N pre-defined domains, where T is the entire training corpus. T_i is the in-domain training data for the i-th domain selected from T using the bilingual cross-entropy based method (Axelrod et al., 2011). The in-domain TM$_i$ and LM$_i$ are trained using the in-domain training data T_i. The general-domain models TM-G and LM-G are trained using the entire training corpus T. S_i is the domain-specific SMT system for the i-th domain, leveraging the in-domain models and the general-domain models as features.

multi-domain adaptation approach.

In this paper, we use MTL to jointly adapt SMT models to multiple domains. Specifically, we develop multiple SMT systems based on mixture models, where each system is tailored for one specific domain with an in-domain Translation Model (TM) and an in-domain Language Model (LM). Meanwhile, all the systems share a same general-domain TM and LM. These SMT systems are considered as several related tasks with a shared feature representation, which fits well into a unified MTL framework. With the MTL-based joint tuning, general knowledge can be better learned by the general-domain models, while domain knowledge can be better exploited by the in-domain models as well. By using a distributed stochastic learning approach (Simianer et al., 2012), we can estimate the feature weights of multiple SMT systems at the same time. Furthermore, we modify the algorithm to treat in-domain and general-domain features separately, which brings regularization to multiple SMT systems in an efficient way. Experimental results have shown that our method can significantly improve the translation quality on multiple domains over a non-adapted baseline. Moreover, the MTL-based adaptation also outperforms the conventional individual adaptation approach towards each domain.

The rest of the paper is organized as follows: The proposed approach is explained in Section 2. Experimental results are presented in Section 3. Section 4 introduces some related work. Section 5 concludes the paper and suggests future research directions.

2 The Proposed Approach

Figure 1 gives an example with N pre-defined domains to illustrate the main idea. There are three steps in the training phase. First, in-domain training data is selected according to the pre-defined domains (Section 2.1). Second, in-domain models and general-domain models are trained to develop the domain-specific SMT systems (Section 2.2). Third, multiple domain-specific SMT systems are tuned jointly by using an MTL-based approach (Section 2.3).

2.1 In-domain Data Selection

In the first step, in-domain bilingual data is selected from all the bilingual data to train in-domain TMs. We use the bilingual cross-entropy based approach (Axelrod et al., 2011) to obtain the in-domain data:

$$[H_{I-src}(s)-H_{G-src}(s)]+[H_{I-tgt}(t)-H_{G-tgt}(t)] \quad (1)$$

where $\{s,t\}$ is a bilingual sentence pair in the entire bilingual corpus. $H_{I-\text{xxx}}(\cdot)$ and $H_{G-\text{xxx}}(\cdot)$ represent the cross-entropy of a string according to an in-domain LM and a general-domain LM, respectively. "xxx" denotes either the source language (src) or the target language (tgt). $H_{I-src}(s) - H_{G-src}(s)$ is the cross-entropy difference of string s between the in-domain and general-domain source-side LMs, and $H_{I-tgt}(t) - H_{G-tgt}(t)$ is the cross-entropy difference of string t between the in-domain and general-domain target-side LMs. This criterion biases towards sentence pairs that are like the in-domain corpus but unlike the general-domain corpus. Therefore, the sentence pairs with lower scores (larger differences) are presumed to be better.

Now, the question is how to find sufficient monolingual data to train in-domain LMs. A straightforward solution is to collect the data from the internet. There are a large number of monolingual webpages with domain information from web portal sites[1], which can be collected to train in-domain LMs. In large-scale real world SMT systems, practical domain adaptation techniques should target more domains rather than just one due to heterogeneous input. Therefore, we use a web crawler to collect monolingual webpages of N domains from web portal sites, for both the source language and the target language. The statistics of web-crawled data is given in Section 3.1. We use the web-crawled monolingual documents to train N in-domain source-side LMs and N in-domain target-side LMs. Additionally, we also train the source-side and target-side general-domain LMs with all the web-crawled documents from different domains. Finally, these in-domain and general-domain LMs are used to select in-domain bilingual data for different domains according to Formula (1).

2.2 SMT Systems with Mixture Models

In the second step, with the selected in-domain training data, we develop SMT systems based on mixture models. In particular, we use the mixture model based approach proposed by Koehn and Schroeder (2007). Specifically, we have developed N SMT systems for N domains respectively, where each system is a typical log-linear model. For each system, the best translation candidate $\hat{f}$ is given by:

$$\hat{f} = \arg\max_{f} \{P(f|e)\} \tag{2}$$

where the translation probability $P(f|e)$ is given by:

$$\begin{aligned} P(f|e) &\propto \sum_{i} w_i \cdot \log \phi_i(f,e) \\ &= \underbrace{\sum_{j \in \mathbf{I}} w_j \cdot \log \phi_j(f,e)}_{\textbf{I}\text{n-domain}} + \underbrace{\sum_{k \in \mathbf{G}} w_k \cdot \log \phi_k(f,e)}_{\textbf{G}\text{eneral domain}} \end{aligned} \tag{3}$$

where $\phi_j(f,e)$ is the in-domain feature function and w_j is the corresponding feature weight. $\phi_k(f,e)$ is the general-domain feature function and w_k is the feature weight. The detailed feature description is as follows:

In-domain features

- An in-domain TM, including phrase translation probabilities and lexical weights for both directions (4 features)
- An in-domain target-side LM (1 feature)
- word count (1 feature)
- phrase count (1 feature)
- NULL penalty (1 feature)
- Number of hierarchical rules used (1 feature)

General-domain features

- A general-domain TM, including phrase translation probabilities and lexical weights for both directions (4 features)
- A general-domain target-side LM (1 feature)

The feature description indicates that each SMT system contains two TMs and two LMs. The in-domain TMs are trained using the selected bilingual training data according to Formula (1), and the general-domain TM is trained using the entire bilingual training data. For the LMs, we re-use the target-side in-domain LMs and general-domain LM trained

[1]Many web portal sites contain domain information for webpages, such as "www.yahoo.com" in English and "www.sina.com.cn" in Chinese and etc. The webpages are often categorized by human editors into different domains, such as politics, sports, business, etc.

for data selection (Section 2.1). Compared with a normal single-model system, the system with mixture models can balance the contributions from the general-domain and in-domain knowledge. Hence it potentially benefits from both.

2.3 MTL-based Tuning

In the third step, the feature weights in multiple domain-specific SMT systems are estimated. Instead of tuning each domain-specific system separately, we treat different systems as related tasks and tune them jointly in an MTL framework. There are two main reasons for MTL-based tuning:

1. Domain-specific translation tasks share the same general-domain LM and TM. MTL often leads to better performance by leveraging commonalities among different tasks.

2. By enforcing that the general-domain LM and TM perform equally across different domains, MTL provides a kind of regularization to prevent over-fitting.

Formally, the objective function of the proposed MTL-based approach is described as follows:

$$\min_{\mathbf{W}} \left\{ \sum_{i=1}^{N} \textbf{Loss}(\mathbf{E}_i, \hat{\mathbf{e}}(\mathbf{F}_i, \mathbf{w}_i)) \right\} \quad (4)$$

where N is the number of pre-defined domains. $\{\mathbf{F}_i,\mathbf{E}_i\}$ is the in-domain development dataset for the i-th domain. $\mathbf{F}_i$ denotes the source sentences and $\mathbf{E}_i$ denotes the reference translations. $\mathbf{w}_i$ is a D-length feature weight column vector for the i-th domain, where D is the dimension of the feature space. $\mathbf{W}$ is a N-by-D matrix, representing $[\mathbf{w}_1|\mathbf{w}_2|\ldots|\mathbf{w}_N]^T$. $\hat{\mathbf{e}}(\mathbf{F}_i, \mathbf{w}_i)$ are the best translations obtained for $\mathbf{F}_i$ with parameters $\mathbf{w}_i$. $\textbf{Loss}(\cdot,\cdot)$ denotes the loss between the system's output and the reference translations. The basic idea of the objective function is to minimize the sum of loss functions for all the domains, rather than one domain at a time. Therefore, by adjusting the in-domain and general-domain feature weights, the translation quality is expected to be good across different domains.

To effectively tune SMT systems jointly, we modify the asynchronous Stochastic Gradient Descend (SGD) Algorithm (Simianer et al., 2012) to optimize objective function (4). We follow the pairwise ranking approach with the perceptron algorithm (Shen and Joshi, 2005) to update feature weights. Let a translation candidate be denoted by its feature vector $\mathbf{v} \in \mathbb{R}^D$, the pairwise preference for training is constructed by ranking two candidates according to the smoothed sentence-level BLEU (Liang et al., 2006). For a preference pair $\mathbf{v}_{[j]}$=($\mathbf{v}^{(1)}, \mathbf{v}^{(2)}$) where $\mathbf{v}^{(1)}$ is preferred, a hinge loss is used:

$$L(\mathbf{w}_i) = (-\langle \mathbf{w}_i, \mathbf{v}^{(1)} - \mathbf{v}^{(2)} \rangle)_+ \quad (5)$$

where $(x)_+ = \max(0, x)$ and $\langle \cdot, \cdot \rangle$ denotes the inner product of two vectors. With the perceptron algorithm (Shen and Joshi, 2005), the gradient of the hinge loss is:

$$\nabla L(\mathbf{w}_i) = \begin{cases} \mathbf{v}^{(2)} - \mathbf{v}^{(1)} & \text{if} \langle \mathbf{w}_i, \mathbf{v}^{(1)} - \mathbf{v}^{(2)} \rangle \leq 0 \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

The training instances for the discriminative learning in pairwise ranking are made by comparing the N-best list of the translation candidates scored by the smoothed sentence-level BLEU (Liang et al., 2006). Following Simianer et al. (2012), the N-best list is divided into three bins: the top 10% (High), the middle 80% (Middle), and the last 10% (Low). These bins are used for pairwise ranking where the translation preference pairs are built between the candidates in High-Middle, Middle-Low, and High-Low, but not the candidates within the same bin, which is shown in Figure 2. The idea is to guarantee that the ranker is more discriminative to prefer the good translations to the bad ones.

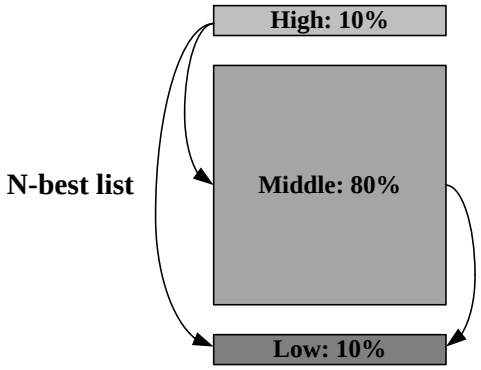

Figure 2: Training instances for pairwise ranking.

Algorithm 1 Modified Asynchronous SGD

1: Distribute N domain-specific decoders to N machines
2: Initialize $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_N \leftarrow 0$
3: **for epochs** $t \leftarrow 0 \ldots T-1$ **do**
4: **for all domains** $d \in \{1 \ldots N\}$: **parallel do**
5: $\mathbf{u}_{d,t,0,0} = \mathbf{w}_d$
6: $S = |\mathbf{F}_d|$
7: **for all** $i \in \{0 \ldots S-1\}$ **do**
8: Decode i-th sentence with $\mathbf{u}_{d,t,i,0}$
9: P = No. of pairs built from the N-best list
10: **for all pairs** $\mathbf{v}_{[j]}, j \in \{0 \ldots P-1\}$ **do**
11: $\mathbf{u}_{d,t,i,j+1} \leftarrow \mathbf{u}_{d,t,i,j} - \eta \nabla L(\mathbf{u}_{d,t,i,j})$
12: **end for**
13: $\mathbf{u}_{d,t,i+1,0} \leftarrow \mathbf{u}_{d,t,i,P}$
14: **end for**
15: **end for**
16: **for all domains** $d \in \{1 \ldots N\}$ **do**
17: $\mathbf{w}_d = \mathbf{u}_{d,t,S,0}$
18: **end for**
19: $\mathbf{W}^G \leftarrow [\mathbf{w}_1^G | \ldots | \mathbf{w}_N^G]^T$
20: **for all domains** $d \in \{1 \ldots N\}$ **do**
21: **for** $k \leftarrow 1 \ldots |\mathbf{w}_d^G|$ **do**
22: $\mathbf{w}_d^G[k] = \frac{1}{N} \sum_{n=1}^{N} \mathbf{W}^G[n][k]$
23: **end for**
24: $\mathbf{w}_d \leftarrow \begin{bmatrix} \mathbf{w}_d^I \\ \mathbf{w}_d^G \end{bmatrix}$
25: **end for**
26: **end for**
27: **return** $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_N$

Our modified algorithm is illustrated in Algorithm 1. Each column vector $\mathbf{w}_i$ is further split into two parts $\mathbf{w}_i^I$ and $\mathbf{w}_i^G$, representing the **I**n-domain and **G**eneral-domain feature weights respectively. In Algorithm 1, we first distribute the domain-specific SMT decoders to different machines and initialize the feature weights (line 1-2). Typically, the SGD algorithm runs in several iterations (In this study, we set the number of epochs T to 20) (line 3). Multiple SMT decoders run in parallel and each decoder updates its feature weights individually using its in-domain development data (line 4-15). For each domain, the domain-specific decoder translates each in-domain development sentence and determines the N-best translations (line 4-8). The preference pairs are built and used to update the parameters by gradient descent with $\eta = 0.0001$ (line 9-13). Each domain-specific decoder translates its in-domain development data multiple times. After each iteration, feature weights from all decoders are collected (line 16-19). In contrast to the original algorithm (Simianer et al., 2012), we only average the general-domain feature weights $\mathbf{w}_1^G, \ldots, \mathbf{w}_N^G$, but do not average the in-domain feature weights (line 20-25). The reason is we hope to leverage the commonalities among these systems. Meanwhile, general knowledge is enforced to be conveyed equally across different domains. Finally, the algorithm returns all the domain-specific feature weights $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_N$ that are used for testing (line 27).

After the joint MTL-based tuning, the feature weights tailored for domain-specific SMT systems are used to translate the testing data. We collect in-domain testing data for each domain to evaluate the domain-specific systems. Although this is not always the case in real applications where the testing domain is known, this study mainly focuses on the effectiveness of the MTL-based tuning approach.

3 Experiments

3.1 Data

We evaluated our MTL-based domain adaptation approach on a large-scale English-to-Chinese machine translation task. The training data consisted of two parts: monolingual data and bilingual data. The monolingual data was used to train the source-side and target-side LMs, both of which were used for data selection in Section 2.1. In addition, the target-side LMs were re-used in the SMT systems as features. As mentioned in Section 2.1, we built a web crawler to collect a large number of webpages from web portal sites in English and Chinese respectively. In the experiments, we mainly focused on six popular domains, namely Business, Entertainment, Health, Science & Technology, Sports, and Politics. For both English and Chinese webpages, the HTML tags were removed and the main content was extracted. The data statistics are shown in Table 1.

The bilingual data we used was mainly mined from the web using the method proposed by Jiang et al. (2009), with a post-processing step using our bilingual data cleaning method (Cui et al., 2013). Therefore, the data quality is pretty good. In addition, we also used the English-Chinese parallel corpus released by LDC[2]. In total, the bilingual data

contained around 30 million sentence pairs, with 404M words in English and 329M words in Chinese. For each domain, we used the cross-entropy based method in Section 2.1 to rank the entire bilingual data, and the top 10% sentence pairs from the ranked bilingual data were selected as the in-domain data to train the in-domain TM. Moreover, we prepared 2,000 in-domain sentences for development and 1,000 in-domain sentences for testing in each domain. The details are shown in Table 2.

3.2 Setup

An in-house hierarchical phrase-based SMT decoder was implemented for our experiments. The CKY decoding algorithm was used and cube pruning was performed with the same default parameter settings as in Chiang (2007). We used a 100-best list from the decoder for the pairwise ranking algorithm. Translation models were trained over the bilingual data that was automatically word-aligned using GIZA++ (Och and Ney, 2003) in both directions, and the diag-grow-final heuristic was used to refine the symmetric word alignment. The phrase tables were filtered to retain top-20 translation candidates for each source phrase for efficiency. An in-house language modeling toolkit was used to train the 4-gram language models with modified Kneser-Ney smoothing (Kneser and Ney, 1995) over the web-crawled data. The evaluation metric for the overall translation quality was case-insensitive BLEU4 (Papineni et al., 2002). A statistical significance test was performed using the bootstrap resampling method (Koehn, 2004).

LDC2006E34, LDC2006E85, LDC2006E92.

3.3 Baseline

We have two baselines. The first baseline is a non-adapted Hiero using our implementation. It contained the general-domain TM and LM, as well as other standard features. In addition, the fix-discount method (Foster et al., 2006) for phrase table smoothing was also used. The system was general-domain oriented and it was tuned by using MERT (Och, 2003) with a combination of six in-domain development datasets. The second baseline is Google Online Translation Service[3]. We obtained the English-to-Chinese translations of the testing data from Google Translation to have a more solid comparison.

Moreover, we also compared our method with the adapted systems towards each domain individually (Koehn and Schroeder, 2007). This is to demonstrate the superiority of our MTL-based tuning approach across different domains.

3.4 Results

The end-to-end translation performance is shown in Table 3. We found that the baseline has a similar performance to Google Translation, with certain domains performed even better (Business, Sci&Tech, Sports, Politics). This demonstrates that the translation quality of our baseline is state-of-the-art. Moreover, we can answer three questions according to the experimental results as follow:

First, is domain mismatch a significant problem for a real world SMT system? We used the same system only with general-domain TM and LM, but tuned towards each domain individually using in-domain dev data. Table 3 shows that the setting "[A] *G*-TM + *G*-LM" performs much better than

[3]http://translate.google.com

	Business	Ent.	Health	Sci&Tech	Sports	Politics
[N] Baseline (*G*-TM + *G*-LM)	27.19	17.87	25.79	25.34	25.53	23.01
Google Translation	26.01	18.44	27.71	25.07	24.08	22.97

[A] (*G*+*I*)-TM + (*G*+*I*)-LM	29.82	19.53	29.03	26.94	33.77	26.09
[A,MTL] (*G*+*I*)-TM + (*G*+*I*)-LM	**30.26**	**19.94**	**29.08**	**27.17**	34.11	**26.50**

Table 3: End-to-end experimental results (BLEU4%) with large-scale training data ($p < 0.05$). "[N]" means the system is non-adapted and tuned using MERT on general-domain dev data. "[A]" denotes that the system is adapted towards each domain individually using MERT on in-domain dev data. "[A,MTL]" indicates that the system was tuned using our MTL-based approach on in-domain dev data. "*I*-TM" and "*G*-TM" denote the in-domain and general-domain translation model. "*I*-LM" and "*G*-LM" denote the in-domain and general-domain language model. We also obtained translations of the testing data using Google Translation for comparison.

the non-adapted baseline across all domains with at least 1.2 BLEU points. In addition, the setting "[A] *G*-TM + *G*-LM" also outperforms Google Translation on all domains. Analogous to previous research, this confirms that the domain mismatch indeed exists and the parameter estimation using in-domain dev data is quite useful.

Second, does the mixture models based adaptation work for a variety of domains? We experimented with different settings with multiple TMs or LMs, or both. It is interesting to note that for large-scale SMT systems, using in-domain models alone is inferior to using the general models alone. The setting "[A] *G*-TM + *G*-LM" is better than the setting "[A] *I*-TM + *I*-LM" across different domains. The reason is the data for general models has already included the in-domain data and the data coverage is much larger, thus the probability estimation is more reliable and the translation quality is much better.

For the LM, the in-domain LM performs better than the general-domain LM because our monolingual data (Table 1) for each domain is already sufficient for training an in-domain LM with good performance. From Table 3, we observed that the setting "[A] (*G*+*I*)-TM + *I*-LM" outperforms "[A] (*G*+*I*)-TM + *G*-LM", with the "Sports" domain being the most significant. For the TM, the performance of the in-domain TM is inferior to the general-domain TM. The results show that the setting "[A] (*G*+*I*)-LM + *G*-TM" is significantly better than "[A] (*G*+*I*)-LM + *I*-TM". The main reason is the data coverage for in-domain TM is much smaller than the general model. When each system uses two TMs and two LMs, it consistently results in better performance, indicating that mixture models are crucial for domain adaptation in SMT.

Third, can MTL further improve the translation quality? We used the MTL-based approach to jointly tune multiple domain-specific systems, leveraging the commonalities among different but related tasks. From Table 3, the MTL-based approach significantly improve the translation quality over the non-adapted baseline, and also outperforms conventional mixture models based methods. In particular, the "Sports" domain benefits the most from the in-domain knowledge, which confirms that domain discrepancy should be addressed and may bring large improvements on certain domains.

3.5 Discussion

According to our experiments, only averaging over the out-of-domain feature weights returned robust and converged results. We do not have theoretically grounded guarantee. However, we observed that the BLEU score of our method on DEV data was slightly lower than that in the baseline system, which indicates the out-of-domain features are less over-fitting on the domain-specific DEV data since

SOURSE	A point begins with a **player** serving the ball. This means one **player** hits the ball towards the other **player**. (The **serve** must be played from behind the baseline and must **land** in the **service box**. Players get two attempts to make a good **serve**.)
REF	得分由一个**球员**发球开始，这是指一个**球员**向另一个**球员**击球。(**发球**时选手必须站在底线之外，球必须要**落在**对方的**发球区**内，每次**发球**允许有一次失误。)
[N] Baseline (*G*-TM + *G*-LM)	舞会始于**玩家**服务的一个点。这意味着**玩家**对其他**玩家**的击球。(该**服务**必须从背后打的基线和必须**降落在**服务框。球员两次试图成为一个好的**服务**。)
[A] (*G+I*)-TM + (*G+I*)-LM	一开始球的**球员**，这意味着一名**球员** 球打向其他**球员**。(必须从底线**发球**，必须在**发球区**的**区域**。球员只有两次尝试去做一个好的**发球**。)
[A,MTL](*G+I*)-TM + (*G+I*)-LM	第一球的**球员**，这意味着一名 **球员**对另一个**球员**击球。(必须在底线后面**发球**，并且必须**降落在**发球区。球员两次试图成为一个好的**发球**。)

Table 4: Examples illustrating some different translations, where the Chinese phrases are translated from the English phrases with the same symbols (e.g., underline, wavy-line, and box). The details are explained in Section 3.5.

we enforced them to play the same role across different domains. It seems that averaging the out-of-domain feature weights can be considered as a kind of regularization.

An example sentence from the Sports domain with translations from different methods is shown in Table 4. In this sentence, the baseline always translates "player" to "玩家" (game player), which should be "球员" (ball player). And, the baseline translates "serve" to "服务" (work for), which should be "发球" (put the ball into play). The phrase "service box" here means "发球区", which denotes the zone where the ball is to be served. However, the baseline incorrectly splits them into two words, then translates "service" to "服务" and "box" to "框". In contrast, the approaches with adapted models are able to translate these words very well.

Both our MTL-based approach and the conventional adaptation methods leverage the mixture models. A natural question is why our MTL-based approach performs better than the individual adaptation. To answer this question, we looked into the details of the tuning and decoding procedures in the MTL-based approach. We observed that the BLEU score on the development data for each system was lower than the score when conducting individual adaptation. Considering that the algorithm enforcing the general features play the same role across different domains, we suspect that MTL-based approach introduces a kind of regularization for each domain-specific system. The regularization prevents the general features from biasing towards certain domains to the extreme. This property is quite important for real world SMT systems. Usually, a sentence is composed of some domain-specific words and some general words, so it is often improper to translate every word in the sentence using the in-domain knowledge. For the example in Table 4, the individual adaptation method "[A] (*G+I*)-TM + (*G+I*)-LM" translates "land" to "区域" (zone) improperly, because "区域" appears more often in the Sports text than the general-domain text. This shows that the individual adaptation methods tend to overfit the in-domain development data. In contrast, the MTL-based approach "[A,MTL](*G+I*)-TM + (*G+I*)-LM" just translates "land" to "降落在" (fall on), which is more appropriate.

4 Related Work

4.1 Domain Adaptation

One direction of domain adaptation explored the data selection and weighting approach to improve the performance of SMT on specific domains. Eck

et al. (2004) first decoded the testing data with a general TM, and then used the translation results to train an adapted LM, which was in turn used to re-decode the testing data. Lü et al. (2007) tried to weight the training data according to the similarity with test data using information retrieval models, while Foster et al. (2010) trained a discriminative model to estimate a weight for each sentence in the training corpus. Other methods conducted data selection based on cross-entropy (Moore and Lewis, 2010), and Axelrod et al. (2011) further extended their cross-entropy based method to the selection of bilingual corpus in the hope that more relevant corpus to the target domain could yield smaller models with better performance. Other methods included using semi-supervised transductive learning techniques to exploit the monolingual in-domain data (Ueffing et al., 2007).

Adaptation methods also involved the utilization of mixture models. Foster and Kuhn (2007) explored a number of variants of utilizing multiple TMs and LMs by interpolation. Koehn and Schroeder (2007) used MERT to simultaneously tune two TMs or LMs. Sennrich (2012) investigated the TM perplexity minimization as a method to set model weights in mixture modeling. In addition, inspired by system combination approaches, Razmara et al. (2012) used the ensemble decoding method to mix multiple translation models, which outperformed a variety of strong baselines.

Generally, most previous methods merely conducted domain adaption for a single domain, rather than multiple domains at the same time. One could also simply build multiple SMT systems that were adapted to multiple domains, but they were often separated and not tuned together. So far, there has been little research into the multi-domain adaptation problem over mixture models for SMT systems, as proposed in this paper.

4.2 Multi-task Learning

In machine learning, MTL is an approach to learn one target problem with other related problems at the same time. This often leads to a better model for the main task because it allows the learner to use the commonality among the tasks. MTL is performed by learning tasks in parallel while using a shared representation. Therefore, what is learned for each task can help other tasks be learned better.

MTL was successfully applied in some Natural Language Processing (NLP) tasks. For example, Blitzer et al. (2006) extended the MTL approach (Ando and Zhang, 2005) to domain adaptation tasks in part-of-speech tagging. Collobert and Weston (2008) proposed using deep neural networks to train a set of tasks, including part-of-speech tagging, chunking, named entity recognition, and semantic roles labeling. They reported that jointly learning these tasks led to superior performance. MTL was also applied in sentiment analysis (Dredze and Crammer, 2008) and web ranking (Chapelle et al., 2011) to address the multi-domain learning and adaptation. In SMT, Duh et al. (2010) proposed using MTL for N-best re-ranking on sparse feature sets, where each N-best list corresponded to a distinct task. Simianer et al. (2012) proposed distributed stochastic learning with feature selection inspired by MTL. The distributed learning approach outperformed several other training methods including MIRA and SGD.

Inspired by these methods, we used MTL to tune multiple SMT systems at the same time, where each system was composed of in-domain and general-domain models. Through a shared feature representation, the commonalities among the SMT systems were better learned by the general models. In addition, domain-specific translation knowledge was also better characterized by the in-domain models.

5 Conclusion and Future Work

In this paper, we propose an MTL-based approach to address multi-domain adaptation for SMT. We first use the cross-entropy based data selection method to obtain in-domain bilingual data. After that, in-domain TMs and LMs are trained for each domain-specific SMT system. In addition, the general-domain TM and LM are also trained and shared across different systems. Finally, MTL is leveraged to tune multiple systems jointly. Experimental results have shown that our approach is quite promising for the multi-domain adaptation problem, and it brings significant improvement over both the non-adapted baselines and the conventional domain adaptation methods with mixture models.

We assume the domain information for testing

data is known beforehand in this study. However, this is not always the case for real world SMT systems. Therefore, to apply our approach in real applications, the domain information needs to be identified automatically. In the future, we will pre-define more popular domains and develop automatic domain classifiers. For those domains that are identified with high confidence, we use the domain-specific system to translate the texts. For other texts, we use the general system to translate them. Furthermore, since our approach is a general training method, we may also combine this approach with other domain adaptation methods to get more performance improvement.

Acknowledgments

We are especially grateful to Nan Yang, Yajuan Duan, Hong Sun and Danran Chen for the helpful discussions. We also thank the anonymous reviewers for their insightful comments.

Abstract

We present a novel translation model, which simultaneously exploits the constituency and dependency trees on the source side, to combine the advantages of two types of trees. We take head-dependents relations of dependency trees as backbone and incorporate phrasal nodes of constituency trees as the source side of our translation rules, and the target side as strings. Our rules hold the property of long distance reorderings and the compatibility with phrases. Large-scale experimental results show that our model achieves significantly improvements over the constituency-to-string (+2.45 BLEU on average) and dependency-to-string (+0.91 BLEU on average) models, which only employ single type of trees, and significantly outperforms the state-of-the-art hierarchical phrase-based model (+1.12 BLEU on average), on three Chinese-English NIST test sets.

1 Introduction

In recent years, syntax-based models have become a hot topic in statistical machine translation. According to the linguistic structures, these models can be broadly divided into two categories: constituency-based models (Yamada and Knight, 2001; Graehl and Knight, 2004; Liu et al., 2006; Huang et al., 2006), and dependency-based models (Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Xiong et al., 2007; Shen et al., 2008; Xie et al., 2011). These two kinds of models have their own advantages, as they capture different linguistic phenomena. Constituency trees describe how words and sequences of words combine to form constituents, and constituency-based models show better compatibility with phrases. However, dependency trees describe the grammatical relation between words of the sentence, and represent long distance dependencies in a concise manner. Dependency-based models, such as dependency-to-string model (Xie et al., 2011), exhibit better capability of long distance reorderings.

In this paper, we propose to combine the advantages of source side constituency and dependency trees. Since the dependency tree is structurally simpler and directly represents long distance dependencies, we take dependency trees as the backbone and incorporate constituents to them. Our model employs rules that represent the source side as head-dependents relations which are incorporated with constituency phrasal nodes, and the target side as strings. A head-dependents relation (Xie et al., 2011) is composed of a head and all its dependents in dependency trees, and it encodes phrase pattern and sentence pattern (typically long distance reordering relations). With the advantages of head-dependents relations, the translation rules of our model hold the property of long distance reorderings and the compatibility with phrases.

Our new model (Section 2) extracts rules from word-aligned pairs of source trees (constituency and dependency) and target strings (Section 3), and translate source trees into target strings by employing a bottom-up chart-based algorithm (Section 4). Compared with the constituency-to-string (Liu et al., 2006) and dependency-to-string (Xie et al., 2011) models that only employ a single type of trees, our

Seattle, Washington, USA, 18-21 October 2013.

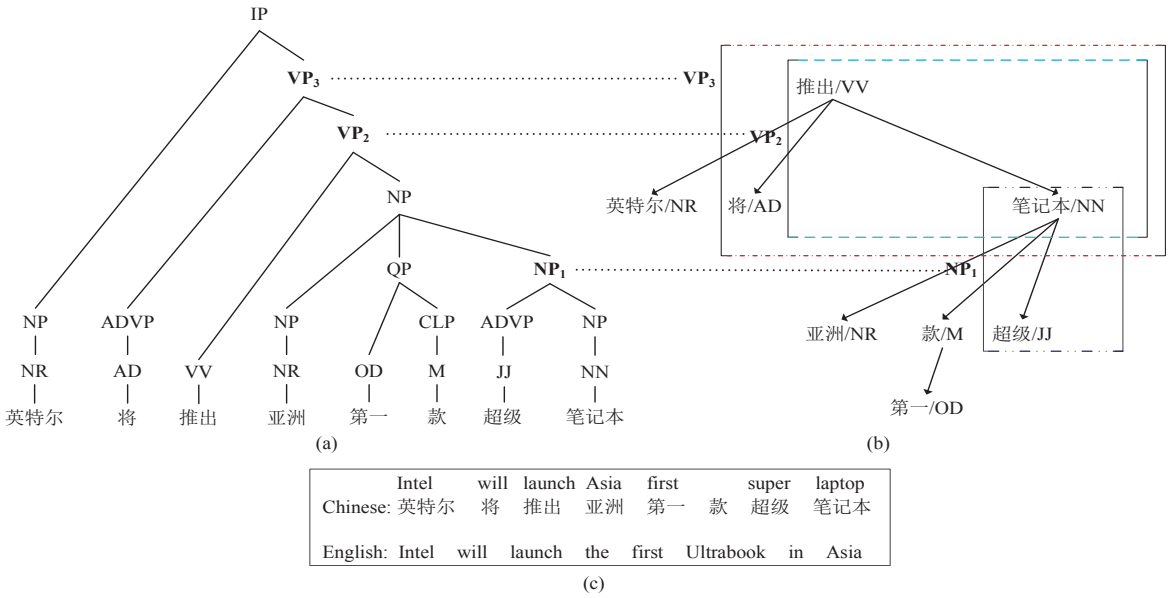

Figure 1: Illustration of phrases that can not be captured by a dependency tree (b) while captured by a constituency tree (a), where the bold phrasal nodes $\mathrm{NP}_1, \mathrm{VP}_2, \mathrm{VP}_3$ indicate the phrases which can not be captured by dependency syntactic phrases. (c) is the corresponding bilingual sentences. The subscripts of phrasal nodes are used for distinguishing the nodes with same phrasal categories.

approach yields encouraging results by exploiting two types of trees. Large-scale experiments (Section 5) on Chinese-English translation show that our model significantly outperforms the state-of-the-art single constituency-to-string model by averaged +2.45 BLEU points, dependency-to-string model by averaged +0.91 BLEU points, and hierarchical phrase-based model (Chiang, 2005) by averaged +1.12 BLEU points, on three Chinese-English NIST test sets.

2 Grammar

We take head-dependents relations of dependency trees as backbone and incorporate phrasal nodes of constituency trees as the source side of our translation rules, and the target side as strings. A head-dependents relation consists of a head and all its dependents in dependency trees, and it can represent long distance dependencies. Incorporating phrasal nodes of constituency trees into head-dependents relations further enhances the compatibility with phrases of our rules. Figure 1 shows an example of phrases which can not be captured by a dependency tree while captured by a constituency tree, such as the bold phrasal nodes NP_1,VP_2 and VP_3. The phrasal node NP_1 in the constituency tree indicates that "超级 笔记本" is a noun phrase and it should be translated as a basic unit, while in the dependency tree it is a non-syntactic phrase. The head-dependents relation in the top level of the dependency tree presents long distance dependencies of the words "英特尔", "将", "推出", and "笔记本" in a concise manner, which is useful for long distance reordering. We adopt this kind of rule representation to hold the property of long distance reorderings and the compatibility with phrases.

Figure 2 shows two examples of our translation rules corresponding to the top level of Figure 1-(b). We can see that r_1 captures a head-dependents relation, while r_2 extends r_1 by incorporating a phrasal node VP_2 to replace the two nodes "推出/VV" and "笔记本/NN". As shown in Figure 1-(b), VP_2 consists of two parts, a head node "推出/VV" and a subtree rooted at the dependent node "笔记本/NN". Therefore, we use VP_2 and the POS tags of the two nodes VV and NN to denote the part covered by VP_2 in r_2, to indicate that the source sequence covered by VP_2 can be translated by a bilingual phrase. Since VP_2 covers a head node "推出/VV", we represent r_2 by constructing a new head node

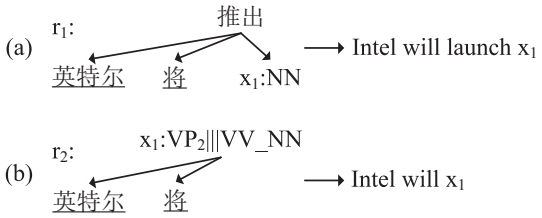

Figure 2: Two examples of our translation rules corresponding to the top level of Figure 1-(b). r_1 captures a head-dependents relation, and r_2 extends r_1 by incorporating a phrasal node VP_2. "x_1:NN" indicates a substitution site which can be replaced by a subtree whose root has POS tag "NN". "x_1:VP_2|||VV_NN" indicates a substitution site which can be replaced by a source phrase covered by a phrasal node VP (the phrasal node consists of two dependency nodes with POS tag VV and NN, respectively). The underline denotes a leaf node.

VP_2|||VV_NN. For simplicity, we use a shorten form CHDR to represent the head-dependents relations with/without constituency phrasal nodes.

Formally, our grammar G is defined as a 5-tuple $G = \langle \Sigma, N_c, N_d, \Delta, R \rangle$, where Σ is a set of source language terminals, N_c is a set of constituency phrasal categories, N_d is a set of categories (POS tags) for the terminals in Σ, Δ is a set of target language terminals, and R is a set of translation rules that include bilingual phrases for translating source language terminals and CHDR rules for translation and reordering. A CHDR rule is represented as a triple $\langle t, s, \sim \rangle$, where:

- t is CHDR with each node labeled by a terminal from Σ or a variable from a set $X = \{x_1, x_2, \cdots\}$ constrained by a terminal from Σ or a category from N_d or a joint category (constructed by the categories from N_c and N_d);
- $s \in (X \cup \Delta)$ denotes the target side string;
- $\sim$ denotes one-to-one links between nonterminals in t and variables in s.

We use the lexicon dependency grammar (Hellwig, 2006) which adopts a bracket representation to express the head-dependents relation and CHDR. For example, the left-hand sides of r_1 and r_2 in Figure 2 can be respectively represented as follows:

(英特尔) (将) 推出 (x_1:NN)

(英特尔) (将) x_1:VP_2|||VV_NN

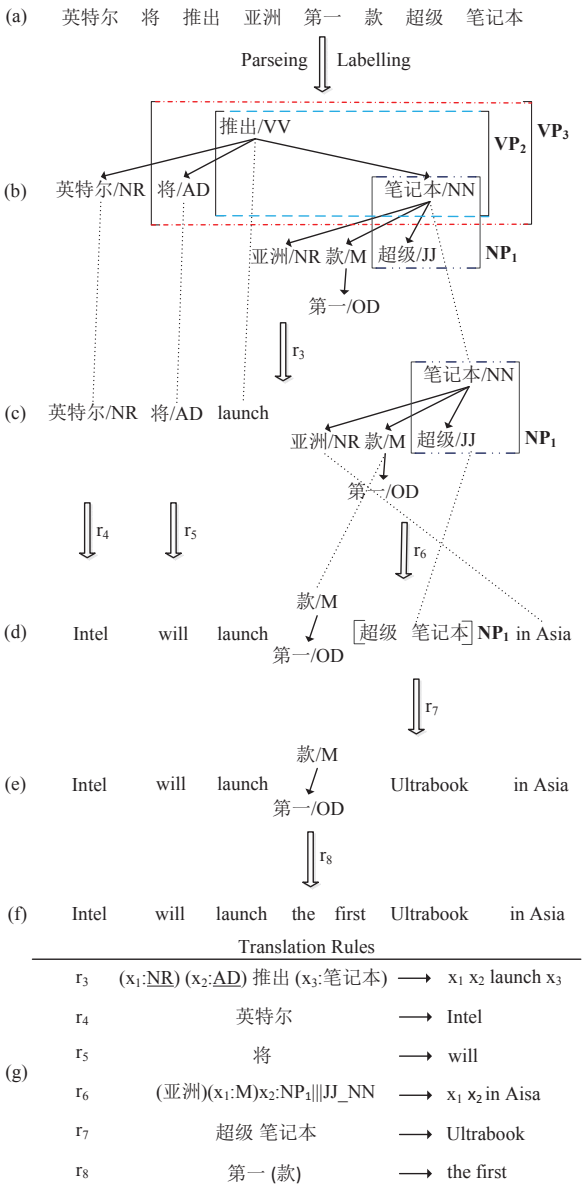

Figure 3: An example derivation of translation. (g) lists all the translation rules. r_3, r_6 and r_8 are CHDR rules, while r_4, r_5 and r_7 are bilingual phrases, which are used for translating source terminals. The dash lines indicate the reordering when employing a translation rule.

The formalized presentation of r_2 in Figure 2-(b):

t = (英特尔) (将) x_1:VP_2|||VV_NN

s = Intel will x_1

$\sim$= x_1:VP_2|||VV_NN $\leftrightarrow$ x_1

where the underline indicates a leaf node.

Figure 3 gives an example of the translation derivation in our model, with the translation rules

listed in (g). r_3, r_6 and r_8 are CHDR rules, while r_4, r_5 and r_7 are bilingual phrases, which are used for translating source language terminals. Given a sentence to translate in (a), we first parse it into a constituency tree and a dependency tree, then label the phrasal nodes from the constituency tree to the dependency tree, and yield (b). Then, we translate it into a target string by the following steps. At the root node, we apply rule r_3 to translate the top level head-dependents relation and results in four unfinished substructures and target strings in (c). From (c) to (d), there are three steps (one rule for one step). We use r_4 to translate "英特尔" to "Intel", r_5 to translate "将" to "will", and r_6 to translate the rightmost unfinished part. Then, we apply r_7 to translate the phrase "超级 笔记本" to "Ultrabook", and yield (e). Finally, we apply r_8 to translate the last fragment to "the first", and get the final result (f).

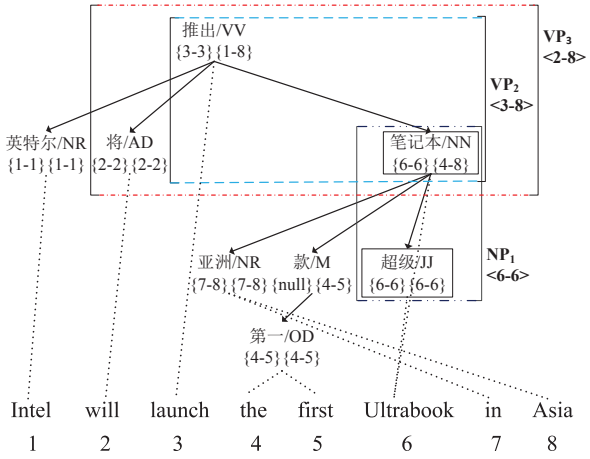

Figure 4: An annotated dependency tree. Each node is annotated with two spans, the former is node span and the latter subtree span. The fragments covered by phrasal nodes are annotated with phrasal spans. The nodes denoted by the solid line box are not nsp consistent.

3 Rule Extraction

In this section, we describe how to extract rules from a set of 4-tuples $\langle C, T, S, A\rangle$, where C is a source constituency tree, T is a source dependency tree, S is a target side sentence, and A is an word alignment relation between T/C and S. We extract CHDR rules from each 4-tuple $\langle C, T, S, A\rangle$ based on GHKM algorithm (Galley et al., 2004) with three steps:

1. Label the dependency tree with phrasal nodes from the constituency tree, and annotate alignment information to the phrasal nodes labeled dependency tree (Section 3.1).

2. Identify acceptable CHDR fragments from the annotated dependency tree for rule induction (Section 3.2).

3. Induce a set of lexicalized and generalized CHDR rules from the acceptable fragments (Section 3.3).

3.1 Annotation

Given a 4-tuple $\langle C, T, S, A\rangle$, we first label phrasal nodes from the constituency tree C to the dependency tree T, which can be easily accomplished by phrases mapping according to the common covered source sequences. As dependency trees can capture some phrasal information by dependency syntactic phrases, in order to complement the information that dependency trees can not capture, we only label the phrasal nodes that cover dependency non-syntactic phrases.

Then, we annotate alignment information to the phrasal nodes labeled dependency tree T, as shown in Figure 4. For description convenience, we make use of the notion of spans (Fox, 2002; Lin, 2004). Given a node n in the source phrasal nodes labeled T with word alignment information, the spans of n induced by the word alignment are consecutive sequences of words in the target sentence. As shown in Figure 4, we annotate each node n of phrasal nodes labeled T with two attributes: *node span* and *subtree span*; besides, we annotate *phrasal span* to the parts covered by phrasal nodes in each subtree rooted at n. The three types of spans are defined as follows:

Definition 1 *Given a node n, its **node span** $nsp(n)$ is the consecutive target word sequence aligned with the node n.*

Take the node "亚洲/NR" in Figure 4 for example, nsp(亚洲/NR)={7-8}, which corresponds to the target words "in" and "Asia".

Definition 2 *Given a subtree T' rooted at n, the **subtree span** $tsp(n)$ of n is the consecutive target word sequence from the lower bound of the nsp of*

all nodes in T' to the upper bound of the same set of spans.

For instance, tsp(笔记本/NN)={4-8}, which corresponds to the target words "the first Ultrabook in Asia", whose indexes are from 4 to 8.

Definition 3 *Given a fragment f covered by a phrasal node, the* ***phrasal span*** $psp(f)$ *of f is the consecutive target word sequence aligned with source string covered by f.*

For example, $psp(\text{VP}_2)$=⟨3-8⟩, which corresponds to the target word sequence "launch the first Ultrabook in Asia".

We say nsp, tsp and psp are *consistent* according to the notion in the phrase-based model (Koehn et al., 2003). For example, nsp(亚洲/NR), tsp(笔记本/NN) and $psp(\text{NP}_1)$ are consistent while nsp(超级/JJ) and nsp(笔记本/NN) are not consistent.

The annotation can be achieved by a single postorder transversal of the phrasal nodes labeled dependency tree. For simplicity, we call the annotated phrasal nodes labeled dependency tree *annotated dependency tree*. The extraction of bilingual phrases (including the translation of head node, dependency syntactic phrases and the fragment covered by a phrasal node) can be readily achieved by the algorithm described in Koehn et al., (2003). In the following, we focus on CHDR rules extraction.

3.2 Acceptable Fragments Identification

Before present the method of acceptable fragments identification, we give a brief description of CHDR fragments. A CHDR fragment is an annotated fragment that consists of a source head-dependents relation with/without constituency phrasal nodes, a target string and the word alignment information between the source and target side. We identify the acceptable CHDR fragments that are suitable for rule induction from the annotated dependency tree. We divide the acceptable CHDR fragments into two categories depending on whether the fragments contain phrasal nodes. If an acceptable CHDR fragment does not contain phrasal nodes, we call it *CHDR-normal fragment*, otherwise *CHDR-phrasal fragment*. Given a CHDR fragment F rooted at n, we say F is acceptable if it satisfies any one of the following properties:

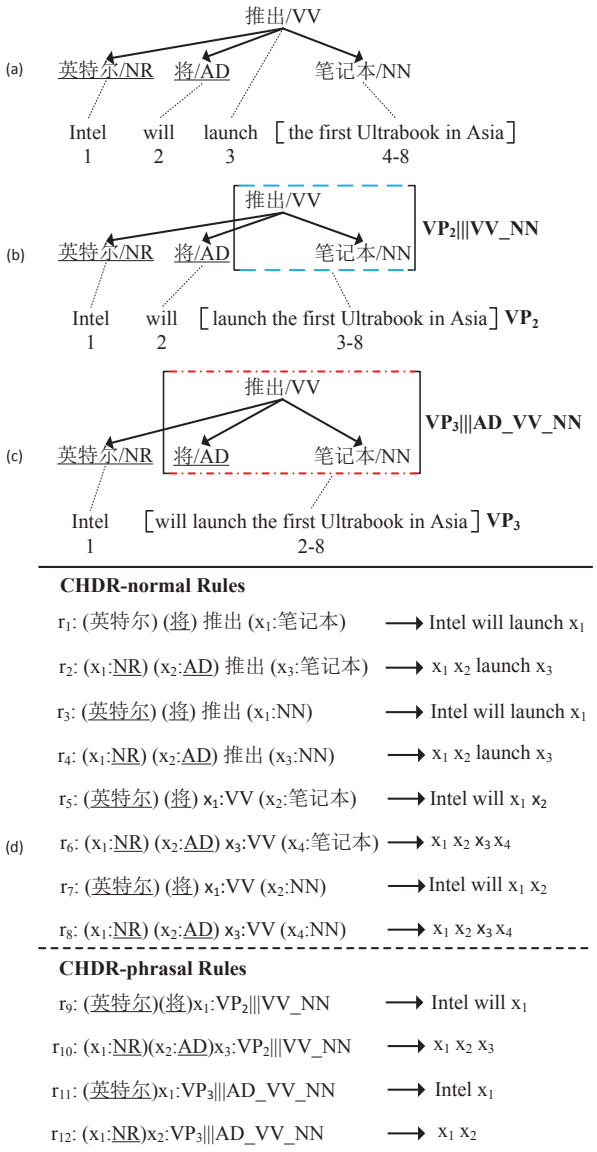

Figure 5: Examples of a CHDR-normal fragment (a), two CHDR-phrasal fragments (b) and (c) that are identified from the top level of the annotated dependency tree in Figure 4, and the corresponding CHDR rules (d) induced from (a), (b) and (c). The underline denotes a leaf node.

1. Without phrasal nodes, the node span of the root n is consistent and the subtree spans of n's all dependents are consistent. For example, Figure 5-(a) shows a CHDR-normal fragment that identified from the top level of the annotated dependency tree in Figure 4, since the nsp(推出/VV), tsp(英特尔/NR), tsp(将/AD) and tsp(笔记本/NN) are consistent.

2. With phrasal nodes, the phrasal spans of phrasal nodes are consistent; and for the other nodes, the node span of head (if it is not covered by any phrasal node) is consistent, and the subtree spans of dependents are consistent. For instance, Figure 5-(b) and (c) show two CHDR-phrasal fragments identified from the top level of Figure 4. In Figure 5-(b), $psp(\text{VP}_2)$, tsp(英特尔/NR) and tsp(将/AD) are consistent. In Figure 5-(c), $psp(\text{VP}_3)$ and tsp(英特尔/NR) are consistent.

The identification of acceptable fragments can be achieved by a single postorder transversal of the annotated dependency tree. Typically, each acceptable fragment contains at most three types of nodes: head node, head of the related CHDR; internal nodes, internal nodes of the related CHDR except head node; leaf nodes, leaf nodes of the related CHDR.

3.3 Rule Induction

From each acceptable CHDR fragment, we induce a set of lexicalized and generalized CHDR rules. We induce CHDR-normal rules and CHDR-phrasal rules from CHDR-normal fragments and CHDR-phrasal fragments, respectively.

We first induce a lexicalized form of CHDR rule from an acceptable CHDR fragment:

1. For a CHDR-normal fragment, we first mark the internal nodes as substitution sites. This forms the input of a CHDR-normal rule. Then we generate the target string according to the node span of the head and the subtree spans of the dependents, and turn the word sequences covered by the internal nodes into variables. This forms the output of a lexicalized CHDR-normal rule.

2. For a CHDR-phrasal fragment, we first mark the internal nodes and the phrasal nodes as substitution sites. This forms the input of a CHDR-phrasal rule. Then we construct the output of the CHDR-phrasal rule in almost the same way with constructing CHDR-normal rules, except that we replace the target sequences covered by the internal nodes and the phrasal nodes with variables.

For example, rule r_1 in Figure 5-(d) is a lexicalized CHDR-normal rule induced from the CHDR-normal fragment in Figure 5-(a). r_9 and r_{11} are CHDR-phrasal rules induced from the CHDR-phrasal fragment in Figure 5-(b) and Figure 5-(c) respectively. As we can see, these CHDR-phrasal rules are partially unlexicalized.

To alleviate the sparseness problem, we generalize the lexicalized CHDR-normal rules and partially unlexicalized CHDR-phrasal rules with unlexicalized nodes by the method proposed in Xie et al., (2011). As the modification relations between head and dependents are determined by the edges, we can replace the lexical word of each node with its category (POS tag) and obtain new head-dependents relations with unlexicalized nodes keeping the same modification relations. We generalize the rule by simultaneously turn the nodes of the same type (head, internal, leaf) into their categories. For example, CHDR-normal rules $r_2 \sim r_7$ are generalized from r_1 in Figure 5-(d). Besides, r_{10} and r_{12} are the corresponding generalized CHDR-phrasal rules. Actually, our CHDR rules are the superset of head-dependents relation rules in Xie et al., (2011). CHDR-normal rules are equivalent with the head-dependents relation rules and the CHDR-phrasal rules are the extension of these rules. For convenience of description, we use the subscript to distinguish the phrasal nodes with the same category, such as VP_2 and VP_3. In actual operation, we use VP instead of VP_2 and VP_3.

We handle the unaligned words of the target side by extending the node spans of the lexicalized head and leaf nodes, and the subtree spans of the lexicalized dependents, on both left and right directions. This procedure is similar with the method of Och and Ney, (2004). During this process, we might obtain $m(m \geq 1)$ CHDR rules from an acceptable fragment. Each of these rules is assigned with a fractional count $1/m$. We take the extracted rule set as observed data and make use of relative frequency estimator to obtain the translation probabilities $P(t|s)$ and $P(s|t)$.

4 Decoding and the Model

Following Och and Ney, (2002), we adopt a general loglinear model. Let d be a derivation that convert a

source phrasal nodes labeled dependency tree into a target string e. The probability of d is defined as:

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \quad (1)$$

where ϕ_i are features defined on derivations and λ_i are feature weights. In our experiments of this paper, the features are used as follows:

- CHDR rules translation probabilities $P(t|s)$ and $P(s|t)$, and CHDR rules lexical translation probabilities $P_{lex}(t|s)$ and $P_{lex}(s|t)$;
- bilingual phrases translation probabilities $P_{bp}(t|s)$ and $P_{bp}(s|t)$, and bilingual phrases lexical translation probabilities $P_{bplex}(t|s)$ and $P_{bplex}(s|t)$;
- rule penalty $exp(-1)$;
- pseudo translation rule penalty $exp(-1)$;
- target word penalty $exp(|e|)$;
- language model $P_{lm}(e)$.

We have twelve features in our model. The values of the first four features are accumulated on the CHDR rules and the next four features are accumulated on the bilingual phrases. We also use a pseudo translation rule (constructed according to the word order of head-dependents relation) as a feature to guarantee the complete translation when no matched rules can be found during decoding.

Our decoder is based on bottom-up chart-based algorithm. It finds the best derivation that convert the input phrasal nodes labeled dependency tree into a target string among all possible derivations. Given the source constituency tree and dependency tree, we first generate phrasal nodes labeled dependency tree T as described in Section 3.1, then the decoder transverses each node in T by postorder. For each node n, it enumerates all instances of CHDR rooted at n, and checks the rule set for matched translation rules. A larger translation is generated by substituting the variables in the target side of a translation rule with the translations of the corresponding dependents. Cube pruning (Chiang, 2007; Huang and Chiang, 2007) is used to find the k-best items with integrated language model for each node.

To balance the performance and speed of the decoder, we limit the search space by reducing the number of translation rules used for each node. There are two ways to limit the rule table size: by a fixed limit (rule-limit) of how many rules are retrieved for each input node, and by a threshold (rule-threshold) to specify that the rule with a score lower than β times of the best score should be discarded. On the other hand, instead of keeping the full list of candidates for a given node, we keep a top-scoring subset of the candidates. This can also be done by a fixed limit (stack-limit) and a threshold (stack-threshold).

5 Experiments

We evaluated the performance of our model by comparing with hierarchical phrase-based model (Chiang, 2007), constituency-to-string model (Liu et al., 2006) and dependency-to-string model (Xie et al., 2011) on Chinese-English translation. First, we describe data preparation (Section 5.1) and systems (Section 5.2). Then, we validate that our model significantly outperforms all the other baseline models (Section 5.3). Finally, we give detail analysis (Section 5.4).

5.1 Data Preparation

Our training data consists of 1.25M sentence pairs extracted from LDC [1] data. We choose NIST MT Evaluation test set 2002 as our development set, NIST MT Evaluation test sets 2003 (MT03), 2004 (MT04) and 2005 (MT05) as our test sets. The quality of translations is evaluated by the case insensitive NIST BLEU-4 metric [2].

We parse the source sentences to constituency trees (without binarization) and projective dependency trees with Stanford Parser (Klein and Manning, 2002). The word alignments are obtained by running GIZA++ (Och and Ney, 2003) on the corpus in both directions and using the "grow-diag-final-and" balance strategy (Koehn et al., 2003). We get bilingual phrases from word-aligned data with algorithm described in Koehn et al. (2003) by running Moses Toolkit [3]. We apply SRI Language Modeling Toolkit (Stolcke and others, 2002) to train a 4-gram

[1] Including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

consdep2str	23.3M+32.5M	**35.57***	**37.68***	**35.62***	**36.29**

Table 1: Statistics of the extracted rules on training data and the BLEU scores (%) on the test sets of different systems. The "+" denotes that the rules are composed of syntactic translation rules and bilingual phrases (32.5M). The "*" denotes that the results are significantly better than all the other systems ($p<0.01$).

language model with modified Kneser-Ney smoothing on the Xinhua portion of the English Gigaword corpus. We make use of the standard MERT (Och, 2003) to tune the feature weights in order to maximize the system's BLEU score on the development set. The statistical significance test is performed by *sign-test* (Collins et al., 2005).

5.2 Systems

We take the open source hierarchical phrase-based system *Moses-chart* (with default configuration), our in-house constituency-to-string system *cons2str* and dependency-to-string system *dep2str* as our baseline systems.

For *cons2str*, we follow Liu et al., (Liu et al., 2006) to strict that the height of a rule tree is no greater than 3 and phrase length is no greater than 7. To keep consistent with our proposed model, we implement the dependency-to-string model (Xie et al., 2011) with GHKM (Galley et al., 2004) rule extraction algorithm and utilize bilingual phrases to translate source head node and dependency syntactic phrases. Our *dep2str* shows comparable performance with Xie et al., (2011), which can be seen by comparing with the results of hierarchical phrase-based model in our experiments. For *dep2str* and our proposed model *consdep2str*, we set rule-threshold and stack-threshold to 10^{-3}, rule-limit to 100, stack-limit to 300, and phrase length limit to 7.

5.3 Experimental Results

Table 1 illustrates the translation results of our experiments. As we can see, our *consdep2str* system has gained the best results on all test sets, with +1.12 BLEU points higher than *Moses-chart*, +2.45 BLEU points higher than *cons2str*, and +0.91 BLEU points higher than *dep2str*, averagely on MT03, MT04 and MT05. Our model significantly outperforms all the other baseline models, with $p<0.01$ on statistical significance test *sign-test* (Collins et al., 2005). By exploiting two types of trees on source side, our model gains significant improvements over constituency-to-string and dependency-to-string models, which employ single type of trees.

Table 1 also lists the statistical results of rules extracted from training data by different systems. According to our statistics, the number of rules extracted by our *consdep2str* system is about 18.88% larger than *dep2str*, without regard to the 32.5M bilingual phrases. The extra rules are CHDR-phrasal rules, which can bring in BLEU improvements by enhancing the compatibility with phrases. We will conduct a deep analysis in the next sub-section.

5.4 Analysis

In this section, we first illustrate the influence of CHDR-phrasal rules in our *consdep2str* model. We calculate the proportion of 1-best translations in test sets that employ CHDR-phrasal rules, and we call this proportion "*CHDR-phrasal Sent.*". Besides, the proportion of CHDR-phrasal rules in all CHDR rules is calculated in these translations, and we call this proportion "*CHDR-phrasal Rule*". Table 2 lists the using of CHDR-phrasal rules on test sets, showing that *CHDR-phrasal Sent.* on all test sets are higher than 50%, and *CHDR-phrasal Rule* on all three test sets are higher than 10%. These results indicate that CHDR-phrasal rules do play a role in decoding.

Furthermore, we compare some actual translations of our test sets generated by *cons2str*, *dep2str* and *consdep2str* systems, as shown in Figure 6. In the first example, the Chinese input holds long distance dependencies "联合国 已经 对 ... 加诸于 ... 表示 关切", which correspond to the sentence pattern "noun+adverb+prepositional

System	MT03	MT04	MT05
CHDR-phrasal Sent.	50.71	61.80	56.19
CHDR-phrasal Rule	10.53	13.55	10.83

Table 2: The proportion (%) of 1-best translations that employs CHDR-phrasal rules (CHDR-phrasal Sent.) and the proportion (%) of CHDR-phrasal rules in all CHDR rules in these translations (CHDR-phrasal Rule).

phrase+verb+noun". *Cons2str* gives a bad result with wrong global reordering, while our *consdep2str* system gains an almost correct result since we capture this pattern by CHDR-normal rules. In the second example, we can see that the Chinese phrase "再次 出现" is a non-syntactic phrase in the dependency tree, and this phrase can not be captured by head-dependents relation rules in Xie et al., (2011), thus can not be translated as one unit. Since we encode constituency phrasal nodes to the dependency tree, "再次 出现" is labeled by a phrasal node "VP" (means verb phrase), which can be captured by our CHDR-phrasal rules and translated into the correct result "reemergence" with bilingual phrases.

By combining the merits of constituency and dependency trees, our *consdep2str* model learns CHDR-normal rules to acquire the property of long distance reorderings and CHDR-phrasal rules to obtain good compatibility with phrases.

6 Related Work

In recent years, syntax-based models have witnessed promising improvements. Some researchers make efforts on constituency-based models (Graehl and Knight, 2004; Liu et al., 2006; Huang et al., 2006; Zhang et al., 2007; Mi et al., 2008; Liu et al., 2009; Liu et al., 2011; Zhai et al., 2012). Some works pay attention to dependency-based models (Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Xiong et al., 2007; Shen et al., 2008; Xie et al., 2011). These models are based on single type of trees.

There are also some approaches combining merits of different structures. Marton and Resnik (2008) took the source constituency tree into account and added soft constraints to the hierarchical phrase-based model (Chiang, 2005). Cherry (2008) utilized dependency tree to add syntactic cohesion to the phrased-based model. Mi and Liu, (2010) proposed a constituency-to-dependency translation model, which utilizes constituency forests on the source side to direct the translation, and dependency trees on the target side to ensure grammaticality. Feng et al. (2012) presented a hierarchical chunk-to-string translation model, which is a compromise between the hierarchical phrase-based model and the constituency-to-string model. Most works make effort to introduce linguistic knowledge into the phrase-based model and hierarchical phrase-based model with constituency trees. Only the work proposed by Mi and Liu, (2010) utilized constituency and dependency trees, while their work applied two types of trees on two sides.

Instead, our model simultaneously utilizes constituency and dependency trees on the source side to direct the translation, which is concerned with combining the advantages of two types of trees in translation rules to advance the state-of-the-art machine translation.

7 Conclusion

In this paper, we present a novel model that simultaneously utilizes constituency and dependency trees on the source side to direct the translation. To combine the merits of constituency and dependency trees, our model employs head-dependents relations incorporating with constituency phrasal nodes. Experimental results show that our model exhibits good performance and significantly outperforms the state-of-the-art constituency-to-string, dependency-to-string and hierarchical phrase-based models. For the first time, source side constituency and dependency trees are simultaneously utilized to direct the translation, and the model surpasses the state-of-the-art translation models.

Since constituency tree binarization can lead to more constituency-to-string rules and syntactic phrases in rule extraction and decoding, which improve the performance of constituency-to-string systems, for future work, we would like to do research on encoding binarized constituency trees to dependency trees to improve translation performance.

Abstract

When using a machine translation (MT) model trained on OLD-domain parallel data to translate NEW-domain text, one major challenge is the large number of out-of-vocabulary (OOV) and new-translation-sense words. We present a method to identify new translations of both known and unknown source language words that uses NEW-domain comparable document pairs. Starting with a joint distribution of source-target word pairs derived from the OLD-domain parallel corpus, our method recovers a new joint distribution that matches the marginal distributions of the NEW-domain comparable document pairs, while minimizing the divergence from the OLD-domain distribution. Adding learned translations to our French-English MT model results in gains of about 2 BLEU points over strong baselines.

1 Introduction

When a statistical machine translation (SMT) model trained on OLD-domain (e.g. parliamentary proceedings) parallel text is used to translate text in a NEW-domain (e.g. medical or scientific), performance degrades drastically. One of the major causes is the large number of NEW-domain words that are out-of-vocabulary (OOV) with respect to the OLD-domain text. Figure 1 shows the OOV rate for text in several NEW-domains, with respect to OLD-domain parliamentary proceedings. Even more challenging are the difficult-to-detect new-translation-sense (NTS) words: French words that are present in both the OLD and NEW domains but that are translated differently in each domain. For example, the French word *enceinte* is mostly translated in parliamentary proceedings as *place*, *house*, or *chamber*; in medical text, the translation is mostly *pregnant*; in scientific text, *enclosures*.

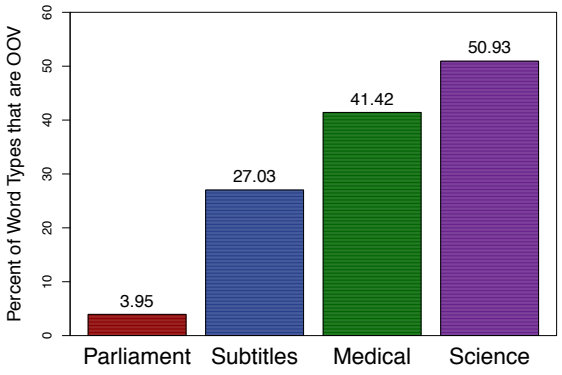

Figure 1: Percent of test set word types by domain that are OOV with respect to five million tokens of OLD-domain French parliamentary proceedings data.

One potential remedy is to collect parallel data in the NEW-domain, from which we can train a new SMT model. Smith et al. (2010), for example, mine parallel text from comparable corpora. Parallel sentences are informative but also rare: in the data released by Smith et al. (2010), only 21% of the foreign sentences have a near-parallel counterpart in the English article.[1] Furthermore, these sentences do not capture all terms. In that same dataset, we find that on average only 20% of foreign and 28% of English word types in a given article are represented in the parallel sentence pairs.

In this work, we seek to learn a joint distribu-

[1] Only 12% of sentences from generally longer English articles have a near-parallel counterpart in the foreign language.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1077–1088,
Seattle, Washington, USA, 18-21 October 2013.

tion of translation probabilities over all source and target word pairs in the NEW-domain. We begin with a maximum likelihood estimate of the joint based on a word aligned OLD-domain corpus and update this distribution using NEW-domain comparable data. We define a model based on a single comparable corpus and then extend it to learn from document aligned comparable corpora with any number of comparable *document pairs*. This approach allows us to identify translations for OOV words in the OLD-domain (e.g. French *cisaillement* and *perçage*, which translate as *shear* and *drilling*, in the scientific domain) as well as new translations for previously observed NTS words (e.g. *enceinte* translates as *enclosures*, not *place*, in the scientific domain). In our MT experiments, we use the learned NEW-domain joint distribution to update our SMT model with translations of OOV and low frequency words; we leave the integration of new translations for NTS words to future work.

Our approach crucially depends on finding comparable document pairs relevant to the NEW-domain. Such pairs could be derived from a number of sources, with document pairings inferred from timestamps (e.g. news articles) or topics (inferred or manually labeled). We use Wikipedia[2] as a source of comparable pairs. So-called "interwiki links" (which link Wikipedia articles written on the same topic but in different languages) act as rough guidance that pages may contain similar information. Our approach does not exploit any Wikipedia structure beyond this signal, and thus is portable to alternate sources of comparable articles, such as multilingual news articles covering the same event.

Our model also relies on the assumption that each comparable document pair describes generally the same concepts, though the order and structure of presentation may differ significantly. The efficacy of this method likely depends on the degree of comparability of the data; exploring the correlation between comparability and MT performance is an interesting question for future work.

2 Previous Work

In prior work (Irvine et al., 2013), we presented a systematic analysis of errors that occur when shifting domains in machine translation. That work concludes that errors resulting from unseen (OOV) and new translation sense words cause the majority of the degradation in translation performance that occurs when an MT model trained on OLD-domain data is used to translate data in a NEW-domain. Here, we target OOV errors, though our marginal matching method is also applicable to learning translations for NTS words.

A plethora of prior work learns bilingual lexicons from monolingual and comparable corpora with many signals including distributional, temporal, and topic similarity (Rapp, 1995; Fung and Yee, 1998; Rapp, 1999; Schafer and Yarowsky, 2002; Schafer, 2006; Klementiev and Roth, 2006; Koehn and Knight, 2002; Haghighi et al., 2008; Mimno et al., 2009; Mausam et al., 2010; Prochasson and Fung, 2011; Irvine and Callison-Burch, 2013). However, this prior work stops short of using these lexicons in translation. We augment a baseline MT system with learned translations.

Our approach bears some similarity to Ravi and Knight (2011), Dou and Knight (2012), and Nuhn et al. (2012); we learn a translation distribution despite a lack of parallel data. However, we focus on the domain adaptation setting. Parallel data in an OLD-domain acts as a starting point (prior) for this translation distribution. It is reasonable to assume an initial bilingual dictionary can be obtained even in low resource settings, for example by crowdsourcing (Callison-Burch and Dredze, 2010) or pivoting through related languages (Schafer and Yarowsky, 2002; Nakov and Ng, 2009).

Daumé III and Jagarlamudi (2011) mine translations for high frequency OOV words in NEW-domain text in order to do domain adaptation. Although that work shows significant MT improvements, it is based primarily on distributional similarity, thus making it difficult to learn translations for low frequency source words with sparse word context counts. Additionally, that work reports results using artificially created monolingual corpora taken from separate source and target halves of a NEW-domain parallel corpus, which may have more lexical overlap with the corresponding test set than we could expect from true monolingual corpora. Our work mines NEW-domain-like document pairs from Wikipedia. In this work, we show that, keeping

[2] www.wikipedia.org

data resources constant, our model drastically outperforms this previous approach. Razmara et al. (2013) take a fundamentally different approach and construct a graph using source language monolingual text and identify translations for source language OOV words by pivoting through paraphrases.

Della Pietra et al. (1992) and Federico (1999) explore models for combining foreground and background distributions for the purpose of language modeling, and their approaches are somewhat similar to ours. However, our focus is on translation.

3 Model

Our goal is to recover a probabilistic translation dictionary in a NEW-domain, represented as a joint probability distribution $p^{\text{new}}(s,t)$ over source/target word pairs. At our disposal, we have access to a joint distribution $p^{\text{old}}(s,t)$ from the OLD-domain (computed from word alignments), plus comparable document pairs in the NEW-domain. From these comparable documents, we can extract raw word frequencies on both the source and target side, represented as marginal distributions $q(s)$ and $q(t)$. The key idea is to estimate this NEW-domain joint distribution to be as similar to the OLD-domain distribution as possible, subject to the constraint that its marginals match those of q.

To illustrate our goal, consider an example. Imagine in the OLD-domain parallel data we find that *accorder* translates as *grant* 10 times and as *tune* 1 time. In the NEW-domain comparable data, we find that *accorder* occurs 5 times, but *grant* occurs only once, and *tune* occurs 4 times. Clearly *accorder* no longer translates as *grant* most of the time; perhaps we should shift much of its mass onto the translation *tune* instead. Figure 2 shows the intuition.

First, we present an objective function and set of constraints over joint distributions to minimize the divergence from the OLD-domain distribution while matching both the source and target NEW-domain marginal distributions. Next, we augment the objective with information about word string similarity, which is particularly useful for the French-English language pair. Optimizing this objective with a single pair of source and target marginals can be performed using an off-the-shelf solver. In practice, though, we have a large set of document pairs, each of which can induce a pair of marginals. Using these per-document marginals provides additional information to the learning function but would overwhelm a common solver. Therefore, we present a sequential learning method for approximately matching the large set of document pair marginal distributions. Finally, we describe how we identify comparable document pairs relevant to the NEW-domain.

3.1 Marginal Matching Objective

Given word-aligned parallel data in the OLD-domain and source and target comparable corpora in the NEW-domain, we first estimate a joint distribution $p^{\text{old}}(s,t)$ over word pairs (s,t) in the OLD-domain, where s and t range over source and target language words, respectively. For the OLD-domain joint distribution, we use a simple maximum likelihood estimate based on non-null automatic word alignments (using grow-diag-final GIZA++ alignments (Och and Ney, 2003)). Next, we find source and target marginal distributions, $q(s)$ and $q(t)$, by relative frequency estimates over the source and target comparable corpora. Our goal is to recover a joint distribution $p^{\text{new}}(s,t)$ for the new domain that matches the marginals, $q(s)$ and $q(t)$, but is minimally different from the original joint distribution, $p^{\text{old}}(s,t)$.

We cast this as a linear programming problem:

$$p^{\text{new}} = \arg\min_{p} \left\| p - p^{\text{old}} \right\|_1 \tag{1}$$

$$\text{subject to: } \sum_{s,t} p(s,t) = 1, \quad p(s,t) \geq 0$$

$$\sum_{s} p(s,t) = q(t), \quad \sum_{t} p(s,t) = q(s)$$

In the objective function, the joint probability matrices p and p^{old} are interpreted as large vectors over all word pairs (s,t). The first two constraints force the result to be a well-formed distribution, and the final two force the marginals to match.

Following prior work (Ravi and Knight, 2011), we would like the matrix to remain as sparse as possible; that is, introduce the smallest number of new translation pairs necessary. A regularization term captures this goal:

$$\Omega(p) = \sum_{\substack{s,t: \\ p^{\text{old}}(s,t)=0}} \lambda_r \times p(s,t) \tag{2}$$

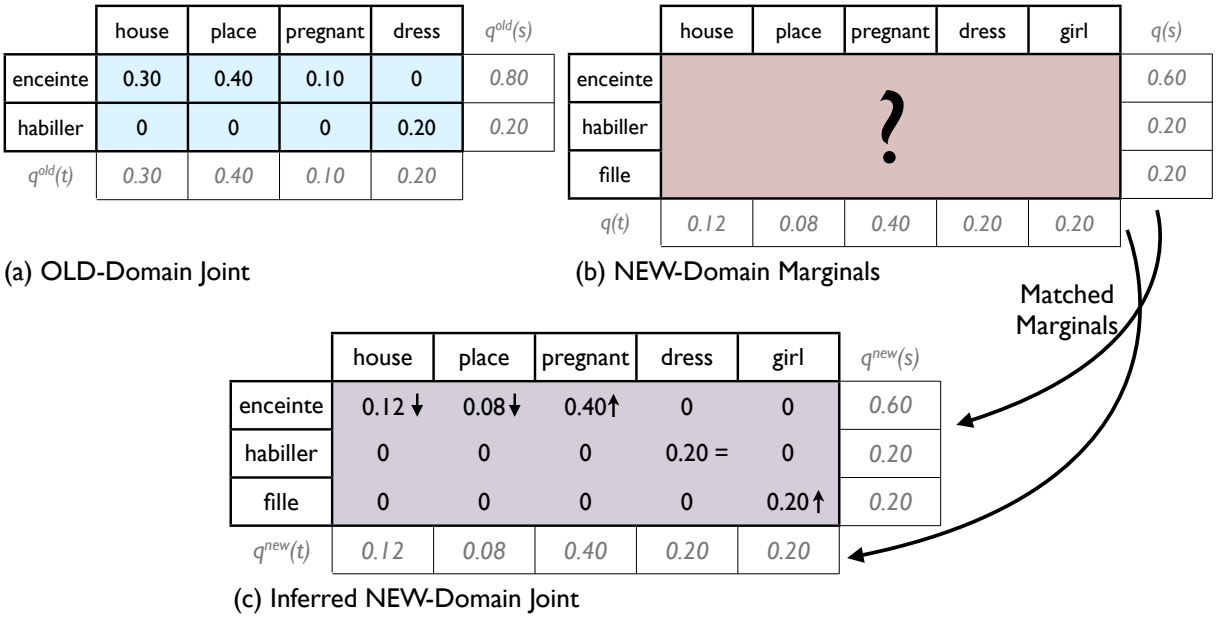

Figure 2: Starting with a joint distribution derived from OLD-domain data, we infer a NEW-domain joint distribution based on the intuition that the new joint should match the marginals that we observe in NEW-domain comparable corpora. In this example, a translation is learned for the previously OOV word *fille*, and *pregnant* becomes a preferred translation for *enceinte*.

If the old domain joint probability $p^{\text{old}}(s,t)$ was nonzero, there is no penalty. Otherwise, the penalty is λ_r times the new joint probability $p(s,t)$. To discourage the addition of translation pairs that are unnecessary in the new domain, we use a value of λ_r greater than one. Thus, the benefit of a more sparse matrix overwhelms the desire for preventing change. Any value greater than one seems to suffice; we use $\lambda_r = 1.1$ in our experiments.

Inspired by the preference for sparse matrices captured by $\Omega(p)$, we include another orthogonal cue that words are translations of one another: their string similarity. In prior work, string similarity was a valuable signal for inducing translations, particularly for closely related languages such as French and English (Daumé III and Jagarlamudi, 2011). We define a penalty function $f(p)$ as follows: if the normalized Levenshtein edit distance between s *without accents* and t is less than 0.2, no penalty is applied; a penalty of 1 is applied otherwise. We chose the 0.2 threshold manually by inspecting results on our development sets.

$$f(p) = \sum_{s,t} p(s,t) \cdot \begin{cases} 0 & \text{if } \frac{\text{lev}(t,\text{strip}(s))}{\text{len}(s)+\text{len}(t)} < 0.2 \\ 1 & \text{otherwise} \end{cases}$$

The objective function including this penalty is:

$$p^{\text{new}} = \arg\min_{p} \left\| p - p^{\text{old}} \right\|_1 + \Omega(p) + f(p)$$

In principle, additional penalties could be encoded in a similar way.[3] This objective can be optimized by any standard LP solver; we use the Gurobi package (Gurobi Optimization Inc., 2013).

3.2 Document Pair Modification

The above formulation applies whenever we have access to comparable *corpora*. However, often we have access to comparable *documents*, such as those given by Wikipedia inter-language links. We modify our approach to take advantage of the document correspondences within our comparable corpus. In particular, we would like to match the marginals for *all document pairs*.[4] By maintaining separate marginal distributions, our algorithm is presented with more

[3] We experimented with penalties measuring document-pair co-occurrence and monolingual frequency differences but did not see gains on our development sets.

[4] This situation is not unique to our application; multiple marginals are likely to exist in many cases.

information. For example, imagine that one document pair uses "dog" and "chien", where another document pair uses "cat" and "chat", each with similar frequency. If we sum these marginals to produce a single marginal distribution, it is now difficult to identify that "dog" should correspond to "chien" and not "chat." Document pair alignments add information at the cost of additional constraints.

An initial formulation of our problem with multiple comparable document pairs might require the p^{new} marginals to match *all* of the document marginals. In general, this constraint set is likely to result in an infeasible problem. Instead, we take an incremental, online solution, considering a single comparable document pair at a time. For document pair k, we solve the optimization problem in Eq (1) to find the joint distribution minimally different from $p^{\text{k-1}}$, while matching the marginals of *this pair only*. This gives a new joint distribution, tuned specifically for this pair. We then update our current guess of the new domain joint *toward* this document-pair-specific distribution, much like a step in stochastic gradient ascent.

More formally, suppose that before processing the kth document we have a guess at the NEW-domain joint distribution, $p^{\text{new}}_{1:k-1}$ (the subscript indicates that it includes *all* document pairs up to and including document $k-1$). We first solve Eq (1) solely on the basis of this document pair, finding a joint distribution p^{new}_{k} that matches the marginals of the kth document pair *only* and is minimally different from $p^{\text{new}}_{1:k-1}$. Finally, we form a new estimate of the joint distribution by moving $p^{\text{new}}_{1:k-1}$ in the direction of p^{new}_{k}, via:

$$p^{\text{new}}_{1:k} = p^{\text{new}}_{1:k-1} + \eta_u \left[p^{\text{new}}_{k} - p^{\text{new}}_{1:k-1} \right]$$

The learning rate η_u is set to 0.001.[5]

This incremental update of parameters is similar to the margin infused relaxed algorithm (MIRA) (Crammer et al., 2006). Like MIRA and the perceptron, there is not an overall "objective" function that we are attempting to optimize (as one would in many stochastic gradient steps). Instead, we're aiming for a solution that makes a small amount of progress on each example, in such a way if it received that example again, it would "do better" (in this case: have a closer match of marginals). Also like MIRA, our learning rate is constant. We parallelize learning with mini-batches for increased speed. Eight parallel learners update an initial joint distribution based on 100 document pairs (i.e. each learner makes 100 incremental updates), and then we merge results using an average over the 8 learned joint distributions.

3.3 Comparable Data Selection

It remains to select comparable document pairs. We assume that we have enough monolingual NEW-domain data in one language to rank comparable document pairs (here, Wikipedia pages) according to how NEW-*domain-like* they are. In particular, we estimate the similarity to a source language (here, French) corpus in the NEW domain. For our experiments, we use the French side of a NEW-domain parallel corpus.[6] We could have targeted our learning even more by using our NEW-domain MT test sets. Doing so would increase the chances that our source language words of interest appear in the comparable corpus. However, to avoid overfitting any particular test set, we use the French side of the training data.

For each Wikipedia document pair, we compute the percent of French phrases up to length four that are observed in the French monolingual NEW-domain corpus and rank document pairs by the geometric mean of the four overlap measures. More sophisticated ways to identify NEW-domain-like Wikipedia pages (e.g. Moore and Lewis (2010)) may yield additional performance gains, but, qualitatively, the ranked Wikipedia pages seemed reasonable to the authors.

4 Experimental setup

4.1 Data

We use French-English Hansard parliamentary proceedings[7] as our OLD-domain parallel corpus. With over 8 million parallel lines of text, it is one of the largest freely available parallel corpora for any lan-

[5] We tuned η_u on semi-extrinsic results on the development set. Note that although 0.001 seems small, the values we are moving are *joint probabilities,* which are tiny and so small learning rates make sense.

[6] We could have, analogously, used the *target language* (English) side of the parallel corpus and measure overlap with the English Wikipedia documents, or even used both.

[7] http://www.parl.gc.ca

guage pair. In order to simulate more typical data settings, we sample every 32nd line, using the resulting parallel corpus of $253,387$ lines and $5,051,016$ tokens to train our baseline model.

We test our model using three NEW-domain corpora: (1) the EMEA medical corpus (Tiedemann, 2009), (2) a corpus of scientific abstracts (Carpuat et al., 2013a), and (3) a corpus of translated movie subtitles (Tiedemann, 2009). We use development and test sets to tune and evaluate our MT models. We use the NEW-domain parallel training corpora *only* for language modeling and for identifying NEW-domain-like comparable documents.

4.2 Machine translation

We use the Moses MT framework (Koehn et al., 2007) to build a standard statistical phrase-based MT model using our OLD-domain training data. Using Moses, we extract a phrase table with a phrase limit of five words and estimate the standard set of five feature functions (phrase and lexical translation probabilities in each direction and a constant phrase penalty feature). We also use a standard lexicalized reordering model and two language models based on the English side of the Hansard data and the given NEW-domain training corpora. Features are combined using a log-linear model optimized for BLEU, using the n-best batch MIRA algorithm (Cherry and Foster, 2012). We call this the "simple baseline." In Section 5.2 we describe several other baseline approaches.

4.3 Experiments

For each domain, we use the marginal matching method described in Section 3 to learn a new, domain-adapted joint distribution, $p_k^{\mathsf{new}}(s,t)$, over all French and English words. We use the learned joint to compute conditional probabilities, $p_k^{\mathsf{new}}(t|s)$, for each French word s and rank English translations t accordingly. First, we evaluate the learned joint directly using the distribution based on the word-aligned NEW-domain development set as a gold standard. Then, we perform end-to-end MT experiments. We supplement phrase tables with translations for OOV and low frequency words (we experiment with training data frequencies less than 101, 11, and 1) and include $p_k^{\mathsf{new}}(t|s)$ and $p_k^{\mathsf{new}}(s|t)$ as new translation features for those supplemental translations. For these new phrase pairs, we use the average lexicalized reordering values from the existing reordering tables. For phrase pairs extracted bilingually, we use the bilingually estimated translation probabilities and uniform scores for the new translation features. We experimented with using $p_k^{\mathsf{new}}(t|s)$ and $p_k^{\mathsf{new}}(s|t)$ to estimate additional lexical translation probabilities for the bilingually extracted phrase pairs but did not observe any gains (experimental details omitted due to space constraints). We re-run tuning in all experiments.

We also perform oracle experiments in which we identify translations for French words in word-aligned development and test sets and append these translations to baseline phrase tables.

5 Results

5.1 Semi-extrinsic evaluation

Before doing end-to-end MT experiments, we evaluate our learned joint distribution, $p_k^{\mathsf{new}}(s,t)$, by comparing it to the joint distribution taken from a word aligned NEW-domain parallel development set, $p^{\mathsf{gold}}(s,t)$. We call this evaluation semi-extrinsic because it involves neither end-to-end MT (our extrinsic task) nor an intrinsic evaluation based on our training objective (L1 norm). We find it informative to evaluate the models using bilingual lexicon induction metrics before integrating our output into full MT. That is, we do not compare the full joint distributions, but, rather, for a given French word, how our learned model ranks the word's most probable translation under the gold distribution. In particular, because we are primarily concerned with learning translations for previously unseen words, we evaluate over OOV French word types. In some cases, the correct translation for OOV words is the identical string (e.g. *na+*, *lycium*). Because it is trivial to produce these translations,[8] we evaluate over the subset of OOV development set French words for which the correct translation is not the same string.

Figure 3 shows the mean reciprocal rank for the learned distribution, $p_k^{\mathsf{new}}(s,t)$, for each domains as a function of the number of comparable document pairs used in learning. In all domains, the comparable document pairs are sorted according to their sim-

[8] And, indeed, by default our decoder copies OOV strings into its output directly.

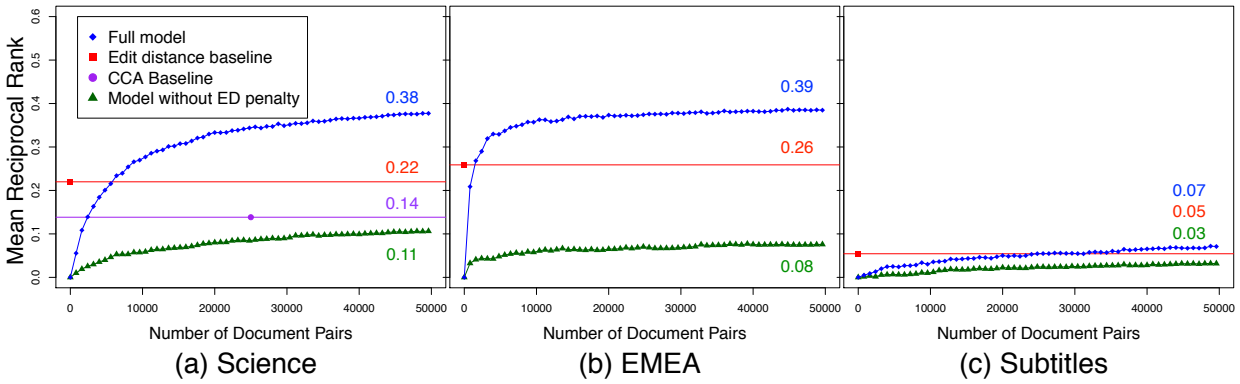

Figure 3: Semi-extrinsic bilingual lexicon induction results. Mean reciprocal rank is computed over all OOV development set words for which identity is not the correct translation.

ilarity with the NEW-domain. Figure 3 also shows the performance of baseline models and our learner without the edit distance penalty. For each source word s, the edit distance (ED) baseline ranks all English words t in our monolingual data by their edit distance with s.[9] The Canonical Correlation Analysis (CCA) baseline uses the approach of Daumé III and Jagarlamudi (2011) and the top $25,000$ ranked document pairs as a comparable corpus. That model performs poorly largely because of sparse word context counts. Interestingly, for Science and EMEA, the performance of our full model at $50,000$ document pairs is higher than the sum of the edit distance baseline and the model without the edit distance penalty, indicating that our approach effectively combines the marginal matching and edit distance signals.

The learning curves for the three domains vary substantially. For Science, learning is gradual and it appears that additional gains could be made by iterating over even more document pairs. In contrast, the model learns quickly for the EMEA domain; performance is stable after $20,000$ document pairs. Given these results and our experience with the two domains, we hypothesize that the difference is due to the fact that the Science data is much more heterogenous than the EMEA data. The Science data includes physics, chemistry, and biology abstracts, among others. The drug labels that make up most of the EMEA data are more homogeneous. In Section 6 we comment on the poor Subtitles performance, which persists in our MT experiments.

We experimented with making multiple learning passes over the document pairs and observed relatively small gains from doing so. In all experiments, learning from some number of additional new document pairs resulted in higher semi-extrinsic performance gains than passing over document pairs which were already observed.

In the case of OOV words, it's clear that learning something about how to translate a previously unobserved French word is beneficial. However, our learning method also learns domain-specific new-translation senses (NTS). Table 1 shows some examples of what the marginal matching method learns for different types of source words (OOVs, low frequency, and NTS).

5.2 MT evaluation

By default, the Moses decoder copies OOV words directly into its translated output. In some cases, this is correct (e.g. *ensembles*, *blumeria*, *google*). In other cases, French words can be translated into English correctly by simply stripping accent marks off of the OOV word and then copying it to the output (e.g. *caméra*, *éléments*, *molécules*). In the Science and EMEA domains, we found that our baseline BLEU scores improved from 21.91 to 22.20 and 23.67 to 24.45, respectively, when we changed the default handling of OOVs to strip accents before

[9] In particular, for each domain and each OOV French word, we ranked the set of all English words that appeared at least five times in the set of 50,000 most NEW-domain like Wikipedia pages. Using a frequency threshold of five helped eliminate French words and improperly tokenized English words from the set of candidates.

French	OLD top $p^{\text{old}}(t\|s)$	NEW top $p^{\text{gold}}(t\|s)$	MM-learned top $p^{\text{new}}(t\|s)$
OOV words			
cisaillement	-	shear strength shearing	shear viscous newtonian
courbure	-	curvature bending curvatures	curvature curved manifold
Low frequency words			
linéaires	linear	linear nonlinear non-linear	linear linearly nonlinear
récepteur	receiver	receptor receiver y1	receptor receiver receptors
New translation sense words			
champ	field jurisdiction scope	field magnetic near-field	field magnetic fields
marche	working march work	walk step walking	march walk walking

Table 1: Hand-picked examples of Science-domain French words and their top English translations in the OLD-domain, NEW-domain, and marginal matching distributions. The first two are OOVs. The next two only appeared four and one time, respectively, in the training data and only aligned to a single English word. The last two are NTS French words: words that appeared frequently in the training data but for which the word's sense in the new domain shifts.

copying into the output. Interestingly, performance on the Subtitles domain text did not change at all with this baseline modification. This is likely due to the fact that there are fewer technical OOVs (the terms typically captured by this accent-stripping pattern) in the subtitles domain.

Throughout our experiments, we found it critical to retain correct 'freebie' OOV translations. In the results presented below, including the baselines, we supplement phrase tables with a new candidate translation but also include accent-stripped identity, or 'freebie,' translations in the table for all OOV words. We experimented with classifying French words as freebies or needing a new translation, but oracle experiments showed very little improvement (about 0.2 BLEU improvement in the Science domain), so instead we simply include both types of translations in the phrase tables.

In addition to the strip-accents baseline, we compare results with four other baselines. First, we drop OOVs from the output translations. Second, like our semi-extrinsic baseline, we rank English words by their edit distance away from each French OOV word (ED baseline). Third, we rank English words by their document-pair co-occurrence score with each French OOV word. That is, for all words w, we compute $D(w)$, the vector indicating the document pairs in which w occurs, over the set of 50,000 document-pairs which are most NEW-*domain-like*. For French and English words s and t, if $D(s)$ and $D(t)$ are dissimilar, it is less likely (s, t) is a valid translation pair. We weight $D(w)$ entries with BM25 (Robertson et al., 1994). For all French OOVs, we rank all English translations according to the cosine similarity between the pair of $D(w)$ vectors. The fourth baseline uses the CCA model described in Daumé III and Jagarlamudi (2011) to rank English words according to their distributional similarity with each French word. For the CCA baseline comparison, we only learned translations using 25,000 Science-domain document pairs, rather than the full 50,000 and for all domains. However, it's unlikely that learning over more data would overcome the low performance observed so far. For the final three baselines, we append French OOV words and their highest ranked English translation to the phrase table. Along with each new translation pair, we include one new phrase table feature with the relevant translation score (edit distance, document similarity, or CCA distributional similarity). For all baselines other than drop-OOVs, we also include accent-stripped translation pairs with an additional indicator feature.

Table 3 shows results appending the top ranked English translation for each OOV French word using each baseline method. None of the alternate baselines outperform the simplest baseline on the subtitles data. Using document pair co-occurrences is the strongest baseline for the Science and EMEA domains. This confirms our intuition that taking advantage of document pair alignments is worthwhile. For Science and EMEA, supplementing a model with OOV translations learned through our marginal matching method drastically outperforms all base-

OOVs translated correctly and incorrectly	
Input	les résistances au **cisaillement** par **poinçonnement** ...
Ref	the punching **shear strengths**...
Baseline	the resistances in **cisaillement** by **poinconnement** ...
MM	the resistances in **shear reinforcement**...
OOV translated incorrectly	
Input	présentation d' un logiciel permettant de gérer les données **temporelles** .
Ref	presentation of software which makes it possible to manage **temporal** data .
Baseline	introduction of a software to manage **temporelles** data .
MM	introduction of a software to manage data **plugged** .
Low frequency French words	
Input	...limite est liée à la **décroissance** très rapide du **couplage** électron-phonon avec la température .
Ref	...limit is linked to the rapid **decrease** of the electron-phonon **coupling** with temperature .
Baseline	...limit is linked to the **decline** very rapid electron-phonon **linkage** with the temperature .
MM	...limit is linked to the **linear** very rapid electron-phonon **coupling** with the temperature .

Table 2: Example MT outputs for Science domain. The baseline strips accents (Table 3). In the first example, the previously OOV word *cisaillement* is translated correctly by an MM-supplemented model. The OOV *poinçonnement* is translated as *reinforcement* instead of *strengths*, which is incorrect with respect to the reference but arguably not bad. In the second example, *temporelles* is not translated correctly in the MM output. In the third example, the MM-hypothesized correct translation of low frequency word *couplage*, *coupling*, is chosen instead of incorrect *linkage*. Also in the third example, the low frequency word *décroissance* is translated as the MM-hypothesized incorrect translation *linear*. In the case of *décroissance*, the baseline's translation, *decline*, is much better than the MM translation *linear*.

lines. Using our model to translate OOV words yields scores of 23.62 and 26.97 in the Science and EMEA domains, or 1.19 and 1.94 BLEU points, respectively, above the strongest baseline. We observe additional gains by also supplementing the model with translations for low frequency French words. For example, when we use our approach to translate source words in the Science domain which appear ten or fewer times in our OLD-domain training data, the BLEU score increases to 24.28.

We tried appending top-k translations, varying k. However, we found that for the baselines as well as our MM translations, using only the top-1 English translations outperformed using more.

Table 3 also shows the result of supplementing a baseline phrase table with oracle OOV translations. Using the marginal matching learned OOV translations takes us 30% and 40% of the way from the baseline to the oracle upper bound for Science and EMEA, respectively.

We have focused on supplementing an SMT model trained on a sample of the Hansard parallel corpus in order to mimic typical data conditions, but we have also performed experiments supplementing a model trained on the full dataset.[10] Beginning with the larger model, we observe performance gains of 0.8 BLEU points for both the EMEA and the Science domains over the strongest baselines, which are based on document similarity, when we add OOV

	Science	EMEA	Subs
Simple Baseline	21.91	23.67	**13.18**
Drop OOVs	20.22	18.95	11.86
Accent-Stripped	22.20	24.45	13.13
ED Baseline	22.10	24.35	12.95
Doc Sim Baseline.	**22.43**	**25.03**	13.02
CCA Baseline	21.41	-	-
MM Freq<1 (OOV)	23.62	26.97	**13.07**
MM Freq<11	**24.28**	**27.26**	12.97
MM Freq<101	23.96	26.82	12.92
Oracle OOV	26.38	29.99	15.06

Table 3: BLEU results using: (1) baselines, (2) phrase tables augmented with top-1 translations for French words with indicated OLD training data frequencies, (3) phrase tables augmented with OOV oracle translations.

[10] We still use the joint that was learned starting with the one estimated over the sample; we may observe greater gains over the full Hansard baseline with a stronger initial joint.

translations. As expected, these gains are less than what we observe when our baseline model is estimated over less data, but they are still substantial.

In all experiments, we have assumed that we have no NEW-domain parallel training data, which is the case for the vast majority of language pairs and domains. However, In the case that we do have some NEW-domain parallel data, OOV rates will be somewhat lower, but our method is still applicable. For example, we would need 2.3 million words of Science (NEW-domain) parallel data to cover just 50% of the OOVs in our Science test set, and 4.3 million words to cover 70%.

6 Discussion

BLEU score performance gains are substantial for the Science and EMEA domains, but we don't observe gains on the subtitles text. We believe this difference relates to the difference between a corpus domain and a corpus register. As Lee (2002) explains, a text's *domain* is most related to its topic, while a text's *register* is related to its type and purpose. For example, religious, scientific, and dialogue texts may be classified as separate registers, while political and scientific expositions may have a single register but different domains. Our science and EMEA corpora are certainly different in domain from the OLD-domain parliamentary proceedings, and our success in boosting MT performance with our methods indicates that the Wikipedia comparable corpora that we mined match those domains well. In contrast, the subtitles data differs from the OLD-domain parliamentary proceedings in both domain and register. Although the Wikipedia data that we mined may be closer in domain to the subtitles data than the parliamentary proceedings,[11] its register is certainly not film dialogues.

Although the use of marginal matching is, to the best of our knowledge, novel in MT, there are related threads of research that might inspire future work. The intuition that we should match marginal distributions is similar to work using no example labels but only label proportions to estimate labels, for example in Quadrianto et al. (2008). Unlike that work, our label set corresponds to entire vocabularies, and we have multiple observed label proportions. Also, while the marginal matching objective seems effective in practice, it is difficult to optimize. A number of recently developed approximate inference methods use a decomposition that bears a strong resemblance to this objective function. Considering the marginal distributions from each document pair to be a separate subproblem, we could approach the global objective of satisfying all subproblems as an instance of dual decomposition (Sontag et al., 2010) or ADMM (Gabay and Mercier, 1976; Glowinski and Marrocco, 1975).

We experiment with French-English because tuning and test sets are available in several domains for that language pair. However, our techniques are directly applicable to other language pairs, including those that are less related. We have observed that many domain-specific terms, particularly in medical and science domains, are borrowed across languages, whether or not the languages are related. Even for languages with different character sets, one could do transliteration before measuring orthographical similarity.

Although we were able to identify translations for some NTS words (Table 1), we did not make use of them in our MT experiments. Recent work has identified NTS words in NEW-domain corpora (Carpuat et al., 2013b), and in future work we plan to incorporate discovered translations for such words into MT.

7 Conclusions

We proposed a model for learning a joint distribution of source-target word pairs based on the idea that its marginals should match those observed in NEW-domain comparable corpora. Supplementing a baseline phrase-based SMT model with learned translations results in BLEU score gains of about two points in the medical and science domains.

Efficient Left-to-Right Hierarchical Phrase-based Translation with Improved Reordering

Maryam Siahbani, Baskaran Sankaran, Anoop Sarkar

Abstract

Left-to-right (LR) decoding (Watanabe et al., 2006b) is a promising decoding algorithm for hierarchical phrase-based translation (Hiero). It generates the target sentence by extending the hypotheses only on the right edge. LR decoding has complexity $O(n^2b)$ for input of n words and beam size b, compared to $O(n^3)$ for the CKY algorithm. It requires a single language model (LM) history for each target hypothesis rather than two LM histories per hypothesis as in CKY. In this paper we present an augmented LR decoding algorithm that builds on the original algorithm in (Watanabe et al., 2006b). Unlike that algorithm, using experiments over multiple language pairs we show two new results: our LR decoding algorithm provides demonstrably more efficient decoding than CKY Hiero, four times faster; and by introducing new distortion and reordering features for LR decoding, it maintains the same translation quality (as in BLEU scores) obtained phrase-based and CKY Hiero with the same translation model.

1 Introduction

Hiero (Chiang, 2007) models translation using a lexicalized synchronous context-free grammar (SCFG) extracted from word aligned bitexts. Typically, CKY-style decoding is used for Hiero with time complexity $O(n^3)$ for source input with n words. Scoring the target language output using a language model within CKY-style decoding requires two histories per hypothesis, one on the left edge of each span and one on the right, due to the fact that the target side is not generated in left to right order, but rather built bottom-up from sub-spans. This leads to complex problems in efficient language model integration and requires state reduction techniques (Heafield et al., 2011; Heafield et al., 2013). The size of a Hiero SCFG grammar is typically larger than phrase-based models extracted from the same data creating challenges in rule extraction and decoding time especially for larger datasets (Sankaran et al., 2012).

In contrast, the LR-decoding algorithm could avoid these shortcomings such as faster time complexity, reduction in the grammar size and the simplified left-to-right language model scoring. It means LR decoding has the potential to replace CKY decoding for Hiero. Despite these attractive properties, we show that the original LR-Hiero decoding proposed by (Watanabe et al., 2006b) does not perform to the same level of the standard CKY Hiero with cube pruning (see Table 3). In addition, the current LR decoding algorithm does not obtain BLEU scores comparable to phrase-based or CKY-based Hiero models for different language pairs (see Table 4). In this paper we propose modifications to the LR decoding algorithm that addresses these limitations and provides, for the first time, a true alternative to the standard CKY Hiero algorithm that uses left-to-right decoding.

We introduce a new extended version of the LR decoding algorithm presented in (Watanabe et al., 2006b) which is demonstrably more efficient than the CKY Hiero algorithm. We measure the efficiency of the LR Hiero decoder in a way that is independent of the choice of system and programming language by measuring the number of language model queries. Although more efficient, the new LR decoding algorithm suffered from lower BLEU scores compared to CKY Hiero. Our analysis of left to right decoding showed that it has more potential for search errors due to early pruning of good hypotheses. This is unlike bottom-up decoding (CKY) which keeps best hypotheses for each span. To address this issue, we introduce two novel features into the Hiero SMT model that deal with reordering and distortion. Our experiments show that LR decoding with these features using prefix lexi-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1089–1099,
Seattle, Washington, USA, 18-21 October 2013.

calized target side rules equals the scores obtained by CKY decoding with prefix lexicalized target side rules and phrase-based translation system. It performs four times fewer language model queries on average, compare to CKY Hiero decoding with unrestricted Hiero rules: 6466.7 LM queries for CKY Hiero (with cube pruning) compared to 1500.45 LM queries in LR Hiero (with cube pruning). While translation quality suffers by only about 0.67 in BLEU score on average, across two different language pairs.

2 Left-to-Right Decoding for Hiero

Hierarchical phrase-based SMT (Chiang, 2005; Chiang, 2007) uses a synchronous context free grammar (SCFG), where the rules are of the form $X \rightarrow \langle \gamma, \alpha \rangle$, where X is a non-terminal, γ and α are strings of terminals and non-terminals.

Chiang (2007) places certain constraints on the extracted rules in order to simplify decoding. This includes limiting the maximum number of non-terminals (rule arity) to two and disallowing any rule with consecutive non-terminals on the foreign language side. It further limits the length of the initial phrase-pair as well as the number of terminals and non-terminals in the rule. For translating sentences longer than the maximum phrase-pair length, the decoder relies on additional glue rules $S \rightarrow \langle X, X \rangle$ and $S \rightarrow \langle SX, SX \rangle$ that allows monotone combination of phrases. The glue rules are used when no rules could match or the span length is larger than the maximum phrase-pair length.

2.1 Rule Extraction for LR Decoding

Left-to-right Hiero (Watanabe et al., 2006b) generates the target hypotheses left to right, but for synchronous context-free grammar (SCFG) as used in Hiero. The target-side rules are constrained to be prefix lexicalized. These constrained SCFG rules are defined as:

$$X \rightarrow \langle \gamma, \bar{b}\, \beta \rangle \tag{1}$$

where γ is a mixed string of terminals and non-terminals. $\bar{b}$ is a terminal sequence prefixed to the possibly empty non-terminal sequence β. For the sake of simplicity, We refer to these type of rules as *GNF rules*[1] in this paper.

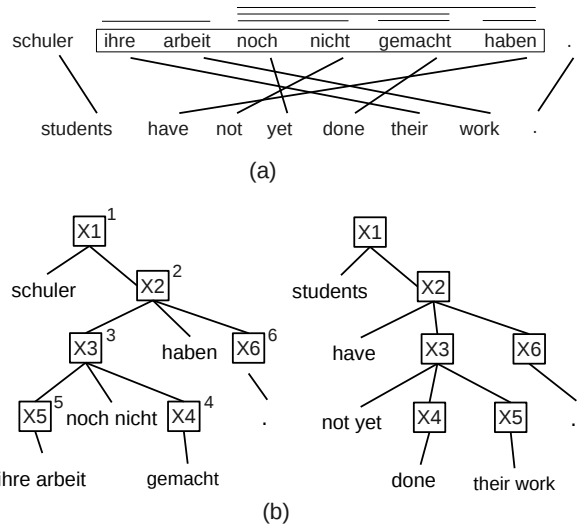

Figure 1: (a): A word-aligned German-English sentence pair. The bars above the source words indicate phrase-pairs having at least two words. (b): its corresponding left-to-right target derivation tree. Superscripts on the source non-terminals show the indices of the rules (see Fig 2) used in derivation.

Rule extraction is similar to Hiero, except any rules violating GNF form on the target side are excluded. Rule extraction considers each smaller source-target phrase pair within a larger phrase pair and replaces the spans with non-terminal X, yielding hierarchical rules. Figure 1(a) shows a word-aligned German-English sentence with a phrase pair $\langle ihre\ arbeit\ noch\ nicht\ gemacht\ haben,\ have\ not\ yet\ done\ their\ work \rangle$ that will lead to a SCFG rule. Given other smaller phrases (marked by bars above the source side), we extract a GNF rule[2]:

$$X \rightarrow \langle X_1\ noch\ nicht\ X_2\ haben, have\ not\ yet\ X_2\ X_1 \rangle \tag{2}$$

In order to avoid data sparsity and for better generalization, Watanabe et al. (2006b) adds four *glue* rules for each lexical rule $\langle \bar{f}, \bar{e} \rangle$ which are analogous to the glue rules defined in (Chiang, 2007) (see above) except that these glue rules for LR decoding

[1] Griebach Normal Form (GNF), although the synchronous grammar is not in this normal form, rather only the target side is prefix lexicalized as if it were in GNF form.

[2] LR-Hiero rule extraction excludes non-GNF rules such as $X \rightarrow \langle X_1\ noch\ nicht\ gemacht\ X_2, X_2\ not\ yet\ done\ X_1 \rangle$.

allow reordering as well.

$$\begin{array}{ll} X \rightarrow \langle \bar{f} X_1, \bar{e} X_1 \rangle & X \rightarrow \langle X_1 \bar{f} X_2, \bar{e} X_1 X_2 \rangle \\ X \rightarrow \langle X_1 \bar{f}, \bar{e} X_1 \rangle & X \rightarrow \langle X_1 \bar{f} X_2, \bar{e} X_2 X_1 \rangle \end{array} \quad (3)$$

It might appear that the restriction that target-side rules be GNF is a severe restriction on the coverage of possible hypotheses compared to the full set of rules permitted by the Hiero extraction heuristic. However there is some evidence in the literature that discontinuous spans on the source side in translation rules is a lot more useful than discontinuous spans in the target side (which is disallowed in the GNF). For instance, (Galley and Manning, 2010) do an extensive study of discontinuous spans on source and target side and show that source side discontinuous spans are very useful but removing discontinuous spans on the target side only lowers the BLEU score by 0.2 points (using the Joshua SMT system on Chinese-English). Removing discontinuous spans means that the target side rules have the form: uX, Xu, XuX, XXu, or uXX of which we disallow Xu, XuX, XXu. Zhang and Zong (2012) also conduct a study on discontinuous spans on source and target side of Hiero rules and conclude that source discontinuous spans are always more useful than discontinuities on the target side with experiments on four language pairs (zh-en, fr-en, de-en and es-en). As we shall also see in our experimental results (see Table 4) we can get close to the BLEU scores obtained using the full set of Hiero rules by using only target lexicalized rules in our LR decoder.

2.2 LR-Hiero Decoding

LR-Hiero decoding uses a top-down depth-first search, which strictly grows the hypotheses in target surface ordering. Search on the source side follows an Earley-style search (Earley, 1970), the dot jumps around on the source side of the rules based on the order of nonterminals on the target side. This search is integrated with beam search or cube pruning to efficiently find the k-best translations.

Several important details about the algorithm of LR-Hiero decoding are implicit and unexplained in (Watanabe et al., 2006b). In this section we describe the LR-Hiero decoding algorithm in more detail than the original description in (Watanabe et al., 2006b). We explain our own modified algorithm for LR decoding with cube pruning in Section 2.3.

Algorithm 1: LR-Hiero Decoding

Input sentence: $\mathbf{f} = f_0 f_1 \dots f_n$
$\mathcal{F}$ = FutureCost($\mathbf{f}$) (Precompute future cost for spans)
for $i = 0, \dots, n$ **do**
  $S_i = \{\}$ (Create empty stacks)
$h_0 = (\langle s \rangle, [[0, n]], \emptyset, \mathcal{F}_{[0,n]})$ (Initial hypothesis 4-tuple)
Add h_0 to S_0 (Push initial hyp into first Stack)
for $i = 0, \dots, n-1$ **do**
  for each h in S_i **do**
    $[u, v]$ = pop(h_s) (Pop first uncovered span from list)
    R = GetSpanRules($[u, v]$) (Extract rules matching the entire span $[u, v]$)
    for $r \in R$ **do**
      h' = GrowHypothesis($h, r, [u, v], \mathcal{F}$) (New hypothesis)
      Add h' to S_l, where $l = |h'_{cov}|$ (Add new hyp to stack)
return $\arg\max(S_n)$

GrowHypothesis$(h, r, [u, v], \mathcal{F})$
  $h' = (h'_t = \emptyset, h'_s = h_s, h'_{cov} = \emptyset, h'_c = 0)$
  $r_X = \{X_j, X_k, \dots | j \lhd k \lhd \dots\}$ (Get NTs in surface order)
  for each X in reverse(r_X) **do**
    push($h'_s, span(X)$) (Push uncovered spans to LIFO list)
  h'_t = Concatenate(h_t, r_t)
  h'_{cov} = UpdateCoverage(h_{cov}, r_s)
  h'_c = ComputeCost($g(h'), \mathcal{F}_{\neg h'_{cov}}$)
  return h'

Algorithm 1 shows the pseudocode for LR decoding. Decoding the example in Figure 1(b) is explained using a walk-through shown in Figure 2. Each partial hypothesis h is a 4-tuple (h_t, h_s, h_{cov}, h_c): consisting of a translation prefix h_t, a (LIFO-ordered) *list* h_s of uncovered spans, source words coverage set h_{cov} and the hypothesis cost h_c. The initial hypothesis is a null string with just a sentence-initial marker $\langle s \rangle$ and the list h_s containing a span of the whole sentence, $[0, n]$. The hypotheses are stored in stacks $S_0, \dots, S_n$, where each stack corresponds to a coverage vector of same size, covering same number of source words (Koehn et al., 2003).

At the beginning of beam search the initial hy-

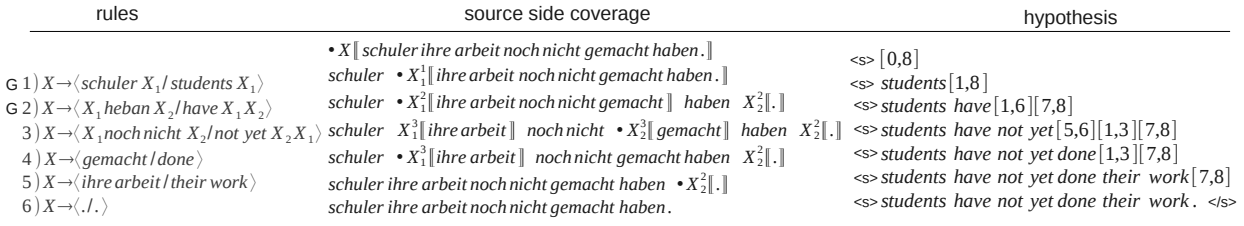

Figure 2: Illustration of the LR-Hiero decoding process in Figure 1. (a) Rules pane show the rules used in the derivation (glue rules are marked by G) (b) Decoder state using Earley dot notation (superscripts show rule#) (c) Hypotheses pane showing translation prefix and ordered list of yet-to-be-covered spans.

pothesis h_0 is added to the decoder stack S_0 (line 6 in Algoorithm 1). Hypotheses in each decoder stack are expanded iteratively, generating new hypotheses, which are added to the latter stacks corresponding to the number of source words covered. In each step it pops from the LIFO list h_s, the span $[u, v]$ of the next hypothesis h to be processed.

All rules that match the entire span $[u, v]$ are then obtained efficiently via pattern matching (Lopez, 2007). *GetSpanRules* addresses possible ambiguities in matched rules to the given span $[u, v]$. For example, given a rule r, with source side r_s : $\langle X_1 \; the \; X_2 \rangle$ and source phrase p : $\langle$*ok, the more the better*$\rangle$. There is ambiguity in matching r to p. *GetSpanRules* returns a distinct matched rule for each possible matching.

The *GrowHypothesis* routine creates a new candidate by expanding given hypothesis h using rule r and computes the complete hypothesis score including language model score. Since the target-side rules are in GNF, the translation prefix of the new hypothesis is obtained by simply concatenating the terminal prefixes of h and r in same order (line 20). *UpdateCoverage* updates source word coverage set using the source side of r. The h_s list is built by pushing the non-terminal spans of rule r in a reverse order (lines 17 and 18). The reverse ordering maintains the left-to-right generation of the target side.

In the walk-through in Figure 2, the derivation process starts by expanding the initial hypothesis h_0 (first item in the right pane of Fig 2) with the rule (rule #1 in left pane) to generate a new partial candidate having a terminal prefix of $\langle s \rangle$ *students* (second item in right pane). The second item in the middle pane shows the current position of the parser employing Earley's dot notation, indicating that the first word has already been translated. Now the decoder considers the second hypothesis and pops the span $[1, 8]$. It then matches the rule (#2) and pushes the spans $[1, 6]$ and $[7, 8]$ into the list h_s in the reverse order of their appearance in the target-side rule. At each step the new hypothesis is added to the decoder stack S_l depending on the number of covered words in the new hypothesis (line 13 in Algorithm 1).

For pruning we use an estimate of the future cost[3] of the spans uncovered by current hypothesis together with the hypothesis cost. The future cost is precomputed (line 2 Algorithm 1) in a way similar to the phrase-based models (Koehn et al., 2007) using only the terminal rules of the grammar. The ComputeCost method (line 22 in Algorithm 1) uses the usual log-linear model and scores a hypothesis based on its different feature scores $g(h')$ and the future cost of the *yet to be covered* spans ($\mathcal{F}_{\neg h'_{cov}}$). Time complexity of left to right Hiero decoding with beam search is $O(n^2 b)$ in practice where n is the length of source sentence and b is the size of beam (Huang and Mi, 2010).

2.3 LR-Hiero Decoding with Cube Pruning

The Algorithm 1 presented earlier does an exhaustive search as it generates all possible partial translations for a given stack that are reachable from the hypotheses in previous stacks. However only a few of these hypotheses are retained, while majority of them are pruned away. The cube pruning technique (Chiang, 2007) avoids the wasteful generation of poor hypotheses that are likely to be pruned away by efficiently restricting the generation to only high scoring partial translations.

We modify the cube pruning for LR-decoding that takes into account the next uncovered span to

[3] Watanabe et al. (2006b) also use a similar future cost, even though it is not discussed in the paper (p.c.).

Algorithm 2: LR-Hiero Decoding with Cube Pruning

1: Input sentence: $\mathbf{f} = f_0 f_1 \dots f_n$
2: $\mathcal{F}$ = FutureCost($\mathbf{f}$) (Precompute future cost for spans)
3: $S_0 = \{\}$ (Create empty initial stack)
4: $h_0 = (\langle s \rangle, [[0, n]], \emptyset, \mathcal{F}_{[0,n]})$ (Initial hypothesis 4-tuple)
5: Add h_0 to S_0 (Push initial hyp into first Stack)
6: **for** $i = 1, \dots, n$ **do**
7: $cubeList = \{\}$ (MRL is max rule length)
8: **for** $p = max(i - \text{MRL}, 0), \dots, i - 1$ **do**
9: $\{G\}$ = Grouped(S_p) (Group based on the first uncovered span)
10: **for** $g \in \{G\}$ **do**
11: $[u, v]$ = g_{span}
12: R = GetSpanRules($[u, v]$)
13: **for** $R_s \in R$ **do**
14: $cube = [g_{hyps}, R_s]$
15: Add $cube$ to $cubeList$
16: S_i = Merge($cubeList, \mathcal{F}$) (Create stack S_i and add new hypotheses to it, see Figure 3)
17: **return** $\arg\max(S_n)$

18: **Merge**($CubeList, \mathcal{F}$)
19: $heapQ = \{\}$
20: **for** each (H, R) in $cubeList$ **do**
21: $[u, v]$ = span of rule R
22: h' = GrowHypothesis($h_1, r_1, [u, v], \mathcal{F}$) (from Algorithm 1)
23: push($heapQ, (h'_c, h', [H, R])$
24: $hypList = \{\}$
25: **while** $|heapQ| > 0$ and $|hypList| < K$ **do**
26: $(h'_c, h', [H, R])$ = pop($heapQ$)
27: push($heapQ, GetNeighbours([H, R])$
28: Add h' to $hypList$
29: **return** $hypList$

be translated indicated by the Earley's dot notation. The Algorithm 2 shows the pseudocode for LR-decoding using cube pruning. The structure of stacks and hypotheses and computing the future cost is similar to Algorithm 1 (lines 1-5). To fill stack S_i, it iterates over previous stacks (line 8 in Algorithm 2) [4]. All hypotheses in each stack S_p (covering p words on the source-side) are first partitioned into a set of groups, $\{G\}$, based on their first uncovered span (line 9) [5]. Each group g is a 2-tuple (g_{span}, g_{hyps}), where g_{hyps} is a list of hypotheses which share the same first uncovered span g_{span}. Rules matching the span g_{span} are obtained from routine *GetSpanRules*, which are then grouped based on unique source side rules (i.e. each R_s contains rules that share the same source side s but have different target sides). Each g_{hyps} and possible R_s[6] create a cube which is added to $cubeList$.

In LR-Hiero, each hypothesis is developed with only one uncovered span, therefore each cube always has just two dimensions: (1) hypotheses with the same number of covered words and similar first uncovered span, (2) rules sharing the same source side. In Figure 3(a), each group of hypotheses, g_{hyps}, is shown in a green box (in stacks), and each rectangle on the top is a cube. Figure 3 is using the example in Figure 2.

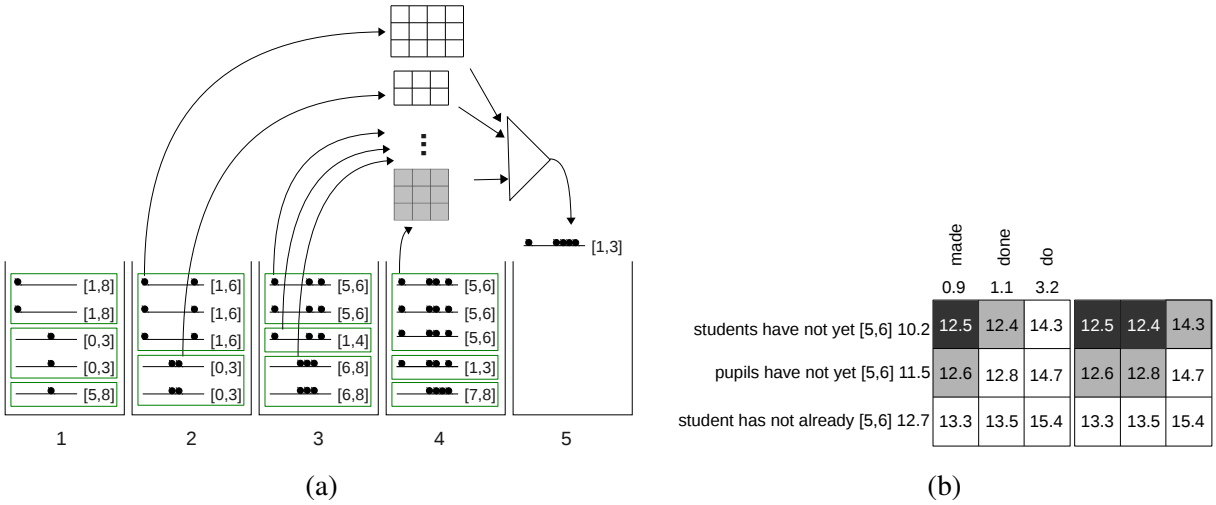
The *Merge* routine is the core function of cube pruning which generates the best hypotheses from all cubes (Chiang, 2007). For each possible cube, (H, R), the best hypothesis is generated by calling $GrowHypothesis(h_1, r_1, \textit{span}, \mathcal{F})$ where h_1 and r_1 are the best hypothesis and rule in H and R respectively (line 22). Figure 3 (b) shows a more detailed view of a cube (shaded cube in Figure 3(a)). Rows are hypotheses and columns are rules which are sorted based on their scores.

The first best hypotheses, h', along with their score, h'_c and corresponding cube, (H, R) are placed in a priority queue, $heapQ$ (triangle in Figure 3). Iteratively the best hypothesis is popped from the queue (line 26) and its neighbours in the cube are added to the priority queue (using $GetNeighbours([H, Q])$). It continues to generate all K best hypotheses. Using cube pruning technique, each stack is filled with K best hypotheses without generating all possible hypotheses in each cube.

[4] As the length of rules are limited (at most MRL), we can ignore stacks with index less than $i - \text{MRL}$

[5] The beam search decoder in Phrase-based system (Huang and Chiang, 2007; Koehn et al., 2007; Sankaran et al., 2010) groups the hypotheses in a given stack based on their coverage vector. But this idea does not work in LRHiero decoding in which the expansion of each hypothesis is restricted to its first uncovered span. We have also tried another way of grouping hypotheses: group by all uncovered spans, h_s. Our experiments did not show any significant difference between the final results (BLEU score), therefore we decided to stick to the simpler idea: using first uncovered span for grouping.

[6] Note that, just rules whose number of terminals in their source side is equal to $i - p$ can be used.



(a) (b)

Figure 3: Example of generating hypotheses in cube pruning using Figure 2: (a) Hypotheses in previous stacks are grouped based on their first uncovered span, and build cubes (grids on top). Cubes are in different sizes because of different number of rules and group sizes. Cubes are fed to a priority queue (triangle) and new hypotheses are iteratively popped from the queue and added to the current stack, S_5. (b) Generating hypotheses from a cube. The top side of the grid denotes the target side of rules sharing the same source side (R_s) along with their scores. Left side of the grid shows the hypotheses in a same group, their first uncovered span and their scores. Hypothesis generated from row 1 and column 1 is added to the queue at first. Once it is popped from the queue, its neighbours (in the grid) are subsequently added to the queue.

Figure 3 (b) shows the derivation of the two best hypotheses from the cube. The best hypothesis of this cube which is likely created from the best hypothesis and rule (left top most entry) is popped at first step. Then, *GetNeighbours* calls *GrowHypothesis* to generate next potential best hypotheses of this cube (neighbours of the popped entry which are shaded in Figure 3(b)). These hypotheses are added to the priority queue. In the next iteration, the best hypothesis is popped from all candidates in the queue and algorithm continues.

3 Features

We use the following standard SMT features for the log-linear model of LR-Hiero: relative-frequency translation probabilities $p(f|e)$ and $p(e|f)$, lexical translation probabilities $p_l(f|e)$ and $p_l(e|f)$, a language model probability, word count and phrase count. In addition we also use the glue rule count and the two reordering penalty features employed by Watanabe et al. (2006b; 2006a). These features compute the *height* and *width* (span size of the entire subtree) of all subtrees which are *backtraced* in the derivation of a hypothesis. A non-terminal X_i is pushed into the LIFO list of a partial hypothesis; it's *backtrace* refers to the set of NTs that must be popped before X_i.

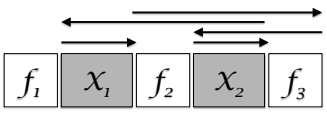
In Figure 1(b), X_2 has two subtrees X_3 and X_6, where X_3 should be processed before X_6. The subtree rooted at X_3 in Figure 1(b) has a height of 2 and span $[1, 6]$ having a width of 5. Similarly, X_4 should be backtraced before X_5 and has height and width of 1. Backtracing applies only for rules having at least two non-terminals. Thus the total height and width penalty for this derivation are 3 and 6 respectively.

However, the height and width features do not distinguish between a rule that reorders the non-terminals in source and target from one that preserves the ordering. Rules #2 and #3 in Figure 2 are treated equally although they have different orderings. The decoder is thus agnostic to this difference and would not be able to exploit this effectively to control reordering and instead would rely on the partial LM score. This issue is exacerbated for glue rules, where the decoder has to choose from different possibilities without any way to favour one over the others. Instead of the rule #2, the decoder could use its reordered version $\langle X_1\ haben\ X_2, have\ X_2\ X_1 \rangle$ leading to a poor translation.

The features we introduce can be used to learn if the model should favour monotone translations at the cost of re-orderings or vice versa and hence can easily adapt to different language pairs. Further, our experiments (see Section 4) suggest that the features h and w are not sufficient by themselves to model reordering for language pairs exhibiting very different syntactic structure.

3.1 Distortion Features

Our distortion features are inspired by their namesake in phrase-based system, with some modifications to adapt the idea for the discontiguous phrases in LR-Hiero grammar.



(a)

$r : \langle f_1 X_1 f_2 X_2 f_3, tX_2X_1 \rangle \quad I = [\vdash, f_1, f_2, f_3, X_2, X_1, \dashv]$

$r : \langle X_1 \textit{ noch nicht } X_2 / \textit{not yet } X_2 X_1 \rangle$

$_1\textit{ihre}_2 \textit{arbeit}_3 \textit{noch}_4 \textit{nicht}_5 \textit{gemacht}_6$

$I = [(1,1),(3,5),(5,6),(1,3),(6,6)]$

(b)

Figure 4: (a) Distortion feature computation using a rule r. (b) Example of distortion computation for applying r_3 on phrase $\langle$*ihre arbeit noch nicht gemacht haben*$\rangle$. subscripts between words show the indices which are used to build I. Distortion would be: $d = 2 + 0 + 5 + 3$.

Consider a rule $r = \langle \gamma, \bar{b} \ \beta \rangle$, with the source term γ being a mixed string of terminals and non-terminals. Representing the non-terminal spans and each sequence of terminals in γ as distinct *items*, our distortion feature counts the total length of *jumps* between the items during Earley parsing.

Figure 4 (a) explains the computation of our distortion feature for an example rule r. Let $I = [I_0, \ldots, I_k]$ be the *items* denoting the terminal sequences and non-terminal spans with I_0 and I_k being dummy items ($\vdash$ and $\dashv$ in Fig) marking the left and right indices of the rule r in input sentence f. Other items are arranged by their realization order on the target-side with the terminal sequences preceding non-terminal spans. The items for the example rule are shown in Figure 4 (a). The distortion feature is computed as follows:

$$d(r) = \sum_{j=1}^{k} |I_j^{\mathcal{L}} - I_{j-1}^{\mathcal{R}}| \tag{4}$$

where superscripts refer to position of left ($\mathcal{L}$) and right ($\mathcal{R}$) edge of each item in the source sentence f. These are then aggregated across the rules of a derivation D as: $d = \sum_{r \in D} d(r)$. For each item I_j, we count the jump from the end of previous item to the beginning of the current. In Figure 4 (a) the jumps are indicated by the arrows above the rule. Figure 4 (b) shows an example of distortion computation for r_3 and phrase $\langle$*ihre arbeit noch nicht gemacht haben*$\rangle$ from Figure 2.

Since the glue rules are likely to be used in the top levels (possibly with large distortion) of the derivation, we would want the decoder to learn the distortion for regular and glue rules separately. We thus use two distortion features for the two rule types and we call them d_p and d_g.

These features do not *directly* model the source-target reordering, but only capture the source-side jumps. Furthermore they apply for both monotone and reordering rules. We now introduce a new feature for exclusively modelling the reordering.

3.2 Reordering Feature

This feature simply counts the number of *reordering rules*, where the non-terminals in source and target sides are reordered. Thus $r_{\langle\rangle} = \text{rule}(D, \langle\rangle)$, where $\text{rule}(D, \langle\rangle)$ is the number of reordering rules in D. Similar to width and height, this feature is applied for rule having at least two non-terminals. This feature is applied to regular and glue rules.

4 Experiments

We conduct different types of experiments to evaluate LR-Hiero decoding developed by cube pruning and integrating new features into LR-Hiero system for two language pairs: German-English (de-en) and Czech-English (cs-en).Table 1 shows the dataset details.

4.1 System Setup

In our experiments we use four baselines as well as our implementation of LR-Hiero (written in Python):

	Corpus	Train/Dev/Test
cs-en	Europarl(v7), CzEng(v0.9); News commentary	7.95M/3000/3003
de-en	Europarl(v7); News commentary	1.5M/2000/2000

Table 1: Corpus statistics in number of sentences

Model	cs-en	de-en
Phrase-based	233.0	77.2
Hiero	1,961.6	858.5
LR-Hiero	230.5	101.3

Table 2: Model sizes (millions of rules). We do not count glue rules for LR-Hiero which are created at runtime as needed.

- **Hiero:** we used Kriya, our open-source implementation of Hiero in Python, which performs comparably to other open-source Hiero systems (Sankaran et al., 2012). Kriya can obtain statistically significantly equal BLEU scores when compared with Moses (Koehn et al., 2007) for several language pairs (Razmara et al., 2012; Callison-Burch et al., 2012).

- **Hiero-GNF:** where we use Hiero decoder with the restricted LR-Hiero grammar (GNF rules).

- **LR-Hiero:** our implementation of LR-Hiero (Watanabe et al., 2006b) in Python.

- **phrase-based:** Moses (Koehn et al., 2007)

- **LR-Hiero+CP:** LR-Hiero decoding with cube pruning.

We use a 5-gram LM trained on the Gigaword corpus and use KenLM (Heafield, 2011) for LM scoring during decoding. We tune weights by minimizing BLEU loss on the dev set through MERT (Och, 2003) and report BLEU scores on the test set. We use comparable pop limits in each of the decoders: 1000 for Moses and LR-Hiero and 500 with cube pruning for CKY Hiero and LR-Hiero+CP. Other extraction and decoder settings such as maximum phrase length, etc. were identical across settings so that the results are comparable.

Table 2 shows how the LR-Hiero grammar is much smaller than CKY-based Hiero.

Model	cs-en #queries / time(ms)	de-en #queries / time(ms)
Hiero	5,679.7 / 16.12	7,231.62 / 20.33
Hiero-GNF	4,952.5 / 14.71	5,858.74 / 18.23
LR-Hiero (1000)	46,333.21 / 163.6	83,518.63 / 328.11
LR-Hiero (500)	24,141.03 / 97.61	42,783.12 / 192.23
LR-Hiero+CP	**1,303.2 / 4.2**	**1,697.7 / 5.67**

Table 3: Comparing average number and time of language model queries.

4.2 Time Efficiency Comparison

To evaluate the performance of LR-Hiero decoding with cube pruning (LR-Hiero+CP), we compare it with three baselines: (i) CKY Hiero, (ii) CKY Hiero-GNF, and (iii) LR-Hiero (without cube pruning) with two different beam size 500 and 1000. When it comes to instrument timing results, there are lots of system level details that we wish to abstract away from, and focus only on the number of "edges" processed by the decoder. In comparison of parsing algorithms, the common practice is to measure the number of edges processed by different algorithms for the same reason (Moore and Dowding, 1991). By analogy to parsing algorithm comparisons, we compare the different decoding algorithms with respect to the number of calls made to the language model (LM) since that directly corresponds to the number of hypotheses considered by the decoder. A decoder is more time efficient if it can consider fewer translation hypotheses while maintaining the same BLEU score. All of the baselines use the same wrapper to query the language model, and we have instrumented the wrapper to count the statistics we need and thus we can say this is a fair comparison. For this experiment we use a sample set of 50 sentences taken from the test sets.

Table 3 shows the results in terms of average number of language model queries and times in milliseconds.

4.3 Reordering Features

To evaluate the new reordering features proposed to LR-Hiero (Section 3.2), LR-Hiero+CP with new features is compared to all baselines. Table 4 shows the BLEU scores of different models in two language pairs. The baseline (Watanabe et al., 2006b) model uses all the features mentioned therein but is

Model	cs-en	de-en
Phrase-based	20.32	24.71
CKY Hiero	20.64	25.52
CKY Hiero-GNF	20.04	24.84
LR-Hiero	18.30	23.47
LR-Hiero + reordering feats	20.20	24.90
LR-Hiero + CP + reordering feats	20.15	24.83
CKY Hiero-GNF + reordering feats	20.52	25.09
CKY Hiero + reordering feats	**20.77**	**25.72**

Table 4: BLEU scores. The rows are grouped such that each group use the same model. The last row in part 2 of table shows LR-Hiero+CP using our new features in addition to the baseline Watanabe features (line *LR-Hiero baseline*). The last part shows CKY Hiero using new reordering features. The reordering features used are d_p, d_g and $r_{\langle\rangle}$. LR-Hiero+CP has a beam size of 500 while LR-Hiero has a beam size of 1000, c.f. with the LM calls shown in Table 3.

worse than both phrase-based and CKY-Hiero baselines by up to 2.3 BLEU points.

All the reported results are obtained from a single optimizer run. However we observed insignificant changes in different tuning runs in our experiments. We find a gain of about 1 BLEU point when we add a single distortion feature d and a further gain of 0.3 BLEU (not shown due to lack of space) when we split the distortion feature for the two rule types (d_p and d_g). The last line in part two of Table 4 shows a consistent gain of 1.6 BLEU over the LR-Hiero baseline for both language pairs. It shows that LR-Hiero maintains the BLEU scores obtained by "phrase-based" and "CKY Hiero-GNF".

We performed statistical significance tests using two different tools: Moses bootstrap resampling and MultEval (Clark et al., 2011). The difference between "LR-Hiero+CP+reordering feat" and three baselines: "phrase-based", "CKY Hiero-GNF", "LR-Hiero+reordering feat" are not statistically significant even for p-value of 0.1 for both tools.

To investigate the impact of proposed reordering features with other decoder or models. We add these features to both Hiero and Hiero-GNF[7]. The last part of Table 4 shows the performance CKY decoder with different models (full Hiero and GNF) with the new reordering features in terms of BLEU score. The results show that these features are helpful in both models. Although, they do not make a big difference in Hiero with full model, they can alleviate the lack of non-GNF rules in Hiero-GNF.

Nguyen and Vogel (2013) integrate traditional phrase-based features: distortion and lexicalized reordering into Hiero as well. They show that such features can be useful to boost the translation quality of CKY Hiero with the full rule set. Nguyen and Vogel (2013) compute the distortion feature in a different way, only applicable to CKY. The distortion for each cell is computed after the translation for non-terminal sub-spans is complete. In LR-decoding, we compute distortion for rules even though we are yet to translate some of the sub-spans. Thus our approach computes the distortion incrementally for the untranslated sub-spans which are later added. Unlike (Nguyen and Vogel, 2013), our distortion feature can be applied to both LR and CKY-decoding (Table 4). We have also introduced another reordering feature (Section 3.2) not proposed previously.

5 Conclusion and Future Work

We provided a detailed description of left-to-right Hiero decoding, many details of which were only implicit in (Watanabe et al., 2006b). We presented an augmented LR decoding algorithm that builds on the original algorithm in (Watanabe et al., 2006b) but unlike that algorithm, using experiments over multiple language pairs we showed two new results: (i) Our LR decoding algorithm provides demonstrably more efficient decoding than CKY Hiero and the original LR decoding algorithm in (Watanabe et al., 2006b). And, (ii) by introducing new distortion and reordering features for LR decoding we show that it maintains the BLEU scores obtained by phrase-based and CKY Hiero-GNF.

CKY Hiero uses standard Hiero-style translation rules capturing better reordering model than prefix lexicalized target-side translation rules used in LR-Hiero. Our LR-decoding algorithm is 4 times faster in terms of LM calls while translation quality suffers by about 0.67 in BLEU score on average.

Unlike Watanabe et al. (2006b), our new features can easily adapt to the reordering requirements of different language pairs. We also introduce the use

[7]Feature $r_{\langle\rangle}$ is defined for SCFG rules and cannot be adopted to phrase-based translation systems; and Moses uses distortion feature therefore we omit Moses from this experiment.

of future cost in decoding algorithm which is an essential part in decoding. We have shown in this paper that left-to-right (LR) decoding can be considered as a potential faster alternative to CKY decoding for Hiero-style machine translation systems.

In future work, we plan to apply lexicalized reordering models to LR-Hiero. It has been shown to be useful for Hiero in some languages therefore it is promising to improve translation quality in LR-Hiero which suffers from lack of modeling power of non-GNF target side rules. We also plan to extend the glue rules in LR-Hiero to provide a better reordering model. We believe such an extension would be very effective in reducing search errors and capturing better reordering models in language pairs involving complex reordering requirements like Chinese-English.

Abstract

This paper addresses the problem of producing a diverse set of plausible translations. We present a simple procedure that can be used with any statistical machine translation (MT) system. We explore three ways of using diverse translations: (1) system combination, (2) discriminative reranking with rich features, and (3) a novel post-editing scenario in which multiple translations are presented to users. We find that diversity can improve performance on these tasks, especially for sentences that are difficult for MT.

1 Introduction

From the perspective of user interaction, the ideal machine translator is an agent that reads documents in one language and produces accurate, high quality translations in another. This interaction ideal has been implicit in machine translation (MT) research since the field's inception. It is the way we interact with commercial MT services (such as Google Translate and Microsoft Translator), and the way MT systems are evaluated (Bojar et al., 2013). Unfortunately, when a real, imperfect MT system makes an error, the user is left trying to guess what the original sentence means.

Multiple Hypotheses. In contrast, when we look at the way other *computer systems* consume output from MT systems (or similarly unreliable tools), we see a different pattern. In a pipeline setting it is commonplace to propagate not just a *single*-best output but the M-best hypotheses (Venugopal et al., 2008). Multiple solutions are also used for reranking (Collins, 2000; Shen and Joshi, 2003; Collins and Koo, 2005; Charniak and Johnson, 2005), tuning (Och, 2003), minimum Bayes risk decoding (Kumar and Byrne, 2004), and system combination (Rosti et al., 2007). When dealing with error-prone systems, knowing about alternatives has benefits over relying on only a single output (Finkel et al., 2006; Dyer, 2010).

Need for Diversity. Unfortunately, M-best lists are a poor surrogate for structured output spaces (Finkel et al., 2006; Huang, 2008). In MT, for example, many translations on M-best lists are extremely similar, often differing only by a single punctuation mark or minor morphological variation. Recent work has explored reasoning about sets using packed representations such as lattices and hypergraphs (Macherey et al., 2008; Tromble et al., 2008; Kumar et al., 2009), or sampling translations proportional to their probability (Chatterjee and Cancedda, 2010). We argue that the implicit goal behind these techniques is to better explore the output space by introducing diversity into the surrogate set.

Overview and Contributions. In this work, we elevate diversity to a first-class status and directly address the problem of generating a set of **diverse, plausible translations**. We use the recently proposed technique of Batra et al. (2012), which produces diverse M-best solutions from a probabilistic model using a generic **dissimilarity** function $\Delta(\cdot, \cdot)$ that specifies how two solutions differ. Our first contribution is a family of dissimilarity functions for MT that admit simple algorithms for generating diverse translations. Other contributions are empirical: we show that diverse translations can lead to improvements for system combination and discriminative reranking. We also perform a novel human

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1100–1111,
Seattle, Washington, USA, 18-21 October 2013.

post-editing evaluation in order to measure whether diverse translations can help users make sense of noisy MT output. We find that diverse translations can help post-editors produce better outputs for sentences that are the most difficult for MT. While we focus on machine translation in this paper, we note that our approach is applicable to other structure prediction problems in NLP.

2 Preliminaries and Notation

Let $\mathcal{X}$ denote the set of all strings in a source language. For an $x \in \mathcal{X}$, let $\mathcal{Y}_x$ denote the set of its possible translations $\mathbf{y}$ in the target language. MT models typically include a latent variable that captures the derivational structure of the translation process. Regardless of its specific form, we refer to this variable as a **derivation** $\mathbf{h} \in \mathcal{H}_x$, where $\mathcal{H}_x$ is the set of possible values of $\mathbf{h}$ for x. Derivations are coupled with translations and we define $\mathcal{T}_x \subseteq \mathcal{Y}_x \times \mathcal{H}_x$ as the set of possible $\langle \mathbf{y}, \mathbf{h} \rangle$ pairs for x.

We use a linear model with a parameter vector $\mathbf{w}$ and a vector $\boldsymbol{\phi}(x, \mathbf{y}, \mathbf{h})$ of feature functions on x, $\mathbf{y}$, and $\mathbf{h}$ (Och and Ney, 2002). The translation of x is selected using a simple decision rule:

$$\langle \hat{\mathbf{y}}, \hat{\mathbf{h}} \rangle = \underset{\langle \mathbf{y}, \mathbf{h} \rangle \in \mathcal{T}_x}{\operatorname{argmax}} \; \mathbf{w}^\intercal \boldsymbol{\phi}(x, \mathbf{y}, \mathbf{h}) \qquad (1)$$

where we also maximize over the latent variable $\mathbf{h}$ for efficiency. Translation models differ in the form of $\mathcal{T}_x$ and the choice of the feature functions $\boldsymbol{\phi}$. In this paper we focus on phrase-based (Koehn et al., 2003) and hierarchical phrase-based (Chiang, 2007) models, which include several bilingual and monolingual features, including n-gram language models.

3 Diversity in Machine Translation

We now address the task of producing a set of diverse high-scoring translations.

3.1 Generating Diverse Translations

We use a recently proposed technique (Batra et al., 2012) that constructs diverse lists via a greedy iterative procedure as follows. Let $\mathbf{y}^1$ be the model-best translation (Eq. 1). On the m-th iteration, the m-th best (diverse) translation is obtained as $\langle \mathbf{y}^m, \mathbf{h}^m \rangle =$

$$\underset{\langle \mathbf{y}, \mathbf{h} \rangle \in \mathcal{T}_x}{\operatorname{argmax}} \; \mathbf{w}^\intercal \boldsymbol{\phi}(x, \mathbf{y}, \mathbf{h}) + \sum_{j=1}^{m-1} \lambda_j \Delta(\mathbf{y}^j, \mathbf{y}) \qquad (2)$$

where Δ is a dissimilarity function and λ_j is the weight placed on dissimilarity to previous translation j relative to the model score. Intuitively, we seek a translation that is highly-scoring under the model while being different (as measured by Δ) from all previous translations. The λ parameters determine the trade-off between model score and diversity. We refer to Eq. (2) as **dissimilarity-augmented** decoding.

The objective in Eq. (2) is a Lagrangian relaxation for an intractable constrained objective specifying a minimum dissimilarity Δ_{min} between translations in the list, i.e., $\Delta(\mathbf{y}^j, \mathbf{y}) \geq \Delta_{min}$ (Batra et al., 2012). Instead of setting the dissimilarity threshold Δ_{min}, we set the weights λ_j. While the formulation allows for a different λ_j for each previous solution j, we simply use a single $\lambda = \lambda_j$ for all j. This was also done in the experiments in (Batra et al., 2012).

Note that if the dissimilarity function factors across the parts of the output variables $\langle \mathbf{y}, \mathbf{h} \rangle$ in the same way as the features $\boldsymbol{\phi}$, then *the same decoding algorithm* can be used as for Eq. (1). We discuss design choices for Δ next.

3.2 Dissimilarity Functions for MT

When designing a dissimilarity function $\Delta(\cdot, \cdot)$ for MT, we want to consider variation both in individual word choice and longer-range sentence structure. We also want a function that can be easily incorporated into extant statistical MT systems. We propose a dissimilarity function that simply counts the number of times any n-gram is present in both translations, then negates. Letting $q = n - 1$:

$$\Delta_n(\mathbf{y}, \mathbf{y}') = -\sum_{i=1}^{|\mathbf{y}|-q} \sum_{j=1}^{|\mathbf{y}'|-q} [\![\mathbf{y}_{i:i+q} = \mathbf{y}'_{j:j+q}]\!] \qquad (3)$$

where $[\![\cdot]\!]$ is the Iverson bracket (1 if input condition is true, 0 otherwise) and $\mathbf{y}_{i:j}$ is the subsequence of $\mathbf{y}$ from word i to word j (inclusive).

Importantly, Eq. (2) can be solved with no change to the decoding algorithm. The dissimilarity terms can simply be incorporated as an additional language model in ARPA format that sets the log-probability to the negated count for each n-gram in previous diverse translations, and sets to zero all other n-grams' log-probabilities and back-off weights.

The advantage of this dissimilarity function is its simplicity. It can be easily used with any translation system that uses n-gram language models without any change to the decoder. Indeed, we use both phrase-based and hierarchical phrase-based models in our experiments below.

4 Related Work

MT researchers have recently started to consider diversity in the context of system combination (Macherey and Och, 2007). Most closely-related is work by Devlin and Matsoukas (2012), who proposed a way to generate diverse translations by varying particular "traits," such as translation length, number of rules applied, etc. Their approach can be viewed as solving Eq. (2) with a richer dissimilarity function that requires a special-purpose decoding algorithm. We chose our n-gram dissimilarity function due to its simplicity and applicability to most MT systems without requiring any change to decoders.

Among other work, Xiao et al. (2013) used bagging and boosting to get diverse system outputs for system combination and Cer et al. (2013) used multiple identical systems trained jointly with an objective function that encourages the systems to generate complementary translations.

There is also similarity between our approach and minimum Bayes risk decoding (Kumar and Byrne, 2004), variational decoding (Li et al., 2009), and other "consensus" decoding algorithms (DeNero et al., 2009). These all seek a single translation that is most similar on average to the model's preferred translations. In this way, they try to capture the model's range of beliefs in a single translation. We instead seek a *set* of translations that, when considered as a whole, similarly express the full range of the model's beliefs about plausible translations for the input.

Also related is work on determinantal point processes (DPPs; Kulesza and Taskar, 2010), an elegant probabilistic model over sets of items that naturally prefers diverse sets. DPPs have been applied to summarization (Kulesza and Taskar, 2011) and discovery of topical threads in document collections (Gillenwater et al., 2012). Unfortunately, in the *structured* setting, DPPs make severely restrictive assumptions on the scoring function, while our framework does not.

5 Experimental Setup

We now embark on an extensive empirical evaluation of the framework presented above. We begin by analyzing our diverse sets of translations, showing how they differ from standard M-best lists (Section 6), followed by three tasks that illustrate how diversity can be exploited to improve translation quality: system combination (Section 7), discriminative reranking (Section 8), and a novel human post-editing task (Section 9). In the remainder of this section, we describe details of our experimental setup.

5.1 Language Pairs and Datasets

We use three language pairs: Arabic-to-English (AR→EN), Chinese-to-English (ZH→EN), and German-to-English (DE→EN). For AR→EN and DE→EN, we used a phrase-based model (Koehn et al., 2003) and for ZH→EN we used a hierarchical phrase-based model (Chiang, 2007).

Each language pair has two tuning and one test set: TUNE1 is used for tuning the baseline systems with minimum error rate training (MERT; Och, 2003), TUNE2 is used for training system combiners and rerankers, and TEST is used for evaluation. There are four references for AR→EN and ZH→EN and one for DE→EN.

For AR→EN, we used data provided by the LDC for the NIST evaluations, which includes 3.3M sentences of UN data and 982K sentences from other (mostly news) sources. Arabic text was preprocessed using an HMM segmenter that splits attached prepositional phrases, personal pronouns, and the future marker (Lee et al., 2003). The common stylistic sentence-initial *w+* (*and*) clitic was removed. The resulting corpus contained 130M Arabic tokens and 130M English tokens. We used the NIST MT06 test set as TUNE1, a 764-sentence subset of MT05 as TUNE2, and MT08 as TEST.

For ZH→EN, we used 303k sentence pairs from the FBIS corpus (LDC2003E14). We segmented the Chinese data using the Stanford Chinese segmenter (Chang et al., 2008) in "CTB" mode, giving us 7.9M Chinese tokens and 9.4M English tokens. We used the NIST MT02 test set as TUNE1, MT05

as TUNE2, and MT03 as TEST.

For DE→EN, we used data released for the WMT2011 shared task (Callison-Burch et al., 2011). German compound words were split using a CRF segmenter (Dyer, 2009). We used the WMT2010 test set as TUNE1, the 2009 test set as TUNE2, and the 2011 test set as TEST.

5.2 Baseline Systems

We used the Moses MT toolkit (Koehn et al., 2007; Hoang et al., 2009) with default settings and features for both phrase-based and hierarchical systems. Word alignment was done using GIZA++ (Och and Ney, 2003) in both directions, with the `grow-diag-final-and` heuristic used to symmetrize the alignments and a max phrase length of 7 used for phrase extraction.

Language models used the target side of the parallel corpus in each case augmented with 24.8M lines (601M tokens) of randomly-selected sentences from the Gigaword v4 corpus (excluding the NY Times and LA Times). We used 5-gram models, estimated using the SRI Language Modeling toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998). The minimum count cut-off for unigrams, bigrams, and trigrams was 1 and the cut-off for 4-grams and 5-grams was 3. Language model inference used KenLM (Heafield, 2011).

Uncased IBM BLEU was used for evaluation (Papineni et al., 2002). MERT was used to train the feature weights for the baseline systems on TUNE1. We used the learned parameters to generate M-best and diverse lists for TUNE2 and TEST to use for subsequent experiments.

5.3 Diverse List Generation

Generating diverse translations depends on two hyperparameters: the n-gram order used by the dissimilarity function Δ_n (§3.2) and the λ_j weights on the dissimilarity terms in Eq. (2). Though our framework permits different λ_j for each j, we use a single λ value for simplicity, as was also done in (Batra et al., 2012). The values of n and λ were tuned on a 200 sentence subset of TUNE1 separately for each language pair (which we call TUNE_{200}), so as to maximize the oracle BLEU score of the diverse lists.[1] We considered n values in $\{2, 3, \ldots, 9\}$ and λ values in $\{0.005, 0.01, 0.05, 0.1\}$. We give details on optimal values for these hyperparameters when discussing particular tasks below.

	AR→EN	ZH→EN	DE→EN
1 best	50.1	36.9	21.8
20 best	54.0	40.3	24.7
200 best	57.5	43.8	27.7
1000 best	59.8	46.4	29.8
unique 20 best	56.6	44.1	26.7
unique 200 best	59.6	46.4	29.5
20 diverse	58.5	46.4	28.6
20 div × 10 best	61.3	48.7	30.3
20 div × 50 best	**63.2**	**50.6**	**31.6**

Table 1: Oracle BLEU scores on TEST for various sizes of M-best and diverse lists. Unique lists were obtained from 1,000-best lists and therefore may not contain the target number of unique translations for all sentences.

Though simple, our approach is computationally expensive as M grows because it requires decoding M times for each sentence. So, we assume $M \leq 20$. But we also extract an N-best list for each of the M diverse translations.[2] Many MT decoders, including the phrase-based and hierarchical implementations in Moses, permit efficient extraction of N-best lists, so we exploit this to obtain larger lists that still exhibit diversity. But we note that these N-best lists for each diverse solution are not in themselves diverse; with more computational power or more efficient algorithms (Devlin and Matsoukas, 2012) we could potentially generate larger, more diverse lists.

6 Analysis of Diverse Lists

We now characterize our diverse lists by comparing them to M-best lists. Table 1 shows oracle BLEU scores on TEST for M-best lists, unique M-best lists, and diverse lists of several sizes. To get unique lists, we first generated 1000-best lists, then retained only the highest-scoring derivation for each unique translation. When comparing M-best and diverse lists of comparable size, the diverse lists al-

[1] Since BLEU does not decompose additively across segments, we chose translations for individual sentences that maximized BLEU+1 (Lin and Och, 2004), then computed "oracle" corpus BLEU of these translations.

[2] We did not consider n-grams from previous N-best lists when computing the dissimilarity function, but only those from the previous *diverse* translations.

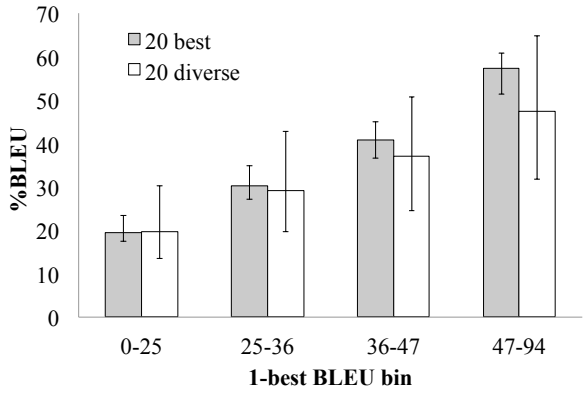

Figure 1: Median, min, and max BLEU+1 of 20-best and 20-diverse lists for the ZH→EN test set, divided into quartiles according to the BLEU+1 score of the 1-best translation, and averaged across sentences in each quartile. Heights of the bars show median and "error bars" indicate max and min.

ways have higher oracle BLEU. The differences are largest when comparing 20-best lists and 20-diverse lists, where they range from 4 to 6 BLEU points.

When generating these diverse lists, we used the n and λ values that were tuned for each language pair to maximize oracle BLEU on TUNE_{200} for the "20 div $\times$ 50 best" configuration. The optimal values of n were 6 for ZH→EN and AR→EN and 7 for DE→EN.[3] When instead tuning to maximize oracle BLEU for 20-diverse lists, the optimal n stayed at 7 for DE→EN, but increased to 7 for AR→EN and 9 for ZH→EN. These values are noticeably larger than n-gram sizes typically used in language modeling and evaluation. They suggest that for optimal oracle BLEU, translations with long-spanning amounts of repeated material should be avoided, while short overlapping n-grams are permitted.

Figure 1 shows other statistics on TEST for ZH→EN. Plots for AR→EN and DE→EN are qualitatively similar. We divided the TEST sentences into quartiles based on BLEU+1 of the 1-best translations from the baseline system. We computed the median, min, and max BLEU+1 on each list and averaged over the sentences in each quartile. As shown in the plot, the ranges of 20-diverse lists subsume those of 20-best lists, though the medians of diverse lists drop when the baseline system has high BLEU score. This matches intuition: when the baseline system is performing well, forcing it to find different translations is likely to result in worse translations. So we may expect diverse lists to be most helpful for more difficult sentences, a point we return to in our experiments below.

7 System Combination Experiments

One way to evaluate the quality of our diverse lists is to use them in system combination, as was similarly done by Devlin and Matsoukas (2012) and Cer et al. (2013). We use the system combination framework of Heafield and Lavie (2010b), which has an open-source implementation (Heafield and Lavie, 2010a).[4]

We use our baseline systems (trained on TUNE1) to generate lists for system combination on TUNE2 and TEST. We compare M-best lists, unique M-best lists, and M-diverse lists, with $M \in \{10, 15, 20\}$.[5] For each choice of list type and M, we trained the system combiner on TUNE2 and tested on TEST with the learned parameters. System combination hyperparameters (whether to use feature length normalization; the size of the k-best lists generated by the system combiner during tuning, $k \in \{300, 600\}$) were chosen to maximize BLEU on TUNE_{200}. Also, we removed the `individual` features from the default feature set because they correspond to individual systems in the combination; they did not seem appropriate for us since our hypotheses all come from the same system.

The results are shown in Table 2. Like Devlin and Matsoukas (2012), we see no gain from system combination using M-best lists. We see some improvement with unique lists, particularly for AR→EN, although it is not consistent across M values. But we see larger improvements with diverse lists for AR→EN and ZH→EN. For these language pairs, our

[3]The optimal values of λ were 0.005 for AR→EN and 0.01 for ZH→EN and DE→EN. Since these values depend on the scale of the weights learned by MERT, they are difficult to interpret in isolation.

[4]The implementation uses MERT to tune parameters, but we found this to be time-consuming and noisy for the larger feature sets. So we used a structured support vector machine learning framework instead (described in Section 8), using multiple iterations of learning interleaved with (system combiner) N-best list generation, and accumulating N-best lists across iterations.

[5]Dissimilarity hyperparameters n and λ were again chosen to maximize oracle BLEU on TUNE_{200}, separately for each M and for each language pair.

	AR→EN			ZH→EN			DE→EN		
	10	15	20	10	15	20	10	15	20
baseline (no system combination)	50.1			36.9			21.8		
M-best	50.2	50.1	50.0	36.7	36.9	37.0	21.7	21.7	21.8
unique M-best (from 1000-best list)	50.6	50.0	50.8	37.1	36.9	37.1	21.8	**21.9**	**21.9**
M-diverse	**51.4**	**51.2**	**51.2**	**37.6**	**37.6**	**37.5**	**22.0**	21.8	21.6

Table 2: System combination results (%BLEU on TEST). Size of lists is $M \in \{10, 15, 20\}$. Highest score in each column is bold.

	AR→EN				ZH→EN				DE→EN			
	q1	q2	q3	q4	q1	q2	q3	q4	q1	q2	q3	q4
baseline	30.1	44.1	55.1	**70.0**	15.2	28.9	41.0	**57.5**	5.3	14.4	23.7	**40.9**
15-best	30.1	44.6	55.5	68.8	15.9	29.2	40.5	56.8	6.0	15.0	23.6	40.0
unique 15-best	30.4	44.7	55.2	68.4	16.7	29.0	41.2	56.6	5.9	14.9	**23.8**	40.6
15-diverse	**31.3**	**45.3**	**57.8**	69.1	**17.7**	**30.6**	**41.7**	56.9	**7.6**	**15.2**	23.4	39.6

Table 3: System combination results (%BLEU on quartiles of TEST, $M = 15$). Source sentences were divided into quartiles (numbered "qn") according to BLEU+1 of the 1-best translations of the baseline system. Highest score in each column is bold.

gains are similar to those seen by Devlin and Matsoukas, but use our simpler dissimilarity function.[6] For DE→EN, results are similar for all settings and do not show much improvement from system combination.

In Table 3, we break down the scores according to 1-best BLEU+1 quartiles, as done in Figure 1.[7] In general, we find the largest gains for the low-BLEU translations. For the two worst BLEU quartiles, we see gains of 1.2 to 2.5 BLEU points, while the gains shrink or disappear entirely for the best quartile. This may be a worthwhile trade-off: a large improvement in the worst translations may be more significant to users than a smaller degredation on sentences that are already being translated well. In addition, quality estimation (Specia et al., 2011; Bach et al., 2011) could be used to automatically determine the BLEU quartile for each sentence. Then system combination of diverse translations might be used only when the 1-best translation is predicted to be of low quality.

8 Reranking Experiments

We now turn to discriminative reranking, which has frequently been used to easily add rich features to a model. It has been used for MT with varying degree of success (Och et al., 2004; Shen et al., 2004; Hildebrand and Vogel, 2008); some have attributed its mixed results to a lack of diversity in the M-best lists traditionally used. We propose diverse lists as a way to address this concern.

8.1 Learning Framework

Several learning formulations have been proposed for M-best reranking. One commonly-used approach in MT is MERT, used in the reranking experiments of Och et al. (2004) and Hildebrand and Vogel (2008), among others. We experimented with MERT and other algorithms, including pairwise ranking optimization (Hopkins and May, 2011), but we found best results using the approach of Yadollahpour et al. (2013), who used a slack-rescaled structured support vector machine (Tsochantaridis et al., 2005) with L2 regularization. As a sentence-level loss, we used negated BLEU+1. We used the 1-slack cutting-plane algorithm of Joachims et al. (2009) for optimization during learning.[8] A more detailed description of the reranker is provided in the supplementary material.

We used 5-fold cross-validation on TUNE2 to choose the regularization parameter C from the set $\{0.01, 0.1, 1, 10\}$. We selected the value yielding the highest average BLEU score across the held-out

[6] They reported +0.8 BLEU from system combination for AR→EN, and saw a further +0.5–0.7 from their new features.

[7] Quartile points are: 39, 49, 61 for AR→EN; 25, 36, and 47 for ZH→EN; and 14.5, 21.1, and 30.3 for DE→EN.

[8] Our implementation uses OOQP (Gertz and Wright, 2003) to solve the quadratic program in the inner loop, which uses HSL, a collection of Fortran codes for large-scale scientific computation (`www.hsl.rl.ac.uk`).

folds. This value was then used for one final round of training on the entirety of TUNE2. Additionally, we tuned the decision to return the parameters at convergence or those that produced the highest training corpus BLEU score. Since we use a sentence-level metric during training (BLEU+1) and a corpus-level metric for final evaluation (BLEU), we found that it was often better to return parameters that produced the highest training BLEU score.

This tuning procedure was repeated for each feature set and for each list type (M-best or diverse). The test set was not used for any of this tuning.

8.2 Features

In addition to the features from the baseline models (14 for phrase-based, 8 for hierarchical), we add 36 more for reranking:

Inverse Model 1 (INVMOD1): We added the "inverse" versions of the three IBM Model 1 features described in Section 2.2 of Hildebrand and Vogel (2008). The first is the probability of the source sentence given the translation under IBM Model 1, the second replaces the $\sum$ with a $\max$ in the first feature, and the third computes the percentage of words whose lexical translation probability falls below a threshold. We also include versions of the first 2 features normalized by the translation length, for a total of 5 INVMOD1 features.

Large LM (LLM): We created a large 4-gram LM by interpolating LMs from the WMT news data, Gigaword, Europarl, and the DE→EN news commentary (NC) corpus to maximize likelihood of a held-out development set (WMT08 test set). We used the average per-word log-probability as the single feature function in this category.

Syntactic LM (SYN): We used the syntactic treelet language model of Pauls and Klein (2012) to compute two features: the translation log probability and the length-normalized log probability.

Finite/Non-Finite Verbs (VERB): We ran the Stanford part-of-speech (POS) tagger (Toutanova et al., 2003) on each translation and added four features: the fraction of *words* tagged as finite/non-finite verbs, and the fraction of *verbs* that are finite/non-finite.[9]

[9]Words tagged as MD, VBP, VBZ, and VBD were counted as finite verbs, and VB, VBG, and VBN were non-finite verbs.

Reranking features	AR→EN best	AR→EN div	ZH→EN best	ZH→EN div	DE→EN best	DE→EN div
N/A (baseline)	50.1		36.9		21.8	
None	50.5	50.7	37.3	37.1	21.9	21.6
+ INVMOD1	50.3	50.8	**37.6**	37.1	22.0	21.8
+ LLM, SYN	50.5	51.1	37.4	37.3	21.7	21.7
+ VERB, DISC	50.4	51.3	37.3	37.3	21.9	22.2
+ GOOG	50.7	51.3	36.8	37.1	21.9	22.2
+ WCLM	51.2	**51.8**	37.3	37.4	22.2	**22.3**

Table 4: Reranking results (%BLEU on TEST).

Discriminative Word/Tag LMs (DISC): For each language pair, we generated 10,000-best lists for TUNE1 and computed BLEU+1 for each. From these lists, we estimated 3- and 5-gram LMs, weighting the n-gram counts by the BLEU+1 scores.[10] We repeated this procedure except using 1 *minus* BLEU+1 as the weight (learning a language model of "bad" translations). This yielded 4 features. The procedure was then repeated using POS tags instead of words, for 8 features in total.

Google 5-Grams (GOOG): Translations were compared to the Google 5-gram corpus (LDC2006T13) to compute: the number of 5-grams that matched, the number of 5-grams that missed, and a set of indicator features that fire if the fraction of 5-grams that matched in the sentence was greater than $\{0.05, 0.1, 0.2, \ldots, 0.9\}$, for a total of 12 features.

Word Cluster LMs (WCLM): Using an implementation provided by Liang (2005), we performed Brown clustering (Brown et al., 1992) on 900k English sentences, including the NC corpus and random sentences from Gigaword. We clustered words that appeared at least twice, once with 300 clusters and again with 1000. We then replaced words with their clusters in a large corpus consisting of the WMT news data, Gigaword, and the NC data. An additional cluster label was used for unknown words. For each of the clusterings (300 and 1000), we estimated 5- and 7-gram LMs with Witten-Bell smoothing (Witten and Bell, 1991). We added 4 features to the reranker, one for the log-probability of the translation under each of the word cluster LMs.

[10]Before estimating LMs, we projected the sentence weights so that the min and max per source sentence were 0 and 1.

List type	Features	
	None	All
20 best	50.3	50.6
100 best	50.6	50.8
200 best	50.4	51.2
1000 best	50.5	51.2
unique 20 best	50.5	51.2
unique 100 best	50.6	51.2
unique 200 best	50.4	51.3
20 diverse	50.5	51.1
20 div × 5 best	50.6	51.4
20 div × 10 best	**50.7**	51.3
20 div × 50 best	**50.7**	**51.8**

Table 5: List comparison for AR→EN reranking.

8.3 Results

Our results are shown in Table 4. We report results using the baseline system alone (labeled "N/A (baseline)"), and reranking standard M-best lists and our diverse lists. For diverse lists, we use the "20 div × 50 best" lists described in Section 5.3, with the tuned dissimilarity hyperparameters reported in Section 6. In the reranking settings, we also report results without adding any additional features (the row labeled "None").[11]

The remaining rows add features. For AR→EN, we see the largest gains, both over the baseline as well as differences between M-best lists and diverse lists. When using all features, we achieve a gain of 0.6 BLEU over M-best reranking and 1.7 BLEU points over the baseline system. The difference of 0.6 BLEU is consistent across feature subsets. We found the WCLM features to give the largest individual improvement, with the remaining feature sets each contributing a small amount. For Chinese and German, the gains and individual differences are smaller. Nonetheless, diverse lists appear to be more robust for these language pairs as features are added.

In Table 5, we compare several sizes and types of lists for AR→EN reranking both with no additional features and with the full set. We see that using 20-diverse lists nearly matches the performance of 200-best lists. Also, retaining 50-best lists for each diverse solution improves BLEU by 0.7.

[11]Though such results have not always been reported in prior work on reranking, we generally found them to improve over the baseline, presumably because seeing more data improves generalization ability.

		Train	
		best	div
Test	best	51.2	51.7
	div	50.5	51.8

Table 6: Comparing M-best and diverse lists for training/testing (AR→EN, all features).

Thus far, when training the reranker on M-best lists, we tested it on M-best lists, and similarly for diverse lists. Table 6 shows what happens with the other two pairings for AR→EN with the full feature set. When training on diverse lists, we see very little difference in BLEU whether testing on M-best or diverse lists. This has a practical benefit: we can use (computationally-expensive) diverse lists during offline training and then use fast M-best lists at test time. When training on M-best lists and *testing* on diverse lists, we see a substantial drop (51.2 vs 50.5). The reranker may be overfitting to the limited scope of translations present in typical M-best lists, thereby hindering its ability to correctly rank diverse lists at test time. These results suggest that part of the benefit of using diverse lists comes from seeing a larger portion of the output space during training.

9 Human Post-Editing Experiments

We wanted to determine whether diverse translations could be helpful to users struggling to understand the output of an imperfect MT system. We consider a post-editing task in which users are presented with translation output without the source sentence, and are asked to improve it. This setting has been studied; e.g., Koehn (2010) presented evidence that monolingual speakers could often produce improved translations for this task, occasionally reaching the level of an expert translator.

Here, we use a novel variation of this task in which *multiple* translations are shown to editors. We compare the use of entries from an M-best list and entries from a diverse list. Again, the original source sentence is not provided. Our goal is to determine whether multiple, diverse translations can help users to more accurately guess the meaning of the original sentence than entries from a standard M-best list. If so, commercial MT systems might permit users to request additional diverse translations for those sentences whose model-best translations are difficult to understand.

9.1 Translation List Post-Editing

We use Amazon Mechanical Turk (MTurk) for this experiment. Workers are shown 3 outputs from an MT system. They are not shown the original sentence, nor are they shown a reference. Based on the 3 imperfect translations, they are asked to write a single fluent English translation that best captures the understood meaning. Half of the time, the worker is shown 3 entries from an M-best list, and the other half of the time 3 entries from a diverse list. We then compare the outputs produced under the two conditions. The goal is to measure whether workers are able to produce translations that are closer in meaning to the (unseen) references when shown diverse translations. We refer to this task as the EDITING task.

To evaluate the outputs, we use a second task in which users are shown a reference translation along with two outputs from the first task: one created from M-best lists and one from diverse lists. Workers in this task are asked to choose which translation is a better match to the reference in terms of meaning, or they can indicate that the translations are of the same quality. We refer to this second task as the EVAL task.

9.2 Dissimilarity Functions

To generate diverse lists for the EDITING task, we use the same dissimilarity function as in reranking, but we tune the hyperparameters n and λ differently. Since our expectation here is that workers may combine information from multiple translations to produce a superior output, we are interested in the *coverage* of the translations in the diverse list, rather than the oracle BLEU score.

We designed a metric based on coverage of entire lists of translations. It is similar to BLEU+1, except (1) it uses n-gram recalls instead of n-gram precisions, (2) there is no brevity penalty term, and (3) it compares a *list* to a set of references and any translation in the list can contribute a match of an n-gram in any reference. Like BLEU, counts are clipped based on those in the references. We maximized this metric over diverse lists of length 5, for $n \in \{2, 3, \ldots, 9\}$ and $\lambda \in \{0.005, 0.01, 0.05, 0.1, 0.2\}$. The optimal values for AR→EN were $n = 4$ and $\lambda = 0.1$, while for ZH→EN they were $n = 4$ and $\lambda = 0.2$. These n values are smaller than for reranking, and the λ values are larger. This suggests that, when maximizing coverage of a small diverse list, more dissimilarity is desired among the translations.

9.3 Detailed Procedure

We focused on AR→EN and ZH→EN for this study. We sampled 200 sentences from their test sets, chosen from among those whose reference translation was between 5 and 25 words. We generated a unique 5-best list for each sentence using our baseline system (described in Section 5.2) and also generated a diverse list of length 5 using the dissimilarity function Δ with hyperparameters tuned using the procedure from the previous section. We untokenized and truecased the translations. We dropped non-ASCII characters because we feared they would confuse our workers. As a result, workers must contend with missing words in the output, often proper nouns.

Given the 2 lists for each sentence, we sampled two integers $i, j \in \{2, 3, 4, 5\}$ without replacement. The indices i and j indicate two entries from the lists. We took translations 1, i, and j from the 5-best list and created an EDITING task from them. We did the same using entries 1, i, and j from the diverse list. We repeated this process 3 times for each sentence, obtaining $3 \times 2 = 6$ tasks for each, giving us a total of 1,200 EDITING tasks per language pair.

The outputs of the EDITING tasks were evaluated with EVAL tasks. For each sentence, we had 3 post-edited outputs generated using entries in 5-best lists and 3 post-edited outputs from diverse lists. We created EVAL tasks for all 9 output pairs, for all 200 sentences per language pair. We additionally gave each task to three MTurk workers. This gave us 10,800 evaluation judgments for the EVAL task.

9.4 Results

Figure 2 shows the quartile breakdown for judgments collected from the EVAL task. The Y axis represents the percentage of judgments for which best/diverse outputs were preferred; the missing percentage for each bin is accounted for by "same" judgments.

We observe an interesting phenomenon. Overall, there is a slight preference for the post-edited outputs of M-best entries ("best") over those from diverse translations ("div"); this preference is clearest

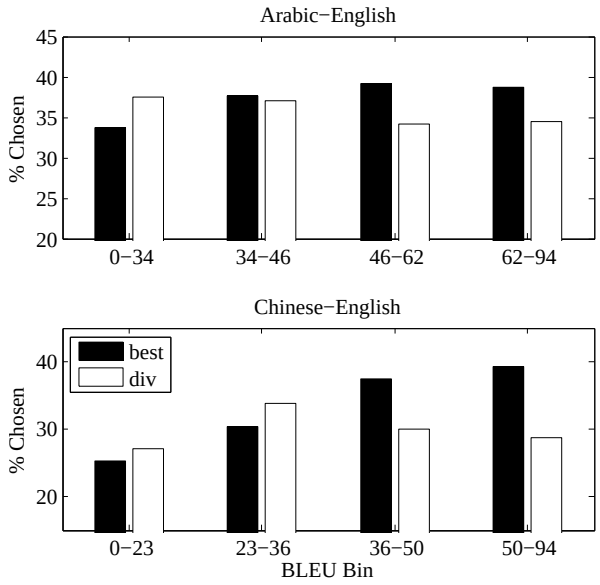

Figure 2: Percentages in which post-edited output given M-best entries ("best") was preferred by human evaluators as compared to post-edited output given diverse translations ("div"), broken down by the BLEU+1 score of the 1-best translation for the sentences. When the baseline system is doing poorly, diversity helps post-editors to produce better translations.

when the baseline system's 1-best translation had a high BLEU score. However, we see this trend reversed for sentences in which the baseline system's 1-best translation had a low BLEU score. In general, when the BLEU score of the baseline system is below 35, it is preferable to give diverse translations to users for post-editing. But when the baseline system does very well, diverse translations do not contribute anything, and in fact hurt because they may distract users from the high-quality (and typically very similar) translations from the 5-best lists.

Estimation of the quality of the output ("confidence estimation") has recently gained interest in the MT community (Specia et al., 2011; Bach et al., 2011; Callison-Burch et al., 2012; Bojar et al., 2013), including specifically for post-editing (Tatsumi, 2009; Specia, 2011; Koponen, 2012). Future work could investigate whether such automatic confidence estimation could be used to identify situations in which diverse translations can be helpful for aiding user understanding.

10 Future Work

Our dissimilarity function captures diversity in the particular phrases used by an MT system, but for certain applications we may prefer other types of diversity. Defining the dissimilarity function on POS tags or word clusters would help us to capture stylistic patterns in sentence structure, as would targeting syntactic structures in syntax-based translation.

A weakness of our approach is its computational expense; by contrast, the method of Devlin and Matsoukas (2012) obtains diverse translations more efficiently by extracting them from a single decoding of an input sentence (albeit with a wide beam). We expect their ideas to be directly applicable to our setting in order to get diverse solutions more cheaply. We also plan to explore methods of explicitly targeting multiple, diverse solutions as part of the search algorithm.

Finally, M-best lists are currently used to approximate structured spaces for many areas of MT, including tuning (Och, 2003), minimum Bayes risk decoding (Kumar and Byrne, 2004), and pipelines (Venugopal et al., 2008). Future work could replace M-best lists with diverse lists in these and related tasks, whether for MT or other areas of structured NLP.

Abstract

While large-scale discriminative training has triumphed in many NLP problems, its definite success on machine translation has been largely elusive. Most recent efforts along this line are not scalable (training on the small dev set with features from top ∼100 most frequent words) and overly complicated. We instead present a very simple yet theoretically motivated approach by extending the recent framework of "violation-fixing perceptron", using forced decoding to compute the target derivations. Extensive phrase-based translation experiments on both Chinese-to-English and Spanish-to-English tasks show substantial gains in BLEU by up to +2.3/+2.0 on dev/test over MERT, thanks to 20M+ sparse features. This is the first successful effort of large-scale online discriminative training for MT.

1 Introduction

Large-scale discriminative training has witnessed great success in many NLP problems such as parsing (McDonald et al., 2005) and tagging (Collins, 2002), but not yet for machine translation (MT) despite numerous recent efforts. Due to scalability issues, most of these recent methods can only train on a small dev set of about a thousand sentences rather than on the full training set, and only with 2,000–10,000 rather "dense-like" features (either unlexicalized or only considering highest-frequency words), as in MIRA (Watanabe et al., 2007; Chiang et al., 2008; Chiang, 2012), PRO (Hopkins and May, 2011), and RAMP (Gimpel and Smith, 2012). However, it is well-known that the most important features for NLP are lexicalized, most of which can not be seen on a small dataset. Furthermore, these methods often involve complicated loss functions and intricate choices of the "target" derivations to update towards or against (e.g. k-best/forest oracles, or hope/fear derivations), and are thus hard to replicate. As a result, the classical method of MERT (Och, 2003) remains the default training algorithm for MT even though it can only tune a handful of dense features. See also Section 6 for other related work.

As a notable exception, Liang et al. (2006) do train a structured perceptron model on the training data with sparse features, but fail to outperform MERT. We argue this is because structured perceptron, like many structured learning algorithms such as CRF and MIRA, assumes exact search, and search errors inevitably break theoretical properties such as convergence (Huang et al., 2012). Empirically, it is now well accepted that standard perceptron performs poorly when search error is severe (Collins and Roark, 2004; Zhang et al., 2013).

To address the search error problem we propose a very simple approach based on the recent framework of "violation-fixing perceptron" (Huang et al., 2012) which is designed specifically for inexact search, with a theoretical convergence guarantee and excellent empirical performance on beam search parsing and tagging. The basic idea is to update when search error happens, rather than at the end of the search. To adapt it to MT, we extend this framework to handle latent variables corresponding to the hidden derivations. We update towards "gold-standard" derivations computed by forced decoding so that each derivation leads to the exact reference translation. Forced decoding is also used as a way of data selection, since those reachable sentence pairs are generally more literal and of higher quality, which the training should focus on. When the reachable subset is small for some language pairs, we augment

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1112–1123,
Seattle, Washington, USA, 18-21 October 2013.

it by including reachable prefix-pairs when the full sentence pair is not.

We make the following contributions:

1. Our work is the first successful effort to scale online structured learning to a large portion of the training data (as opposed to the dev set).

2. Our work is the first to use a principled learning method customized for inexact search which updates on partial derivations rather than full ones in order to fix search errors. We adapt it to MT using latent variables for derivations.

3. Contrary to the common wisdom, we show that simply updating towards the exact reference translation is helpful, which is much simpler than k-best/forest oracles or loss-augmented (e.g. hope/fear) derivations, avoiding sentence-level BLEU scores or other loss functions.

4. We present a convincing analysis that it is the search errors and standard perceptron's inability to deal with them that prevent previous work, esp. Liang et al. (2006), from succeeding.

5. Scaling to the training data enables us to engineer a very rich feature set of sparse, lexicalized, and non-local features, and we propose various ways to alleviate overfitting.

For simplicity and efficiency reasons, in this paper we use phrase-based translation, but our method has the potential to be applicable to other translation paradigms. Extensive experiments on both Chinese-to-English and Spanish-to-English tasks show statistically significant gains in BLEU by up to +2.3/+2.0 on dev/test over MERT, and up to +1.5/+1.5 over PRO, thanks to 20M+ sparse features.

2 Phrase-Based MT and Forced Decoding

We first review the basic phrase-based decoding algorithm (Koehn, 2004), which will be adapted for forced decoding.

2.1 Background: Phrase-based Decoding

We will use the following running example from Chinese to English from Mi et al. (2008):

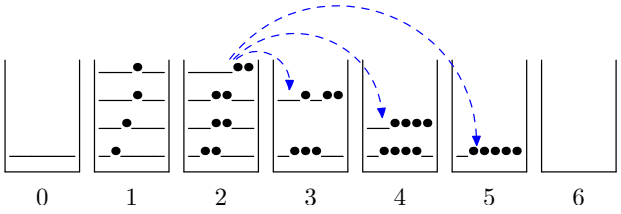

Figure 1: Standard beam-search phrase-based decoding.

Bùshí yǔ Shālóng jǔxíng le huìtán
Bush with Sharon hold -ed meeting

'Bush held a meeting with Sharon'

Phrase-based decoders generate partial target-language outputs in left-to-right order in the form of *hypotheses* (or states) (Koehn, 2004). Each hypothesis has a *coverage vector* capturing the source-language words translated so far, and can be extended into a longer hypothesis by a phrase-pair translating an uncovered segment. For example, the following is one possible derivation:

$$\frac{\dfrac{\dfrac{(0\_\_\_\_\_) : (0, \text{“”})}{(\bullet_1\_\_\_\_\_) : (s_1, \text{“Bush”})}\ r_1}{(\bullet\_\_\bullet\bullet\bullet_6) : (s_2, \text{“Bush held talks”})}\ r_2}{(\bullet\bullet\bullet_3\bullet\bullet\bullet) : (s_3, \text{“Bush held talks with Sharon”})}\ r_3$$

where a $\bullet$ in the coverage vector indicates the source word at this position is "covered" and where each s_i is the score of each state, each adding the rule score and the distortion cost (dc) to the score of the previous state. To compute the distortion cost we also need to maintain the ending position of the last phrase (e.g., the $_3$ and $_6$ in the coverage vectors). In phrase-based translation there is also a *distortion-limit* which prohibits long-distance reorderings.

The above states are called $-$LM states since they do not involve language model costs. To add a bigram model, we split each $-$LM state into a series of $+$LM states; each $+$LM state has the form $(v,^a)$ where a is the last word of the hypothesis. Thus a $+$LM version of the above derivation might be:

$$\frac{\dfrac{\dfrac{(0\_\_\_\_\_,^{\text{<s>}}) : (0, \text{“<s>”})}{(\bullet_1\_\_\_\_\_,^{\text{Bush}}) : (s'_1, \text{“<s> Bush”})}\ r_1}{(\bullet\_\_\bullet\bullet\bullet_6,^{\text{talks}}) : (s'_2, \text{“<s> Bush held talks”})}\ r_2}{(\bullet\bullet\bullet_3\bullet\bullet\bullet,^{\text{Sharon}}) : (s'_3, \text{“<s> Bush held ... with Sharon”})}\ r_3$$

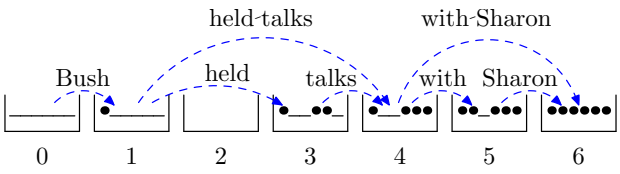

Figure 2: Forced decoding and y-good derivation lattice.

where the score of applying each rule now also includes a *combination cost* due to the bigrams formed when applying the phrase-pair, e.g.

$$s'_3 = s'_2 + s(r_3) + dc(|6-3|) - \log P_{lm}(\text{with} \mid \text{talk})$$

To make this exponential-time algorithm practical, beam search is the standard approximate search method (Koehn, 2004). Here we group +LM states into n bins, with each bin B_i hosting at most b states that cover exactly i Chinese words (see Figure 1).

2.2 Forced Decoding

The idea of forced decoding is to consider only those (partial) derivations that can produce (a prefix of) the exact reference translation (assuming single reference). We call these partial derivations "y-good" derivations (Daumé, III and Marcu, 2005), and those that deviate from the reference translation "y-bad" derivations. The forced decoding algorithm is very similar to +LM decoding introduced above, with the new "forced decoding LM" to be defined as only accepting two consecutive words on the reference translation, ruling out any y-bad hypothesis:

$$P_{forced}(b \mid a) = \begin{cases} 1 & \text{if } \exists j, \text{ s.t. } a = y_j \text{ and } b = y_{j+1} \\ 0 & \text{otherwise} \end{cases}$$

In the +LM state, we can simply replace the boundary word by the index on the reference translation:

$$\frac{\dfrac{\dfrac{(0\_\_\_\_\_,{}^{0}) : (0, \text{“<s>”})}{(\bullet_1\_\_\_\_,{}^{1}) : (w'_1, \text{“<s> Bush”})}\, r_1}{(\bullet\_\_\bullet\bullet\bullet_6,{}^{3}) : (w'_2, \text{“<s> Bush held talks”})}\, r_2}{(\bullet\bullet\bullet_3\bullet\bullet\bullet,{}^{5}) : (w'_3, \text{“<s> Bush held talks with Sharon”})}\, r_3$$

The complexity of this forced decoding algorithm is reduced to $O(2^n n^3)$ where n is the source sentence length, without the expensive bookkeeping for English boundary words.

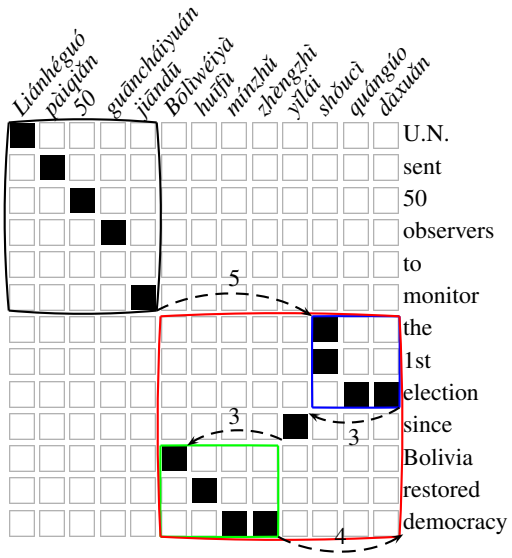

Figure 3: Example of unreachable sentence pair and reachable prefix-pair. The first big jump is disallowed for a distortion limit of 4, but we can still extract the top-left box as a reachable prefix-pair. Note that this example is perfectly reachable in syntax-based MT.

2.3 Reachable Prefix-Pairs

In practice, many sentence pairs in the parallel text fail in forced decoding due to two reasons:

1. **distortion limit**: long-distance reorderings are disallowed but are very common between languages with very different word orders such as English and Chinese.

2. **noisy alignment and phrase limit**: the word-alignment quality (typically from GIZA++) are usually very noisy, which leads to unnecessarily big chunks of rules beyond the phrase limit.

If we only rely on the reachable whole sentence pairs, we will not be able to use much of the training set for Chinese-English. So we propose to augment the set of reachable examples by considering reachable prefix-pairs (see Figure 3 for an example).

3 Violation-Fixing Perceptron for MT

Huang et al. (2012) establish a theoretical framework called "violation-fixing perceptron" which is tailored for structured learning with inexact search and has provable convergence properties. The high-level idea is that standard full update does not fix search errors; to do that we should instead update when search error occurs, e.g., when the gold-

standard derivation falls below the beam. Huang et al. (2012) show dramatic improvements in the quality of the learned model using violation-fixing perceptron (compared to standard perceptron) on incremental parsing and part-of-speech tagging.

Since phrase-based decoding is also an incremental search problem which closely resembles beam-search incremental parsing, it is very natural to employ violation-fixing perceptron here for MT training. Our goal is to produce the exact reference translation, or in other words, we want at least one y-good derivation to survive in the beam search.

To adapt the violation-fixing perceptron framework to MT we need to extend the framework to handle latent variables since the gold-standard derivation is not observed. This is done in a way similar to the latent variable structured perceptron (Zettlemoyer and Collins, 2005; Liang et al., 2006; Sun et al., 2009) where each update is from the best (y-bad) derivation towards the best y-good derivation in the current model; the latter is a constrained search which is exactly forced decoding in MT.

3.1 Notations

We first establish some necessary notations. Let $\langle x, y \rangle$ be a sentence pair in the training data, and

$$d = r_1 \circ r_2 \circ \ldots \circ r_{|d|}$$

be a (partial) derivation, where each $r_i = \langle c(r_i), e(r_i) \rangle$ is a rule, i.e., a Chinese-English phrase-pair. Let $|c(d)| \triangleq \sum_i |c(r_i)|$ be the number of Chinese words covered by this derivation, and $e(d) \triangleq e(r_1) \circ e(r_2) \ldots \circ e(r_{|d|})$ be the English prefix generated so far. Let $D(x)$ be the set of all possible partial derivations translating part of the input sentence x. Let $pre(y) \triangleq \{y_{[0:j]} \mid 0 \leq j \leq |y|\}$ be the set of prefixes of the reference translation y, and $good_i(x, y)$ be the set of partial y-good derivations whose English side is a prefix of the reference translation y, and whose Chinese projection covers exactly i words on the input sentence x, i.e.,

$$good_i(x, y) \triangleq \{d \in D(x) \mid e(d) \in pre(y), |c(d)| = i\}.$$

Conversely, we define the set of y-bad partial derivations covering i Chinese words to be:

$$bad_i(x, y) \triangleq \{d \in D(x) \mid e(d) \notin pre(y), |c(d)| = i\}.$$

Basically, at each bin B_i, y-good derivations $good_i(x, y)$ and y-bad ones $bad_i(x, y)$ compete for the b slots in the bin:

$$B_0 = \{\epsilon\} \quad (1)$$

$$B_i = \mathbf{top}^b \bigcup_{j=1..l} \{d \circ r \mid d \in B_{i-j}, |c(r)| = j\} \quad (2)$$

where r is a rule covering j Chinese words, l is the phrase-limit, and $\mathbf{top}^b\ S$ is a shorthand for $\mathbf{argtop}^b_{d \in S}\ \mathbf{w} \cdot \mathbf{\Phi}(x, d)$ which selects the top b derivations according to the current model $\mathbf{w}$.

3.2 Algorithm 1: Early Update

As a special case of violation-fixing perceptron, early update (Collins and Roark, 2004) stops decoding whenever the gold derivation falls off the beam, makes an update on the prefix so far and move on to the next example. We adapt it to MT as follows: if at a certain bin B_i, all y-good derivations in $good_i(x, y)$ have fallen off the bin, then we stop and update, rewarding the best y-good derivation in $good_i(x, y)$ (with respect to current model $\mathbf{w}$), and penalizing the best y-bad derivation in the same step:

$$d_i^+(x, y) \triangleq \mathop{\mathbf{argmax}}_{d \in good_i(x,y)} \mathbf{w} \cdot \mathbf{\Phi}(x, d) \quad (3)$$

$$d_i^-(x, y) \triangleq \mathop{\mathbf{argmax}}_{d \in bad_i(x,y) \cap B_i} \mathbf{w} \cdot \mathbf{\Phi}(x, d) \quad (4)$$

$$\mathbf{w} \leftarrow \mathbf{w} + \Delta\mathbf{\Phi}(x,\ d_i^+(x, y),\ d_i^-(x, y)) \quad (5)$$

where $\Delta\mathbf{\Phi}(x, d, d') \triangleq \mathbf{\Phi}(x, d) - \mathbf{\Phi}(x, d')$ is a shorthand notation for the difference of feature vectors. Note that the set $good_i(x, y)$ is independent of the beam search and current model and is instead precomputed in the forced decoding phase, whereas the negative signal $d_i^-(x, y)$ depends on the beam.

In practice, however, there are exponentially many y-good derivations for each reachable sentence pair, and our goal is just to make sure (at least) one y-good derivation triumphs at the end. So it is possible that at a certain bin, all y-good partial derivations fall off the bin, but the search can still continue and produce the exact reference translation through some other y-good path that avoids that bin. For example, in Figure 1, the y-good states in steps 3 and 5 are not critical; it is totally fine to miss them in the search as long as we save the y-good states

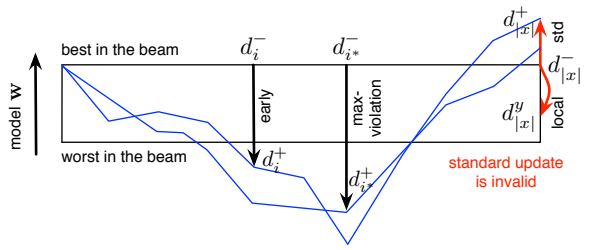

Figure 4: Illustration of four update methods. The blue paths denote (possibly lots of) gold-standard derivations from forced decoding. Standard update in this case is invalid as it reinforces the error of $\mathbf{w}$ (Huang et al., 2012).

in bins 1, 4 and 6. So we actually use a "softer" version of the early update algorithm: only stop and update when there is no hope to continue. To be more concrete, let l denote the phrase-limit then we stop where there are l consecutive bins without any y-good states, and update on the first among them.

3.3 Algorithm 2: Max-Violation Update

While early update learns substantially better models than standard perceptron in the midst of inexact search, it is also well-known to be converging much slower than the latter, since each update is on a (short) prefix. Huang et al. (2012) propose an improved method "*max-violation*" which updates at the worst mistake instead of the first, and converges much faster than early update with similar or better accuracy. We adopt this idea here as follows: decode the whole sentence, and find the step i^* where the difference between the best y-good derivation and the best y-bad one is the biggest. This amount of difference is called the amount of "violation" in Huang et al. (2012), and the place of maximum violation is intuitively the site of the biggest mistake during the search. More formally, the update rule is:

$$i^* \triangleq \operatorname*{argmin}_i \mathbf{w} \cdot \Delta\boldsymbol{\Phi}(x,\, d_i^+(x,y),\, d_i^-(x,y)) \quad (6)$$

$$\mathbf{w} \leftarrow \mathbf{w} + \Delta\boldsymbol{\Phi}(x,\, d_{i^*}^+(x,y),\, d_{i^*}^-(x,y)) \quad (7)$$

3.4 Previous Work: Standard and Local Updates

We compare the above new update methods with the two existing ones from Liang et al. (2006).

Standard update (also known as "bold update" in Liang et al. (2006)) simply updates at the very end, from the best derivation in the beam towards the best gold-standard derivation (regardless of whether it survives the beam search):

$$\mathbf{w} \leftarrow \mathbf{w} + \Delta\boldsymbol{\Phi}(x, d_{|x|}^+(x,y), d_{|x|}^-(x,y)) \quad (8)$$

Local update, however, updates towards the derivation in the final bin that is most similar to the reference y, denoted $d_{|x|}^y(x,y)$:

$$d_{|x|}^y(x,y) = \operatorname*{argmax}_{d \in B_{|x|}} \mathrm{Bleu}^{+1}(y, e(d)) \quad (9)$$

$$\mathbf{w} \leftarrow \mathbf{w} + \Delta\boldsymbol{\Phi}(x, d_{|x|}^y(x,y), d_{|x|}^-(x,y)) \quad (10)$$

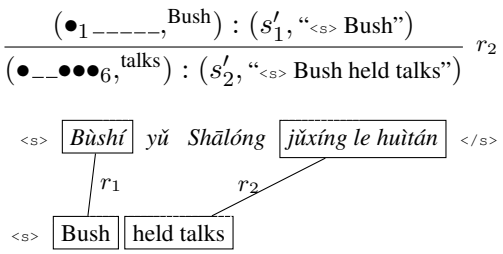
where $\mathrm{Bleu}^{+1}(\cdot,\cdot)$ returns the sentence-level BLEU.

Liang et al. (2006) observe that standard update performs worse than local update, which they attribute to the fact that the former often update towards a gold derivation made up of "unreasonable" rules. Here we give a very different but theoretically more reasonable explanation based on the theory of Huang et al. (2012), who define an update $\Delta\boldsymbol{\Phi}(x, d^+, d^-)$ to be **invalid** if d^+ scores higher than d^- (i.e., $\mathbf{w} \cdot \Delta\boldsymbol{\Phi}(x, d^+, d^-) > 0$, or update $\Delta\mathbf{w}$ points to the same direction as $\mathbf{w}$ in Fig. 4), in which case there is no "violation" or mistake to fix. Perceptron is guaranteed to converge if all updates are valid. Clearly, early and max-violation updates are valid. But standard update is not: it is possible that at the end of search, the best y-good derivation $d_{|x|}^+(x,y)$, though pruned earlier in the search, ranks even higher in the current model than anything in the final bin (see Figure 4). In other words, there is no mistake at the final step, while there must be some search error in earlier steps which expels the y-good subderivation. We will see in Section 5.3 that invalid updates due to search errors are indeed the main reason why standard update fails. Local update, however, is always valid in that definition.

Finally, it is worth noting that in terms of implementation, standard and max-violation are the easiest, while early update is more involved.

4 Feature Design

Our feature set includes the following 11 dense features: LM, four conditional and lexical translation probabilities ($p_c(e|f)$, $p_c(f|e)$, $p_l(e|f)$, $p_l(f|e)$), length and phrase penalties, distortion cost, and three lexicalized reordering features. All these features are inherited from Moses (Koehn et al., 2007).



features for applying r_2 on span $x_{[3:6]}$

WordEdges	$c(r_2)_{[0]} = \textit{jǔxíng}$, $c(r_2)_{[-1]} = \textit{huìtán}$ $e(r_2)_{[0]} = \text{held}$, $e(r_2)_{[-1]} = \text{talks}$ $x_{[2:3]} = \textit{Shālóng}$, $x_{[6:7]} = \text{</s>}$, $\lvert c(r_2)\rvert = 3$ ... (**combos** of the above **atomic** features) ...
non-local	$e(r_0 \circ r_1)_{[-2:]} \circ id(r_2)$ $id(r_1) \circ id(r_2)$

Figure 5: Examples of WordEdges and non-local features. The notation uses the Python style subscript syntax.

4.1 Local Sparse Features: Ruleid & WordEdges

We first add the rule identification feature for each rule: $id(r_i)$. We also introduce lexicalized **WordEdges** features, which are shown to be very effective in parsing (Charniak and Johnson, 2005) and MT (Liu et al., 2008; He et al., 2008) literatures. We use the following atomic features when applying a rule $r_i = \langle c(r_i), e(r_i)\rangle$: the source-side length $|c(r_i)|$, the boundary words of both $c(r_i)$ and $e(r_i)$, and the surrounding words of $c(r_i)$ on the input sentence x. See Figure 5 for examples. These atomic features are concatenated to generate all kinds of **combo features**.

Chinese	English	class size		budget
word		52.9k	64.2k	5
characters	-	3.7k	-	3
Brown cluster, full string		200		3
Brown cluster, prefix 6		6	8	2
Brown cluster, prefix 4		4	4	2
POS tag		52	36	2
word type	-	4	-	1

Table 1: Various levels of backoff for WordEdges features. Class size is estimated on the small Chinese-English dataset (Sec. 5.3). The POS tagsets are ICTCLAS for Chinese (Zhang et al., 2003) and Penn Treebank for English (Marcus et al., 1993).

4.2 Addressing Overfitting

With large numbers of lexicalized combo features we will face the overfitting problem, where some combo features found in the training data are too rare to be seen in the test data. Thus we propose three ways to alleviate this problem.

First, we introduce various levels of backoffs for each word w (see Table 1). We include w's Brown cluster and its prefixes of lengths 4 and 6 (Brown et al., 1992), and w's part-of-speech tag. If w is Chinese we also include its word type (punctuations, digits, alpha, or otherwise) and (leftmost or rightmost) character. In such a way, we significantly increase the feature coverage on unseen data.

However, if we allow arbitrary combinations, we can extract a hexalexical feature (4 Chinese + 2 English words) for a local window in Figure 5, which is unlikely to be seen at test time. To control model complexity we introduce a *feature budget* for each level of backoffs, shown in the last column in Table 1. The total budget for a combo feature is the sum of the budgets of all atomic features. In our experiments, we only use the combo features with a total budget of 10 or less, i.e., we can only include bilexical but not trilexical features, and we can include for example combo features with one Chinese word plus two English tags (total budget: 9).

Finally, we use two methods to alleviate overfitting due to one-count rules: for large datasets, we simply remove all one-count rules, but for small datasets where out-of-vocabulary words (OOVs) abound, we use a simple leave-one-out method: when training on a sentence pair (x, y), do not use the one-count rules extracted from (x, y) itself.

4.3 Non-Local Features

Following the success of non-local features in parsing (Huang, 2008) and MT (Vaswani et al., 2011), we also introduce them to capture the contextual information in MT. Our non-local features, shown in Figure 5, include bigram rule-ids and the concatenation of a rule id with the translation history, i.e. the last two English words. Note that we also use backoffs (Table 1) for the words included. Experiments (Section 5.3) show that although the set of non-local features is just a tiny fraction of all features, it contributes substantially to the improvement in BLEU.

Scale	Language Pair	Training Data # sent.	Training Data # words	Reachability sent.	Reachability words	# feats	ΔBLEU # refs	ΔBLEU dev/test	Sections
small	CH-EN	30K	0.8M/1.0M	21.4%	8.8%	7M	4	+2.2/2.0	5.2, 5.3

Table 2: Overview of all experiments. The ΔBLEU column shows the absolute improvements of our method MAX-FORCE on dev/test sets over MERT. The Chinese datasets also use prefix-pairs in training (see Table 3).

5 Experiments

In order to test our approach in different language pairs, we conduct three experiments, shown in Table 2, on two significantly different language pairs (long vs. short distance reorderings), Chinese-to-English (CH-EN) and Spanish-to-English (SP-EN).

5.1 System Preparation and Data

We base our experiments on **Cubit**, a state-of-art phrase-based system in Python (Huang and Chiang, 2007).[1] We set phrase-limit to 7 in rule extraction, and beam size to 30 and distortion limit 6 in decoding. We compare our violation-fixing perceptron with two popular tuning methods: MERT (Och, 2003) and PRO (Hopkins and May, 2011).

For word alignments we use GIZA++-ℓ_0 (Vaswani et al., 2012) which produces sparser alignments, alleviating the garbage collection problem. We use the SRILM toolkit (Stolcke, 2002) to train a trigram language model with modified Kneser-Ney smoothing on 1.5M English sentences.

Our dev and test sets for CH-EN task are from the newswire portion of 2006 and 2008 NIST MT Evaluations (616/691 sentences, 18575/18875 words), with four references.[2] The dev and test sets for SP-EN task are from newstest2012 and newstest2013, with only one reference. Below both MERT and PRO tune weights on the dev set, while our method on the training set. Specifically, our method only uses the dev set to know when to stop training.

5.2 Forced Decoding Reachability on Chinese

As mentioned in Section 2.2, we perform forced decoding to select reachable sentences from the training data; this part is done with exact search without any beam pruning. Figure 6 shows the reachability ratio vs. sentence length on the small CH-EN training data, where the ratio decreases sharply with sentence length, and increases with distortion limit. We can see that there are a lot of long distance reorderings beyond small distortion limits. In the extreme case of unlimited distortion, a large amount of sentences will be reachable, but at the cost of much slower decoding ($O(n^2V^2)$ in beam search decoding, and $O(2^n n^3)$ in forced decoding). In fact forced decoding is too slow in the unlimited mode that we only plot reachability for sentences up to 30 words.

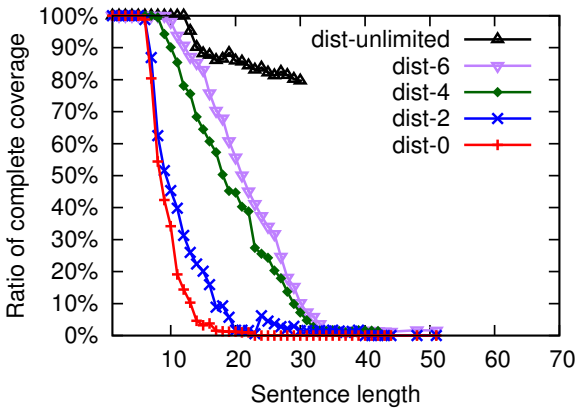

Figure 6: Reachability ratio vs. sentence length on the small CH-EN training set.

	small sent.	small words	large sent.	large words
full	21.4%	8.8%	32.1%	12.7%
+prefix	61.3%	24.6%	67.3%	32.8%

Table 3: Ratio of sentence reachability and word coverage on the two CH-EN training data (distortion limit: 6).

Table 3 shows the statistics of forced decoding on both small and large CH-EN training sets. In the

[2] We use the "average" reference length to compute the brevity penalty factor, which does not decrease with more references unlike the "shortest" heuristic.

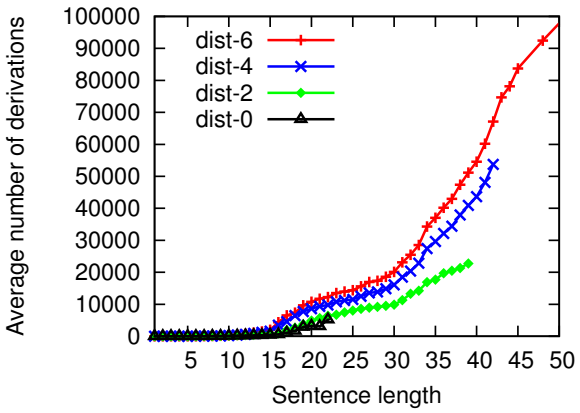

Figure 7: Average number of derivations in gold lattices.

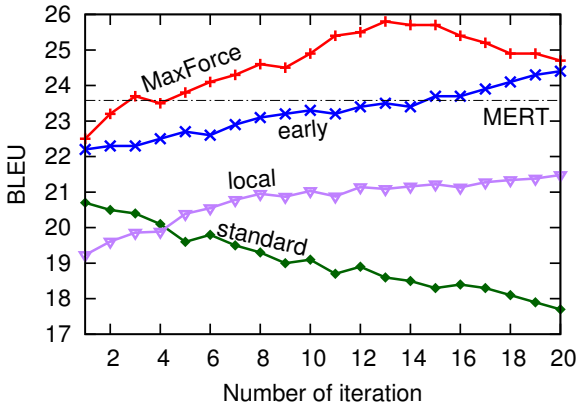

Figure 8: BLEU scores on the heldout dev set for different update methods (trained on small CH-EN data).

small data-set, 21.4% sentences are fully reachable which only contains 8.8% words (since shorter sentences are more likely to be reachable). Larger data improves reachable ratios significantly thanks to better alignment quality, but still only 12.7% words can be used. In order to add more examples for perceptron training, we pick all non-trivial reachable prefix-pairs (with 5 or more Chinese words) as additional training examples (see Section 2.2). As shown in Table 3, with prefix-pairs we can use about 1/4 of small data and 1/3 of large data for training, which is 10x and 120x bigger than the 616-sentence dev set.

After running forced decoding, we obtain gold translation lattice for each reachable sentence (or prefix) pair. Figure 7 shows, as expected, the average number of gold derivations in these lattices grows exponentially with sentence length.

5.3 Analysis on Small Chinese-English Data

Figure 8 shows the BLEU scores of different learning algorithms on the dev set. MAXFORCE[3] performs the best, peaking at iteration 13 while early update learns much slower (the first few iterations are faster than other methods due to early stopping but this difference is immaterial later). The local and standard updates, however, underperform MERT; in particular, the latter gets worse as training goes on.

As analysized in Section 3.4, the reason why standard update (or "bold update" in Liang et al. (2006)) fails is that inexact search leads to many invalid updates. This is confirmed by Figure 9, where more

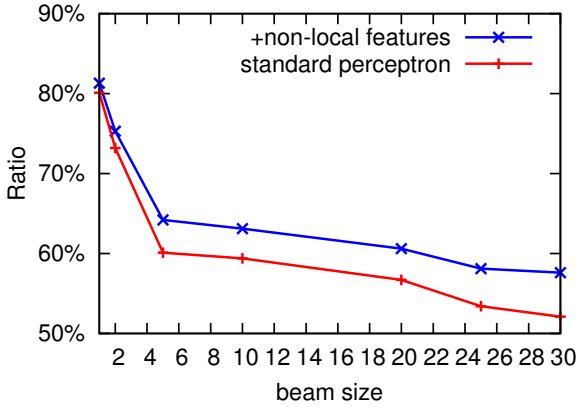

Figure 9: Ratio of invalid updates in standard update.

than half of the updates remain invalid even at a beam of 30. These analyses provide an alternative but theoretically more reasonable explanation to the findings of Liang et al. (2006): while they blame "unreasonable" gold derivations for the failure of standard update, we observe that it is the search errors that make the real difference, and that an update that respects search errors towards a gold subderivation is indeed helpful, even if that subderivation might be "unreasonable".

In order to speedup training, we use mini-batch parallelization of Zhao and Huang (2013) which has been shown to be much faster than previous parallelization methods. We set the mini-batch size to 24 and train MAXFORCE with 1, 6, and 24 cores on a small subset of the our original reachable sen-

[3]Stands for **Max**-Violation Perceptron w/ **Force**d Decoding

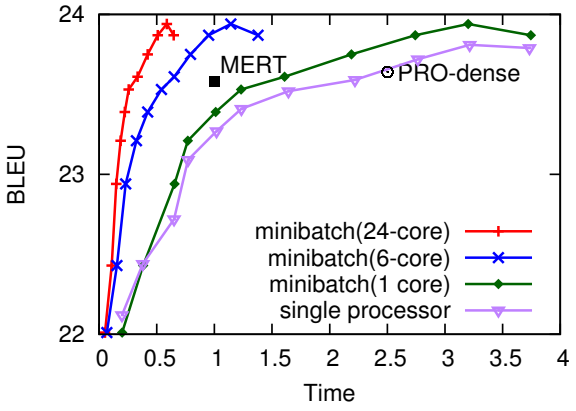

Figure 10: Minibatch parallelization speeds up learning.

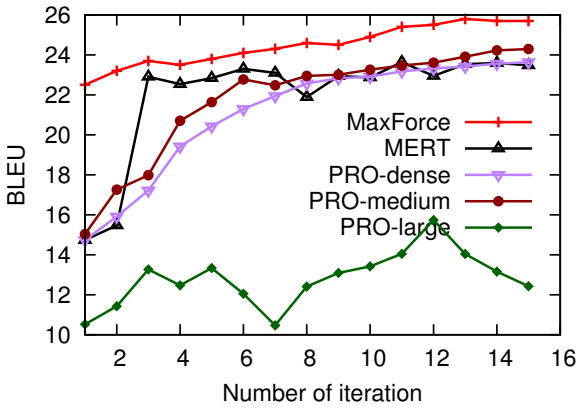

Figure 11: Comparison between different training methods. Ours trains the training set while others on dev set.

tences. The number of sentence pairs in this subset is 1,032, which contains similar number of words to our 616-sentence dev set (since reachable sentences are much shorter). Thus, it is reasonable to compare different learning algorithms in terms of speed and performance. Figure 10 shows that first of all, minibatch improves BLEU even in the serial setting, and when run on 24 cores, it leads to a speedup of about 7x. It is also interesting to know that on 1 CPU, minibatch perceptron takes similar amount of time to reach the same performance as MERT and PRO.

Figure 11 compares the learning curves of MAXFORCE, MERT, and PRO. We test PRO in three different ways: PRO-dense (dense features only), PRO-medium (dense features plus top 3K most frequent sparse features[4]), and PRO-large (dense features plus all sparse features). The results show that PRO-dense performs almost the same as MERT but with a stabler learning curve while PRO-medium improves by +0.6. However, PRO-large decreases the performance significantly, which indicates PRO is not scalable to truly sparse features. By contrast, our method handles large-scale sparse features well and outperforms all other methods by a large margin and with a stable learning curve.

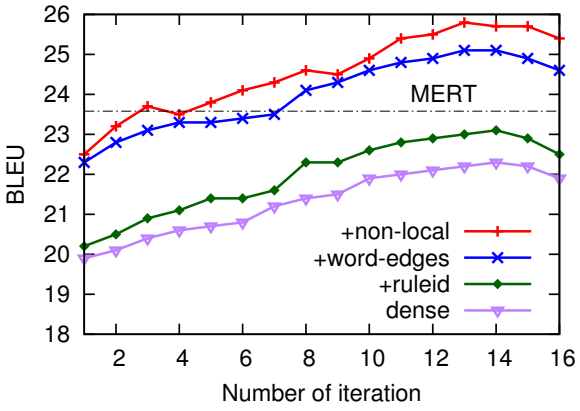

Figure 12: Incremental contributions of different feature sets (dense features, ruleid, WordEdges, and non-local).

type	count	%	BLEU
dense	11	-	22.3
+ruleid	+9,264	+0.1%	+0.8
+WordEdges	+7,046,238	+99.5%	+2.0
+non-local	+22,536	+0.3%	+0.7
all	7,074,049	100%	25.8

Table 4: Feature counts and incremental BLEU improvements. MAXFORCE with all features is +2.2 over MERT.

We also investigate the individual contribution from each group of features (ruleid, WordEdges, and non-local features). So we perform experiments by adding each group incrementally. Figure 12 shows the learning curves and Table 4 lists the counts and incremental contributions of different feature sets. With dense features alone MAXFORCE does not do

[4]To prevent overfitting we remove all lexicalized features and only use Brown clusters. It is difficult to engineer the right feature set for PRO, whereas MAXFORCE is much more robust.

system	algorithm	# feat.	dev	test
Moses	MERT	11	25.5	22.5
Cubit	MERT	11	25.4	22.5
	PRO	11	25.6	22.6
		3K	26.3	23.0
		36K	17.7	14.3
	MAXFORCE	23M	**27.8**	**24.5**

Table 5: BLEU scores (with four references) using the large CH-EN data. Our approach is +2.3/2.0 over MERT.

well because perceptron is known to suffer from features of vastly different scales. Adding ruleid helps, but still not enough. WordEdges (which is the vast majority of features) improves BLEU by +2.0 points and outperforms MERT, when sparse features totally dominate dense features. Finally, the 0.3% non-local features contribute a final +0.7 in BLEU.

5.4 Results on Large Chinese-English Data

Table 5 shows all BLEU scores for different learning algorithms on the large CH-EN data. The MERT baseline on Cubit is essentially the same as Moses. Our MAXFORCE activates 23M features on reachable sentences and prefixes in the training data, and takes 35 hours to finish 15 iterations on 24 cores, peaking at iteration 13. It achieves significant improvements over other approaches: +2.3/+2.0 points over MERT and +1.5/+1.5 over PRO-medium on dev/test sets, respectively.

5.5 Results on Large Spanish-English Data

In SP-EN translation, we first run forced decoding on the training set, and achieve a very high reachability of 55% (with the same distortion limit of 6), which is expected since the word order between Spanish and English are more similar than than between Chinese and English, and most SP-EN reorderings are local. Table 6 shows that MAXFORCE improves the translation quality over MERT by +1.3/+1.1 BLEU on dev/test. These gains are comparable to the improvements on the CH-EN task, since it is well accepted in MT literature that a change of δ in 1-reference BLEU is roughly equivalent to a change of 2δ with 4 references.

system	algorithm	# feat.	dev	test
Moses	MERT	11	27.4	24.4
Cubit	MAXFORCE	21M	**28.7**	**25.5**

Table 6: BLEU scores **(with one reference)** on SP-EN.

6 Related Work

Besides those discussed in Section 1, there are also some research on tuning sparse features on the training data, but they integrate those sparse features into the MT log-linear model as a single feature weight, and tune its weight on the dev set (e.g. (Liu et al., 2008; He et al., 2008; Wuebker et al., 2010; Simianer et al., 2012; Flanigan et al., 2013; Setiawan and Zhou, 2013; He and Deng, 2012; Gao and He, 2013)). By contrast, our approach learns sparse features only on the training set, and use dev set as held-out to know when to stop.

Forced decoding has been used in the MT literature. For example, open source MT systems Moses and cdec have implemented it. Liang et al. (2012) also use the it to boost the MERT tuning by adding more y-good derivations to the standard k-best list.

7 Conclusions and Future Work

We have presented a simple yet effective approach of structured learning for machine translation which scales, for the first time, to a large portion of the whole training data, and enables us to tune a rich set of sparse, lexical, and non-local features. Our approach results in very significant BLEU gains over MERT and PRO baselines. For future work, we will consider other translation paradigms such as hierarchical phrase-based or syntax-based MT.

Abstract

This paper studies the problem of identifying users who use multiple userids to post in social media. Since multiple userids may belong to the same author, it is hard to directly apply supervised learning to solve the problem. This paper proposes a new method, which still uses supervised learning but does not require training documents from the involved userids. Instead, it uses documents from other userids for classifier building. The classifier can be applied to documents of the involved userids. This is possible because we transform the document space to a similarity space and learning is performed in this new space. Our evaluation is done in the online review domain. The experimental results using a large number of userids and their reviews show that the proposed method is highly effective.

1 Introduction

It is common knowledge that some users in social media register multiple accounts/userids to post articles, blogs, reviews, etc. There are many reasons for doing this. For example, due to past postings, a user may become despised by others. He/she then registers another userid in order to regain his/her status. A user may also use multiple userids to instigate controversy or debates to popularize a topic to make it "hot" or even just to promote activities at a website. Yet, a user may also use multiple userids to post fake or deceptive opinions to promote or demote some products (Liu, 2012). It is thus important to develop technologies to identify such *multi-id users*. This paper deals with this problem based on writing style and other linguistic clues.

Problem definition: Given a set of userids $ID = \{id_1, \ldots, id_n\}$ and each id_i has a set of documents D_i, we want to identify userids that belong to the same physical author.

The main related works to ours are in the area of authorship attribution (AA), which aims to identify authors of documents. AA is often solved using supervised learning. Let $A = \{a_1, \ldots, a_k\}$ be a set of authors (or classes) and each author $a_i \in A$ has a set of training documents D_i. A classifier is then built to decide the author a of each test document d, where $a \in A$. We will discuss this and other related works in Section 2.

This supervised AA formulation, however, is not suitable for our task because we only have userids but not real authors. Since some of the userids may belong to the same author, we cannot treat each userid as a class because in that case, we will be classifying based on userids, which won't help us find authors with multiple userids (see Section 7 also).

This paper proposes a novel algorithm. To simplify the presentation, we assume that at most two userids can belong to a single author, but the algorithm can be extended to handle more than two userids from the same author. Using this assumption, the algorithm works in two steps:

1. *Candidate identification*: For each userid id_i, we first find the most likely userid id_j ($i \neq j$) that may have the same author as id_i. We call id_j the *candidate* of id_i. We also call this function *candid-iden*, i.e., id_j = *candid-iden*(id_i). For easy presentation, here we only use one argument for

* The work was mainly done when the first author was visiting the University of Illinois at Chicago.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1124–1135,
Seattle, Washington, USA, 18-21 October 2013.

candid-iden. In the computation, it needs more arguments (see Section 4).

2. *Candidate confirmation*: In the reverse order, we apply the function *candid-iden* on id_j, which produces id_k, i.e., $id_k = candid\text{-}iden(id_j)$.

   Decision making: If $k = i$, we conclude that id_i and id_j are from the same author. Otherwise, id_i and id_j are not from the same author.

The key of the algorithm is *candid-iden*. An obvious approach for *candid-iden* is to use an information retrieval method. We can first split the documents D_i of each id_i into two subsets, a *query set* Q_i and a *sample set* S_i. We then compare each query document in Q_i with each sample document in S_j from other userids id_j ($\in ID - \{id_i\}$). *Cosine* can be used here for similarity comparison. All the similarity scores are then aggregated and used to rank the userids in $ID - \{id_i\}$. The top ranked userid is the candidate for id_i. Note that partitioning the documents of a userid id_i into the query set Q_i and the sample set S_i is crucial here. We cannot use all documents in D_i to compare with all documents in D_j. If so and we get $candid\text{-}iden(id_i) = id_j$, we will definitely get $candid\text{-}iden(id_j) = id_i$ since the similarity function is symmetric.

This cosine similarity based method, however, does not work well (see Section 7). We propose a supervised learning method to compute the scores. For this, we need to reformulate the problem.

The idea of this reformulation is to learn in a similarity space rather than in the original document space as in traditional AA. In the new formulation, each document *d* is still represented as a feature vector, but the vector no longer represents the document *d* itself. Instead, it represents a set of similarities between the document *d* and a query *q*. We call this method *learning in the similarity space* (LSS).

Specifically, in LSS, each document *d* is first represented with a *document space vector* (called a *d-vector*) based on the document itself as in the traditional classification learning of AA. Each feature in the *d*-vector is called a *d-feature* (*document-feature*). A query document *q* is represented in the same way. We then produce a *similarity vector sv* (called *s-vector*) for *d*. *sv* consists of a set of similarity values between document *d* (in a *d*-vector) and query *q* (in a *d*-vector):

$$sv = Sim(d, q),$$

where *Sim* is a similarity function consists of a set of similarity measures. Thus, the *d*-vector for document *d* in the document space is transformed to an *s*-vector *sv* for *d* in the similarity space. Each feature in *sv* is called an *s-feature*. For example, we have the following *d*-vector for query *q*:

q: 1:1 2:1 6:2

where *x*:*z* represents a *d*-feature *x* (a word) and its frequency *z* in *q*. We also have two non-query documents, one is d_1 which is written by the author of query *q* and the other is d_2 which is not written by query author *q*. Their *d*-vectors are:

d_1: 1:2 2:1 3:1 d_2: 2:2 3:1 5:2

If we use *cosine* as the first similarity measure in *Sim*, we can generate an *s*-feature 1:0.50 for d_1 ($cosine(q, d_1) = 0.50$) and an *s*-feature 1:0.27 for d_2 ($cosine(q, d_2) = 0.27$). If we have more similarity measures more *s*-features can be produced. The resulting two *s*-vectors for d_1 and d_2 with their class labels, 1 and -1, are as follows:

d_1: 1 1:0.50 … d_2: -1 1:0.27 …

Class 1 means "written by author of query *q*", also called *q-positive*, and class -1 means "not written by author of query *q*", also called *q-negative*.

LSS gives us a two-class classification problem. In this formulation, a test userid and his/her documents do not have to be seen in training as long as a set of known documents from this userid is available. Any supervised learning method can be used to build a classifier. We use SVM. The resulting classifier is employed to compute a score for each review to be used in the two-step algorithm above to find the candidate for each userid and then the userids with the same authors.

Due to the use of query documents, the LSS formulation has some resemblance to document ranking based on learning to rank (Li, 2011; Liu, 2011). However, LSS is very different because we turn the problem into a supervised classification problem. The key difference between learning to rank and classification is that ranking will always put some documents at the top even if the desired documents do not exist. However, classification will not return any document if the desired documents do not exist in the test data (unless there are classification errors). Our Type II experiments in Section 7 were specifically designed for testing such non-existence situations.

Using online review as the application domain, we conduct experiments on a large number of reviews and their author/reviewer userids from Amazon.com. The results show that the proposed algorithm is highly accurate and outperforms three strong baselines markedly.

2 Related Work

A similar problem was attempted in (Chen et al., 2004) in the context of open forums where users interact with each other in their discussions. Their method is based on post relationships and intervals between posts. It does not use any linguistic clues. It is thus not applicable to domains like online reviews. Reviews do not involve user interactions since each review is independent of other reviews. Novak et al. also solved the same problem under the name of "Anti-aliasing" (Novak et al., 2004). They used a clustering based method which assumed the number of actual authors is known. This is unrealistic in practice as there is no way to know which author has and does not have multiple ids.

Our work is also related to authorship attribution (AA). However, to our knowledge, our problem has not been attempted in AA. Existing works focused on two main themes: finding good writing style features, and developing effective classification methods. On finding good features (d-features in our case), it was found that the most promising features are function words (Mosteller, 1964; Argamon and Levitan, 2004; Argamon et al., 2007) and rewrite rules (Halteren et al., 1996). Length (Gamon 2004; Graham et al., 2005), richness (Halteren et al., 1996; Koppel and Schler, 2004), punctuations (Graham et al., 2005), character n-grams (Grieve, 2007; Hedegaard and Simonsen, 2011), word *n*-grams (Burrows, 1992; Sanderson and Guenter 2006), POS *n*-grams (Gamon, 2004; Hirst and Feiguina, 2007), syntactic category pairs (Narayanan et al., 2012) are also useful.

On classification, numerous methods have been tried, e.g., Bayesian analysis (Mosteller, 1964), discriminant analysis (Stamatatos et al., 2000), PCA (Hoover, 2001), neural networks (Graham et al., 2005; Zheng et al., 2006; Graham et al., 2005), clustering (Sanderson and Guenter, 2006), decision trees (Uzuner and Katz, 2005; Zhao and Zobel, 2005), regularized least squares classification (Narayanan et al., 2012), and SVM (Diederich et al., 2000; Gamon 2004; Koppel and Schler, 2004; Hedegaard and Simonsen, 2011). Among them, SVM was found to be most accurate (Li et al., 2006; Kim et al., 2011). Although we also use supervised learning, we do not learn in the original document space as these existing methods do. The transformation is important because it enables us to use documents from other authors in training. The traditional supervised learning (TSL) cannot do that. In our case, the only documents that TSL can use for training are the queries in the testing set. However, as we will see in our experiments, such a method performs poorly.

Since we use online reviews as our experiment domain, our work is related to fake review detection (Jindal and Liu, 2008) as imposters can use multiple userids to post fake reviews. Existing research has proposed many methods to detect fake reviewers (Lim et al., 2010; Wang et al., 2011; Mukherjee et al., 2012) and fake reviews (Jindal and Liu, 2008; Ott et al., 2011, 2012; Li et al., 2011; Feng et al., 2012). However, none of them identifies userids belonging to the same person.

3 Learning in the Similarity Space

We now formulate the proposed supervised learning in the similarity space (LSS), which will be used in the *candid-iden* function in our algorithm to be discussed in Section 4.

The key difference between LSS and the classic document space learning is in the document representation. Another difference is in the testing phase. We discuss testing first.

Test data: We are given:

- A query q from query author (userid) aq
- A set of test documents $DT = \{dt_1, \ldots, dt_m\}$.

Goal: classify the test documents into those authored by aq and those not authored by aq.

We note the following points:

i) This is like a retrieval scenario, but we use supervised learning to perform the task.

ii) Unlike traditional supervised classification, here the test query author aq does not have to be used in training. But we are given a query document q from aq. Clearly, in practice, we can have multiple query documents from aq, which we will discuss in Section 4.

Training document representation: As noted earlier, each document is represented with a similarity vector (*s-vector*) computed using a similarity

1. **For** each author $ar_i \in AR$
2. select a set of query documents $Q_i \subseteq DR_i$
3. **For** each query $q_{ij} \in Q_i$
// produce positive *s*-training examples
4. select a set of documents from author ar_i
$DR_{ij} \subseteq DR_i - \{q_{ij}\}$
5. **For** each document $dr_{ijk} \in DR_{ij}$
6. produce an *s*-training example for dr_{ijk},
($Sim(dr_{ijk}, q_{ij})$, 1)
// produce negative *s*-training examples
7. select a set of documents from the rest of authors
$DR_{ij,rest} \subseteq (DR_1 \cup \ldots \cup DR_n) - DR_i$
8. **For** each document $dr_{ijk,rest} \in DR_{ij,rest}$
9. produce an *s*-training example for $dr_{ijk,rest}$,
($Sim(dr_{ijk,rest}, q_{ij})$, -1)

Figure 1: Generating *s*-training examples

// Author ar_1 –
// positive (1) *s*-training examples
($Sim(dr_{111}, q_{11})$, 1), …, ($Sim(dr_{11p}, q_{11})$, 1)
…
($Sim(dr_{1k1}, q_{1k})$, 1), …, ($Sim(dr_{1kp}, q_{1k})$, 1)
// negative (-1) *s*-training examples
($Sim(dr_{111.rest}, q_{11})$, -1), …, ($Sim(dr_{11u.rest}, q_{11})$, -1)
…
($Sim(dr_{1k1.rest}, q_{1k})$, -1), …, ($Sim(dr_{1ku.rest}, q_{1k})$, -1)
…

Figure 2: *s*-training examples

function *Sim*. *Sim* takes a query document and a non-query document and produces a vector of similarity values or s-features to represent the non-query document. We present the detail below:

Let the set of training authors be $AR = \{ar_1, .., ar_n\}$. Each author ar_i has a set of documents DR_i. Each document in DR_i is first represented with a document vector (or *d*-vector). The algorithm for producing the training set, called *s-training set*, is given in Figure 1.

We randomly select a small set of queries Q_i from documents DR_i of each author ar_i (lines 1, and 2). For each query $q_{ij} \in Q_i$ (line 3), it selects a set of documents DR_{ij} also from DR_i (excluding q_{ij}) of the same author (line 4) to be the positive documents for q_{ij}, called *q-positive* and labeled 1. Then, for each document dr_{ijk} in DR_{ij}, a *q*-positive *s*-training example with the label 1 is generated for dr_{ijk} by computing the similarities of q_{ij} and dr_{ijk} using the similarity function *Sim* (lines 5, 6). In line 7, it selects a set of documents $DR_{ij,rest}$ from other authors to be the negative documents for q_{ij}, called *q*-negative and labeled -1. For each document $dr_{ijk,rest}$ in $DR_{ij,rest}$ (line 8), a *q*-negative *s*-training example with label -1 is generated for dr_{ijk} by computing the similarities of q_{ij} and $dr_{ijk,rest}$ using *Sim* (line 9). How to select Q_i, DR_{ij} and $DR_{ij,rest}$ (lines 2, 4 and 7) is left open intentionally to give flexibility in implementation.

1. **For** each document set D_i of $id_i \in ID$ **do**
2. partition D_i into two subsets:
(1) query set Q_i and (2) sample set S_i;
3. **For** each document set D_i of $id_i \in ID$ **do**
// step 1: *candidate identification*
4. id_j = candid-iden(id_i, *ID*), $i < j$;
// step 2: *candidate confirmation*
5. id_k = candid-iden(id_j, *ID*), $k \neq j$;
6. **If** $k = i$ **then** id_i and id_j are from the same author
8. **else** id_i and id_j are not from the same author

Figure 3: Identifying userids from the same authors

Function candidate-iden(id_i, *ID*)
1. **For** each sample document set S_j of $id_j \in ID$-$\{id_i\}$ **do**
2. $pcount[id_j]$, $psum[id_j]$, $psqsum[id_j]$, $max[id_j] = 0$;
3. **For** each query $q_i \in Q_i$ **do**
4. **For** each sample $s_{jf} \in S_j$ **do**
5. $ss_{jf} = <(id_i, q_i), (Sim(s_{jf}, q_i), ?)>$;
6. Classify ss_{jf} using the classifier built earlier;
7. **If** ss_{jf} is classified positive, i.e., 1 **then**
8. $pcount[id_j] = pcount[id_j] + 1$;
9. $psum[id_j] = psum[id_j] + ss_{jf}.score$
10 $psqsum[id_j] = psqsum[id_j] + (ss_{jf}.score)^2$
11. **If** $ss_{if}.score > max[id_j]$ **then**
12. $max[id_j] = sr_{jf}.score$
// Four methods to decide which id_j is the candidate for id_i
13. **If** for all $id_j \in ID$-$\{id_i\}$, $pcount[id_i] = 0$ **then**
14. $cid = \arg\max_{id_j \in ID-\{id_i\}} (\max[id_j])$
15. **Else** $cid = \arg\max_{id_j \in ID-\{id_i\}} (\frac{pcount[id_j]}{|S_j|})$ **// 1. Voting**
16. $cid = \arg\max_{id_j \in ID-\{id_i\}} (\frac{psum[id_j]}{|S_j|})$ // 2. **ScoreSum**
17. $cid = \arg\max_{id_j \in ID-\{id_i\}} (\frac{(psum[id_j])^2}{|S_j|})$ // 3. **ScoreSqSum**
18. $cid = \arg\max_{id_j \in ID-\{id_i\}} (\max[id_j])$ **// 4. ScoreMax**
19. return *cid*;

Figure 4: Identifying the candidate

This formulation gives us a two-class classification problem. The classes are 1 (*q-positive* meaning "written by author of query q_{ij}") and -1 (*q-negative* meaning "not written by author of query q_{ij}." Figure 2 shows what the *s*-training data looks like. For easy presentation, we assume that there are *k* queries in every Q_i, and *p* documents in every DR_{ij} and *u* documents in every $DR_{ij,rest}$. The number of authors is *n*. Each author ar_i generates $k \times (p+u)$ *s*-training examples. As we will see in Section 7, *k* can be very small, even 1.

Complexity: In the worst case, every document

can serve as a query or a non-query document. Then we need to compute all pairwise document similarities. If the number of training documents is m, the complexity is $O(m^2)$, which is both space and computation expensive. However, in practice, we don't need all pairwise comparisons. Only a small subset is sufficient (see Section 7).

Test document representation: Like training documents, test documents are represented as *s*-vectors as well in the similarity space.

Given a query q from author aq and a set of test documents DT, each test document dt_i is converted to a *s*-vector $sv_i = Sim(dt_i, q)$. To reflect sv_i is computed based on query q from author aq, a *s-test* case is thus represented as $<(aq, q), (sv_i, ?)>$.

Training: A binary classifier is learned using the *s*-training data. Each *s*-training example is represented with (sv, y), where sv is an *s*-vector and y ($\in \{1, -1\}$) is its class. Any supervised learning algorithm, e.g., SVM, can be applied.

Testing: The classifier is applied to each *s*-test case $<(aq, q), (sv_i, ?)>$ (where $sv_i = S(dt_i, q)$) to give it a class *q-positive* or *q-negative*. Note that the classifier is only applied on sv_i.

In most cases, classification based on a single query is inaccurate. Using multiple queries of an author can classify much more accurately.

4 Identify Userids of the Same Author

We now expand the sketch of the two-step algorithm in Section 1 based on the problem statement in Section 1. The algorithm is given in Figure 3.

Lines 1-2 partitions the documents set D_i of each id_i in $ID = \{id_1, id_2, \ldots, id_n\}$, the set of userids that we are working on. How to do the partition is flexible (see Section 7). Line 4 is the step 1 of candidate identification, and line 5 is the step2 of candidate confirmation. Lines 6-8 is the decision making of step 2 (see Section 1). Line 6 produced a classification score using the classifier described in Section 3. The key function here is *candid-iden*. Its algorithm is in Figure 4.

The *candid-iden* function takes two arguments: the query userid id_i and the whole set of userids ID. It classifies each sample ss_{jf} in sample set S_j of $id_j \in ID\text{-}\{id_i\}$ to positive (q_i-positive) or negative (q_i-negative) (lines 4, 5, 6). We then aggregate the classification results to determine which userid is likely to have the same author as id_i.

One simple aggregation method is voting. We count the total number of positive classifications of the sample documents of each userid in $ID\text{-}\{id_i\}$. The userid id_j with the highest count is the candidate *cid* which may share the same author as query id_i. *cid* is returned as the candidate.

There are also other methods, which can depend on what output value the classifier produces. Here we propose four methods including the voting method above. The other three methods requires the classifier to produces a prediction score, which reflects the positive and negative certainty. Many classification algorithms produce such a score. Here we use SVM. For each classification, SVM outputs a positive or negative score indicating the certainty that the test case is positive or negative.

To save space, all four alternative methods are given in Figure 4. Line 2 initializes some variables for recording the aggregated values for the final decision making. The four methods are as follows:

1). **Voting**: For each sample from userid id_j, if it is classified as positive, one vote/count is added to $pcount[id_j]$. The userid with the highest *pcount* is regarded as the candidate userid, *cid* (line 15). Note that the normalization is applied because the sizes of the sample sets S_j can be different for different userids. Lines 13 and 14 mean that if all documents of all userids are classified as negative ($pcount[id_j] = 0$, which also implies $psum[id_j] = psqsum[id_j] = 0$), we use method 4).

2). **ScoreSum**: This method works similarly to the voting method above except that instead of counting positive classifications, this method sums up all scores of positive classifications in $psum[id_j]$ for each userid (line 9). The decision is also made similarly (line 16).

3). **ScoreSqSum**: This method works similarly to ScoreSum above except that it sums up the squared scores of positive classifications in $psqsum[id_j]$ for each userid (line 10). The decision is also made similarly (line 17).

4). **ScoreMax**: This method works similarly to the voting method as well except that it finds the maximum classification score for the documents of each userid (lines 11 and 12). The decision is made in line 18.

5 D-features

We now compute *s*-features (similarity features)

for each non-query document based on a query document. Since *s*-features are calculated using *d*-features of a non-query document and a query document, we thus discuss *d*-features first, which are extracted from each document itself. We employ 26 *d*-features in four categories: length *d*-features, frequency based *d*-features, tf.idf based *d*-features, and richness *d*-features. Although many features below have been used in various tasks before, our key contribution is solving a new problem based on a new learning formulation (LSS).

Length d-feature: We derive three length *d*-features from each raw document: (1) *average sentence length* (in terms of word count); (2) *average word length* (in terms of character count in one word); (3) *average document length* (in terms of word count in one document).

Frequency based d-features: We extract lexical, syntactic, and stylistic tokens from the raw documents and the parsed syntactic trees to produce the following features:

- *Lexical tokens: word unigrams*
- *Syntactic tokens:* content-independent structures: POS n-grams ($1 \leq n \leq 3$) and rewrite rules (Halteren et al., 1996; Hirst and Feiguina, 2007). A rewrite rule is a combination of a node and its immediate constituents in a syntactic tree. For example, the rewrite rule for "the best book" is NP->DT+JJS+NN.
- *Common stylistic token: K*-length word ($1 \leq K \leq 15$), punctuations, and 157 function words (*www.flesl.net/Vocabulary/SinglewordLists/functionwordlist.php*).
- *Review specific stylistic tokens:* These tokens reflect styles of reviews: *all cap words*, *pairs of quotation marks*, *pairs of brackets*, *exclamatory marks*, *contractions*, *two or more consecutive non-alphanumeric characters*, *model auxiliaries* (e.g., *should*, *must*), word "*recommend*" or "*recommended*", *sentences with the first letter capitalized*, *sentences starting with This is (this is) or This was* (*this was*). We then treat these tokens as pseudo-words and count their frequency to form frequency *d*-features.

TF-IDF based d-feature: For the tokens listed in the frequency based features above, we also compute their tf.idf values. We list these two kinds of *d*-features separately because they will be used for different *s*-features later.

Richness d-features: This is a set of vocabulary richness functions used to quantify the diversity of vocabulary in text (Holmes and Forsyth, 1995). In this paper, we apply them to the counts of word unigrams, POS *n*-grams ($1 \leq n \leq 3$), and rewrite rules. Here POS *n*-grams and rewrite rules are treated as pseudo-words. Let *T* be the total number of tokens (words or pseudo-words), and *V(T)* be the number of different tokens in a document, *v* be the highest frequency of occurrence of a token, and *V(m, T)* be the number of tokens which occur *m* times in the document. We use the following six richness measures (Yule, 1944; Burrows, 1992; Halteren et al., 1996) given in Table 1: Yule's characteristic (*K*), Hapax dislegomena (*S*), Simpson's index (*D*), Honorës measure (*R*), Brunet's measure (*W*), and Hapax legomena (*H*). They give us a set of richness *d*-features about word unigrams, POS n-grams, and rewrite rules.

Table 1. Richness metrics

$K = 10^4 * \frac{\sum_{m=1}^{v} (m^2 * V(m,T) - T)}{T^2}$	$S = \frac{V(2,T)}{V(T)}$
$D = \frac{\sum_{m=1}^{v} (m*(m-1)*V(m,T))}{T*(T-1)}$	$R = \frac{100*\log(T)}{1 - V(1,T)/V(T)}$
$H = V(1,T)$	$W = T^{V(T)^{-a}}, a = 0.17$

6 S-Features

The extracted *d*-features are transformed into *s*-features, which are a set of similarity functions on two documents. We adopt five types of *s*-features.

Sim4 Length s-features: This is a set of four similarity functions defined by us. They are used for *d*-feature vectors of length. The four formulae are given in Table 2, where l_{wq}. (l_{wd}), l_{sq}. (l_{sd}), and l_{rq}. (l_{rd}) denote the average word, sentence, and document length respectively, either in query *q* or non-query document *d*. They produce four *s*-features.

Table 2. Sim4 for computing length s-features

$1/(1+\log(1+\lvert l_{wq} - l_{wd} \rvert))$
$1/(1+\log(1+\lvert l_{sq} - l_{sd} \rvert))$
$1/(1+\log(1+\lvert l_{rq} - l_{rd} \rvert))$
$\sum_{m \in \{w,s,r\}} (l_{mq} * l_{md}) / \sqrt{\sum_{m \in \{w,s,r\}} (l_{mq})^2} * \sqrt{\sum_{m \in \{w,s,r\}} (l_{md})^2}$

Sim3 Sentence s-features: This is a set of three sentence similarity functions (Metzler et al., 2005). We apply them (called Sim3) to documents. Sim3 *s*-features are used for frequency based *d*-features. The three formulae are given in Table 3, where $f(t, s)$ is the frequency count of token t in a document s, and l_q and l_d are the average document length of the query and non-query document, respectively.

Table 3. Sim3 for computing sentence s-features

$\sum_{t\in q\cap d} f(t,d)/(\sum_{t\in q} f(t,q)+\sum_{t\in d} f(t,d)-\sum_{t\in q\cap d} f(t,d))$
$\log_{t\in q\cap d}(\frac{N}{f(t,d)})*\frac{\sum_{t\in q\cap d} f(t,d)}{\sum_{t\in q} f(t,q)+\sum_{t\in d} f(t,d)-\sum_{t\in q\cap d} f(t,d)}$
$\frac{1}{1+\log(1+\lvert l_q-l_d\rvert)}*\sum_{t\in q\cap d}\frac{N*idf(t)}{1+\lvert f(t,q)-f(t,d)\rvert}$

Sim7 Retrieval s-features: This is a set of seven similarity functions (Table 4) applicable to all frequency based *d*-features. These functions were used in information retrieval (Cao et al., 2006).

Table 4. Sim7 for computing retrieval *s*-features

$\sum_{t\in q\cap d}\log(f(t,d)+1)$	$\sum_{t\in q\cap d}\log(\frac{\lvert D\rvert}{f(t,d)}+1)$
$\sum_{t\in q\cap d}\log(idf(t))$	$\sum_{t\in q\cap d}\log(\frac{f(t,d)}{\lvert d\rvert}+1)$
$\sum_{t\in q\cap d}\log(\frac{f(t,d)}{\lvert d\rvert}*idf(t)+1)$	$\log(BM25score)$
$\sum_{t\in q\cap d}\log(\frac{f(t,d)}{\lvert d\rvert}*\frac{\lvert D\rvert}{f(t,d)}+1)$	

In Table 4, $f(t, d)$ denotes the frequency count of token t in a non-query document d, q denotes the query, D is the entire collection, |.| is the size of a set, and *idf* is the inverse document frequency. These 7 formulae can produce 7 *s*-features.

SimC tf-idf s-feature: This is the *cosine* similarity used for *d*-vectors represented by the tf.idf based *d*-features. SimC tf-idf produces one *s*-feature.

SimC Richness s-feature: This is also cosine similarity. However, it is applied to the richness *d*-feature vectors, and produces one *s*-feature.

7 Experimental Evaluation

We now evaluate the proposed approach and compare it with baselines. All our experiments use the SVM^{perf} classifier (Joachims, 2006).

7.1 Experiment Setup

Experiment Data: We use a set of reviews and their authors/reviewers from Amazon.com as our experiment data. We select the authors who have posted more than 30 reviews in the book category. After cleaning, we have 831 authors, 731 authors for training and 100 authors for testing. The numbers of reviews in the training and test author set are 59256 and 14308, respectively. We use the Stanford parser (Klein and Manning, 2003) to generate the grammar structure of review sentences for extracting syntactic *d*-features. Note that the authors here are in fact userids. However, since they are randomly selected from a large number of userids, the probability that two sampled userids belong to the same person is very small. Thus, it should be safe to assume that each userid here represents a unique author.

Training data: We randomly choose 1 (one) review for each author as the query and all of his/her other reviews as *q*-positive reviews. The *q*-negative reviews consist of reviews randomly selected from the other 730 authors, two reviews per author. We also tried to use more queries from each author, but they make little difference.

Test data: The test authors are all unseen, i.e., their reviews have not been used in training. We prepare the test case for each author as follows.

We first divide the reviews of each author into two equal subsets. The purpose is to simulate the situation where there are two userids id_{ia} and id_{ib} from the same author a_i. Our objective is that given one userid id_{ia} and its query set, we want to find the other userid id_{ib} from the same author.

For the review subset of id_{ia} (or id_{ib}), we randomly select 9 reviews as the *query set* and another 10 reviews as the *sample set* for the userid. The two sets are disjoint. We don't use more queries or sample reviews from each author since in the review domain most authors do not have many reviews (Jindal and Liu, 2008). In the experiments, we will vary the number of test userids, the number of queries, and the number of samples. We use the following format to describe each test data: T<n>_Q<n>S<n>, where T denotes the total number of test userids, Q the query set and S the sample set, and <n> a number. For example, T50_Q9S10 stands for a test data with 50 userids, and for each userid, 9 reviews are selected as queries and 10 reviews are selected as samples. * rep-

resents a wildcard whose value we can vary.

Note that we use this "artificial" data rather than manually labeled data for our experiments because it is very hard to reliably label any gold-standard data manually in this case. The problem is similar to labeling fake reviews. In the fake review detection research, researchers have manually label fake reviews and reviewers (Yoo and Gretzel 2009; Lim et al., 2010; Li et al., 2011; Wang et al., 2011). However, based on the actual fake reviews written using Amazon Mechanical Turk, Ott et al. (2011) have showed that the accuracy of human labeling of fake reviews is very poor. We also believe that our test data is realistic for evaluation as we can image that the two sets of reviews are from two accounts (userids) of the same author (reviewer).

Two types of experiments: For each author with two userids, we conduct two types of tests.

- **Type I**: Identify two userids belong to the same author. The experiment runs iteratively to test every userid. In each iteration, we plant one userid of an author in the test set and use the other userid of the same author as the query userid. That is, in the i^{th} run, the test data consist of the following two components:
  1. Query userid id_{ia} and its query set Q_{ia}
  2. Test userids $\{id_{1a}, \ldots, id_{(i-1)a}, id_{ib}, \ldots, id_{ma}\}$ and their corresponding sample review sets $\{S_{1a}, \ldots, S_{(i-1)a}, S_{ib}, \ldots, S_{ma}\}$.

  Note that the query userid id_{ia} and the test userid id_{ib} are from the same author. Our objective is to use Q_{ia} to find id_{ib} through S_{ib}.

  Evaluation measure: We use precision, recall, and F_1 score to evaluate Type I experiments as we want to identify all matching pairs. The errors are "no pair" and "wrong pair" found.
- **Type II**: Type II experiments test the cases when no pair exists. That is, we do not plant any matching userid for the query userid. Then, the algorithm should not find anything. For the i^{th} run, the test data has these components:
  1. Query userid id_{ia} and its query set Q_{ia}
  2. Test userids $\{id_{1a}, \ldots, id_{(i-1)a}, id_{(i+1)a}, \ldots, id_{ma}\}$ and their sample review sets $\{S_{1a}, \ldots, S_{(i-1)a}, S_{(i+1)a}, \ldots, S_{ma}\}$. id_{ib} is not planted.

  Evaluation measure: Here we cannot use precision and recall because we are not trying to find any pairs. We thus use accuracy as our measure. For each id_i, if no pair is found, it is correct. If a pair is found, it is wrong.

Baseline methods: As mentioned eariler, there are only two works that tried to identify multi-id users. The first is that in (Chen et al., 2004). However, as we discussed in related work, their approach is not applicable to reviews. The other is that in (Novak et al., 2004), which used clustering but assumed that the number of actual authors (or clusters) is known. This is unrealistic in practice. Thus we designed three new baselines:

TSL: This baseline is based on the traditional supervised learning (TSL). We use it to evaluate how the traditional approach performs in the original feature space. In this case, each document in TSL has to be represented as a vector of d-features or traditional n-gram features. For each test userid *id*, we build a SVM classifier based on the *one vs. all* strategy. That is, for training we use *id*'s queries in T*_Q*S10 as the positive documents, and all queries of the other test userids (e.g., 99 userids if the test data has 100 userids) as the negative documents. Note that TSL cannot use the 731 userids for training as in LSS because they do not appear in the test data. In testing, userid *id*'s sample (non-query) documents in T*_Q*S10 are used as positive documents, and the sample documents of all other test userids are used as negative documents.

SimUG: It uses the word unigrams to compare the cosine similarity of queries and samples. Cosine similarity with unigrams is the most widely used document similarity measure.

SimAD: It uses all *d*-features to compare the cosine similarity of queries and samples.

For both *SimUG* and *SimAD*, their cosine similarity values are used in place of SVM scores of LSS or TSL. We then apply the same 4 strategies to decide the final author attribution except voting as cosine similarity cannot classify.

7.2 Results and analysis

1) Effects of positive/total ratio in training set: Since our data is highly skewed and too many negative cases may not be good for classification, we thus performed this experiment to find a good ratio. Table 5 shows the results for Type I experiments. From Table 5, we can see that the results are highly accurate. Even for 100 userids, our method can correctly identify 85% cases. Here we use the data sets T*_Q9S10 and the decision method is ScoreSqSum, which produces the best result. The

results for Type II experiments (Table 6) are also accurate. In most cases, the values of accuracy are higher than 90%. For all our experiments below, we use the model/classifier trained with 0.4 ratio.

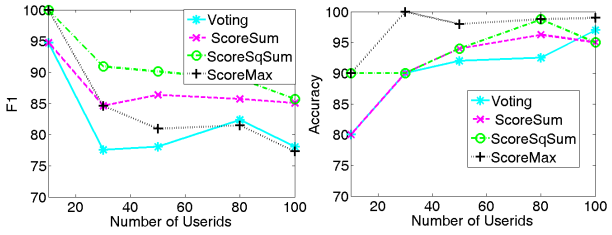
Table 5. Positive(p)/total(t) ratio in training (Type I)

	p/t	10	30	50	80	100
F1	0.3	**100.00**	84.62	86.36	**88.89**	83.72
	0.4	**100.00**	**91.91**	90.11	**88.89**	85.71
	0.5	**100.00**	90.91	**91.30**	**88.89**	87.01
	0.6	94.74	82.35	87.64	85.71	86.36
	0.7	94.74	84.62	86.36	86.53	**87.64**

Table 6. Positive(p)/total(t) ratio in training (Type II)

	p/t	10	30	50	80	100
Accuracy	0.3	90.00	90.00	92.00	97.50	94.00
	0.4	**90.00**	**90.00**	**94.00**	**98.75**	**95.00**
	0.5	80.00	86.67	94.00	97.75	95.00
	0.6	80.00	86.67	90.00	93.75	92.00
	0.7	80.00	86.67	90.00	95.00	92.00

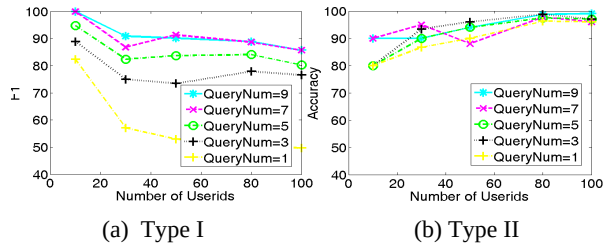
(2) Effects of different decision methods: We show the results of the four proposed decision methods: Voting, ScoreSum, ScoreSqSum, and ScoreMax, using our basic data of T*_Q9S10 with varied number of test userids. Figure 5(a) shows that ScoreSqSum is the best for Type I experiments. Figure 5(b) shows ScoreMax is the best for Type II, but ScoreSqSum also does very well. Below, ScoreSqSum is used as our default method because Type I is more important than Type II.



(a) Type I (b) Type II

Figure 5: Effect of different decision methods

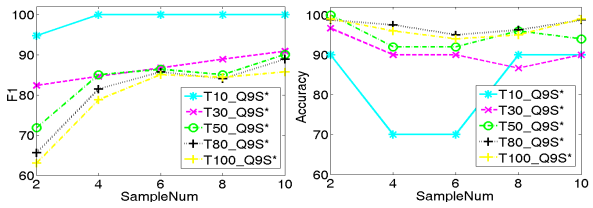
(3) Effects of number of queries per userid: Figure 6 shows the results of different numbers of queries. We see that more queries give better results, which is easy to understand because more queries give more information. We use 9 queries per userid in all other experiments.



(a) Type I (b) Type II

Figure 6: Effect of different numbers of queries

(4) Effects of number of samples per userid: We tried 2, 4, 6, 8, 10 samples per userid. Although there are some fluctuations for Type II (Fig.7(b)), we can see an upward trend for Type I in Fig. 7(a). This indicates that more sample documents give better results in general. The main reason again is that more samples from a userid give more identifying information about the userid. We use 10 test documents (samples) per userid in all experiments.



(a) Type I (b) Type II

Figure 7: Effect of different number of samples

(5) Impact of individual s-feature sets: Here we show the effectiveness of individual s-feature sets. From Table 7, we see that Sim7Retrieval s-features are extremely important for Type I test. Removing Sim7Retrieval causes about 10% to 20% F_1 score drop on different datasets. SimCTfidf s-features are also useful. The impacts of other s-features are small. The same applies to Type II test (Table 8). On average, using all features is the best. Hence we use all features in all other experiments above.

Table 7. Using different s-features (Type I)

T*_Q9S10	F1 10	F1 30	F1 50	F1 80	F1 100

No Sim4Len	90.00	93.33	96.00	96.25	96.00
No SimCRichness	90.00	90.00	94.00	96.25	96.00
No SimCTfidf	90.00	86.67	94.00	93.75	97.00
No Sim7Retrieval	80.00	90.00	94.00	94.00	96.00
No Sim3Sent	90.00	93.33	92.00	98.75	93.00

(6) Comparing with the three baselines: Similar to our method, the training data for TSL is highly skewed as it uses a *one-vs.-all* strategy. Hence we also investigate the effect of p/t ratio in training for TSL. Results show that 0.4 ratio is the best setting.

Thus this setting is adopted for TSL in the following experiments. Note that we cannot conduct p/t ratio experiments for SimAD and SimUG as they are unsupervised methods. We use ScoreMax for TSL, ScoreSqSum for SimUG and SimAD, respectively, since they perform the best for their corresponding approaches. Tables 9 and 10 show the results of our LSS method and the baseline methods for Type I and II tests respectively. For TSL, we use all *d*-features. Unigram features gave TSL much worse results and are thus not included here.

Table 9: Comparison with baselines (Type I)

		10	30	50	80	100
LSS	**Pre**	100.00	100.00	100.00	100.00	98.68
	Rec	100.00	83.33	82.00	80.00	75.76
	F1	**100.00**	**90.91**	**90.11**	**88.89**	**85.71**
TSL	**Pre**	50.00	50.00	33.33	0.00	0.00
	Rec	11.11	3.45	2.08	0.00	0.00
	F1	18.18	6.45	3.92	0.00	0.00
SimUG	**Pre**	100.00	100.00	100.00	100.00	100.00
	Rec	70.00	46.67	48.00	48.75	43.00
	F1	82.35	63.64	64.86	65.55	60.14
SimAD	**Pre**	100.00	75.00	100.00	33.33	0.00
	Rec	20.00	10.35	2.00	1.28	0.00
	F1	33.33	18.18	3.92	2.47	0.00

Table 10: Comparison with baselines (Type II)

Accuracy	**10**	**30**	**50**	**80**	**100**
LSS	90.00	90.00	94.00	98.75	95.00
TSL	90.00	96.67	98.00	98.75	99.00
SimUG	96.00	93.33	96.00	96.25	97.00
SimAD	90.00	96.67	98.00	98.75	99.00

From Tables 9 and 10, we can make the following observations.

- For Type I, F_1 scores of LSS are markedly better than those of the three baselines. The results of SimUG also drop more quickly than LSS with the increased number of userids. SimAD's results are extremely poor. These show that LSS is much more superior to the unsupervised methods. TSL performed the worst, indicating that traditional supervised learning is inappropriate for this task. There are two main reasons: First, for *one vs. all* learning, the negative training data actually contain positive documents which are written by the same author using another userid as the positive data, which confuses the classifier. Second, TSL is unable to build an accurate classifier using the small number of queries (which are training data). In contrast, our LSS method can exploit a large number of other authors who do not have to appear in testing and thus achieves the huge improvements.
- For Type II, LSS also performs very well. The baselines perform well too and even better, which is not surprising because they have difficulty in finding matching pairs for Type I. Since Type II datasets have no author with multiple userids, naturally the baselines will do well for Type II. But that is useless because when there are authors with multiple usersids (Type I), they are unable to find them well.

In summary, we can conclude that for Type I tests (there are authors with multiple userids), LSS is dramatically better than all baseline methods. For Type II tests (there is no author with multiple userids), it also performs very well.

8 Conclusion

This paper proposed a novel method to identify userids that may be from the same author. The core of the method is a supervised learning method which learns in a similarity space rather than the document space. This learning method is able to better determine whether a document may be written by a known author, although no document from the author has been used in training (as long as we have some documents from the author to serve as queries). To the best of our knowledge, there is no existing method based on linguistic analysis for solving the problem. Our experimental results based on a large number of reviewers and their reviews show that the proposed algorithm is highly accurate. It outperforms three baselines markedly.

Abstract

While much work has considered the problem of latent attribute inference for users of social media such as Twitter, little has been done on non-English-based content and users. Here, we conduct the first assessment of latent attribute inference in languages beyond English, focusing on gender inference. We find that the gender inference problem in quite diverse languages can be addressed using existing machinery. Further, accuracy gains can be made by taking language-specific features into account. We identify languages with complex orthography, such as Japanese, as difficult for existing methods, suggesting a valuable direction for future research.

1 Introduction

A 2012 study reported that US-based Twitter users now account for only 28% of all active accounts on the platform (Semiocast, 2012). Brazil, Japan, India, and Indonesia all rank in the top 10, each with over 5% of all users. These and other findings confirm that Twitter enjoys widespread international popularity and usage. This is also reflected in the multinational community of researchers who study human behavior on Twitter and related platforms, e.g. (Sakaki et al., 2010; Tumasjan et al., 2010; Kim and Park, 2012).

It is remarkable, then, that advances in latent attribute inference on social media have been largely confined to English content, e.g. (Liu and Ruths, 2013; Zamal et al., 2012; Pennacchiotti and Popescu, 2011; Conover et al., 2011a). This bias may be partially explained in the context of the research being conducted largely by anglophone researchers. Nonetheless, it has created a notable silence in the literature concerning the large-scale analysis of languages, cultures, and people on social media who do not employ English.

In this paper, we examine the problem of latent attribute inference outside the English-language context. To our knowledge, this is the first such study ever conducted. Here we specifically focus on gender inference, as it has been the basis for significant work in recent years (Liu et al., 2012; Zamal et al., 2012; Pennacchiotti and Popescu, 2011; Rao et al., 2010; Burger et al., 2011). Our work makes two contributions. First, we quantify the extent to which established gender inference methods can be used with non-English Twitter content. Second, we explore the capacity for unique features of other languages (besides English) to improve inference accuracy. This second aspect, in particular, acknowledges the fact that latent attribute inference may be easier in some languages due not to conventions in word usage, but to syntactic structure.

In order to assess the extent to which existing gender inference machinery works for users who use languages other than English, we assembled Twitter datasets for languages that are both prevalent on Twitter and representative of diverse language families: Japanese, Indonesian, Turkish, and French. Each dataset consisted of approximately 1000 users who tweeted primarily in a given language. We used Amazon Mechanical Turk to manually label each user with their gender, using a language-agnostic labeling strategy (Liu and Ruths, 2013). For classification, we employed a performant support vector machine-based (SVM) technique that has been used in a range of studies, e.g. (Rao et al., 2010; Burger et al., 2011; Zamal et al., 2012).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1136–1145,
Seattle, Washington, USA, 18-21 October 2013.

We found that, without any modification to the types of features given to the SVM, the classifier accuracy was comparable on English, French, and Indonesian. Turkish actually performed much better, achieving 87% on average. Gender in Japanese, in contrast, could not be reliably inferred with any reasonable accuracy (61% on average) despite numerous attempts to preprocess the tweets and tune the classifier to accommodate the language's complex orthography. This indicates that existing approaches may not generalize well to language systems with thousands of distinct unigrams (as opposed to tens or hundreds in the other languages considered).[1]

To evaluate the extent to which language-specific features might be used to boost the accuracy of the SVM classifier further, we focused on French. French is a valuable case study because, unlike English, it has a number of syntax-based mechanisms that can encode the gender of the speaker. The most common instantiation of gender marking is the modification of adjective and some past participle endings to match the gender of the subject in constructions beginning with "je suis" (trans. "I am") constructions. A classifier based on this insight achieved average accuracy of 90% on the vast majority of French users, surpassing the accuracy of standard techniques on English or French.

Overall, our results show that, with little modification, existing gender inference machinery can perform comparably to English on several other languages. There are clear areas for substantial improvement: incorporating language-specific features and, in the case of Japanese, finding better ways of accommodating the complex orthography. These findings identify promising directions for future research and will, hopefully, call attention to an important area in the latent attribute inference domain in need of further work.

2 Background

Non-English Twitter data mining and studies. Existing work on non-English Twitter content can been divided into two groups: surveys of the use of several languages on the platform and studies of a social phenomenon in a non-English body of tweets. To our knowledge, only a handful of the former variety exist. One recent paper characterized the relationship between language and geography (Mocanu et al., 2012). Another measured how high-level tweet features (i.e., link, mention, and hashtag frequencies) vary across languages (Weerkamp et al., 2011). These papers show that tweet structure and content can differ widely across languages.

More work has been done in the latter category: analysis of social phenomena in a non-English context. A well-known study evaluated usage of Twitter in the aftermath of the 2010 earthquake in Japan (Sakaki et al., 2010). Another Japanese-oriented study evaluated the impact of television on tweeted content (Akioka et al., 2010). Within this category, another recurring research topic is the analysis of political discussion and elections. Outside of English-based analysis, some attention has been given to European and East Asian elections, e.g. (Tumasjan et al., 2010; Giglietto, 2012; Kim and Park, 2012). However, few of these studies have considered measures beyond simple hashtag frequencies, relative mention counts among politicians, and retweet counts. The only study using more complex features for computational text analysis involved sentiment analysis of a set of German tweets (Tumasjan et al., 2010). However, the tweets in this study (conducted at a German university) were translated into English prior to analysis, a step which underscores the significant bias towards English in the literature on analyzing microtext, and the tools available to researchers in this domain.

Gender inference methods. Gender inference is a field of research situated with the broader area of latent attribute inference. The majority of recent work in this area has focused on Twitter users (Rao et al., 2010; Pennacchiotti and Popescu, 2011; Conover et al., 2011b; Burger et al., 2011; Rao and Yarowsky, 2010; Liu and Ruths, 2013; Liu et al., 2012; Zamal et al., 2012). Classifiers have been built, predominantly, using support vector machines, e.g. (Rao et al., 2010; Pennacchiotti and Popescu, 2011; Burger et al., 2011; Zamal et al., 2012), though boosted decision trees and latent dirichlet allocation systems have also been evaluated, e.g. (Pennacchiotti and Popescu, 2011; Conover et al., 2011b). With one exception, gender inference accuracy has been re-

[1] In this work, *unigram*, *bigram*, and *k-gram* refer to one, two, and k-character sequences in a language's written form.

ported between 80% and 85%. The one study which reported 90% accuracy involved the use of a dataset which has been shown to be quite different from typical anglophone Twitter users (Burger et al., 2011). This same study did involve non-English Twitter users, but did not analyze the performance of the classifier on different languages (e.g. break down performance by language, examine to what extent its results were due to better performance on some languages), or indeed discuss fully which languages were present in their sample. Thus, little can be inferred from Burger et al.'s study about the relative performance of attribute inference methods on different languages, which is the focus of our paper.

Language families. Human languages can be classified into different *language families*, defined as a set of languages which are all descended from a single, ancient parent language. Languages which are genetically related (in the same family), however distantly, tend to share many more characteristics than languages from different families.

Each language considered in this paper belongs to a different language family: French to Indo-European, Turkish to Altaic, Japanese to Japonic, and Indonesian to Austronesian. Thus, these languages are completely genetically unrelated, by definition. Further, they are both geographically and culturally dispersed. While they all have some loanwords from English, these constitute a tiny fraction of each language's vocabulary. This selection of languages allows us to conduct the most far-reaching survey of non-English latent attribute inference performance to date.

A variety of features make each language selected interesting within the gender inference context. French is noteworthy for its grammatical gender. All nouns, including people, are grammatically "male" or "female." English, in contrast, has separate pronouns for people of different genders (e.g., "he", "she"), but does not have *grammatical* gender. (Besides a handful of exceptions like "waiter"/"waitress", there are no words besides pronouns which have different "masculine" and "feminine" forms.) Indonesian, Turkish, and Japanese are all so-called *genderless languages*. Like many languages of the world, they do not have distinct male and female pronouns (like English and French), or grammatical gender (like French).

3 General Gender Inference

In order to evaluate the extent to which existing gender inference machinery can be used on users whose tweets are in languages other than English, we developed gender-labeled datasets of Twitter users for each language and then evaluated the performance of a classifier on each.

3.1 Data

The core data for this project consisted of four datasets of content from Twitter users who tweeted predominantly in one of four languages—French, Indonesian, Turkish, and Japanese—collected using the methods described below.

Data collection. In order to identify users for candidate inclusion in a particular language's (hereafter the *target language*) dataset, we walked the streaming output of the Twitter firehose and evaluated the language of each tweet using the language models provided by the Natural Language Toolkit (Bird, 2006). Users associated with tweets written in the target language were added to a list. 5000 such users were identified for each language. The latest 1000 tweets for each user were downloaded. This comprised the base for the target language dataset.

Assigning gender labels. In prior work, e.g. (Rao et al., 2010; Pennacchiotti and Popescu, 2011; Zamal et al., 2012), the dominant way of obtaining datasets consisting of Twitter users with high-confidence gender-labels is to use gender-name associations. The use of name-gender associations are problematic when non-English content is considered because databases of anglophone name-gender associations are no longer useful (Mislove et al., 2011). We instead used Amazon Mechanical Turk workers to identify the gender of the person shown in the profile picture associated with a user's account (Liu and Ruths, 2013). In our datasets, each user's profile picture was coded by 5 separate workers. Users with non-photographic or celebrity-based profile pictures was discarded, as well as any users with profile pictures where the gender could not be confidently assessed (less than 4 out of 5 votes for one gender).

Table 1 shows the final composition of each dataset. In Japanese and Indonesian, we observed

Table 1: The composition of the different language datasets used in this study.

Language	# Males	# Females	Total Size
French	437	506	943
Indonesian	977	2260	3237
Turkish	1672	1937	3609
Japanese	309	520	829

a notable difference in the number of males and females in the dataset. Measures were taken to ensure that classifier results were not biased by these differences within the datasets.

3.2 Methods

The majority of prior work in gender inference (and latent inference in general) has used support vector machines (SVMs). We followed prior work in this regard, particularly since our intent here is to evaluate the relevance of existing gender inference machinery on other languages. For the present study, we adopted an SVM-based classifier, described in (Zamal et al., 2012), that incorporated nearly all features used in prior work and showed comparable (and sometimes better) accuracy than other methods. Parameter values and kernel choices for the SVM are discussed in the source paper.

Feature set. SVM classifiers require that each object to be classified be represented by a fixed-length feature vector. The features we employed were: k-top words, k-top digrams and trigrams, k-top hashtags, k-top mentions, tweet/retweet/hashtag/link/mention frequencies, and out/in-neighborhood size. Note that "*k-top X* features" (e.g., k-top hashtags) refers to the k most discriminating items of that type for each label (i.e., Male/Female). Thus, *k-top words* is actually $2k$ features: the k words most associated with males and the k words most associated with females.

This list of features is the same set of features used in (Zamal et al., 2012), except that *k-top stems* and *k-top co-stems* were both dropped in our version. Both of these feature types are specific to English. Of course, word stems do exist in other languages, however we found that stemmers (the algorithms that identify and extract the appropriate stem from a word) were not available across the whole bank of languages. Therefore, we omitted these stem and co-stem features. We also added features for the usage frequencies of Eastern-style and Western-style emoticons but saw no discernible change in accuracy; thus, these features are not discussed further.

It is important to note that all features included in our classifier are language-agnostic. An n-gram is simply an n-character sequence drawn from the alphabet and additional symbols (numbers, punctuation, etc.) present in tweets written in the target language. Words are sequences of characters that are bounded by whitespace or punctuation. Hashtags are words proceeded by a pound ("#") character, mentions by an "@" symbol. A system that properly supports unicode strings can implement all of these notions without knowing anything about the target language it is operating on.

Tokenization of Japanese. While all the definitions provided above for the SVM features are *operational*, there is a glaring disconnect between the whitespace-border definition of a word and written conventions in Japanese. Specifically, in Japanese words are generally not separated by whitespace.

We used a tokenizer to insert whitespace into Japanese text to break up words. Tokenization was done using Kuromoji, the software Japanese morphological analyzer used and supported by the Apache software Foundation (Atilika, 2012). Notably, this tool tokenizes the mixed character sets that are often used in informal Japanese writing.

As tokenization does involves some language-specific processing, its use here somewhat undermines the objective set out for this project. Thus, we report the accuracy achieved for both untokenized and tokenized Japanese tweets. Curiously, tokenization was found to not make a difference in overall average accuracy.

3.3 Results

For each dataset, 5-fold cross validation was used to assess the classifier's performance. The value of $k = 20$ was used for all k-top features, though the results reported are robust to changes of this value within reason (between 10 and 30). If the numbers of male and female users were unbalanced in a dataset, the larger set was subsampled randomly to obtain a set of users the same size as the smaller labeled set. During the training process, the actual

Table 2: The accuracy of the SVM-based classifier on each of the language datasets. In the case of Japanese, the performance is given for both the tokenized and untokenized versions of the dataset. (Note that tokenization did not affect overall accuracy.)

Language	Male	Female	Overall
French	0.79	0.73	0.76
Indonesian	0.87	0.80	0.83
Turkish	0.89	0.85	0.87
Japanese (t)	0.50	0.76	0.63
Japanese (u)	0.58	0.68	0.63

values of the features were extracted from the training users (e.g., the k-top differentiating words for males and females were identified). In this way, the gender model implemented by the SVM *was* language-specific, in the sense that a particular language's gender model contained a different set of features. We call our method language-agnostic on the grounds that, given a labeled set of users and tweets drawn from a particular language, a model can be built without any knowledge of the structure or content of the language itself.

Tables in Supplementary Material show the features for the classifier built over each language's entire dataset. Note that to conduct the cross-fold evaluation, new models (and hence different features) were recomputed for each fold. As a result, the features reported are slightly different from those that might have appeared in the models for a given fold. Manual inspection, however, revealed that differences were slight. The features reported in the Supplementary Material can be safely considered a consensus among the models for the individual folds.

The accuracy of the classifier for each language is shown in Table 2. Overall, the classifier demonstrated good performance on all languages except for Japanese. Below, we consider the results for each of the four languages in turn. In each case we discuss language-specific trends in which words were most informative for inferring user gender, and thus help explain the classifier's performance. Throughout, we omit discussion of non-alphanumeric "words" (such as punctuation or emoticons), and call the k-top discriminating words for male and female users the *k-top male words* and *k-top female words*.

French. The k-top words for men and women are of very different grammatical types. Most male words are prepositions or articles (16/25; e.g. *de* 'of', *un* 'a/one'); a few others are basic grammatical words (*ne* '[part of] not', *et* 'and'), or pronouns or verb forms referring to a single person or object (he/she/it), as well as one noun (*France*). In contrast, many female words (11/25) are pronouns or basic verb forms referring to the speaker or a single addressee (*je* 'I', *mon/mes/ma* 'my', *tu* 'you', *j'ai* 'I have'). Others are pronouns or basic verbs refer to a single person or object (*elle*, 'she/it', *c'est* 'it's'), as well as a few other frequent words (*trop* 'too much', *pas* '[part of] not', *oui* 'yes'). The most salient pattern is that use of words (pronouns, basic verbs) associated with talking about the speaker or addressee indicates a tweet is more likely to be from a female user. Heavy use of other common function words, specifically prepositions and articles, suggests a male user. These patterns reflect known gender differences in word usage by male and female French speakers (Witsen, 1981).

Indonesian. Indonesian achieved performance closest to the inference accuracy for English reported in the literature. The k-top lists for men and women give some justification for why the classifier performed well. Some differences can be tentatively linked to general trends in how men and women use language differently across cultures. 5/25 of men's k-top words are nouns which are either related to soccer (*vs* 'versus', *chelsea* '[name of UK soccer team]', *pemain* 'player') or which could be related to soccer (*jakarta*, *indonesia*, *malam* 'night'); in contrast, no women's words are nouns. It seems plausible that men tweet about soccer significantly more than women. In such a situation, a reasonable concern is that our classifier discriminated soccer from non-soccer enthusiasts rather than males from females. To address this, we confirmed that these topic-based words were not required for accurate classification: a classifier in which soccer words were explicitly removed performed just as well (83.8% vs. 83.3%).

More interestingly, many of the k-top words correspond to men and women using different terms of address and self-reference. Among the k-top words, 7/25 for men and 4/25 for women are terms

of address or self-reference. The terms men use are mostly highly informal, including the slang term *lu* (you) and the English borrowing *bro*; the address terms women use are mostly medium-formality, such as *aku* (I) and *kamu* (you). Thus, women seem to be using "more polite" self-reference and address terms than men on average on Indonesian Twitter, in line with the more general tendency for women to use polite forms more frequently than men cross-culturally (Holmes, 1995).

Turkish. Turkish achieved notably high accuracy: the highest of all four languages considered. In fact, to our knowledge, this is the highest accuracy achieved in the entire Twitter gender inference literature on a dataset drawn from the Twitter general population. The k-top lists of male and female words again give some justification for the classifier's performance. Many differences between the male and female lists can be linked to men and women talking about different topics, or to different people. Several of the male words refer to soccer (*gol* 'goal', *galatasaray* 'popular Istanbul team', *maç* 'match', *at* '[part of imperative for] score'), which men plausibly tweet about more. As with Indonesian, a concern is that topics represent a biased sample of the population. Thus, we tested a classifier with soccer-specific terms removed, and again found no difference in accuracy (86% vs. 87%). Many other k-top words are familiar terms of address for men (*lan*, *abi*, *karde sim*, *adam*, *kanka*) or a greeting used mainly between men (*eyvallah*), suggesting that male users are addressing or discussing men more often than female users are. In contrast, 9/25 of the k-top female words are pronouns referring to the speaker, a familiar addressee, or a third party (he/she/it), while none of the k-top male words are, suggesting female users are more often talking directly about themselves or to others. Finally, 2/25 of the k-top male words are profanity (*amk*, *ulan*), while none of the female k-top words are, suggesting male users swear more.

Japanese. Beyond the Japanese classifier's generally poor accuracy, it is striking that tokenization did not improve overall accuracy. This indicates that once words were properly tokenized, no additional gender-distinguishing signal could be extracted. This may be an indication that word-based features carry little information in languages with complex orthography, such as Japanese (with many thousands of unigrams).

Despite the classifier's poor performance, the k-top discriminating words for male and female users differ in interesting ways. Some differences can be understood as resulting from known general trends in how Japanese men and women's use language. Japanese speakers have a choice of many first-person singular pronouns (equivalent to "I"), which signal different levels of politeness and of male versus female speech. The pronoun *boku* (僕) is associated with informal male speech; accordingly, it is among the k-top male words. Japanese also uses an extensive system of verb forms corresponding to different levels of politeness, and honorifics (affixes for names used when referring to others). Women tend to use polite verb forms and honorifics more frequently than men in Japanese speech (Peng, 1981). In agreement with this pattern, several polite verb forms (*-masu*, *-mashi*) and a polite honorific (*o-*) are among the k-top female words, as is a diminutive honorific often used to refer to women (*-chan*).

4 Language-specific Features and Inference

While the classifier performed well across a diverse set of languages, recall that all features used by the SVM were language-agnostic. A natural question concerns the extent to which language-specific features relevant to the attribute of interest (e.g., gender) might improve the classifier's performance.

We examine this question within the context of French. Where gender inference is concerned, French is quite interesting because information about the gender of nouns (including the speaker) is often obligatorily marked in the syntax: many words have different 'masculine' and 'feminine' forms for referring to male and female nouns, including the speaker. Thus, it is in principle often possible to infer the gender of the speaker by which form they use, although it is not clear a priori that this method will work for Twitter data.

4.1 Method

French grammar dictates that which forms of words are used often reflects the gender of the speaker.

Adjectives and past participles all have masculine and feminine forms, which are often spelled differently, and in addition often pronounced differently.Adjectives must agree in gender with the noun they refer to. For example, "I am happy" would be *je suis heureuse* for a female speaker and *je suis heureux* for a male speaker (literally "I-am-happy"); *heureuse* and *heureux* are the feminine and masculine singular forms of the adjective, and are pronounced differently. Past participles of verbs also agree with the gender of the subject or object of the verb, for certain verbs and constructions. For example, "I went" would be *je suis allée* for a female speaker and *je suis allé* for a male speaker (here *suis* is used to form the simple past of the verb *aller*, 'to go'); *allé* and *allée* are the masculine and feminine forms of the past participle of *aller*, and are pronounced the same.

Note that the phrase *je suis* ("I am") occurs in both the adjectival and verbal constructions referring to the speaker; however, the function of *suis* differs between the two. *suis* is the first-person singular form of the verb *être* ("to be"), and functions as a copula when followed by an adjective ("I am happy") but as an auxiliary verb to mark the past tense, when followed by the past participle of certain verbs ("I went"). For our purposes, what is important is that, in both cases, a following adjective or past participle will take on the gender of the speaker.

When this construction occurs in a tweet, it is likely that *je* is referring to the author of the tweet, and the rules of French grammar dictate that the gender of the associated adjective or past participle should reflect the gender of the tweet's author. We implemented a classifier that used this logic to classify the gender of francophone Twitter users. It is worth emphasizing that the *existence* of adjectives and participles which reflect the speaker's gender does not automatically make gender identification in French tweets a trivial task. First, given the prevalence of non-standard spelling and grammar on Twitter and other online platforms, French users may sometimes not use the 'correct' gender marked form reflecting their actual gender—especially given that the male and female forms for a given adjective or participle are often pronounced the same. Second, even if gender-marked constructions are used correctly, they may not occur sufficiently often in tweets to be a reliably used for speaker gender identification. Both of these concerns are borne out in our French dataset, as described further below; the question addressed in the experiment is how useful the signal provided by gender-marked forms is, despite these two sources of noise.

Table 3: The set of patterns that were considered to be suis-constructions when encountered in a tweet.

jn suis pas, jm suis, jmsuis, jnmsuis pas, jnsuis pas, je ne suis pas, je suis pas, jsuis, jensuis pas, jemsuis, jnesuis pas, jmesuis, je me suis, je ne me suis pas

Unlike the probabilistic SVM classifier, the suis-construction classifier can be made entirely deterministic. For a given user, the set of tweets containing a suis-construction are identified, $T_{suis}(u)$. Of these, we can identify the number of those tweets that involve an adjective or past participle with a female ending $T^F_{suis}(u) \subseteq T_{suis}(u)$. Labeling a user involves selecting a threshold based on $T^F_{suis}(u)$ and $T_{suis}(u)$ below which a user receives one label and above which the user receives the other label.

Detecting suis-constructions. As expected, cursory inspection of tweets revealed that Twitter users often employed shorthand forms of the suis-construction. We accounted for this by conducting a manual survey of the shorthand forms of the suis-construction. A catalog of regular expressions was drawn up that matched the different suis-construction forms we identified, shown in Table 3.

Recognizing the gender of the adjective or past participle involved in a suis-construction required a second processing stage. The Lexique lexical database was used to tag the word trailing the suis-construction (New and Landing, 2012). If the tag was not an adjective or verb, the construction was discarded as it would not contain a gender indication. If the word was recognized as an adjective or verb, Lexique would also return the gender, which would be returned as the gender indication for that particular suis-construction.

Threshold selection. We evaluated a number of policies for assigning the user's gender based on the relative values of $T^F_{suis}(u)$ and $T_{suis}(u)$. In the end, however, the best performing threshold was $T^F_{suis}(u) > 1$: simply labeling as female any user

Table 4: The component-wise and overall accuracy of the combined suis-construction and SVM classifier.

Component	# users	Male Acc	Female Acc	Overall Acc
suis-const.	723	0.91	0.90	0.90
SVM	220	0.70	0.54	0.62
Overall	943	0.86	0.82	0.83

who employed the female construction even once. This threshold makes sense given the plausible intuition that females will (almost always) be the only users to employ a female suis-construction; however, it is quite sensitive to uses of female suis-constructions by males.

Mixed classifier. Since not all users had tweets which contained suis-constructions, we combined the SVM-based classifier used previously with the suis-construction-based classifier. The SVM component was applied to any users who lacked suis-constructions entirely in their tweet history. Any user who used even one suis-construction would be labeled according to the $T^F_{suis}(u) > 1$ threshold.

4.2 Results

We ran our classifier on the French dataset, obtaining the results shown in Table 4.

Coverage of the suis-construction. In spite of our concerns over the occurrence frequency and detectability of the suis-construction in tweets, our results show that suis-constructions were found in tweets belonging to nearly 75% of all users in the dataset. This suggests that the suis-construction classifier has quite broad coverage of the population. Of course, given the essential role of the verb "être" in French (like the role of "to be" in English), its frequent use is expected. Nonetheless, the flexible use of grammar and spelling in Twitter and other online contexts raised a genuine concern that occurrences of the suis-construction might not be detected. In fact, when we looked through the tweets of users who were flagged as not having useful suis-constructions in their tweets, we discovered that many actually did. The issue was that they employed highly irregular spellings that our implementation was not able to pick up. Thus, with additional refinement, it may be possible to improve the suis-construction coverage further, well beyond 80%.

Performance of the suis-construction classifier. On the set of users for which the suis-construction was detected, the classifier did very well, achieving an average accuracy of 90%. Recall that the threshold used to generate the results in Table 4 was $T^F_{suis}(u) > 1$. We tested other (larger) thresholds and found that the performance of the method dramatically and monotonically decreased. This was largely due to female users being misclassified as males, indicating that females do not exclusively use female suis-constructions (this was confirmed via manual inspection of a number of female tweet histories). This is different from males, most of whom are quite strict about using only male suis-constructions. Since forming the female form of an adjective or participle typically requires adding an additional character (or more) to the base of the word, this may reflect a tendency towards dropping gender modifiers in favor of typing less.

Performance of the SVM classifier. While the suis-construction classifier performed well, the SVM component did not do nearly as well on the Twitter users that could not be labeled using the suis-construction, achieving an average performance of 62%. At this level of accuracy, the classifier is performing barely better than a random classifier, which would have achieved around 50% accuracy on the label-balanced testing data. This result stands in opposition to our earlier finding that French users could be labeled with 75% accuracy. This disparity suggests that the non-suis-construction users comprise a particularly difficult-to-classify group.

The suis-construction as a filter. The finding that the SVM classifier performed poorly in the combined classification setting suggests that the suis-construction classifier is acting as a very effective filter for users that are hard for it to classify. While we might have preferred better classification accuracy all around, this result is still interesting and useful. Such filters can decrease classification error by simply flagging those users who cannot be easily classified, leaving them to be handled more carefully by more powerful classifiers or human coding. This is precisely the function that the suis-construction classifier appears to play (in addition to classifying the

other users).

This result suggests a question for future work: whether it is possible to build classifiers that accurately label the sets of users that are discarded by the suis-construction classifier.

Performance of the combined classifier. Despite the relatively poor performance of the SVM component, the accuracy of the combined classifier improved on the original SVM-only classifier by 8%, which is a substantial increase in accuracy. With some additional focus on classifying the difficult users who could not be labeled by suis-construction usage, we feel that this accuracy can be increased upwards of 90%.

5 Discussion

In this project, we have extended, for the first time, the latent attribute inference problem to users who tweet primarily in languages other than English. Our study offers several notable insights.

Existing approaches generalize. While accuracy levels certainly vary across languages, overall an existing SVM-based classifier, when trained on users from a given language, can classify the gender of other users from that same language with accuracy comparable to performance reported for English. We suspect that this result will generalize to the inference of other demographic characteristics (e.g., age and political orientation), though this must be explored in future work.

Complex orthography creates unique issues. Japanese stands out as being utterly unclassifiable using existing SVM-based approaches and feature sets. Even efforts to bridge some of the orthographic disconnects between the Japanese language and the assumptions made by the SVM failed to improve performance. This stands out as a clear direction for future work, particularly since apparent issues with the large number of unigrams used by Japanese will create issues for handling (Mandarin) Chinese, the world's most-spoken language.

Language-specific features boost performance. While unsurprising that customizing a classifier to the peculiarities of a given language boosts performance, our use of the suis-construction in French highlights how particular linguistic features may be uniquely well suited to the inference of particular attributes. The results obtained for French stand in contrast to various, relatively unsuccessful attempts to boost gender inference by incorporating syntactic features of English into the classifier (e.g., using stems and co-stems). It seems that some languages have features better suited for certain classification tasks. Identifying and leveraging such features will be an interesting and fruitful direction for future work.

Classifiers as a linguist's tool. In each language, a number of the k-top words align with or suggest gender-specific conventions in that particular language. That a language-agnostic classifier provided such insights highlights its potential for exploring language-specific word usage patterns and nuances. For example, sociolinguistics (a subfield of linguistics) has long studied the different ways men and women use language, especially in spontaneous speech (Eckert and McConnell-Ginet, 2003); recent work has begun to examine how language is used differently by men and women online as well (Bamman et al., 2012). Such studies could be radically scaled up in terms of the number of languages considered using a language-agnostic gender classifier.

6 Conclusion

Though there has been relatively little investigation into latent attribute inference outside of English-language content, we consider it both a fruitful and important area for future research. Here, we have evaluated the capacity for existing inference methods to be used outside their intended English-language context. Furthermore, we have shown how language-specific features might be incorporated in order to boost classifier accuracy further. The positive results suggest that latent attribute inference in the non-English context as a research direction worthy of further attention.

Abstract

Recent investigations into grounded models of language have shown that holistic views of language and perception can provide higher performance than independent views. In this work, we improve a two-dimensional multimodal version of Latent Dirichlet Allocation (Andrews et al., 2009) in various ways. (1) We outperform text-only models in two different evaluations, and demonstrate that low-level visual features are directly compatible with the existing model. (2) We present a novel way to integrate visual features into the LDA model using unsupervised clusters of images. The clusters are directly interpretable and improve on our evaluation tasks. (3) We provide two novel ways to extend the bimodal models to support three or more modalities. We find that the three-, four-, and five-dimensional models significantly outperform models using only one or two modalities, and that nontextual modalities each provide separate, disjoint knowledge that cannot be forced into a shared, latent structure.

1 Introduction

In recent years, an increasing body of work has been devoted to multimodal or "grounded" models of language where semantic representations of words are extended to include perceptual information. The underlying hypothesis is that the meanings of words are explicitly tied to our perception and understanding of the world around us, and textual-information alone is insufficient for a complete understanding of language.

The *language grounding problem* has come in many different flavors with just as many different approaches. Some approaches apply semantic parsing, where words and sentences are mapped to logical structure meaning (Kate and Mooney, 2007). Others provide automatic mappings of natural language instructions to executable actions, such as interpreting navigation directions (Chen and Mooney, 2011) or robot commands (Tellex et al., 2011; Matuszek et al., 2012). Some efforts have tackled tasks such as automatic image caption generation (Feng and Lapata, 2010a; Ordonez et al., 2011), text illustration (Joshi et al., 2006), or automatic location identification of Twitter users (Eisenstein et al., 2010; Wing and Baldridge, 2011; Roller et al., 2012).

Another line of research approaches grounded language knowledge by augmenting distributional approaches of word meaning with perceptual information (Andrews et al., 2009; Steyvers, 2010; Feng and Lapata, 2010b; Bruni et al., 2011; Silberer and Lapata, 2012; Johns and Jones, 2012; Bruni et al., 2012a; Bruni et al., 2012b; Silberer et al., 2013). Although these approaches have differed in model definition, the general goal in this line of research has been to enhance word meaning with perceptual information in order to address one of the most common criticisms of distributional semantics: that the "meaning of words is entirely given by other words" (Bruni et al., 2012b).

In this paper, we explore various ways to integrate new perceptual information through novel computational modeling of this grounded knowledge into a multimodal distributional model of word meaning. The model we rely on was originally developed by

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1146–1157,
Seattle, Washington, USA, 18-21 October 2013.

Andrews et al. (2009) and is based on a generalization of Latent Dirichlet Allocation. This model has previously been shown to provide excellent performance on multiple tasks, including prediction of association norms, word substitution errors, semantic inferences, and word similarity (Andrews et al., 2009; Silberer and Lapata, 2012). While prior work has used the model only with feature norms and visual attributes, we show that low-level image features are directly compatible with the model and provide improved representations of word meaning. We also show how simple, unsupervised clusters of images can act as a semantically useful and qualitatively interesting set of features. Finally, we describe two ways to extend the model by incorporating three or more modalities. We find that each modality provides useful but disjoint information for describing word meaning, and that a hybrid integration of multiple modalities provides significant improvements in the representations of word meaning. We release both our code and data to the community for future research.[1]

2 Related Work

The language grounding problem has received significant attention in recent years, owed in part to the wide availability of data sets (e.g. Flickr, Von Ahn (2006)), computing power, improved computer vision models (Oliva and Torralba, 2001; Lowe, 2004; Farhadi et al., 2009; Parikh and Grauman, 2011) and neurological evidence of ties between the language, perceptual and motor systems in the brain (Pulvermüller et al., 2005; Tettamanti et al., 2005; Aziz-Zadeh et al., 2006).

Many approaches to multimodal research have succeeded by abstracting away raw perceptual information and using high-level representations instead. Some works abstract perception via the usage of symbolic logic representations (Chen et al., 2010; Chen and Mooney, 2011; Matuszek et al., 2012; Artzi and Zettlemoyer, 2013), while others choose to employ concepts elicited from psycholinguistic and cognition studies. Within the latter category, the two most common representations have been association norms, where subjects are given a cue word and name the first (or several) associated words that come to mind (e.g., Nelson et al. (2004)), and feature norms, where subjects are given a cue word and asked to describe typical properties of the cue concept (e.g., McRae et al. (2005)).

Griffiths et al. (2007) helped pave the path for cognitive-linguistic multimodal research, showing that Latent Dirichlet Allocation outperformed Latent Semantic Analysis (Deerwester et al., 1990) in the prediction of association norms. Andrews et al. (2009) furthered this work by showing that a bimodal topic model, consisting of both text and feature norms, outperformed models using only one modality on the prediction of association norms, word substitution errors, and semantic interference tasks. In a similar vein, Steyvers (2010) showed that a different feature-topic model improved predictions on a fill-in-the-blank task. Johns and Jones (2012) take an entirely different approach by showing that one can successfully infer held out feature norms from weighted mixtures based on textual similarity. Silberer and Lapata (2012) introduce a new method of multimodal integration based on Canonical Correlation Analysis, and performs a systematic comparison between their CCA-based model and others on association norm prediction, held out feature prediction, and word similarity.

As computer vision techniques have improved over the past decade, other research has begun directly using visual information in place of feature norms. The first work to do this with topic models is Feng and Lapata (2010b). They use a Bag of Visual Words (BoVW) model (Lowe, 2004) to create a bimodal vocabulary describing documents. The topic model using the bimodal vocabulary outperforms a purely textual based model in word association and word similarity prediction. Bruni et al. (2012a) show how a BoVW model may be easily combined with a distributional vector space model of language using only vector concatenation. Bruni et al. (2012b) show that the *contextual* visual words (i.e. the visual features around an object, rather than of the object itself) are even more useful at times, suggesting the plausibility of a sort of distributional hypothesis for images. More recently, Silberer et al. (2013) show that visual attribute classifiers, which have been immensely successful in object recognition (Farhadi et al., 2009), act as excellent substitutes for feature

[1] http://stephenroller.com/research/emnlp13

norms. Other work on modeling the meanings of verbs using video recognition has also begun showing great promise (Mathe et al., 2008; Regneri et al., 2013).

The Computer Vision community has also benefited greatly from efforts to unify the two modalities. To name a few examples, Rohrbach et al. (2010) and Socher et al. (2013) show how semantic information from text can be used to improve zero-shot classification (i.e., classifying never-before-seen objects), and Motwani and Mooney (2012) show that verb clusters can be used to improve activity recognition in videos.

3 Data

Our experiments use several existing and new data sets for each of our modalities. We employ a large web corpus and a large set of association norms. We also introduce two new overlapping data sets: a collection of feature norms and a collection of images for a number of German nouns.

3.1 Textual Modality

For our **Text** modality, we use deWaC, a large German web corpus created by the WaCKy group (Baroni et al., 2009) containing approximately 1.7B word tokens. We filtered the corpus by: removing words with unprintable characters or encoding troubles; removing all stopwords; removing word types with a total frequency of less than 500; and removing documents with a length shorter than 100. The resulting corpus has 1,038,883 documents consisting of 75,678 word types and 466M word tokens.

3.2 Cognitive Modalities

Association Norms (AN) is a collection of association norms collected by Schulte im Walde et al. (2012). In association norm experiments, subjects are presented with a cue word and asked to list the first few words that come to mind. With enough subjects and responses, association norms can provide a common and detailed view of the meaning components of cue words. After removing responses given only once in the entire study, the data set contains a total of 95,214 cue-response pairs for 1,012 nouns and 5,716 response types.

Feature Norms (FN) is our new collection of feature norms for a group of 569 German nouns. We present subjects on Amazon Mechanical Turk with a cue noun and ask them to give between 4 and 8 typical descriptive features of the noun. Subjects are given ten example responses; one such example is a cue of *Tisch* 'table' and a response of *hat Beine* 'has legs'. After collection, subjects who are obvious spammers or did not follow instructions are manually filtered. Responses are manually corrected for spelling mistakes and semantically normalized.[2] Finally, responses which are only given once in the study are removed. The final data set contains 11,714 cue-response pairs for 569 nouns and 2,589 response types.

Note that the difference between association norms and feature norms is subtle, but important. In AN collection, subjects simply name related words as fast as possible, while in FN collection, subjects must carefully *describe* the cue.

3.3 Visual Modalities

BilderNetle ("little ImageNet" in Swabian German) is our new data set of German noun-to-ImageNet synset mappings. ImageNet is a large-scale and widely used image database, built on top of WordNet, which maps words into groups of images, called synsets (Deng et al., 2009). Multiple synsets exist for each meaning of a word. For example, ImageNet contains two different synsets for the word *mouse*: one contains images of the animal, while the other contains images of the computer peripheral. This BilderNetle data set provides mappings from German noun types to images of the nouns via ImageNet.

Starting with a set of noun compounds and their nominal constituents von der Heide and Borgwaldt (2009), five native German speakers and one native English speaker (including the authors of this paper) work together to map German nouns to ImageNet synsets. With the assistance of a German-English dictionary, the participants annotate each word with all its possible meanings. After discussing the annotations with the German speakers, the English speaker manually map the word meanings to synset senses in ImageNet. Finally, the German speakers review samples of the images for each word to en-

[2] For brevity, we include the full details of the spammer identification, cleansing process and normalization techniques in the Supplementary Materials.

sure the pictures accurately reflect the original noun in question. Not all words or meanings are mapped to ImageNet, as there are a number of words without entries in ImageNet, but the resulting data set contains a considerable amount of polysemy. The final data set contains 2022 word-synset mappings for just 309 words. All but three of these words overlap with our data set of feature norms. After extracting sections of images using bounding boxes when available by ImageNet (and using the entire image when bounding boxes are unavailable), the data set contains 1,305,602 images.

3.3.1 Image Processing

After the collection of all the images, we extracted simple, low-level computer vision features to use as modalities in our experiments.

First, we compute a simple Bag of Visual Words (BoVW) model for our images using SURF keypoints (Bay et al., 2008). SURF is a method for selecting points-of-interest within an image. It is faster and more forgiving than the commonly known SIFT algorithm. We compute SURF keypoints for every image in our data set using SimpleCV[3] and randomly sample 1% of the keypoints. The keypoints are clustered into 5,000 visual codewords (centroids) using k-means clustering (Sculley, 2010), and images are then quantized over the 5,000 codewords. All images for a given word are summed together to provide an average representation for the word. We refer to this representation as the **SURF** modality.

While this is a standard, basic BoVW model, each individual codeword on its own may not provide a large degree of semantic information; typically a BoVW representation acts predominantly as a feature space for a classifier, and objects can only be recognize using collections of codewords. To test that similar concepts should share similar visual codewords, we cluster the BoVW representations for all our images into 500 clusters with k-means clustering, and represent each word as membership over the image clusters, forming the **SURF Clusters** modality. The number of clusters is chosen arbitrarily. Ideally, each cluster should have a common object or clear visual attribute, and words are express in terms of these visual commonalities.

[3] `http://simplecv.org`

We also compute GIST vectors (Oliva and Torralba, 2001) for every image using LearGIST (Douze et al., 2009). Unlike SURF descriptors, GIST produces a single vector representation for an image. The vector does not find points of interest in the image, but rather attempts to provide a representation for the overall "gist" of the whole image. It is frequently used in tasks like scene identification, and Deselaers and Ferrari (2011) shows that distance in GIST space correlates well with semantic distance in WordNet. After computing the GIST vectors, each textual word is represented as the centroid GIST vector of all its images, forming the **GIST** modality.

Finally, as with the SURF features, we clustered the GIST representations for our images into 500 clusters, and represented words as membership in the clusters, forming the **GIST Clusters** modality.

4 Model Definition

Our experiments are based on the multimodal extension of Latent Dirichlet Allocation developed by Andrews et al. (2009). Previously LDA has been successfully used to infer unsupervised joint topic distributions over words and feature norms together (Andrews et al., 2009; Silberer and Lapata, 2012). It has also been shown to be useful in joint inference of text with visual attributes obtained using visual classifiers (Silberer et al., 2013). These multimodal LDA models (hereafter, mLDA) have been shown to be qualitatively sensible and highly predictive of several psycholinguistic tasks (Andrews et al., 2009). However, prior work using mLDA is limited to two modalities at a time. In this section, we describe bimodal mLDA and define two methods for extending it to three or more modalities.

4.1 Latent Dirichlet Allocation

Latent Dirichlet Allocation (Blei et al., 2003), or LDA, is an unsupervised Bayesian probabilistic model of text documents. It assumes that all documents are probabilistically generated from a shared set of K common topics, where each topic is a multinomial distribution over the vocabulary (notated as β), and documents are modeled as mixtures of these shared topics (notated as θ). LDA assumes every document in the corpus is generated using the fol-

lowing generative process:

1. A document-specific topic distribution, $\theta_d \sim Dir(\alpha)$ is drawn.
2. For the ith word in the document,
   (a) A topic assignment $z_i \sim \theta_d$ is drawn,
   (b) and a word $w_i \sim \beta_{z_i}$ is drawn and observed.

The task of Latent Dirichlet Allocation is then to automatically infer the latent document distribution θ_d for each document $d \in \mathcal{D}$, and the topic distribution β_k for each of the $k = \{1, \ldots, K\}$ topics, given the data. The probability that the ith word of document d is

$$p(w_i, \theta_d) = \sum_k p(w_i|\beta_k)p(z_i = k|\theta_d).$$

4.2 Multimodal LDA

Andrews et al. (2009) extend LDA to allow for the inference of document and topic distributions in a multimodal corpus. In their model, a document consists of a set of (word, feature) pairs,[4] rather than just words, and documents are still modeled as mixtures of shared topics. Topics consist of multinomial distributions over words, β_k, but are extended to also include multinomial distributions over features, ψ_k. The generative process is amended to include these feature distributions:

1. A document-specific topic distribution, $\theta_d \sim Dir(\alpha)$ is drawn.
2. For the ith (word, feature) pair in the document,
   (a) A topic assignment $z_i \sim \theta_d$ is drawn;
   (b) a word $w_i \sim \beta_{z_i}$ is drawn;
   (c) a feature $f_i \sim \psi_{z_i}$ is drawn;
   (d) the pair (w_i, f_i) is observed.

The conditional probability of the ith pair (w_i, f_i) is updated appropriately:

$$p(w_i, f_i, \theta_d) = \sum_k p(w_i|\beta_k)p(f_i|\psi_k)p(z_i = k|\theta_d).$$

The key aspect to notice is that the observed word w_i and feature f_i are conditionally independent given the topic selection, z_i. This powerful extension allows for joint inference over both words and features, and topics become the key link between the text and feature modalities.

[4]Here, and elsewhere, *feature* and f simply refer to a token from a nontextual modality and should not be confused with the machine learning sense of *feature*.

4.3 3D Multimodal LDA

We can easily extend the bimodal LDA model to incorporate three or more modalities by simply performing inference over n-tuples instead of pairs, and still mandating that each modality is conditionally independent given the topic. We consider the ith tuple $(w_i, f_i, f'_i, \ldots)$ in document d to have a conditional probability of:

$$p(w_i, f_i, f'_i, \ldots, \theta_d) = \sum_k p(w_i|\beta_i)p(f_i|\psi_k)p(f'_i|\psi'_i)\cdots p(z_i = k|\theta_d)$$

That is, we simply take the original mLDA model of Andrews et al. (2009) and generalize it in the same way they generalize LDA. At first glance, it seems that the inference task should become more difficult as the number of modalities increases and observed tuples become sparser, but the task remains roughly the same difficulty, as all of the observed elements of a tuple are conditionally independent given the topic assignment z_i.

4.4 Hybrid Multimodal LDA

3D Multimodal LDA assumes that all modalities share the same latent topic structure, θ_d. It is possible, however, that all modalities do *not* share some latent structure, but the modalities can still combine in order to enhance word meaning. The intuition here is that language usage is guided by all information gained in all modalities, but knowledge gained from one modality may not always relate to another modality. For example, the color red and the feature "is sweet" both enhance our understanding of strawberries. However, one cannot see that strawberries are sweet, so one should not correlate the color red with the feature "is sweet."

To this end, we define Hybrid Multimodal LDA. In this setting, we perform separate, bimodal mLDA inference according to Section 4.2 for each of the different modalities, and then concatenate the topic distributions for the words. In this way, Hybrid mLDA assumes that every modality shares some latent structure with the text in the corpus, but the latent structures are not shared between non-textual modalities.

For example, to generate a hybrid model for text, feature norms and SURF, we separately perform bimodal mLDA for the text/feature norms modalities and the text/SURF modalities. This provides us with two topic-word distributions: $\beta^{FN}_{k,w}$ and $\beta^{S}_{k',w}$, and the hybrid model is simply the concatenation of the two distributions,

$$\beta^{FN\&S}_{j,w} = \begin{cases} \beta^{FN}_{j,w} & 1 \leq j \leq K^{FN}, \\ \beta^{S}_{j-K^{FN},w} & K^{FN} < j \leq K^{FN} + K^{S}, \end{cases}$$

where K^{FN} indicates the number of topics for the Feature Norm modality, and likewise for K^S.

4.5 Inference

Analytical inference of the posterior distribution of mLDA is intractable, and must be approximated. Prior work using mLDA has used Gibbs Sampling to approximate the posterior, but we found this method did not scale with larger values of K, especially when applied to the relatively large deWaC corpus.

To solve these scaling issues, we implement Online Variational Bayesian Inference (Hoffman et al., 2010; Hoffman et al., 2012) for our models. In Variational Bayesian Inference (VBI), one approximates the true posterior using simpler distributions with free variables. The free variables are then optimized in an EM-like algorithm to minimize difference between the true and approximate posteriors. Online VBI differs from normal VBI by using randomly sampled minibatches in each EM step rather than the entire data set. Online VBI easily scales and quickly converges in all of our experiments. A listing of the inference algorithm may be found in the Supplementary Materials and the source code is available as open source.

5 Experimental Setup

5.1 Generating Multimodal Corpora

In order to evaluate our algorithms, we first need to generate multimodal corpora for each of our non-textual modalities. We use the same method as Andrews et al. (2009) for generating our multimodal corpora: for each word token in the text corpus, a feature is selected stochastically from the word's feature distribution, creating a word-feature pair. Words without grounded features are all given the same *placeholder* feature, also resulting in a word-feature pair.[5] That is, for the feature norm modality, we generate (word, feature norm) pairs; for the SURF modality, we generate (word, codeword) pairs, etc. The resulting stochastically generated corpus is used in its corresponding experiments.

The 3D text-feature-association norm corpus is generated slightly differently: for each word in the original text corpus, we check the existence of multimodal features in either modality. If a word had no features, it is represented as a triple (word, placeholder$_{FN}$, placeholder$_{AN}$). If the word had only feature norms, but no associations, it is generated as (word, feature, placeholder$_{AN}$), and similarly for association norms without feature norms. In the case of words with presence in both modalities, we generate *two* triples: (word, feature, placeholder$_{AN}$) and (word, placeholder$_{FN}$, association). This allows association norms and feature norms to influence each other via the document mixtures θ, but avoids falsely labeling explicit relationships between randomly selected feature norms and associations.[6] Other 3D corpora are generated using the same general procedure.

5.2 Evaluation

We evaluate each of our models with two data sets: a set of compositionality ratings for a number of German noun-noun compounds, and the same association norm data set used as one of our training modalities in some settings.

Compositionality Ratings is a data set of compositionality ratings originally collected by von der Heide and Borgwaldt (2009). The data set consists of 450 concrete, depictable German noun compounds along with compositionality ratings with regard to their constituents. For each compound, 30 native German speakers are asked to rate how related the meaning of the compound is to each of its constituents on a scale from 1 (highly opaque; entirely noncompositional) to 7 (highly transparent; very compositional). The mean of the 30 judgments

[5] Placeholder features must be hardcoded to have equal probability over all topics to prevent all placeholder pairs from aggregating into a single topic.

[6] We did try generating the random triples without placeholders, but the generated explicit relationships are overwhelmingly detrimental in the settings we attempted.

is taken as the gold compositionality rating for each of the compound-constituent pairs. For example, *Ahornblatt* 'maple leaf' is rated highly transparent with respect to its constituents, *Ahorn* 'maple' and *Blatt* 'leaf', but *Löwenzahn* 'dandelion' is rated non-compositional with respect to its constituents, *Löwe* 'lion' and *Zahn* 'tooth'.

We use a subset of the original data, comprising of all two-part noun-noun compounds and their constituents. This data set consists of 488 compositionality ratings (244 compound-head and 244 compound-modifier ratings) for 571 words. 309 of the targets have images (the entire image data set); 563 have feature norms; and all 571 of have association norms.

In order to predict compositionality, for each compound-constituent pair $(w_{compound}, w_{constituent})$, we compute negative symmetric KL divergence between the two words' topic distributions, where symmetric KL divergence is defined as

$$sKL(w_1||w_2) = KL(w_1||w_2) + KL(w_2||w_1),$$

and KL divergence is defined as

$$KL(w_1||w_2) = \sum_k \ln\left(\frac{p(t=k|w_1)}{p(t=k|w_2)}\right) p(t=k|w_1).$$

The values of $-sKL$ for all compound-constituent word pairs are correlated with the human judgments of compositionality using Spearman's ρ, a rank-order correlation coefficient. Note that, since KL divergence is a measure of *dissimilarity*, we use *negative* symmetric KL divergence so that our ρ correlation coefficient is positive. For example, we compute both $-sKL(Ahornblatt, Ahorn)$ and $-sKL(Ahornblatt, Blatt)$, and so on for all 488 compound-constituent pairs, and then correlate these values with the human judgments.

Additionally, we also evaluate using the **Association Norms** data set described in Section 3. Since it is not sensible to evaluate association norm prediction when they are also used as training data, we omit this evaluation for this modality. Following Andrews et al. (2009), we measure association norm prediction as an average of percentile ranks. For all possible pairs of words in our vocabulary, we compute the negative symmetric KL divergence between the two words. We then compute the percentile ranks of similarity for each word pair, e.g., "cat" is more similar to "dog" than 97.3% of the rest of the vocabulary. We report the weighted mean percentile ranks for all cue-association pairs, i.e., if a cue-association is given more than once, it is counted more than once.

5.3 Model Selection and Hyperparameter Optimization

In all settings, we fix all Dirichlet priors at 0.1, use a learning rate 0.7, and use minibatch sizes of 1024 documents. We do not optimize these hyperparameters or vary them over time. The high Dirichlet priors are chosen to prevent sparsity in topic distributions, while the other parameters are selected as the best from Hoffman et al. (2010).

In order to optimize the number of topics K, we run five trials of each modality for 2000 iterations for $K = \{50, 100, 150, 200, 250\}$ (a total of 25 runs per setup). We select the value or K for each model which minimizes the average perplexity estimate over the five trials.

6 Results

6.1 Predicting Compositionality Ratings

Table 1 shows our results for each of our selected models with our compositionality evaluation. The 2D models employing feature norms and association norms do significantly better than the text-only model (two-tailed t-test). This result is consistent with other works using this model with these features (Andrews et al., 2009; Silberer and Lapata, 2012).

We also see that the SURF visual words are able to provide notable, albeit not significant, improvements over the text-only modality. This confirms that the low-level BoVW features do carry semantic information, and are useful to consider individually. The GIST vectors, on the other hand, perform almost exactly the same as the text-only model. These features, which are usually more useful for comparing overall image likeness than object likeness, do not *individually* contain semantic information useful for compositionality prediction.

The performance of the visual modalities reverses when we look at our cluster-based models. Text

combined with SURF clusters is our worst performing system, indicating our clusters of images with common visual words are actively working against us. The clusters based on GIST, on the other hand, provide a minor improvement in compositionality prediction.

All of our 3D models are better than the text-only model, but they show a performance drop relative to one or both of their comparable bimodal models. The model combining text, feature norms, and association norms is especially surprising: despite the excellent performance of each of the bimodal models, the 3D model performs significantly worse than either of its components ($p < .05$). This indicates that these modalities provide new insight into word meaning, but cannot be forced into the same latent structure.

The hybrid models show massive performance increases across the board. Indeed, our 5 modality hybrid model obtains a performance nearly twice that of the text-only model. Not only do all 6 hybrid models do significantly better than the text-only models, they show a highly significant improvement over their individual components ($p < .001$ for all 16 comparisons). Furthermore, improvements generally continue to grow significantly with each additional modality we incorporate into the hybrid model ($p < .001$ for all but the .404 to .406 comparison, which is not significant). Clearly, there is a great deal to learn from combining three, four and even five modalities, but the modalities are learning *disjoint* knowledge which cannot be forced into a shared, latent structure.

The Hybrid models are the concatenation of the corresponding Bimodal mLDA models.

6.2 Predicting Association Norms

Table 2 shows the average weighted predicted rank similarity between all cue words and associates and trials. Here we see that feature norms do not seem to be improving performance on the association norms. This is slightly unexpected, but consistent with the result that feature norms seem to provide helpful, but disjoint semantic information as association norms.

We see that the image modalities are much more useful than they are in compositionality prediction. The SURF modality does extremely well in particular, but the GIST features also provide statistically significant improvements over the text-only model. Since the SURF and GIST image features tend to capture object-likeness and scene-likeness respectively, it is possible that words which share associates are likely related through common settings and objects that appear with them. This seems to provide additional evidence of Bruni et al. (2012b)'s suggestion that something like a distributional hypothesis of images is plausible.

Once again, the clusters of images using SURF causes a dramatic drop in performance. Combined with the evidence from the compositionality assessment, this shows that the SURF clusters are actively confusing the models and not providing semantic information. GIST clusters, on the other hand, are providing a marginal improvement over the text-only model, but the result is not significant. We take a qualitative look into the GIST clusters in the next section.

Once again, we see that the 3D models are ineffective compared to their bimodal components, but the hybrid models provide at least as much information as their components. The Feature Norms and GIST Clusters hybrid model significantly improves over both components.[7] The final four-modality hybrid significantly outperforms all comparable models. As with the compositionality evaluation, we conclude that the image and and feature norm models are providing disjoint semantic information that cannot be forced into a shared latent structure, but still augment each other when combined.

7 Qualitative Analysis of Image Clusters

In all research connecting word meaning with perceptual information, it is desirable that the inferred representations be directly interpretable. One nice property of the cluster-based modalities is that we may represent each cluster as its prototypical images, and examine whether the prototypes are related to the topics.

We chose to limit our analysis to the GIST clusters for two primary reasons: first, the SURF clusters did not perform well in our evaluations, and second, preliminary investigation into the SURF clusters show that the majority of SURF clusters are nearly identical. This indicates our SURF clusters are likely hindered by poor initialization or parameter selection, and may partially explain their poor performance in evaluations.

We select our single best Text + GIST Clusters trial from the Compositionality evaluation and look at the topic distributions for words and image clusters. For each topic, we select the three clusters with the highest weight for the topic, $p(c|\psi_k)$. We extract the five images closest to the cluster centroids, and select two topics whose prototypical images are the most interesting and informative. Figure 1 shows these selected topics.

The first example topic contains almost exclusively water-related terms. The first image, extracted from the most probable cluster, does not at first seem related to water. Upon further inspection, we find that many of the water-related pictures are scenic views of lakes and mountains, often containing a cloudy sky. It seems that the GIST cluster does not tend to group images of water, but rather nature scenes that may contain water. This relationship is more obvious in the second picture, especially when one considers the water itself contains reflections of the trees and mountain.

The second topic contains time-related terms. The "@card@" term is a special token for all non-zero and non-one numbers. The second word, "Uhr", is polysemous: it can mean *clock*, an object which tells the time, or *o'clock*, as in *We meet at 2 o'clock* ("Wir treffen uns um 2 Uhr.") The three prototypical pictures are not pictures of clocks, but round, detailed objects similar to clocks. We see GIST has a preference toward clustering images based on the predominant shape of the image. Here we see the clusters of GIST images are not providing a definite semantic relationship, but an overwhelming visual one.

8 Conclusions

In this paper, we evaluated the role of low-level image features, SURF and GIST, for their compatibility with the multimodal Latent Dirichlet Allocation model of Andrews et al. (2009). We found both fea-

[7] The gain is smaller than compared to SURF Hybrid, but there is much less variance in the trials.

Most Probable Words	Translations	Prototypical Images
Wasser Schiff See Meer Meter Fluß	water ship lake sea meter river	
@card@ Uhr Freitag Sonntag Samstag Montag	(number) clock Friday Sunday Saturday Monday	
Figure 1: Example topics with prototypical images for the Text + GIST Cluster modality. The first topic shows water-related words, as well scenes which often appear with water. The second shows clock-like objects, but not clocks.

ture sets were directly compatible with multimodal LDA and provided significant gains in their ability to predict association norms over traditional text-only LDA. SURF features also provided significant gains over text-only LDA in predicting the compositionality of noun compounds.

We also showed that words may be represented in terms of membership of image clusters based on the low-level image features. Image clusters based on GIST features were qualitatively interesting, and were able to give improvements over the text-only model.

Finally, we showed two methods for extending multimodal LDA to three or more modalities: the first as a 3D model with a shared latent structure between all modalities, and the second where latent structures were inferred separately for each modality and joined together into a hybrid model. Although the 3D model was unable to compete with its bimodal components, we found the hybrid model consistently improved performance over its component modalities. We conclude that the combination of many modalities provides the best representation of word meaning, and that each nontextual modality is discovering disjoint information about word meaning that cannot be forced into a global latent structure.

Acknowledgments

We would like to thank the UT Natural Language Learning Reading Group and the anonymous EMNLP reviewers for their most helpful comments and suggestions. We would also like to thank the members of the SemRel group at IMS for their considerable help in the construction of BilderNetle.

The authors acknowledge the Texas Advanced Computing Center (TACC) for providing the grid computing resources necessary for these results. Abstract

It has recently been shown that different NLP models can be effectively combined using dual decomposition. In this paper we demonstrate that PCFG-LA parsing models are suitable for combination in this way. We experiment with the different models which result from alternative methods of extracting a grammar from a treebank (retaining or discarding function labels, left binarization versus right binarization) and achieve a labeled Parseval F-score of 92.4 on Wall Street Journal Section 23 – this represents an absolute improvement of 0.7 and an error reduction rate of 7% over a strong PCFG-LA product-model baseline. Although we experiment only with binarization and function labels in this study, there is much scope for applying this approach to other grammar extraction strategies.

1 Introduction

Because of the large amount of possibly contradictory information contained in a treebank, learning a phrase-structure-based parser implies making several choices regarding the prevalent annotations which have to be kept – or discarded – in order to guide the learning algorithm. These choices, which include whether to keep function labels and empty nodes, how to binarize the trees and whether to alter the granularity of the tagset, are often motivated empirically by parsing performance rather than by the different aspects of the language they may be able to capture.

Recently Rush et al. (2010), Martins et al. (2011) and Koo et al. (2010) have shown that Dual Decomposition or Lagrangian Relaxation is an elegant framework for combining different types of NLP tasks or for building parsers from simple *slave* processes that only check partial well-formedness. Here we propose to follow this idea, but with a different objective. We want to mix different parsers trained on different versions of a treebank each of which makes some annotation choices in order to learn more specific or richer information. We will use state-of-the-art unlexicalized probabilistic context-free grammars with latent annotations (PCFG-LA) in order to compare our approach with a strong baseline of high-quality parses. Dual Decomposition is used to mix several systems (between two and four) that may in turn be combinations of grammars, here products of PCFG-LAs (Petrov, 2010). The systems being combined make different choices with regard to i) function labels and ii) grammar binarization.

(b) Left Binarized example (c) Right Binarized example

Figure 1: Binarization with markovization

Common sense would suggest that information in the form of function labels – syntactic labels such as SBJ and PRD and semantic labels such as TMP and LOC – might help in obtaining a fine-grained analysis. On the other hand, the independence hypothe-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1158–1169,
Seattle, Washington, USA, 18-21 October 2013.

sis on which CFGs rely and on which most popular parsers are based may be too strong to learn the dependencies between functions across the parse trees. Also, the number of parameters increases with the use of function labels and this can affect the learning process.

At first glance, binarization need not be an issue, as CFGs admit a binarized form recognizing exactly the same language. But binarization can be associated with horizontal markovization and in this case the recognized language will differ. Furthermore this can impose an unwanted emphasis on what frontier information is more relevant to learning (beginning or end of constituents). In the toy example of Figure 1, the original grammar consisting of a unique rule extracted from one tree only recognizes the string `bcdef`, while the grammar learned from the left binarized and markovized tree recognizes (among others) `bcdef` and `bdcef` and the grammar learned from the right binarized and markovized tree recognizes (among others) `bcdef` and `bcedf`.

We find that i) retaining the function labels in non-terminal categories loses its negative impact on parsing as the number of grammars increases in PCFG-LA product models, ii) the function labels themselves can be recovered with near state-of-the-art-accuracy, iii) combining grammars with and without function labels using dual decomposition is beneficial, iv) combining left and right-binarized grammars using dual decomposition also leads to better trees and, v) our best results (a Parseval labeled F-score of 92.4, a Stanford labeled attachment score (LAS) of 93.0 and a penn2malt unlabeled attachment score (UAS) of 94.3 on Section 23 of the Wall Street Journal) are obtained by combining three grammars which encode different function label/binarization decisions.

The paper is organized as follows. § 2 reviews related work. § 3 presents approximate PCFG-LA parsers as linear models, while § 4 shows how we can use dual decomposition to derive an algorithm for combining these models. Experimental results are presented and discussed in § 5.

2 Related Work

Parser Model Combination It is well known that improved parsing performance can be achieved by leveraging the alternative perspectives provided by several parsing models rather than relying on just one. Examples are parser co-training (Steedman et al., 2003; Sagae and Tsujii, 2007), voting over phrase structure constituents or dependency arcs (Henderson and Brill, 1999; Sagae and Tsujii, 2007; Surdeanu and Manning, 2010), dependency parsing stacking (Nivre and McDonald, 2008), product model PCFG-LA parsing (Petrov, 2010), using dual decomposition to combine dependency and phrase structure models (Rush et al., 2010) or several non-projective dependency parsing models (Koo et al., 2010; Martins et al., 2011), and using expectation propagation, a related approach to dual decomposition, to combine lexicalized, unlexicalized and PCFG-LA models (Hall and Klein, 2012). In this last example, the models must factor in the same way: in other words, the grammars must use the same binarization scheme. In our study, we employ PCFG-LA product models with dual decomposition, and we relax the constraints on factorization, as we require only a loose coupling of the models.

Function Label Parsing Although function labels have been available in the Penn Treebank (PTB) for almost twenty years (Marcus et al., 1994), they have been to a large extent overlooked in English parsing research — most studies that report parsing results on Section 23 of the Wall Street Journal (WSJ) use parsing models that are trained on a version of the WSJ trees where the function labels have been removed. Notable exceptions are Merlo and Musillo (2005) and Gabbard et al. (2006) who each trained a parsing model on a version of the PTB with function labels intact. Gabbard et al. (2006) found that parsing accuracy was not affected by keeping the function labels. There have also been attempts to use machine learning to recover the function labels post-parsing (Blaheta and Charniak, 2000; Chrupala et al., 2007). We recover function labels as part of the parsing process, and use dual decomposition to combine parsing models with and without function labels. We are not aware of any other work that leverages the benefits of both types of models.

Grammar Binarization Matsuzaki et al. (2005) compare binarization strategies for PCFG-LA parsing, and conclude that the differences between them have a minor effect on parsing accuracy as the num-

ber of latent annotations increases beyond two. Hall and Klein (2012) are forced to use head binarization when combining their lexicalized and unlexicalized parsers. Dual decomposition allows us to combine models with different binarization schemes.

3 Approximation of PCFG-LAs as Linear Models

In this section, we explain how we can use PCFG-LAs to devise linear models suitable for the dual decomposition framework.

3.1 PCFG-LA

Let us recall that PCFG-LAs are defined as tuples $G = (\mathcal{N}, \mathcal{T}, \mathcal{H}, \mathcal{R}_\mathcal{H}, S, p)$ where:

- $\mathcal{N}$ is a set of observed non-terminals, among which S is the distinguished initial symbol,
- $\mathcal{T}$ is a set of terminals (words),
- $\mathcal{H}$ is a set of *latent annotations* or hidden states,
- $\mathcal{R}_\mathcal{H}$ is a set of annotated rules, of the form $a[h_1] \rightarrow b[h_2]\ c[h_3]$ for internal rules[1] and $a[h_1] \rightarrow w$ for lexical rules. Here $a, b, c \in \mathcal{N}$ are non-terminals, $w \in \mathcal{T}$ is a terminal and $h_1, h_2, h_3 \in \mathcal{H}$ are latent annotations. Following Cohen et al. (2012) we also define the set of skeletal rules $\mathcal{R}$, in other words, rules without hidden states, of the form $a \rightarrow b\ c$ or $a \rightarrow w$.
- $p : \mathcal{R}_\mathcal{H} \rightarrow \mathbb{R}_{\geq 0}$ defines the probabilities associated with rules conditioned on their left-hand side. Like Petrov and Klein (2007), we impose that the initial symbol S has only one latent annotation. In other words, among rules with S on the left-hand side, only those of the form $S[0] \rightarrow \gamma$ are in $\mathcal{R}_\mathcal{H}$.

With such a grammar G we can define probabilities over trees in the following way. We will consider two types of trees, annotated trees and skeletal trees. An annotated tree is a sequence of rules from $\mathcal{R}_\mathcal{H}$, while a skeletal tree is a sequence of skeletal rules from R. An annotated tree $T_\mathcal{H}$ is obtained by left-most derivation from $S[0]$. Its probability is:

$$p(T_\mathcal{H}) = \prod_{r \in T_\mathcal{H}} p(r) \tag{1}$$

We define a projection ρ from annotated trees to skeletal trees. $\rho(T_\mathcal{H})$ is a tree T isomorphic to $T_\mathcal{H}$ with the same terminal and non-terminal symbols labeling nodes, without hidden states. The probability of a skeletal tree T is a sum of the probabilities of all annotated trees that admit T as their projection.

$$p(T) = \sum_{T_\mathcal{H} \in \rho^{-1}(T)} \prod_{r \in T_\mathcal{H}} p(r) \tag{2}$$

PCFG-LA parsing amounts to, given a sequence of words, finding the most probable skeletal tree with this sequence as its yield according to a grammar G:

$$T^* = \arg\max_T \sum_{T_\mathcal{H} \in \rho^{-1}(T)} \prod_{r \in T_\mathcal{H}} p(r) \tag{3}$$

Because of this alternation of sum and products, the parsing problem is intractable. Moreover, the PCFG-LAs do not belong to the family of linear models that are assumed in the Lagrangian framework of (Rush and Collins, 2012). We now turn to approximations for the parsing problem in order to address both issues.

3.2 Variational Inference and MaxRule

Variational inference is a common technique to approximate a probability distribution p with a cruder one q, as close as possible to the original one, by minimizing the Kullback-Liebler divergence between the two – see for instance (Smith, 2011), chapter 5 for an introduction. Matsuzaki et al. (2005) showed that one can easily find such a cruder distribution for PCFG-LAs and demonstrated experimentally that this approximation gives good results. More precisely, they find a PCFG that only recognizes the input sentence where the probabilities $q(r_s)$ of the rules are set according to their marginal probabilities in the original PCFG-LA parse forest. The parameters r_s are skeletal rules with *span information*. Distribution q is defined in Figure 2.

Other approximations are possible. In particular, Petrov and Klein (2007) found that normalizing by the forest probability (in other words the inside probability of the root node) give better exper-

[1] For brevity and without loss of generality, we omit unary and n-ary rules, as PCFG-LA admit a Chomsky normal form.

$$
\begin{aligned}
score(a \to b\,c, i, j, k) &= \sum_{x,y,z \in \mathcal{H}} P_{\text{out}}^{i,k}\big(a[x]\big) \cdot p\big(\, a[x] \to b[y]\; c[z]\,\big) \cdot P_{\text{in}}^{i,j}\big(b[y]\big) \cdot P_{\text{in}}^{j,k}\big(c[z]\big) \\
norm(a \to b\,c, i, j, k) &= \sum_{x \in \mathcal{H}} P_{\text{in}}^{i,k}\big(a[x]\big) \cdot P_{\text{out}}^{i,k}\big(a[x]\big) \\
score(a \to w, i) &= \sum_{x \in \mathcal{H}} P_{\text{out}}^{i,i}\big(a[x]\big) \cdot p\big(a[x] \to w\big) \\
norm(a \to w, i) &= \sum_{x \in \mathcal{H}} P_{\text{in}}^{i,i}\big(a[x]\big) \cdot P_{\text{out}}^{i,i}\big(a[x]\big) \\
q(r_s) &= \left[\frac{score(r_s)}{norm(r_s)} \text{ (Variational Inference)}\right] \text{ or } \left[\frac{score(r_s)}{P_{\text{in}}^{0,n}\,(S[0])} \text{ (MaxRule-Product)}\right]
\end{aligned}
$$

Figure 2: Variational Inference for PCFG-LA. P_{in} and P_{out} denote inside and outside probabilities.

imental results although its interpretation as variational inference is still unclear. This approximation is called MaxRule-Product and amounts to replacing the $norm$ function (see Figure 2).

In both cases, the probability of a skeletal tree now becomes a simple product of parameters associated with anchored skeletal rules. For our purpose, the consequence is twofold:

1. The parsing problem becomes tractable by applying standard PCFG algorithms relying on dynamic programming (CKY for example).

2. Equivalent to probability, a score σ can be defined as the logarithm of the probability. The parsing problem becomes[2]:

$$
\begin{aligned}
T^* &= \arg\max_T \prod_{r_s \in T} q(r_s) \\
&= \arg\max_T \sum_{r_s \in T} \log q(r_s) \\
&= \arg\max_T \sum_{r_s \in \mathcal{F}} w_{r_s} \cdot \mathbf{1}\{r_s \in T\} \\
&= \arg\max_T \sigma(T)
\end{aligned}
$$

Thus, from a PCFG-LA we are able to define a linear model whose parameters are the log-probabilities of the rules in distribution q.

[2]We denote the parse forest of a sentence by $\mathcal{F}$ and the characteristic function of a set by $\mathbf{1}$.

3.3 Products of PCFG-LAs

Although PCFG-LA training is beyond the scope of this paper, it is worthwhile mentioning that the most common way to learn their parameters relies on Expectation-Maximization which is not guaranteed to find the optimal estimation. Fortunately, this can be partly overcome by combining grammars that only differ on the initial parameterization of the EM algorithm. The probability of a skeletal tree is the product of the probabilities assigned by each single grammar G_i.

$$
T^* = \arg\max_T \prod_{i=1}^{n} q_{G_i}(T) \tag{4}
$$

Since grammars only differ by their numerical parameters (i.e. skeletal rules are the same), inference can be efficiently implemented using dynamic programming (Petrov, 2010).

Scoring with n such grammars now becomes:

$$
\begin{aligned}
T^* &= \arg\max_T \sum_{i=1}^{n} \sum_{r \in T} \log q_{G_i}(r) &(5)\\
&= \arg\max_T \sum_{r \in T} \sum_{i=1}^{n} \log q_{G_i}(r) &(6)
\end{aligned}
$$

The distributions q_{G_i} still have to be computed independently – and possibly in parallel – but the final decoding can be performed jointly. This is still a linear model for PCFG-LA parsing, but restricted to grammars that share the same skeletal rules.

4 Dual Decomposition

In this section, we show how we derive an algorithm to work out the best parse according to a set of n grammars that do not share the exact same skeletal rules. As such, the grammars' product cannot be easily conducted inside the parser to produce and score a same and unique best tree, and we now consider a *c(ompound)-parse* as a tuple $(T_1 \dots T_n)$ of n *compatible* trees. Each grammar G_i is responsible for scoring tree T_i, and we seek to obtain the *c-parse* that maximizes the sum of the scores of its different trees. For a *c-parse* to be consistent, we have to precisely define the parts on which the trees must agree to be compatible with each other, so that we can model these as agreement constraints.

4.1 Compound Parse Consistency

Let us suppose we have a set of phrase-structure parsers trained on different versions of the same treebank. Hence, some elements in the charts will either be the same or can be mapped to each other provided an equivalence relation and we define consensus between parsers on these elements.

When the grammar is not functionally annotated, phrase-structure trees can be decomposed into a set of anchored (syntactical) categories X_s, asserting that a category X is in the tree at position[3] s. Thus, such a tree T can be described by means of a boolean vector $z(T)$ indexed by anchored labels X_s, where $z(T)_{X_s} = 1$ if X_s is in T and 0 otherwise.

We will differentiate the set of *natural* non-terminals that occur in the treebanks from the set of *artificial* non-terminals that do not occur in the treebank and are the results of a binarization with markovization. As these artificial non-terminals disappear after reversing binarization in solution trees, they do not play any role in the consensus between parsers, and we only consider natural non-terminals in the set of anchored labels.

When the grammar is functionally annotated, each label $\bar{X}$ in a tree is a pair (X, F), where X is a syntactical category and F is a function label. In this case, in order to manage the consensus with non-functional grammars, we decompose such a tree into two sets: a set of anchored categories X_s and a set of anchored function labels F_s. Thus, a tree T can be described by means of two boolean vectors:

- $z(T)$ indexed by anchored categories X_s, $z(T)_{X_s} = 1$ if there exists a function label F so that $(X, F)_s$ is in T, and 0 otherwise;
- $\zeta(T)$ indexed by anchored function labels F_s, $\zeta(T)_{F_s} = 1$ if there exists a category X so that $(X, F)_s$ is in T, and 0 otherwise.

In the present work, a compound parse $(T_1 \dots T_n)$ is said to be consistent iff every tree shares the same set of *anchored categories*, i.e. iff:

$$\forall (i,j) \in [\![1,n]\!]^2,\ z(T_i) = z(T_j)$$

4.2 Combining Parsers through Dual Decomposition

Like previous applications, we base our reasoning on the assumption that computing the optimal score with each grammar G_i can be efficiently calculated, which is the case for approximate PCFG-LA parsing. We follow the presentation of the decomposition from (Martins et al., 2011) to explain how we can combine several PCFG-LA parsers together.

For a sentence s, we want to obtain the best consistent compound parse from a set of n parsers:

$$(P): \quad \textit{find} \quad \arg\max_{(T_1 \dots T_n) \in \mathcal{C}} \sum_{p=1}^{n} \sigma_p(T_p) \tag{7}$$

$$\textit{s.t.} \ \forall (i,j) \in [\![1,n]\!]^2,\ z(T_i) = z(T_j) \tag{8}$$

where $\mathcal{C} = \mathcal{F}_1(s) \times \dots \times \mathcal{F}_n(s)$ is the product of parse forests $\mathcal{F}_i(s)$, and $\mathcal{F}_i(s)$ is the set of trees in grammar G_i whose yields are the input sentence s.

Solving this problem with an exact algorithm is intractable. While artificial nodes could be inferred using a traditional parsing algorithm based on dynamic programming (i.e. CKY), the natural nodes require a coupling of the parsers' items to enforce the fact that natural daughter nodes must be identical (or equivalent) with the same spans for all parsers. Since the debinarization of markovized rules enables the creation of arbitrarily long n-ary rules, in the worst case the number of natural daughters to check is exponential in the size of the span to infer. Even if

[3] The anchor s of a label is composed of the span (i, j), denoting that the label covers terminals of the input sentence from index i to index j. In case the grammar contains unary non-lexical rules, the anchor also discriminates the different positions in a sequence of unary rules.

we bound the length of debinarized rules, the problem is hardly tractable.

As this problem is intractable, even for approximate PCFG-LA parsing, we apply the iterate method presented in (Komodakis et al., 2007) for MRFs, also applied for joint tasks in NLP such as combined parsing and POS tagging in (Rush et al., 2010).

First, we introduce a *witness* vector u in order to simplify constraints in (8). Problem (P) can then be written in an equivalent form :

$$(P): \quad \textit{find} \quad o_P = \max_{(T_1 \dots T_n) \in \mathcal{C}} \sum_{i=1}^{n} \sigma_i(T_i) \tag{9}$$

$$\textit{s.t.} \quad \forall i \in [\![1, n]\!],\ z(T_i) = u \tag{10}$$

Next, we proceed to a Lagrangian decomposition. This decomposition is a two-step process:

Step 1 (Relaxation): the coupling constraints (10) are removed by introducing a vector of Lagrange multipliers $\Lambda_i = (\lambda_{i,X_s})_{X_s}$ for each parser i, indexed by anchored categories X_s, and writing the equivalent problem:

$$(RP): \quad \mathrm{o}_{RP} = \max_{u, T_{1\dots n}} \min_{\Lambda} f(u, T_{1\dots n}, \Lambda)$$

where:

$$f(u, T_{1\dots n}, \Lambda) = \sum_i \sigma_i(T_i) + \sum_i (z(T_i) - u) \cdot \Lambda_i$$

Intuitively, we can see the equivalence of (RP) and (P) with the following reasoning:

- whenever all constraints (10) are met, the second sum in f is nullified and $f(u, T_{1\dots n}, \Lambda) = \sum_i \sigma_i(T_i)$, which is a finite value and precisely the objective function maximized in (P);
- if there is at least one (i, X, s) such that $z(T_i)_{X_s} \neq u_{X_s}$, then the value of $\sum_i (z(T_i) - u) \cdot \Lambda_i$ can be made arbitrarily small by an appropriate choice of λ_{i,X_s}; in this case, $\min_\Lambda f(u, T_{1\dots n}, \Lambda) = -\infty$. Thus, (RP) can not reach its maximum at a point where constraints (10) are not satisfied.

Step 2 (dualization): the dual problem (LP) is obtained by permuting $\max$ and $\min$ in (RP):

$$(LP1): \quad \mathrm{o}_{LP} = \min_{\Lambda} \max_{u, T_{1\dots n}} f(u, T_{1\dots n}, \Lambda)$$

Finally, u can be removed from $(LP1)$ by adding the constraint: $\sum_i \Lambda_i = 0$. As a matter of fact, one can see that if this constraint is not matched, $\max_{u, T_{1\dots n}} f(u, T_{1\dots n}, \Lambda) = +\infty$ and $(LP1)$ can not reach its minimum on such a point. We can now find the maximum of f by maxing each T_i independently of each other. The dual problem becomes:

$$(LP): \quad \mathrm{o}_{LP} = \min_{\Lambda} \sum_{i=1}^{n} \max_{T_i \in \mathcal{F}_i} (\sigma_i(T_i) + z(T_i) \cdot \Lambda_i)$$

$$s.t. \quad \sum_i \Lambda_i = 0$$

Minimization in (LP) can be solved iteratively using the projected subgradient method. Finding a subgradient amounts to computing the optimal solution (Rush and Collins, 2012) for each of the n subproblems (the *slave* problems in the terminology of (Martins et al., 2011) and (Komodakis et al., 2007)) which can be done efficiently, by incorporating the calculation of the penalties in the parsing algorithm, and in parallel. Until the agreement constraints are met (or a maximal number of iterations τ), the Lagrangian multipliers are updated according to the deviations from the average solutions (i.e. updates are zeros for a natural span if the parsers agree on it). This leads to Algorithm 1.

It should be noted that the DP charts are built and pruned during the first iteration only ($t = 0$); further iterations do not require recreating the DP chart, which is memory intensive and time consuming, nor recomputing the approximate distribution for variational inference. As DP on the pruned charts is a fast process, the bottleneck of the algorithm still is in the first calculation of slave solutions.

The stepsize sequence $(\alpha_t)_{0 \leq t}$ must be diminishing and non-summable, that is to say: $\forall t, \alpha_t \geq 0$, $\lim_{t \to \infty} \alpha_t = 0$ and $\sum_{t=0}^{\infty} \alpha_t = \infty$. In practice, we set $\alpha_t = \frac{1}{1 + c(t)}$ where $c(t)$ is the number of times the objective function o_P has increased since iterations began.

Solving $(\mathbf{P})$: it is easy to see that o_{LP} is an upper bound of o_P, but we do not necessarily have

Algorithm 1 Find best compound parse with constraints on natural spans

Require: n parsers $\{p_i\}_{1 \leq i \leq n}$
  for all i, syntactical category X, anchor s **do**
    $\lambda^{(0)}_{i,X_s} = 0$
  end for
  for $t = 0 \rightarrow \tau$ **do**
    for all parsers p_i **do**
    $T_i^{(t)} \leftarrow \arg\max_{T \in \mathcal{F}_i} \left(\sigma_i(T) + z(T) \cdot \Lambda_i^{(t)}\right)$
    end for
    for all parsers p_i **do**
      $\Delta_i^{(t)} \leftarrow \alpha_t \left(z\left(T_i^{(t)}\right) - \frac{\sum_{1 \leq j \leq n} z\left(T_j^{(t)}\right)}{n} \right)$
      $\Lambda_i^{(t+1)} \leftarrow \Lambda_i^{(t)} + \Delta_i^{(t)}$
    end for
    if $\Delta_i^{(t)} = 0$ for all i **then**
      Exit loop
    end if
  end for
  return $(T_1^{(\tau)}, \cdots, T_n^{(\tau)})$

strong duality (i.e. $o_{LP} = o_P$) due to the facts that parse forests are discrete sets. Furthermore, they get pruned independently of each other. Thus, the algorithm is not guaranteed to find a t such that $z(T_i^{(t)})$ is the same for every parser i. However – see (Koo et al., 2010) – if it does reach such a state, then we have the guarantee of having found an exact solution of the primal problem (P). We show in the experiments that this occurs very frequently.

5 Experiments

5.1 Experimental Setup

We perform our experiments on the WSJ sections of the PTB with the usual split: sections 2 to 21 for training, section 23 for testing, and we run benchmarks on section 22. `evalb` is used for evaluation.

We use the LORG parser modified with Algorithm 1. [4] All grammars are trained using 6 split/merge EM cycles. For the handling of unknown words, we removed all words occurring once in the training set and replaced them by their morphological signature (Attia et al., 2010). Grammars for products are obtained by training with 16 random seeds for each setting. We use the approximate algorithm MaxRule-Product (Petrov and Klein, 2007).

The basic settings are a combination of the two following parameters:

left or right binarization: we conjecture that this affects the quality of the parsers by impacting the recognition of left and right constituent frontiers. We set vertical markovization to 1 (no parent annotation) and horizontal markovization to 0 (we drop all left/right annotations).

with or without functional annotations: in particular when non-terminals are annotated with multiple functions, all are kept.

5.2 Products of Grammars

We first evaluate each setting on its own before combining them. We test the 4 different settings on the development set, using a single grammar or a product of n grammars. Results are reported on Figure 3. We can see that right binarization performs better than left binarization. Contrary to the results of Gabbard et al. (2006), function labels are detrimental for parsing performance for one grammar only. However, they do not penalize performance when using the product model with 8 grammars or more.

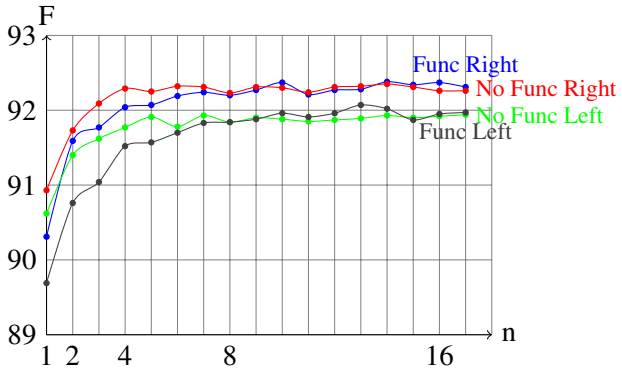

Figure 3: F1 for products of n grammars on the dev. set

EM is not guaranteed to find the optimal model and the problem is made harder by the increased number of parameters. Product models effectively alleviate this *curse of dimensionality* by letting some models compensate for the errors made by others.

On the other hand, as differences between left and right binarization settings remain over all product sizes, right binarization seems more useful on its own. The first part of Table 1 gives F-score and

[4] The LORG parser is available at `https://github.com/CNGLdlab/LORG-Release` and the modification at `https://github.com/jihelhere/LORG-Release/tree/functional_c11`.

Exact Match results of the product models with 16 grammars on the development set.

5.3 Combinations with Dual Decomposition

We now turn to a series of experiments combining product models of 16 grammars. In all these experiments, we set the maximum number of iterations in Algorithm 1 to 1000. The system then returns the first element of the c-parse. We first try to combine two settings in four different combinations:

DD Right Bin the two right-binarized systems – with and without functions – the system returns the function-labeled parse;

DD Left Bin the two left-binarized systems – with and without functions – the system returns the function-labeled parse;

DD Func the two systems with functions – left and right binarization – the system returns the right-binarized parse;

DD No Func the two systems without functions – left and right binarization – the system returns the right-binarized parse;

Results are in the second part of Table 1. Unsurprisingly, the best configuration is the one combining the two best product systems (with right binarization) but all combined systems perform better than their single components.

Setting	F	EX
No Func Right	92.26	42.97
No Func Left	91.92	42.91
Func Right	92.37	43.35
Func Left	91.95	43.15
DD Right Bin	92.71	44.44
DD Left Bin	92.23	43.97
DD Func	92.51	44.79
DD No Func	92.52	44.08
DD3	92.86	45.03
DD4	92.82	45.14

Table 1: Parse evaluation on development set.

We also combine 3 and 4 parsers to see if combining the above **DD Right Bin** setting with information that could improve the recognition of beginning of constituents can be helpful. We have 2 settings:

DD3 The 2 right-binarized parsers combined with the left binarized parser without functions,

DD4 The 4 parsers together.

In both cases the system returns the right-binarized function annotated parse. The results are shown in the last part of Table 1. These 2 new configurations give similar F-scores, better than all 2-parser configurations.

We conclude from these results that left-binarization and right-binarization capture different linguistic aspects, even in the case of heavy horizontal markovization, and that the method we propose enables a practical integration of these models.

Table 2 shows for each setting how often the systems agree before 1000 iterations of Algorithm 1. As one might expect, the more diverse the systems are, the lower the rate of agreement.

Setting	Rate
DD Right Bin	99.24
DD Left Bin	99.12
DD Func	98.53
DD No Func	99.12
DD3	96.18
DD4	94.53

Table 2: Rate of certificates of optimality on the dev set.

5.4 Evaluation of Function Labeling

We also evaluate the quality of the function labels. We compare the results obtained directly from the parser output with results obtained with Funtag, a state-of-the-art functional tagger that is applied on parser output, using a *gold model* trained on sections 02 to 21 of the WSJ (Chrupala et al., 2007).

Setting	SYSTEM FUN	FUNTAG
No Func Right	–	90.41
No Func Left	–	90.26
Func Right	89.61	90.37
Func Left	89.29	90.40
DD Right Bin	89.50	90.38
DD Left Bin	89.11	90.31
DD Func	89.54	90.49
DD No Func	–	90.36
DD3	89.48	90.42
DD4	89.57	90.45

Table 3: Function labeling F1 on development set.

The results are shown in Table 3. First, we can see that the parser output is always outperformed by Funtag. This is expected from a context-free parser

that has a limited domain of locality with strong independence constraints, compared to a voted-SVM classifier that can rely on arbitrarily rich features. Second, the quality of the Funtag prediction seems to be influenced by the fact that parser already handle functions and by the accuracy of the parser (Parseval F-score). This is because we use a model trained on the gold reference and so the closer the parser output is from the reference, the better the prediction. On the other hand, this is not the case with parser predicted functions, where the best system is the right-binarized product model with functions, with very similar performance obtained by the combinations consisting of 2 function parsers, settings **DD Func** and **DD4**. This tends to indicate that the constraints we have set to define consistencies in c-parses, focusing on syntactical categories, do not help in retrieving better function labels. This suggests some possible further improvements where parsers with functional annotations should be forced to agree on these too.

5.5 Evaluation of Dependencies

Setting	Stanford		LTH		p2m
	LAS	UAS	LAS	UAS	UAS
Func Right	92.18	94.32	89.51	93.92	94.2
No Func Right	92.03	94.47	65.31	92.22	94.2
Func Left	91.86	94.06	89.28	93.75	93.9
No Func Left	91.83	94.29	65.33	92.18	94.1
DD Right Bin	92.56	94.60	89.81	94.17	94.5
DD Left Bin	92.01	94.38	89.62	94.05	94.2
DD Func	92.19	94.36	89.67	94.06	94.2
DD No Func	92.19	94.57	65.44	92.37	94.3
DD3	92.77	94.79	90.04	94.33	94.5
DD4	92.59	94.62	89.95	94.24	94.4

Table 4: Dependency accuracies on the dev set

Dependency-based evaluation of phrase structure parser output has been used in recent years to provide a more rounded view on parser performance and to compare with direct dependency parsers (Cer et al., 2010; Petrov et al., 2010; Nivre et al., 2010; Foster et al., 2011; Petrov and McDonald, 2012). We evaluate our various parsing models on their ability to recover three types of dependencies: basic Stanford dependencies (de Marneffe and Manning, 2008)[5], LTH dependencies (Johansson and Nugues, 2007)[6] and *penn2malt* dependencies.[7] The latter are a simpler version of the LTH dependencies but are still used when reporting unlabeled attachment scores for dependency parsing.

The results, shown in Table 4, mirror the constituency evaluation results in that the dual decomposition results tend to outperform the basic product model results, and combining three or four grammars using dual decomposition yields the highest scores. The differences between the **Func** and **No Func** results highlight an important difference between the Stanford and LTH dependency schemes. The tool used to produce Stanford dependencies has been designed to work with phrase structure trees that do not contain function labels. In contrast, the LTH tool makes use of function label information in phrase structure trees. Thus, their availability results in only a moderate improvement in LAS for the Stanford dependencies and a very striking improvement for the LTH dependencies. By retaining function labels during parsing, we have shown that LTH dependencies can be recovered with a high level of accuracy without having to resort to a post-parsing function labeling step.

5.6 Test Set Results

We now evaluate our various systems on the test set (the first half of Table 5) and compare these results with state-of-the-art systems (the second half of Table 5). We present parser accuracy results, measured using Parseval F-score and *penn2malt* UAS, and, for our systems, function label accuracy for labels produced during parsing and after parsing using Funtag. We also carried out statistical significance testing[8] on the F-score differences between our various systems on the development and test sets. The results

[5]We used the latest version at the time of writing, i.e. 3.20.

[6]`nlp.cs.lth.se/software/treebank_converter`. It is recommended that LTH is used with the version of the Penn Treebank which contains the more detailed NP bracketing provided by Vadas and Curran (2007). However, to facilitate comparison with other parsers and dependency schemes, we did not use it in our experiments. We ran the converter with the *rightBranching=false* option to indicate that we are using the version without extra noun phrase bracketing.

[7]`stp.lingfil.uu.se/~nivre/research/Penn2Malt`. The English head-finding rules of Yamada and Matsumoto (2003), supplied on the website, are employed.

[8]We used Dan Bikel's `compare.pl` script which uses stratified shuffling to compute significance. We consider a p value < 0.05 to indicate a statistically significant difference.

Setting	F	UAS	Fun	Funtag
Func Right	91.73	93.9	91.02	91.88

Table 6: Statistical Significance Testing

We measured the performance of DD4 on the test set. It is approximately 3 times slower than the slowest product model (left binarization with function labels) and 7 slower than the fastest one (right binarization without function labels). This system performs on average 85.5 iterations of the DD algorithm. If we exclude the non-converging cases (5.1% of the cases), this drops to 39.4.

Finally we compare our results with systems trained and evaluated on the PTB, see the lower half of Table 5. Our product models are not different from those presented in (Petrov, 2010) and it is not surprising to see that the F-scores are similar. More interestingly our DD4 setting improves on these results and compares favorably with systems relying on richer syntactic information, such as the discriminative parser of (Huang, 2008) that makes use of non-local features to score trees and the TSG parser of (Shindo et al., 2012) that can take into account larger tree fragments: this would indicate that by combining our parsers we extend the domain of locality, horizontally with binarization schemes and vertically with function labels. Our system also performs better than the combination system presented in (Zhang et al., 2009) that only relies on material from the PTB[9] but a more detailed comparison is difficult: this system does not use products of latent models and more generally their method is orthogonal to ours. We also include for comparison state-of-the-art dependency parsing results (Bohnet and Nivre, 2012).

6 Conclusion

We presented an algorithm and a set of experiments showing that grammar extraction strategies can be combined in an elegant way and give state-of-the-art results when applied to high-quality phrase-based parsers. As well as repeating these experiments for languages which rely more on function annotation, we also plan to apply our method to other types of annotations, e.g. more linguistically motivated binarization strategies or – of particular interest to us – annotation of empty elements.

Acknowledgments

We are grateful to the reviewers for their helpful comments. We also thank Joachim Wagner for providing feedback on an early version of the paper. This work has been partially funded by the Labex EFL (ANR/CGI).

[9] Their other system relying on the self-trained version of the BLLIP parser achieves 92.6 F1.

Abstract

NLP models have many and sparse features, and regularization is key for balancing model overfitting versus underfitting. A recently repopularized form of regularization is to generate fake training data by repeatedly adding noise to real data. We reinterpret this noising as an explicit regularizer, and approximate it with a second-order formula that can be used during training without actually generating fake data. We show how to apply this method to structured prediction using multinomial logistic regression and linear-chain CRFs. We tackle the key challenge of developing a dynamic program to compute the gradient of the regularizer efficiently. The regularizer is a sum over inputs, so we can estimate it more accurately via a semi-supervised or transductive extension. Applied to text classification and NER, our method provides a $>1\%$ absolute performance gain over use of standard L_2 regularization.

1 Introduction

NLP models often have millions of mainly sparsely attested features. As a result, balancing overfitting versus underfitting through good weight regularization remains a key issue for achieving optimal performance. Traditionally, L_2 or L_1 regularization is employed, but these simple types of regularization penalize all features in a uniform way without taking into account the properties of the actual model.

An alternative approach to regularization is to generate fake training data by adding random noise to the input features of the original training data. Intuitively, this can be thought of as simulating missing features, whether due to typos or use of a previously unseen synonym. The effectiveness of this technique is well-known in machine learning (Abu-Mostafa, 1990; Burges and Schölkopf, 1997; Simard et al., 2000; Rifai et al., 2011a; van der Maaten et al., 2013), but working directly with many corrupted copies of a dataset can be computationally prohibitive. Fortunately, feature noising ideas often lead to tractable deterministic objectives that can be optimized directly. Sometimes, training with corrupted features reduces to a special form of regularization (Matsuoka, 1992; Bishop, 1995; Rifai et al., 2011b; Wager et al., 2013). For example, Bishop (1995) showed that training with features that have been corrupted with additive Gaussian noise is equivalent to a form of L_2 regularization in the low noise limit. In other cases it is possible to develop a new objective function by marginalizing over the artificial noise (Wang and Manning, 2013; van der Maaten et al., 2013).

The central contribution of this paper is to show how to efficiently simulate training with artificially noised features in the context of log-linear structured prediction, without actually having to generate noised data. We focus on dropout noise (Hinton et al., 2012), a recently popularized form of artificial feature noise where a random subset of features is omitted independently for each training example. Dropout and its variants have been shown to outperform L_2 regularization on various tasks (Hinton et al., 2012; Wang and Manning, 2013; Wan et al., 2013). Dropout is is similar in spirit to feature bagging in the deliberate removal of features, but performs the removal in a preset way rather than randomly (Bryll et al., 2003; Sutton et al., 2005; Smith et al., 2005).

*Both authors contributed equally to the paper

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1170–1179,
Seattle, Washington, USA, 18-21 October 2013.

Our approach is based on a second-order approximation to feature noising developed among others by Bishop (1995) and Wager et al. (2013), which allows us to convert dropout noise into a form of adaptive regularization. This method is suitable for structured prediction in log-linear models where second derivatives are computable. In particular, it can be used for multiclass classification with maximum entropy models (a.k.a., softmax or multinomial logistic regression) and for the sequence models that are ubiquitous in NLP, via linear chain Conditional Random Fields (CRFs).

For linear chain CRFs, we additionally show how we can use a noising scheme that takes advantage of the clique structure so that the resulting noising regularizer can be computed in terms of the pairwise marginals. A simple forward-backward-type dynamic program can then be used to compute the gradient tractably. For ease of implementation and scalability to semi-supervised learning, we also outline an even faster approximation to the regularizer. The general approach also works in other clique structures in addition to the linear chain when the clique marginals can be computed efficiently.

Finally, we extend feature noising for structured prediction to a transductive or semi-supervised setting. The regularizer induced by feature noising is label-independent for log-linear models, and so we can use unlabeled data to learn a better regularizer. NLP sequence labeling tasks are especially well suited to a semi-supervised approach, as input features are numerous but sparse, and labeled data is expensive to obtain but unlabeled data is abundant (Li and McCallum, 2005; Jiao et al., 2006).

Wager et al. (2013) showed that semi-supervised dropout training for logistic regression captures a similar intuition to techniques such as entropy regularization (Grandvalet and Bengio, 2005) and transductive SVMs (Joachims, 1999), which encourage confident predictions on the unlabeled data. Semi-supervised dropout has the advantage of only using the predicted label probabilities on the unlabeled data to modulate an L_2 regularizer, rather than requiring more heavy-handed modeling of the unlabeled data as in entropy regularization or expectation regularization (Mann and McCallum, 2007).

In experimental results, we show that simulated feature noising gives more than a 1% absolute boost in performance over L_2 regularization, on both text classification and an NER sequence labeling task.

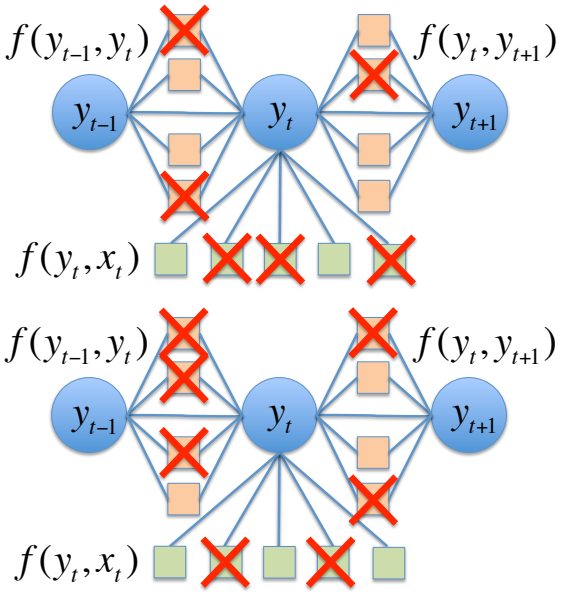

Figure 1: An illustration of dropout feature noising in linear-chain CRFs with only transition features and node features. The green squares are node features $f(y_t, x_t)$, and the orange squares are edge features $f(y_{t-1}, y_t)$. Conceptually, given a training example, we sample some features to ignore (generate fake data) and make a parameter update. Our goal is to train with a roughly equivalent objective, without actually sampling.

2 Feature Noising Log-linear Models

Consider the standard structured prediction problem of mapping some input $x \in \mathcal{X}$ (e.g., a sentence) to an output $\mathbf{y} \in \mathcal{Y}$ (e.g., a tag sequence). Let $f(\mathbf{y}, x) \in \mathbb{R}^d$ be the feature vector, $\theta \in \mathbb{R}^d$ be the weight vector, and $\mathbf{s} = (s_1, \ldots, s_{|\mathcal{Y}|})$ be a vector of scores for each output, with $s_{\mathbf{y}} = f(\mathbf{y}, x) \cdot \theta$. Now define a log-linear model:

$$p(\mathbf{y} \mid x; \theta) = \exp\{s_{\mathbf{y}} - A(\mathbf{s})\}, \qquad (1)$$

where $A(\mathbf{s}) = \log \sum_{\mathbf{y}} \exp\{s_{\mathbf{y}}\}$ is the log-partition function. Given an example $(x, \mathbf{y})$, parameter estimation corresponds to choosing θ to maximize $p(\mathbf{y} \mid x; \theta)$.

The key idea behind feature noising is to artificially corrupt the feature vector $f(\mathbf{y}, x)$ randomly

into some $\tilde{f}(\mathbf{y}, x)$ and then maximize the average log-likelihood of $\mathbf{y}$ given these corrupted features—the motivation is to choose predictors θ that are robust to noise (missing words for example). Let $\tilde{\mathbf{s}}$, $\tilde{p}(\mathbf{y} \mid x; \theta)$ be the *randomly* perturbed versions corresponding to $\tilde{f}(\mathbf{y}, x)$. We will also assume the feature noising preserves the mean: $\mathbb{E}[\tilde{f}(\mathbf{y}, x)] = f(\mathbf{y}, x)$, so that $\mathbb{E}[\tilde{\mathbf{s}}] = \mathbf{s}$. This can always be done by scaling the noised features as described in the list of noising schemes.

It is useful to view feature noising as a form of regularization. Since feature noising preserves the mean, the feature noising objective can be written as the sum of the original log-likelihood plus the difference in log-normalization constants:

$$\mathbb{E}[\log \tilde{p}(\mathbf{y} \mid x; \theta)] = \mathbb{E}[\tilde{\mathbf{s}}_{\mathbf{y}} - A(\tilde{\mathbf{s}})] \quad (2)$$

$$= \log p(\mathbf{y} \mid x; \theta) - R(\theta, x), \quad (3)$$

$$R(\theta, x) \stackrel{\text{def}}{=} \mathbb{E}[A(\tilde{\mathbf{s}})] - A(\mathbf{s}). \quad (4)$$

Since $A(\cdot)$ is convex, $R(\theta, x)$ is always positive by Jensen's inequality and can therefore be interpreted as a regularizer. Note that $R(\theta, x)$ is in general non-convex.

Computing the regularizer (4) requires summing over all possible noised feature vectors, which can imply exponential effort in the number of features. This is intractable even for flat classification. Following Bishop (1995) and Wager et al. (2013), we approximate $R(\theta, x)$ using a second-order Taylor expansion, which will allow us to work with only means and covariances of the noised features. We take a quadratic approximation of the log-partition function $A(\cdot)$ of the noised score vector $\tilde{\mathbf{s}}$ around the the unnoised score vector $\mathbf{s}$:

$$A(\tilde{\mathbf{s}}) \approxeq A(\mathbf{s}) + \nabla A(\mathbf{s})^\top (\tilde{\mathbf{s}} - \mathbf{s}) \quad (5)$$

$$+ \frac{1}{2}(\tilde{\mathbf{s}} - \mathbf{s})^\top \nabla^2 A(\mathbf{s})(\tilde{\mathbf{s}} - \mathbf{s}).$$

Plugging (5) into (4), we obtain a new regularizer $R^{\mathrm{q}}(\theta, x)$, which we will use as an approximation to $R(\theta, x)$:

$$R^{\mathrm{q}}(\theta, x) = \frac{1}{2}\mathbb{E}[(\tilde{\mathbf{s}} - \mathbf{s})^\top \nabla^2 A(\mathbf{s})(\tilde{\mathbf{s}} - \mathbf{s})] \quad (6)$$

$$= \frac{1}{2} \operatorname{tr}(\nabla^2 A(\mathbf{s}) \operatorname{Cov}(\tilde{\mathbf{s}})). \quad (7)$$

This expression still has two sources of potential intractability, a sum over an exponential number of noised score vectors $\tilde{\mathbf{s}}$ and a sum over the $|\mathcal{Y}|$ components of $\tilde{\mathbf{s}}$.

Multiclass classification If we assume that the components of $\tilde{\mathbf{s}}$ are independent, then $\operatorname{Cov}(\tilde{\mathbf{s}}) \in \mathbb{R}^{|\mathcal{Y}| \times |\mathcal{Y}|}$ is diagonal, and we have

$$R^{\mathrm{q}}(\theta, x) = \frac{1}{2} \sum_{\mathbf{y} \in \mathcal{Y}} \mu_{\mathbf{y}}(1 - \mu_{\mathbf{y}}) \operatorname{Var}[\tilde{s}_{\mathbf{y}}], \quad (8)$$

where the mean $\mu_{\mathbf{y}} \stackrel{\text{def}}{=} p_\theta(\mathbf{y} \mid x)$ is the model probability, the variance $\mu_{\mathbf{y}}(1 - \mu_{\mathbf{y}})$ measures model uncertainty, and

$$\operatorname{Var}[\tilde{s}_{\mathbf{y}}] = \theta^\top \operatorname{Cov}[\tilde{f}(\mathbf{y}, x)]\theta \quad (9)$$

measures the uncertainty caused by feature noising.[1] The regularizer $R^{\mathrm{q}}(\theta, x)$ involves the product of two variance terms, the first is non-convex in θ and the second is quadratic in θ. Note that to reduce the regularization, we will favor models that (i) predict confidently and (ii) have stable scores in the presence of feature noise.

For multiclass classification, we can explicitly sum over each $\mathbf{y} \in \mathcal{Y}$ to compute the regularizer, but this will be intractable for structured prediction.

To specialize to multiclass classification for the moment, let us assume that we have a separate weight vector for each output $\mathbf{y}$ applied to the same feature vector $g(x)$; that is, the score $s_{\mathbf{y}} = \theta_{\mathbf{y}} \cdot g(x)$. Further, assume that the components of the noised feature vector $\tilde{g}(x)$ are independent. Then we can simplify (9) to the following:

$$\operatorname{Var}[\tilde{s}_{\mathbf{y}}] = \sum_j \operatorname{Var}[g_j(x)]\theta_{yj}^2. \quad (10)$$

Noising schemes We now give some examples of possible noise schemes for generating $\tilde{f}(\mathbf{y}, x)$ given the original features $f(\mathbf{y}, x)$. This distribution affects the regularization through the variance term $\operatorname{Var}[\tilde{s}_{\mathbf{y}}]$.

- *Additive Gaussian*: $\tilde{f}(\mathbf{y}, x) = f(\mathbf{y}, x) + \varepsilon$, where $\varepsilon \sim \mathcal{N}(0, \sigma^2 I_{d \times d})$.

[1] Here, we are using the fact that first and second derivatives of the log-partition function are the mean and variance.

In this case, the contribution to the regularizer from noising is $\mathrm{Var}[\tilde{s}_{\mathbf{y}}] = \sum_j \sigma^2 \theta_{yj}^2$.

- *Dropout*:

  $\tilde{f}(\mathbf{y}, x) = f(\mathbf{y}, x) \odot z$, where $\odot$ takes the elementwise product of two vectors. Here, z is a vector with independent components which has $z_i = 0$ with probability δ, $z_i = \frac{1}{1-\delta}$ with probability $1 - \delta$. In this case, $\mathrm{Var}[\tilde{s}_{\mathbf{y}}] = \sum_j \frac{g_j(x)^2 \delta}{1-\delta} \theta_{yj}^2$.

- *Multiplicative Gaussian*:

  $\tilde{f}(\mathbf{y}, x) = f(\mathbf{y}, x) \odot (1 + \varepsilon)$, where $\varepsilon \sim \mathcal{N}(0, \sigma^2 I_{d \times d})$. Here, $\mathrm{Var}[\tilde{s}_{\mathbf{y}}] = \sum_j g_j(x)^2 \sigma^2 \theta_{yj}^2$. Note that under our second-order approximation $R^{\mathrm{q}}(\theta, x)$, the multiplicative Gaussian and dropout schemes are equivalent, but they differ under the original regularizer $R(\theta, x)$.

2.1 Semi-supervised learning

A key observation (Wager et al., 2013) is that the noising regularizer R (8), while involving a sum over examples, is independent of the output $\mathbf{y}$. This suggests estimating R using unlabeled data. Specifically, if we have n labeled examples $\mathcal{D} = \{x_1, x_2, \ldots, x_n\}$ and m unlabeled examples $\mathcal{D}_{\text{unlabeled}} = \{u_1, u_2, \ldots, u_n\}$, then we can define a regularizer that is a linear combination the regularizer estimated on both datasets, with α tuning the tradeoff between the two:

$$R_*(\theta, \mathcal{D}, \mathcal{D}_{\text{unlabeled}}) \tag{11}$$
$$\stackrel{\text{def}}{=} \frac{n}{n + \alpha m} \Big(\sum_{i=1}^{n} R(\theta, x_i) + \alpha \sum_{i=1}^{m} R(\theta, u_i) \Big).$$

3 Feature Noising in Linear-Chain CRFs

So far, we have developed a regularizer that works for all log-linear models, but—in its current form—is only practical for multiclass classification. We now exploit the decomposable structure in CRFs to define a new noising scheme which does not require us to explicitly sum over all possible outputs $\mathbf{y} \in \mathcal{Y}$. The key idea will be to noise each local feature vector (which implicitly affects many $\mathbf{y}$) rather than noise each $\mathbf{y}$ independently.

Assume that the output $\mathbf{y} = (y_1, \ldots, y_T)$ is a sequence of T tags. In linear chain CRFs, the feature vector f decomposes into a sum of local feature vectors g_t:

$$f(\mathbf{y}, x) = \sum_{t=1}^{T} g_t(y_{t-1}, y_t, x), \tag{12}$$

where $g_t(a, b, x)$ is defined on a pair of consecutive tags a, b for positions $t - 1$ and t.

Rather than working with a score $s_{\mathbf{y}}$ for each $\mathbf{y} \in \mathcal{Y}$, we define a collection of *local scores* $\mathbf{s} = \{s_{a,b,t}\}$, for each tag pair (a, b) and position $t = 1, \ldots, T$. We consider noising schemes which independently set $\tilde{g}_t(a, b, x)$ for each a, b, t. Let $\tilde{\mathbf{s}} = \{\tilde{s}_{a,b,t}\}$ be the corresponding collection of noised scores.

We can write the log-partition function of these local scores as follows:

$$A(\mathbf{s}) = \log \sum_{y \in \mathcal{Y}} \exp \left\{ \sum_{t=1}^{T} s_{y_{t-1}, y_t, t} \right\}. \tag{13}$$

The first derivative yields the edge marginals under the model, $\mu_{a,b,t} = p_\theta(y_{t-1} = a, y_t = b \mid x)$, and the diagonal elements of the Hessian $\nabla^2 A(\mathbf{s})$ yield the marginal variances.

Now, following (7) and (8), we obtain the following regularizer:

$$R^{\mathrm{q}}(\theta, x) = \frac{1}{2} \sum_{a,b,t} \mu_{a,b,t}(1 - \mu_{a,b,t}) \, \mathrm{Var}[\tilde{s}_{a,b,t}], \tag{14}$$

where $\mu_{a,b,t}(1 - \mu_{a,b,t})$ measures model uncertainty about edge marginals, and $\mathrm{Var}[\tilde{s}_{a,b,t}]$ is simply the uncertainty due to noising. Again, minimizing the regularizer means making confident predictions and having stable scores under feature noise.

Computing partial derivatives So far, we have defined the regularizer $R^{\mathrm{q}}(\theta, x)$ based on feature noising. In order to minimize $R^{\mathrm{q}}(\theta, x)$, we need to take its derivative.

First, note that $\log \mu_{a,b,t}$ is the difference of a restricted log-partition function and the log-partition function. So again by properties of its first derivative, we have:

$$\nabla \log \mu_{a,b,t} = \mathbb{E}_{p_\theta(\mathbf{y} \mid x, y_{t-1}=a, y_t=b)}[f(\mathbf{y}, x)] - \mathbb{E}_{p_\theta(\mathbf{y} \mid x)}[f(\mathbf{y}, x)]. \tag{15}$$

Using the fact that $\nabla \mu_{a,b,t} = \mu_{a,b,t} \nabla \log \mu_{a,b,t}$ and the fact that $\mathrm{Var}[\tilde{s}_{a,b,t}]$ is a quadratic function in θ, we can simply apply the product rule to derive the final gradient $\nabla R^{\mathrm{q}}(\theta, x)$.

3.1 A Dynamic Program for the Conditional Expectation

A naive computation of the gradient $\nabla R^{\mathrm{q}}(\theta, x)$ requires a full forward-backward pass to compute $\mathbb{E}_{p_\theta(\mathbf{y} | y_{t-1}=a, y_t=b, x)}[f(\mathbf{y}, x)]$ for each tag pair (a, b) and position t, resulting in a $\mathcal{O}(K^4 T^2)$ time algorithm.

In this section, we reduce the running time to $\mathcal{O}(K^2 T)$ using a more intricate dynamic program. By the Markov property of the CRF, $\mathbf{y}_{1:t-2}$ only depends on (y_{t-1}, y_t) through y_{t-1} and $\mathbf{y}_{t+1:T}$ only depends on (y_{t-1}, y_t) through y_t.

First, it will be convenient to define the partial sum of the local feature vector from positions i to j as follows:

$$G_{i:j} = \sum_{t=i}^{j} g_t(y_{t-1}, y_t, x). \tag{16}$$

Consider the task of computing the feature expectation $\mathbb{E}_{p_\theta(\mathbf{y} | y_{t-1}=a, y_t=b)}[f(\mathbf{y}, x)]$ for a fixed (a, b, t). We can expand this quantity into

$$\sum_{\mathbf{y}: y_{t-1}=a, y_t=b} p_\theta(\mathbf{y}_{-(t-1:t)} \mid y_{t-1} = a, y_t = b) G_{1:T}.$$

Conditioning on y_{t-1}, y_t decomposes the sum into three pieces:

$$\sum_{\mathbf{y}: y_{t-1}=a, y_t=b} [g_t(y_{t-1} = a, y_t = b, x) + F_t^a + B_t^b],$$

where

$$F_t^a = \sum_{\mathbf{y}_{1:t-2}} p_\theta(\mathbf{y}_{1:t-2} \mid y_{t-1} = a) G_{1:t-1}, \tag{17}$$

$$B_t^b = \sum_{\mathbf{y}_{t+1:T}} p_\theta(\mathbf{y}_{t+1:T} \mid y_t = b) G_{t+1:T}, \tag{18}$$

are the expected feature vectors summed over the prefix and suffix of the tag sequence, respectively. Note that F_t^a and B_t^b are analogous to the forward and backward messages of standard CRF inference, with the exception that they are vectors rather than scalars.

We can compute these messages recursively in the standard way. The forward recurrence is

$$F_t^a = \sum_b p_\theta(y_{t-2} = b \mid y_{t-1} = a) \left[g_t(y_{t-2} = b, y_{t-1} = a, x) + F_{t-1}^b \right],$$

and a similar recurrence holds for the backward messages B_t^b.

Running the resulting dynamic program takes $\mathcal{O}(K^2 T q)$ time and requires $\mathcal{O}(KTq)$ storage, where K is the number of tags, T is the sequence length and q is the number of active features. Note that this is the same order of dependence as normal CRF training, but there is an additional dependence on the number of active features q, which makes training slower.

4 Fast Gradient Computations

In this section, we provide two ways to further improve the efficiency of the gradient calculation based on ignoring long-range interactions and based on exploiting feature sparsity.

4.1 Exploiting Feature Sparsity and Co-occurrence

In each forward-backward pass over a training example, we need to compute the conditional expectations for all features active in that example. Naively applying the dynamic program in Section 3 is $\mathcal{O}(K^2 T)$ for each active feature. The total complexity has to factor in the number of active features, q. Although q only scales linearly with sentence length, in practice this number could get large pretty quickly. For example, in the NER tagging experiments (*cf.* Section 5), the average number of active features per token is about 20, which means $q \simeq 20T$; this term quickly dominates the computational costs. Fortunately, in sequence tagging and other NLP tasks, the majority of features are sparse and they often co-occur. That is, some of the active features would fire and only fire at the same locations in a given sequence. This happens when a particular token triggers multiple rare features.

We observe that all indicator features that only fired once at position t have the same conditional expectations (and model expectations). As a result, we can collapse such a group of features into a single

feature as a preprocessing step to avoid computing identical expectations for each of the features. Doing so on the same NER tagging experiments cuts down q/T from 20 to less than 5, and gives us a 4 times speed up at no loss of accuracy. The exact same trick is applicable to the general CRF gradient computation as well and gives similar speedup.

4.2 Short-range interactions

It is also possible to speed up the method by resorting to approximate gradients. In our case, the dynamic program from Section 3 together with the trick described above ran in a manageable amount of time. The techniques developed here, however, could prove to be useful on larger tasks.

Let us rewrite the quantity we want to compute slightly differently (again, for all a, b, t):

$$\sum_{i=1}^{T} \mathbb{E}_{p_\theta(\mathbf{y}|x, y_{t-1}=a, y_t=b)}[g_i(y_{i-1}, y_i, x)]. \quad (19)$$

The intuition is that conditioned on y_{t-1}, y_t, the terms $g_i(y_{i-1}, y_i, x)$ where i is far from t will be close to $\mathbb{E}_{p_\theta(\mathbf{y}|x)}[g_i(y_{i-1}, y_i, x)]$.

This motivates replacing the former with the latter whenever $|i-k| \geq r$ where r is some window size. This approximation results in an expression which only has to consider the sum of the local feature vectors from $i-r$ to $i+r$, which is captured by $G_{i-r:i+r}$:

$$\begin{aligned} &\mathbb{E}_{p_\theta(\mathbf{y}|y_{t-1}=a, y_t=b, x)}[f(\mathbf{y}, x)] - \mathbb{E}_{p_\theta(\mathbf{y}|x)}[f(\mathbf{y}, x)] \\ &\quad \approx \mathbb{E}_{p_\theta(\mathbf{y}|y_{t-1}=a, y_t=b, x)}[G_{t-r:t+r}] \\ &\qquad - \mathbb{E}_{p_\theta(\mathbf{y}|x)}[G_{t-r:t+r}]. \end{aligned} \quad (20)$$

We can further approximate this last expression by letting $r = 0$, obtaining:

$$g_t(a, b, x) - \mathbb{E}_{p_\theta(\mathbf{y}|x)}[g_t(y_{t-1}, y_t, x)]. \quad (21)$$

The second expectation can be computed from the edge marginals.

The accuracy of this approximation hinges on the lack of long range dependencies. Equation (21) shows the case of $r = 0$; this takes almost no additional effort to compute. However, for some of our experiments, we observed a 20% difference with the real derivative. For $r > 0$, the computational savings are more limited, but the bounded-window method is easier to implement.

Dataset	q	d	K	N_{train}	N_{test}

5 Experiments

We show experimental results on the CoNLL-2003 Named Entity Recognition (NER) task, the SANCL Part-of-speech (POS) tagging task, and several document classification tasks.[2] The datasets used are described in Table 1. We used standard splits whenever available; otherwise we split the data at random into a test set and a train set of equal sizes (RCV1_4, TDT2). CoNLL has a development set of size 51578, which we used to tune regularization parameters. The SANCL test set is divided into 3 genres, namely `answers`, `newsgroups`, and `reviews`, each of which has a corresponding development set.[3]

5.1 Multiclass Classification

We begin by testing our regularizer in the simple case of classification where $\mathcal{Y} = \{1, 2, \ldots, K\}$ for K classes. We examine the performance of the noising regularizer in both the fully supervised setting as well as the transductive learning setting.

In the transductive learning setting, the learner is allowed to inspect the test features at train time (without the labels). We used the method described in Section 2.1 for transductive dropout.

[2]The document classification data are available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets` and `http://www.cad.zju.edu.cn/home/dengcai/Data/TextData.html`

[3]The SANCL dataset has two additional genres—emails and weblogs—that we did not use, as we did not have access to development sets for these genres.

Dataset	K	None	L_2	Drop	+Test
CoNLL	5	78.03	80.12	80.90	81.66
20news	20	81.44	82.19	83.37	84.71
RCV1$_4$	4	95.76	95.90	96.03	96.11
R21578	65	92.24	92.24	92.24	92.58
TDT2	30	97.74	97.91	98.00	98.12

Table 2: Classification performance and transductive learning results on some standard datasets. None: use no regularization, Drop: quadratic approximation to the dropout noise (8), +Test: also use the test set to estimate the noising regularizer (11).

Dataset	K	L_2	Drop	+Unlabeled
CoNLL	5	91.46	91.81	92.02
20news	20	76.55	79.07	80.47
RCV1$_4$	4	94.76	94.79	95.16
R21578	65	90.67	91.24	90.30
TDT2	30	97.34	97.54	97.89

Table 3: Semisupervised learning results on some standard datasets. A third (33%) of the full dataset was used for training, a third for testing, and the rest as unlabeled.

5.1.1 Semi-supervised Learning with Feature Noising

In the transductive setting, we used test data (without labels) to learn a better regularizer. As an alternative, we could also use unlabeled data in place of the test data to accomplish a similar goal; this leads to a semi-supervised setting.

To test the semi-supervised idea, we use the same datasets as above. We split each dataset evenly into 3 thirds that we use as a training set, a test set and an unlabeled dataset. Results are given in Table 3.

In most cases, our semi-supervised accuracies are lower than the transductive accuracies given in Table 2; this is normal in our setup, because we used less labeled data to train the semi-supervised classifier than the transductive one.[4]

5.1.2 The Second-Order Approximation

The results reported above all rely on the approximate dropout regularizer (8) that is based on a second-order Taylor expansion. To test the validity of this approximation we compare it to the Gaussian method developed by Wang and Manning (2013) on a two-class classification task.

We use the 20-newsgroups `alt.atheism` vs `soc.religion.christian` classification task; results are shown in Figure 2. There are 1427 examples with 22178 features, split evenly and randomly into a training set and a test set.

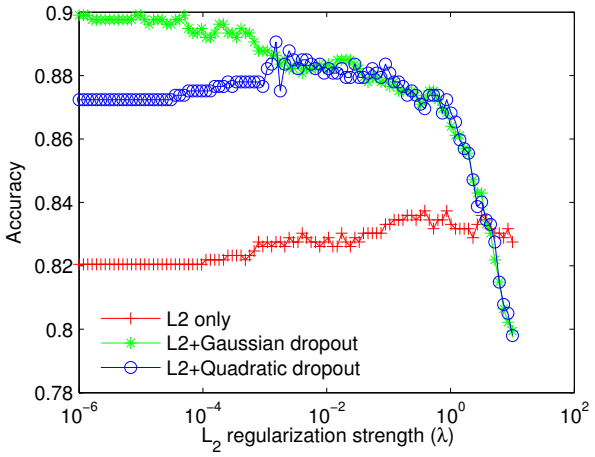

Figure 2: Effect of λ in $\lambda\|\theta\|_2^2$ on the testset performance. Plotted is the test set accuracy with logistic regression as a function of λ for the L_2 regularizer, Gaussian dropout (Wang and Manning, 2013) + additional L_2, and quadratic dropout (8) + L_2 described in this paper. The default noising regularizer is quite good, and additional L_2 does not help. Notice that no choice of λ in L_2 can help us combat overfitting as effectively as (8) without underfitting.

Over a broad range of λ values, we find that dropout plus L_2 regularization performs far better than using just L_2 regularization for any value of λ. We see that Gaussian dropout appears to perform slightly better than the quadratic approximation discussed in this paper. However, our quadratic approximation extends easily to the multiclass case and to structured prediction in general, while Gaussian dropout does not. Thus, it appears that our approximation presents a reasonable trade-off between

[4] The CoNNL results look somewhat surprising, as the semi-supervised results are better than the transductive ones. The reason for this is that the original CoNLL test set came from a different distributions than the training set, and this made the task more difficult. Meanwhile, in our semi-supervised experiment, the test and train sets are drawn from the same distribution and so our semi-supervised task is actually easier than the original one.

computational efficiency and prediction accuracy.

5.2 CRF Experiments

We evaluate the quadratic dropout regularizer in linear-chain CRFs on two sequence tagging tasks: the CoNLL 2003 NER shared task (Tjong Kim Sang and De Meulder, 2003) and the SANCL 2012 POS tagging task (Petrov and McDonald, 2012) .

The standard CoNLL-2003 English shared task benchmark dataset (Tjong Kim Sang and De Meulder, 2003) is a collection of documents from Reuters newswire articles, annotated with four entity types: *Person*, *Location*, *Organization*, and *Miscellaneous*. We predicted the label sequence $\mathcal{Y} = \{\text{LOC, MISC, ORG, PER, O}\}^T$ without considering the BIO tags.

For training the CRF model, we used a comprehensive set of features from Finkel et al. (2005) that gives state-of-the-art results on this task. A total number of 437906 features were generated on the CoNLL-2003 training dataset. The most important features are:

- The word, word shape, and letter n-grams (up to 6gram) at current position
- The prediction, word, and word shape of the previous and next position
- Previous word shape in conjunction with current word shape
- Disjunctive word set of the previous and next 4 positions
- Capitalization pattern in a 3 word window
- Previous two words in conjunction with the word shape of the previous word
- The current word matched against a list of name titles (e.g., Mr., Mrs.)

The $F_{\beta=1}$ results are summarized in Table 4. We obtain a 1.6% and 1.1% absolute gain on the test and dev set, respectively. Detailed results are broken down by precision and recall for each tag and are shown in Table 6. These improvements are significant at the 0.1% level according to the paired bootstrap resampling method of 2000 iterations (Efron and Tibshirani, 1993).

For the SANCL (Petrov and McDonald, 2012) POS tagging task, we used the same CRF framework with a much simpler set of features

- word unigrams: w_{-1}, w_0, w_1
- word bigram: (w_{-1}, w_0) and (w_0, w_1)

$F_{\beta=1}$	None	L_2	Drop
Dev	89.40	90.73	91.86
Test	84.67	85.82	87.42

Table 4: CoNLL summary of results. None: no regularization, Drop: quadratic dropout regularization (14) described in this paper.

$F_{\beta=1}$	None	L_2	Drop
	`newsgroups`		
Dev	91.34	91.34	91.47
Test	91.44	91.44	91.81
	`reviews`		
Dev	91.97	91.95	92.10
Test	90.70	90.67	91.07
	`answers`		
Dev	90.78	90.79	90.70
Test	91.00	90.99	91.09

Table 5: SANCL POS tagging $F_{\beta=1}$ scores for the 3 official evaluation sets.

We obtained a small but consistent improvement using the quadratic dropout regularizer in (14) over the L_2-regularized CRFs baseline.

Although the difference on SANCL is small, the performance differences on the test sets of `reviews` and `newsgroups` are statistically significant at the 0.1% level. This is also interesting because here is a situation where the features are extremely sparse, L_2 regularization gave no improvement, and where regularization overall matters less.

6 Conclusion

We have presented a new regularizer for learning log-linear models such as multiclass logistic regression and conditional random fields. This regularizer is based on a second-order approximation of feature noising schemes, and attempts to favor models that predict confidently and are robust to noise in the data. In order to apply our method to CRFs, we tackle the key challenge of dealing with feature correlations that arise in the structured prediction setting in several ways. In addition, we show that the regularizer can be applied naturally in the semi-supervised setting. Finally, we applied our method to a range of different datasets and demonstrate consistent gains over standard L_2 regularization. Inves-

tigating how to better optimize this non-convex regularizer online and convincingly scale it to the semi-supervised setting seem to be promising future directions.

Abstract

One of the language phenomena that n-gram language model fails to capture is the topic information of a given situation. We advance the previous study of the Bayesian topic language model by Wallach (2006) in two directions: one, investigating new priors to alleviate the sparseness problem caused by dividing all n-grams into exclusive topics, and two, developing a novel Gibbs sampler that enables moving multiple n-grams across different documents to another topic. Our blocked sampler can efficiently search for higher probability space even with higher order n-grams. In terms of modeling assumption, we found it is effective to assign a topic to only some parts of a document.

1 Introduction

N-gram language model is still ubiquitous in NLP, but due to its simplicity it fails to capture some important aspects of language, such as difference of word usage in different situations, sentence level syntactic correctness, and so on. Toward language model that can consider such a more global context, many extensions have been proposed from lexical pattern adaptation, e.g., adding cache (Jelinek et al., 1991) or topic information (Gildea and Hofmann, 1999; Wallach, 2006), to grammaticality aware models (Pauls and Klein, 2012).

Topic language models are important for use in e.g., *unsupervised language model adaptation*: we want a language model that can adapt to the domain or topic of the current situation (e.g., a document in SMT or a conversation in ASR) automatically and select the appropriate words using both topic and syntactic context. Wallach (2006) is one such model, which generate each word based on local context and global topic information to capture the difference of lexical usage among different topics.

However, Wallach's experiments were limited to bigrams, a toy setting for language models, and experiments with higher-order n-grams have not yet been sufficiently studied, which we investigate in this paper. In particular, we point out the two fundamental problems caused when extending Wallach's model to a higher-order: *sparseness* caused by dividing all n-grams into exclusive topics, and *local minima* caused by the deep hierarchy of the model. On resolving these problems, we make several contributions to both computational linguistics and machine learning.

To address the first problem, we investigate incorporating a global language model for ease of sparseness, along with some priors on a suffix tree to capture the difference of *topicality* for each context, which include an *unsupervised* extension of the doubly hierarchical Pitman-Yor language model (Wood and Teh, 2009), a Bayesian generative model for *supervised* language model adaptation. For the second inference problem, we develop a novel blocked Gibbs sampler. When the number of topics is K and vocabulary size is V, n-gram topic model has $O(KV^n)$ parameters, which grow exponentially to n, making the local minima problem even more severe. Our sampler resolves this problem by moving many customers in the hierarchical Chinese restaurant process at a time.

We evaluate various models by incremental calculation of test document perplexity on 3 types of corpora having different size and diversity. By combining the proposed prior and the sampling method, our Bayesian model achieve much higher accuracies than the naive extension of Wallach (2006) and shows results competitive with the unigram rescaling (Gildea and Hofmann, 1999), which require

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1180–1190,
Seattle, Washington, USA, 18-21 October 2013.

huge computational cost at prediction, with much faster prediction time.

2 Basic Models

All models presented in this paper are based on the Bayesian n-gram language model, the hierarchical Pitman-Yor process language model (HPYLM). In the following, we first introduce the HPYLM, and then discuss the topic model extension of Wallach (2006) with HPYLM.

2.1 HPYLM

Let us first define some notations. W is a vocabulary set, $V = |W|$ is the size of that set, and $u, v, w \in W$ represent the word type.

The HPYLM is a Bayesian treatment of the n-gram language model. The generative story starts with the unigram word distribution G_ϕ, which is a V-dimensional multinomial where $G_\phi(w)$ represents the probability of word w. The model first generates this distribution from the PYP as $G_\phi \sim \mathrm{PYP}(a, b, G_0)$, where G_0 is a V-dimensional uniform distribution ($G_0(u) = \frac{1}{V}; \forall u \in W$) and acts as a prior for G_ϕ and a, b are hyperparameters called discount and concentration, respectively. It then generates all bigram distributions $\{G_u\}_{u \in W}$ as $G_u \sim \mathrm{PYP}(a, b, G_\phi)$. Given this distributions, it successively generates 3-gram distributions $G_{uv} \sim \mathrm{PYP}(a, b, G_u)$ for all $(u, v) \in W^2$ pairs, which encode a natural assumption that contexts having common suffix have similar word distributions. For example, two contexts "he is" and "she is", which share the suffix "is", are generated from the same (bigram) distribution G_{is}, so they would have similar word distributions. This process continues until the context length reaches $n-1$ where n is a prespecified n-gram order (if $n = 3$, the above example is a complete process). We often generalize this process using two contexts h and h' as

$$G_h \sim \mathrm{PYP}(a, b, G_{h'}), \tag{1}$$

where $h = ah'$, in which a is a leftmost word of h.

We are interested in the posterior word distribution following a context h. Our training corpus $\mathbf{w}$ is a collection of n-grams, from which we can calculate the posterior $p(w|h, \mathbf{w})$, which is often explained with the Chinese restaurant process (CRP):

$$p(w|h, \mathbf{w}) = \frac{c_{hw} - a t_{hw}}{c_{h\cdot} + b} + \frac{a t_{h\cdot} + b}{c_{h\cdot} + b} p(w|h', \mathbf{w}), \tag{2}$$

where c_{hw} is an observed count of n-gram hw called customers, while t_{hw} is a hidden variable called tables. $c_{h\cdot}$ and $t_{h\cdot}$ represents marginal counts: $c_{h\cdot} = \sum_w c_{hw}$ and $t_{h\cdot} = \sum_w t_{hw}$. This form is very similar to the well-known Kneser-Ney smoothing, and actually the Kneser-Ney can be understood as a heuristic approximation of the HPYLM. This characteristic enables us to build the state-of-the-art language model into a more complex generative model.

2.2 Wallach (2006) with HPYLM

Wallach (2006) is a generative model for a document collection that combines the topic model with a Bayesian n-gram language model. The latent Dirichlet allocation (LDA) (Blei et al., 2003) is the most basic topic model, which generates each word in a document based on a unigram word distribution defined by a topic allocated to that word. The bigram topic model of Wallach (2006) simply replaces this unigram word distribution (a multinomial) for each topic with a bigram word distribution [1]. In other words, ordinary LDA generates word conditioning *only* on the latent topic, whereas the bigram topic model generates conditioning on *both* the latent topic and the previous word, as in the bigram language model. Extending this model with a higher order n-gram is trivial; all we have to do is to replace the bigram language model for each topic with an n-gram language model.

The formal description of the generative story of this n-gram topic model is as follows. First, for each topic $k \in 1, \cdots, K$, where K is the number of topics, the model generates an n-gram language model G_h^k.[2] These n-gram models are generated by the PYP, so $G_h^k \sim \mathrm{PYP}(a, b, G_{h'}^k)$ holds. The model then generate a document collection. For each document $j \in 1, \cdots, D$, it generates a K-

[1] This is the model called *prior 2* in Wallach (2006); it consistently outperformed the other prior. Wallach used the Dirichlet language model as each topic, but we only explore the model with HPYLM because its superiority to the Dirichlet language model has been well studied (Teh, 2006b).

[2] We sometimes denote G_h^k to represent a language model of topic k, not a specific multinomial for some context h, depending on the context.

dimensional topic distribution θ_j by a Dirichlet distribution $\mathrm{Dir}(\boldsymbol{\alpha})$ where $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \cdots, \alpha_K)$ is a prior. Finally, for each word position $i \in 1, \cdots, N_j$ where N_j is the number of words in document j, i-th word's topic assignment z_{ji} is chosen according to θ_j, then a word type w_{ji} is generated from $G^{z_{ji}}_{h_{ji}}$ where h_{ji} is the last $n-1$ words preceding w_{ji}. We can summarize this process as follows:

1. Generate topics:
   For each $h \in \phi, \{W\}, \cdots, \{W\}^{n-1}$:
     For each $k \in 1, \cdots, K$:
       $G^k_h \sim \mathrm{PYP}(a, b, G^k_{h'})$

2. Generate corpora:
   For each document $j \in 1, \cdots D$:
     $\theta_j \sim \mathrm{Dir}(\boldsymbol{\alpha})$
     For each word position $i \in 1, \cdots, N_j$:
       $z_{ji} \sim \theta_j$
       $w_{ji} \sim G^{z_{ji}}_{h_{ji}}$

3 Extended Models

One serious drawback of the n-gram topic model presented in the previous section is *sparseness*. At inference, as in LDA, we assign each n-gram a topic, resulting in an exclusive clustering of n-grams in the corpora. Roughly speaking, when the number of topics is K and the number of all n-grams in the training corpus is N, a language model of topic k, G^k_h is learned using only about $O(N/K)$ instances of the n-grams assigned the topic k, making each G^k_h much sparser and unreliable distribution.

One way to alleviate this problem is to place another n-gram model, say G^0_h, which is shared with all topic-specific n-gram models $\{G^k_h\}^K_{k=1}$. However, what is the best way to use this special distribution? We explore two different approaches to incorporate this distribution in the model presented in the previous section. In one model, the HIERARCHICAL model, G^0_h is used as a prior for all other n-gram models, where G^0_h exploits global statistics across all topics $\{G^k_h\}$. In the other model, the SWITCHING model, no statistics are shared across G^0_h and $\{G^k_h\}$, but some words are directly generated from G^0_h regardless of the topic distribution.

3.1 HIERARCHICAL Model

Informally, what we want to do is to establish hierarchies among the global G^0_h and other topics $\{G^k_h\}$. In Bayesian formalism, we can explain this using an abstract distribution $\mathcal{F}$ as $G^k_h \sim \mathcal{F}(G^0_h)$. The problem here is making the appropriate choice for the distribution $\mathcal{F}$. Each topic word distribution already has hierarchies among $n-1$-gram and n-gram contexts as $G^k_h \sim \mathrm{PYP}(a, b, G^k_{h'})$. A natural solution to this problem is the doubly hierarchical Pitman-Yor process (DHPYP) proposed in Wood and Teh (2009). Using this distribution, the new generative process of G^k_h is

$$G^k_h \sim \mathrm{PYP}(a, b, \lambda G^k_{h'} + (1-\lambda) G^0_h), \qquad (3)$$

where λ is a new hyperparameter that determines mixture weight. The dependencies among G^0_h and $\{G^k_h\}$ are shown in Figure 1. Note that the generative process of G^0_h is the same as the HPYLM (1).

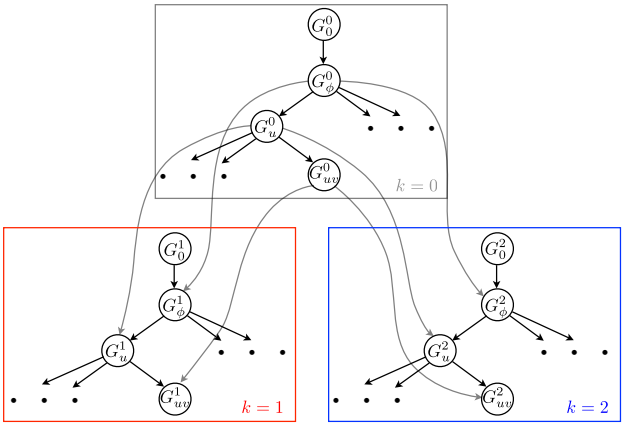

Figure 1: Variable dependencies of the HIERARCHICAL model. $\{u, v\}$ are word types, k is a topic and each G^k_h is a multinomial word distribution. For example, G^2_{uv} represents a word distribution following the context uv in topic 2.

Let us clarify the DHPYP usage differences between our model and the previous work of Wood and Teh (2009). A key difference is the problem setting: Wood and Teh (2009) is aimed at the *supervised* adaptation of a language model for a specific domain, whereas our goal is *unsupervised* adaptation. In Wood and Teh (2009), each G^k_h for $k \in 1, 2, \cdots$ corresponds to a language model of a specific domain and the training corpus for each k is prespecified and fixed. For ease of data sparseness of domain-specific corpora, latent model G^0_h exploits shared statistics among G^k_h for $k = 1, 2, \cdots$. In contrast, with our model, each G^k_h is a topic, so it must perform the clustering of n-grams in addition to ex-

ploiting the latent G_h^0. This makes inference harder and requires more careful design of λ.

Modeling of λ We can better understand the role of λ in (3) by considering the posterior predictive form corresponds to (2), which is written as

$$p(w|h,k,\mathbf{w}) = \frac{c_{hw}^k - at_{hw}^k}{c_{h\cdot}^k + b} + \frac{at_{h\cdot}^k + b}{c_{h\cdot}^k + b} q(w|h,k,\mathbf{w}), \quad (4)$$

$$q(w|h,k,\mathbf{w}) = \lambda p(w|h',k,\mathbf{w}) + (1-\lambda)p(w|h,0,\mathbf{w}),$$

where c, t with superscript k corresponds to the count existing in topic k. This shows us that λ determines the back-off behavior: which probability we should take into account: the shorter context of the same topic $G_{h'}^k$ or the full context of the global model G_h^0. Wood and Teh (2009) shares this variable across all contexts of the same length, for each k, but this assumption may not be the best. For example, after the context "in order", we can predict the word "to" or "that", and this tendency is unaffected by the topic. We call this property of context the *topicality* and say that "in order" has *weak topicality*. Therefore, we place λ as a distinct value for each context h, which we share across all topics. We designate this λ determined by h λ_h in the following. Moreover, similar contexts may have similar values of λ_h. For example, the two contexts "of the" and "in the", which share the suffix "the", both have a *strong topicality*[3]. We encode this assumption by placing hierarchical Beta distributions on the suffix tree across all topics:

$$\lambda_h \sim \mathrm{Beta}(\gamma\lambda_{h'}, \gamma(1-\lambda_{h'})) = \mathrm{DP}(\gamma, \lambda_{h'}), \quad (5)$$

where DP is the hierarchical Dirichlet process (Teh et al., 2006), which has only two atoms in {0,1} and γ is a concentration parameter. As in HPYLM, we place a uniform prior $\lambda_0 = 1/2$ on the base distribution of the top node ($\lambda_\phi \sim \mathrm{DP}(\gamma, \lambda_0)$).

Having generated the topic component of the model, the corpus generating process is the same as the previous model because we only change the generating process of G_h^k for $k = 1, \cdots, K$.

[3]These words can be used very differently depending on the context. For example, in a teen story, "in the room" or "in the school" seems more dominant than "in the corpora" or "in the topic", which is likely to appear in this paper.

3.2 SWITCHING Model

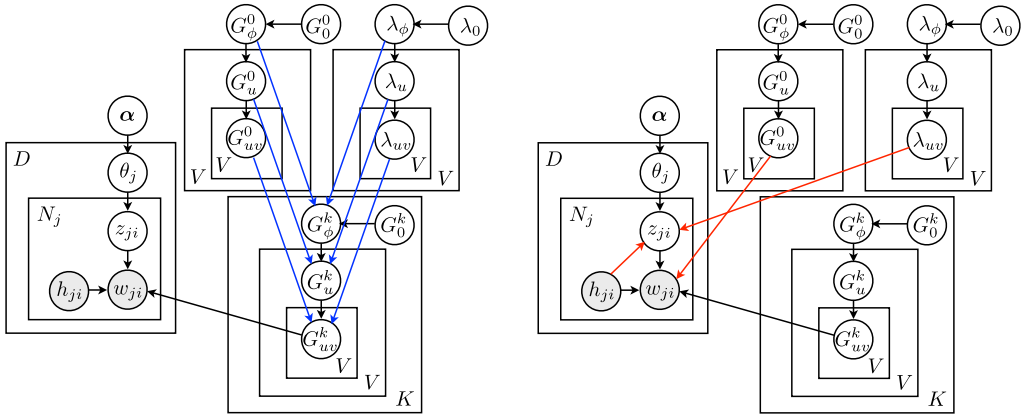
Our second extension also exploits the global G_h^0, albeit differently than the HIERARCHICAL model. In this model, the relationship of G_h^0 to the other $\{G_h^k\}$ is *flat*, not *hierarchical*: G_h^0 is a special topic that can generate a word. The model first generates each language model of $k = 0, 1, 2, \cdots, K$ independently as $G_h^k \sim \mathrm{PYP}(a, b, G_{h'}^k)$. When generating a word, it first determines whether to use global model G_h^0 or topic model $\{G_h^k\}_{k=1}^K$. Here, we use the λ_h introduced above in a similar way: the probability of selecting $k = 0$ for the next word is determined by the previous context. This assumption seems natural; we expect the G_h^0 to mainly generate common n-grams, and the topicality of each context determines how common that n-gram might be. The complete generative process of this model is written as follows:

1. Generate topics:
   For each $h \in \phi, \{V\}, \cdots, \{V\}^{n-1}$:
   $\lambda_h \sim \mathrm{DP}(\gamma, \lambda'_h)$
   For each $k \in 0, \cdots, K$:
   $G_h^k \sim \mathrm{PYP}(a, b, G_{h'}^k)$
2. Generate corpora:
   For each document $j \in 1, \cdots D$:
   $\theta_j \sim \mathrm{Dir}(\boldsymbol{\alpha})$
   For each word position $i \in 1, \cdots, N_j$:
   $l_{ji} \sim \mathrm{Bern}(\lambda_{h_{ji}})$
   If $l_{ji} = 0$: $z_{ji} = 0$
   If $l_{ji} = 1$: $z_{ji} \sim \theta_j$
   $w_{ji} \sim G_{h_{ji}}^{z_{ji}}$

The difference between the two models is their usage of the global model G_h^0. For a better understanding of this, we provide a comparison of their graphical models in Figure 2.

4 Inference

For posterior inference, we use the collapsed Gibbs sampler. In our models, all the latent variables are $\{G_h^k, \lambda_h, \theta_j, \mathbf{z}, \Theta\}$, where $\mathbf{z}$ is the set of topic assignments and $\Theta = \{a, b, \gamma, \boldsymbol{\alpha}\}$ are hyperparameters, which are treated later. We collapse all multinomials in the model, i.e., $\{G_h^k, \lambda_h, \theta_j\}$, in which G_h^k and λ_h are replaced with the Chinese restaurant process of PYP and DP respectively. Given the training corpus $\mathbf{w}$, the target posterior distribution is $p(\mathbf{z}, \mathbf{S}|\mathbf{w}, \Theta)$, where $\mathbf{S}$ is the set of seating arrangements of all restaurants. To distinguish the two types of restaurant, in the following, we refer the *restaurant* to indi-



(a) HIERARCHICAL (b) SWITCHING

Figure 2: Graphical model representations of our two models in the case of a 3-gram model. Edges that only exist in one model are colored.

cate the collapsed state of G_h^k (PYP), while we refer the *restaurant of* λ_h to indicates the collapsed state of λ_h (DP). We present two different types of sampler: a *token-based sampler* and a *table-based sampler*. For both samplers, we first explain in the case of our basic model (Section 2.2), and later discuss some notes on our extended models.

4.1 Token-based Sampler

The token-based sampler is almost identical to the collapsed sampler of the LDA (Griffiths and Steyvers, 2004). At each iteration, we consider the following conditional distribution of z_{ji} given all other topic assignments $\mathbf{z}^{-ji}$ and $\mathbf{S}^{-ji}$, which is the set of seating arrangements with a customer corresponds to w_{ji} removed, as

$$p(z_{ji}|\mathbf{z}^{-ji}, \mathbf{S}^{-ji}) \propto p(z_{ji}|\mathbf{z}^{-ji}) p(w_{ji}|z_{ji}, h_{ji}, \mathbf{S}^{-ji}), \tag{6}$$

where $p(w_{ji}|z_{ji}, h_{ji}, \mathbf{S}^{-ji}) =$

$$\frac{c_{hw}^k - at_{hw}^k}{c_{h\cdot}^k + b} + \frac{at_{h\cdot}^k + b}{c_{h\cdot}^k + b} p(w_{ji}|z_{ji}, h_{ji}, \mathbf{S}^{-ji}) \tag{7}$$

is a predictive word probability under the topic z_{ji}, and

$$p(z_{ji}|\mathbf{z}^{-ji}) = \frac{n_{jk}^{-ji} + \alpha_k}{N_j - 1 + \sum_{k'} \alpha_{k'}}, \tag{8}$$

where n_{jk}^{-ji} is the number of words that is assigned topic k in document j excluding w_{ji}, which is the same as the LDA. Given the sampled topic z_{ji}, we update the language model of topic z_{ji}, by adding customer w_{ji} to the restaurant specified by z_{ji} and context h_{ji}. See Teh (2006a) for details of these customer operations.

HIERARCHICAL Adding customer operation is slightly changed: When a new table is added to a restaurant, we must track the label $l \in \{0, 1\}$ indicating the parent restaurant of that table, and add the customer corresponding to l to the restaurant of λ_h. See Wood and Teh (2009) for details of this operation.

SWITCHING We replace $p(z_{ji}|\mathbf{z}^{-ji})$ with

$$p(z_{ji}|\mathbf{z}^{-ji}) = \begin{cases} p(l_{ji} = 0|h_{ji}) & (z_{ji} = 0) \\ p(l_{ji} = 1|h_{ji}) \cdot \frac{n_{jk}^{-ji} + \alpha_k}{\sum_{k \neq 0} n_{jk}^{-ji} + \sum_{k'} \alpha_{k'}} & (z_{ji} \neq 0), \end{cases} \tag{9}$$

where $p(l_{ji}|h_{ji})$ is a predictive of l_{ji} given by the CRP of $\lambda_{h_{ji}}$. We need not assign a label to a new table, but rather we always add a customer to the restaurant of λ_h according to whether the sampled topic is 0 or not.

4.2 Table-based Sampler

One problem with the token-based sampler is that the seating arrangement of the internal restaurant would never be changed unless a new table is created (or an old table is removed) in its child restaurant. This probability is very low, particularly in the restaurants of shallow depth (e.g., unigram or

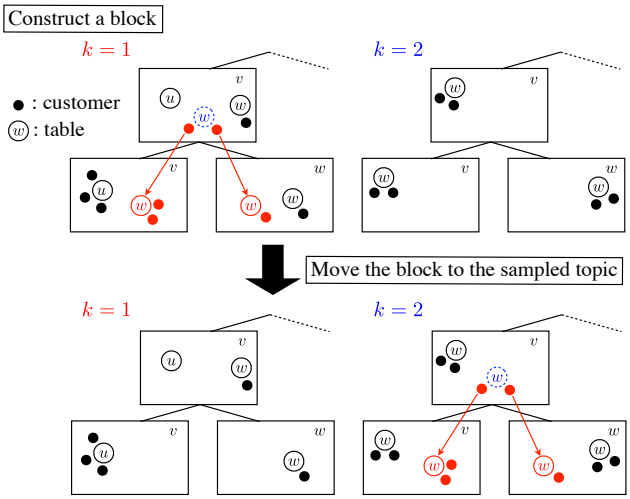


Figure 3: Transition of the state of restaurants in the table-based sampler when the number of topics is 2. $\{u, v, w\}$ are word types. Each box represents a restaurant where the type in the upper-right corner indicates the context. In this case, we can change the topic of the three 3-grams (vvw, vvw, uvw) in some documents from 1 to 2 at the same time.

bigram restaurants) because these restaurants have a larger number of customers and tables than those of deep depth, leading to get stack in undesirable local minima. For example, imagine a table in the restaurant of context "hidden" (depth is 2) and some topic, served "unit". This table is connected to tables in its child restaurants corresponding to some 3-grams (e.g., "of hidden unit" or "train hidden unit"), whereas similar n-grams, such as those of "of hidden units" or "train hidden units" might be gathered in another topic, but collecting these n-grams into the same topic might be difficult under the token-based sampler. The *table-based sampler* moves those different n-grams having common suffixes jointly into another topic.

Figure 3 shows a transition of state by the table-based sampler and Algorithm 4.2 depicts a high-level description of one iteration. First, we select a table in a restaurant, which is shown with a dotted line in the figure. Next, we descend the tree to collect the tables connected to the selected table, which are pointed by arrows. Because this connection cannot be preserved in common data structures for a restaurant described in Teh (2006a) or Blunsom et al. (2009), we select the child tables randomly. This is correct because customers in CRP are exchangeable, so we can restore the parent-child relations arbitrarily. We continue this process recursively until reaching the leaf nodes, obtaining a block of seating arrangement S. After calculating the conditional distribution, we sample new topic assignment for this block. Finally, we move this block to the sampled topic, which potentially changes the topic of many words across different documents, which are connected to customers in a block at leaf nodes (this connection is also arbitrary).

Algorithm 1 Table-based sampler

for all table **in** all restaurants **do**
  Remove a customer from the parent restaurant.
  Construct a block of seating arrangement S by descending the tree recursively.
  Sample topic assignment $z_S \sim p(z_S|S, \mathbf{S}^{-S}, \mathbf{z}^{-S})$.
  Move S to sampled topic, and add a customer to the parent restaurant of the first selected table.
end for

Conditional distribution Let $\mathbf{z}_S$ be the block of topic assignments connected to S and z_S be a variable indicating the topic assignment. Thanks to the exchangeability of all customers and tables in one restaurant (Teh, 2006a), we can imagine that customers and tables in S have been added to the restaurants last. We are interested in the following conditional distribution: (conditioning Θ is omitted)

$$p(z_S = k'|S, \mathbf{S}^{-S}, \mathbf{z}^{-S}) \propto p(S|\mathbf{S}^{-S}, k')p(z_S = k'|\mathbf{z}^{-S}),$$

where $p(S|\mathbf{S}^{-S}, k')$ is a product of customers' actions moving to another topic, which can be decomposed as:

$$p(S|\mathbf{S}^{-S}, k') = p(w|k', h) \prod_{s \in S} p(s|k') \quad (10)$$

$$p(s|k') = \frac{\prod_{i=0}^{t_s - 1}(b + a(t_{h_s w}^{k'(-s)} + i)) \prod_{j=1}^{c_{si}}(j - a)}{(b + c_{h_s w\cdot}^{k'(-s)})^{\overline{c_{s\cdot}}}} \quad (11)$$

$$\propto \frac{\prod_{i=0}^{t_s - 1}(b + a(t_{h_s w}^{k'(-s)} + i))}{(b + c_{h_s w\cdot}^{k'(-s)})^{\overline{c_{s\cdot}}}}. \quad (12)$$

Let us define some notations used above. Each $s \in S$ is a part of seating arrangements in a restaurant, there being t_s tables, i-th of which with c_{si} customers, with h_s as the corresponding context. A restaurant of context h and topic k has t_{hw}^k tables served dish w, i-th of which with c_{hwi}^k customers. Superscripts $-s$ indicate excluding the contribution

of customers in s, and $x^{\overline{n}} = x(x+1)\cdots(x+n-1)$ is the ascending factorial. In (10) $p(w|k', h)$ is the parent distribution of the first selected table, and the other $p(s|k')$ is the seating arrangement of customers. The likelihood for changing topic assignments across documents must also be considered, which is $p(z_S = k'|\mathbf{z}^{-S})$ and decomposed as:

$$p(z_S = k'|\mathbf{z}^{-S}) = \prod_j \frac{(n^{-S}_{jk'} + \alpha_{k'})^{\overline{n_j(S)}}}{(N^{-S}_j + \sum_k \alpha_k)^{\overline{n_j(S)}}}, \quad (13)$$

where $n_j(S)$ is the number of word tokens connected with S in document j.

HIERARCHICAL We skip tables on restaurants of $k = 0$, because these tables are all from other topics and we cannot construct a block. The effects of λ can be ignored because these are shared by all topics.

SWITCHING In the SWITCHING, $p(z_S = k'|\mathbf{z}^{-S})$ cannot be calculated in a closed form because $p(l_{ji}|h_{ji})$ in (9) would be changed dynamically when adding customers. This problem is the same one addressed by Blunsom and Cohn (2011), and we follow the same approximation in which, when we calculate the probability, we fractionally add tables and customers recursively.

4.3 Inference of Hyperparameters

We also place a prior on each hyperparameter and sample value from the posterior distribution for every iteration. As in Teh (2006a), we set different values of a and b for each depth of PYP, but share across all topics and sample values with an auxiliary variable method. We also set different value of γ for each depth, on which we place $\mathrm{Gamma}(1, 1)$. We make the topic prior $\boldsymbol{\alpha}$ asymmetric: $\boldsymbol{\alpha} = \beta\boldsymbol{\alpha}_0; \beta \sim \mathrm{Gamma}(1, 1), \boldsymbol{\alpha}_0 \sim \mathrm{Dir}(\mathbf{1})$.

5 Related Work

HMM-LDA (Griffiths et al., 2005) is a composite model of HMM and LDA that assumes the words in a document are generated by HMM, where only one state has a document-specific topic distribution. Our SWITCHING model can be understood as a lexical extension of HMM-LDA. It models the topicality by context-specific binary random variables, not by hidden states. Other n-gram topic models have focused mainly on information retrieval. Wang et al. (2007) is a topic model on automatically segmented chunks. Lindsey et al. (2012) extended this model with the hierarchical Pitman-Yor prior. They also used switching variables, but for a different purpose: to determine the segmenting points. They treat these variables completely independently, while our model employs a hierarchical prior to share statistical strength among similar contexts.

Our primary interest is language model adaptation, which has been studied mainly in the area of speech processing. Conventionally, this adaptation has relied on a heuristic combination of two separately trained models: an n-gram model $p(w|h)$ and a topic model $p(w|d)$. The unigram rescaling, which is a product model of these two models, perform better than more simpler models such as linear interpolation (Gildea and Hofmann, 1999). There are also some extensions to this method (Tam and Schultz, 2009; Huang and Renals, 2008), but these methods have one major drawback: at prediction, the rescaling-based method requires normalization across vocabulary at each word, which prohibits use on applications requiring dynamic (incremental) adaptation, e.g., settings where we have to update the topic distribution as new inputs come in. Tam and Schultz (2005) studied on this incremental settings, but they employ an interpolation. The practical interest here is whether our Bayesian models can rival the rescaling-based method in terms of prediction power. We evaluate this in the next section.

Corpus	min. appear	# types	training set # docs	training set # tokens	test set # docs	test set # tokens

6 Experiments

6.1 Settings

We test the effectiveness of presented models and the blocked sampling method on unsupervised language model adaptation settings. Specifically we

Figure 4: (a)–(c): Comparison of negative log-likelihoods at training of HPYTM ($K = 50$). Lower is better. HPYTM is trained on both token- and table-based samplers, while HPYTM$_{token}$ is trained only on the token-based sampler. (d)–(f): Test perplexity of various 3-gram models as a function of number of topics on each corpus.

concentrate on the *dynamic* adaptation: We update the posterior of language model given previously observed contexts, which might be decoded transcripts at that point in ASR or MT.

We use three corpora: the Brown, BNC and NIPS. The Brown and BNC are balanced corpora that consist of documents of several genres from news to romance. The Brown corpus comprises 15 categories. We selected two documents from each category for the test set, and use other 470 documents for the training set. For the NIPS, we randomly select 1,500 papers for training and 50 papers for testing. For BNC, we first randomly selected 400 documents from a written corpus and then split each document into smaller documents every 100 sentences, leading to 6,262 documents, from which we randomly selected 100 documents for testing, and other are used for training. See Table 1 for the pre-processing of unknown types and the resulting corpus statistics.

For comparison, besides our proposed HIERARCHICAL and SWITCHING models, we prepare various models for baseline. HPYLM is a n-gram language model without any topics. We call the model without the global G_h^0 introduced in Section 2.2 HPYTM. To see the effect of the table-based sampler, we also prepare HPYTM$_{token}$, which is trained only on the token-based sampler. RESCALING is the unigram rescaling. This is a product model of an n-gram model $p(w|h)$ and a topic model $p(w|d)$, where we learn each model separately and then combine them by:

$$p(w|h,d) \propto \left(\frac{p(w|d)}{p(w)}\right)^{\beta} p(w|h). \qquad (14)$$

We set β in (14) to 0.7, which we tuned with the Brown corpus.

6.2 Effects of Table-based Sampler

We first evaluate the effects of our blocked sampler at training. For simplicity, we concentrate on the HPYTM with $K = 50$. Table 4(a)–(c) shows negative likelihoods of the model during training. On all corpora, the model with the table-based sampler reached the higher probability space with much faster speed on both 3-gram and 4-gram models.

6.3 Perplexity Results

Training For burn-in, we ran the sampler as follows: For HPYLM, we ran 100 Gibbs iterations. For RESCALING, we ran 900 iterations on LDA and 100 iterations on HPYLM. For all other models, we ran 500 iterations of the Gibbs; HPYTM$_{token}$ is trained only on the token-based sampler, while for other models, the table-based sampler is performed after the token-based sampler.

Evaluation We have to adapt to the topic distribution of unseen documents incrementally. Although previous works have employed incremental EM (Gildea and Hofmann, 1999; Tam and Schultz, 2005) because their inference is EM/VB-based, we use the left-to-right method (Wallach et al., 2009), which is a kind of particle filter updating the posterior topic distribution of a test document. We set the number of particles to 10 and resampled each particle every 10 words for all experiments. To get the final perplexity, after burn-in, we sampled 10 samples every 10 iterations of Gibbs, calculated a test perplexity for each sample, and averaged the results.

Comparison of 3-grams Figure 4(d)–(f) shows perplexities when varying the number of topics. Generally, compared to the HPYTM$_{token}$, the HPYTM got much perplexity gains, which again confirm the effectiveness of our blocked sampler. Both our proposed models, the HIERARCHICAL and the SWITCHING, got better performances than the HPYTM, which does not place the global model G_h^0. Our SWITCHING model consistently performed the best. The HIERARCHICAL performed somewhat worse than the RESCALING when K become large, but the SWITCHING outperformed that.

Comparison of 4-grams and beyond We summarize the results with higher order n-grams in Table 2, where we also show the time for prediction. We fixed the number of topics $K = 100$ because we saw that all models but HPYTM$_{token}$ performed best at $K = 100$ when $n = 3$. Generally, the results are consistent with those of $n = 3$. The models with $n = \infty$ indicate a model extension using the Bayesian variable-order language model (Mochihashi and Sumita, 2008), which can naturally be integrated with our generative models. By this extension, we can prune unnecessary nodes stochastically during training. We can see that this ∞-gram did not hurt performances, but the sampled model get much more compact; in BNC, the number of nodes of the SWITCHING with 4-gram is about 7.9M, while the one with ∞-gram is about 3.9M. Note that our models require no explicit normalization, thereby drastically reducing the time for prediction compared to the RESCALING. This difference is especially remarkable when the vocabulary size becomes large.

		NIPS		BNC

SWITCHING	∞	100.4	1369	125.7	1006

Table 2: Comparison of perplexity and the time require for prediction (in seconds). The number of topics is fixed to 100 on all topic-based models.

We can see that our SWITCHING performed consistently better than the HIERARCHICAL. One reason for this result might be the mismatch of prediction of the topic distribution in the HIERARCHICAL. The HIERARCHICAL must allocate some (not global) topics to every word in a document, so even the words to which the SWITCHING might allocate the global topic (mainly function words; see below) must be allocated to some other topics, causing a mismatch of allocations of topic.

6.4 Qualitative Results

To observe the behavior in which the SWITCHING allocates some words to the global topic, in Figure 5, we show the posterior of allocating the topic 0 or not at each word in a part of the NIPS training corpus. We can see that the model elegantly identified content and function words, learning the topic distribution appropriately using only semantic contexts. These same results in the HIERARCHICAL are presented in Table 3, where we show some relations between λ_h and context h. Contexts that might be likely to precede nouns have a higher value of λ_h,

there has been much recent work on measuring image statistics and on learning probability distributions on images . we observe that the mapping from images to statistics is many-to-one and show it can be quantified by a phase space factor .

while prefixes of idioms have a lower value. The ∞-gram extension gives us the posterior of n-gram order $p(n|h)$, which can be used to calculate the probability of a word ordering composing a phrase in topic k as $p(w, n|k, h) \propto p(n|h)p(w|k, n, h)$. In Table 4, we show some higher probability topic-specific phrases from the model trained on the NIPS.

7 Conclusion

We have presented modeling and algorithmic contributions to the existing Bayesian n-gram topic model. We explored two different priors to incorporate a global model, and found the effectiveness of the flat structured model. We developed a novel blocked Gibbs move for these types of models to accelerate inference. We believe that this Gibbs operation can be incorporated with other models having a similar hierarchical structure. Empirically, we demonstrate that by a careful model design and efficient inference, a well-defined Bayesian model can rival the conventional heuristics.

Abstract

In this paper we report an empirical study on semi-supervised Chinese word segmentation using co-training. We utilize two segmenters: 1) a word-based segmenter leveraging a word-level language model, and 2) a character-based segmenter using character-level features within a CRF-based sequence labeler. These two segmenters are initially trained with a small amount of segmented data, and then iteratively improve each other using the large amount of unlabelled data. Our experimental results show that co-training captures 20% and 31% of the performance improvement achieved by supervised training with an order of magnitude more data for the SIGHAN Bakeoff 2005 PKU and CU corpora respectively.

1 Introduction

In the literature there exist two general models for supervised Chinese word segmentation, the word-based approach and the character-based approach. The word-based approach searches for all possible segmentations, usually created using a dictionary, for the optimal one that maximizes a certain utility. The character-based approach treats segmentation as a character sequence labeling problem, indicating whether a character is located at the boundary of a word. Typically the word-based approach uses word level features, such as word n-grams and word length; while the character-based approach uses character level information, such as character n-grams. Both approaches have their own advantages and disadvantages, and there has been some research in combining the two approaches to improve the performance of supervised word segmentation.

In this research we are trying to take advantage of the word-based and the character-based approaches in the semi-supervised setting for Chinese word segmentation, where there is only a limited amount of human-segmented data available, but there exists a relatively large amount of in-domain unsegmented data. The goal is to make use of the in-domain unsegmented data to improve the ultimate performance of word segmentation. According to Sun et al. (2009), "the two approaches [word-based and character-based approaches] are either based on a particular view of segmentation." This naturally motivates the use of co-training, which utilizes two models trained on different views of the input labeled data which then iteratively *educate* each other with the unlabelled data. At the end of the co-training iterations, the initially weak models achieve improved performance. Co-training has been successfully applied in many natural language processing tasks. In this paper we describe an empirical study of applying co-training to semi-supervised Chinese word segmentation. Our experimental results show that co-training captures 20% and 31% of the performance improvement achieved by supervised training with an order of magnitude more data for the SIGHAN Bakeoff 2005 PKU and CU corpora respectively.

In section 2 we review the two supervised approaches and co-training algorithm in more detail. In section 3 we describe our implementation of the co-training word segmentation. In section 4 we de-

scribe our co-training experiments. In section 5 we conclude the paper.

2 Related Work

In this section, we first review the related research on the word-based and the character-based approaches for Chinese word segmentation, and comparatively analyze these two supervised approaches. We then review the related research on co-training.

2.1 Supervised Word Segmentation

2.1.1 Word-Based Segmenter

Given a character sequence $c_1c_2...c_n$, the word-based approach searches in all possible segmentations for one that maximizes a pre-defined utility function, formally represented as in Equation 1. The search space, $GEN(c_1c_2...c_n)$, can be represented as a lattice, where each vertex represents a character boundary index and each arc represents a word candidate which is the sequence of characters within the index range. A dictionary[1] can be used to generate such a lattice. For example, given the character sequence "发展中国家" and a dictionary that contains the words {发展，中国，国家} and all single Chinese characters, the search space is illustrated in Figure 1.

$$\hat{W} = arg \max_{W \in GEN(c_1c_2...c_n)} Util(W) \quad (1)$$

Dynamic programming such as Viterbi decoding is usually used to search for the optimized segmentation. The utility can be as simple as the negation of number of words (i.e. $Util(W) = -\mid W \mid$), which gives a reasonable performance if the dictionary used for generating the search space has a good coverage. Alternatively one can search for the segmentation that maximizes the word sequence probability $P(W)$ (i.e. $Util(W) = P(W)$). With a Markov assumption, $P(W)$ can be calculated using a language model as in Equation 2.

$$\begin{aligned} P(W) &= P(w_1w_2...w_m) \\ &= P(w_1).P(w_2|w_1)...P(w_n|w_1w_2...w_{n_1}) \\ &= P(w_1)P(w_2|w_1)...P(w_n|w_{n-1}) \end{aligned} \quad (2)$$

More generally, the utility can be formulated as a semi-Markov linear model, defined as Equation 3, in which Φ is the feature function vector, and Θ is the parameter vector that can be learned from training data using different techniques: Liang (2005), Gao et al. (2005), and Zhang and Clark (2007) use averaged perceptron; Nakagawa (2004) uses general iterative scaling; Andrew (2006) uses semi-Markov CRF; and Sun (2010) uses a passive-aggressive learning algorithm.

$$Util(W) = \Theta^T \Phi(c_1c_2...c_n, W) \quad (3)$$

2.1.2 Character-Based Segmenter

The character-based approach treats word segmentation as a character sequence labeling problem, to label each character with its location in a word, first proposed by Xue (2003).[2] The basic labeling scheme is to use two tags: 'B' for the beginning character of a word and 'O' for other characters (Peng et al., 2004). Xue (2003) use a four-tag scheme based on some linguistic intuitions: 'B' for the beginning character, 'I' for the internal characters, 'E' for the ending character, and 'S' for single-character word. For example, the word sequence "洽谈会 很 成功" can be labelled as 洽\B 谈\I 会\E 很\S 成\B 功\E. Zhao et al. (2010) further extend this scheme by using six tags.

Training and decoding of the character labeling problem is similar to part-of-speech tagging, which

[1] A dictionary is not a must to create the search space but it could shrink the search space and also lead to improved segmentation performance.

[2] Teahan et al. (2000) use a character language model to determine whether a word boundary should be inserted after each character, which can also be considered as a character-based approach as well.

is also generally formulated as a linear model. Many machine learning techniques have been explored: Xue (2003) use a maximum entropy model; Peng et al. (2004) use linear-chain CRF; Liang (2005) uses averaged perceptron; Sun et al. (2009) use a discriminative latent variable approach.

2.1.3 Comparison and Combination

It is more natural to use word-level information, such as word n-grams and word length, in a word-based segmenter; while it is more natural to use character-level information, such as character n-grams, in a character-based segmenter. Sun (2010) gives a detailed comparison of the two approaches from both the theoretical and empirical perspectives. Word-level information has greater representational power in terms of contextual dependency, while character-level information is better at morphological analysis in terms of word internal structures.

On one hand, features in a character-based model are usually defined in the neighboring n-character window; and an order-K CRF can only look at the labels of the previous K characters. Given that many words contain more than one character, a word-based model can examine a wider context. Thus the contextual dependency information encoded in a character-based model is generally weaker than in a word-based model. Andrew (2006) also shows that semi-Markov CRF makes strictly weaker independence assumptions than linear CRF and so a word-based segmenter using an order-K semi-Markov model is more expressive than a character-based model using an order-K CRF.

On the other hand, Chinese words have internal structures. Chinese characters can serve some morphological functions in a word. For example, the character 们 usually works as a suffix to signal plural; the character 者 can also be a suffix meaning a group of people; and 阿 generally works as a prefix before a person's nickname that has one character. Such morphological information is extremely useful for identifying unknown words. For example, a character-based model can learn that 阿 is usually tagged as 'B' and the next character is usually tagged as 'E'. Thus even when 阿甘 is not an existing word in the training data, a character-based model might still be able to correctly label it as 阿\B 甘\E.

Recent advanced Chinese word segmenters, either word-based or character-based, have been trying to make use of both word-level and character-level information. For example, Nakagawa (2004) integrates the search space of a character-based model into a word-based model; Andrew (2006) converts CRF-type features into semi-CRF features in his semi-Markov CRF segmenter; Sun et al. (2009) add word identify information into their character-based model; and Sun (2010) combine the two approaches at the system level using bootstrap aggregating.

2.2 Co-Training

The co-training approach was first introduced by Blum and Mitchell (1998). Theoretical analysis of its effectiveness is given in (Blum and Mitchell, 1998; Dasgupta et al., 2001; Abney, 2002). Co-training works by partitioning the feature set into two conditionally independent views (given the true output). On each view a statistical model can be trained. The presence of multiple distinct views of the data can be used to train separate models, and then each model's predictions on the unlabeled data are used to augment the training set of the other model.

Figure 2 depicts a general co-training framework. The inputs are two sets of data, a labelled set S and an unlabelled set U. Generally S is small and U is large. Two statistical models M1 and M2 are used, which are built on two sets of data L1 and L2 initialized as S but then incrementally increased in each iteration. C is a cache holding a small subset of U to be labelled by both models (Blum and Mitchell, 1998; Abney, 2002). In some applications, C is not used and both models label the whole set of U (i.e. C==U) (Collins and Singer, 1999; Nigam and Ghani, 2000; Pierce and Cardie, 2001). The stopping criteria can be, for example, when U is empty, or when a certain number of iterations are executed.

In step 5 and 6 during each iteration, some data labelled by M1 are selected and added to the training set L2, and vice versa. Several selection algorithms have been proposed. Dasgupta et al. (2001) and Abney (2002) use a selection algorithm that tries to maximize the agreement rate between the two models. The more popular selection algorithm is to choose the K examples that have the highest con-

```
Input:
    S is the labelled data
    U is the unlabelled data
Variables:
    L1 is the training data for View One
    L2 is the training data for View Two
    C is a cache holding a small subset of U
Initialization:
    L1 <- S
    L2 <- S
    C <- randomly sample a subset of U
    U <- U - C
REPEAT:

fidence score (Nigam and Ghani, 2000; Pierce and Cardie, 2001). In order to balance the class distributions in the training data L1 and L2, Blum and Mitchell (1998) select P positive examples and Q negative examples that have the highest confidence scores respectively. Wang et al. (2007) and Guz et al. (2007) use disagreement-based selection, which adds to L2, data that is labeled by M1 and M2 with high and low confidence respectively, with the intuition that such data are more useful and compensatory to M2. Finally, instead of adding the selected data to the training data, Tur (2009) propose the co-adaptation approach which linearly interpolates the existing model with the new model built with the new selected data.

3 Segmentation With Co-Training

3.1 Design of Two Segmenters

The use of co-training needs two statistical models that satisfy the following three conditions. First, in theory these two models need to be built on two conditionally independent views. However this is a very strong assumption and many large-scale NLP problems do not have a natural split of features to satisfy this assumption. In practice it has been shown that co-training can still achieve improved performance when this assumption is violated, but conforming to the conditionally independent assumption leads to a bigger gain (Nigam and Ghani, 2000; Pierce and Cardie, 2001). Thus we should strive to have the two models less correlated. Second, the two models both need to be effective for the task, that is, each of the models itself can perform the task reasonably well. Third, the decoding and training of the two models need to be efficient, as in co-training we need to segment the unlabelled data and re-train the models in each iteration. In the following we describe our design of the two segmenters.

Word-based segmenter In the word-based segmenter, we utilize a statistical n-gram language model and try to optimize the language modeling score together with a word insertion penalty, as show in Equation 4. K is a per-word penalty that is pre-determined with 10 fold cross-validation on the SIGhan PKU training set. We train a Kneser-Ney backoff language model from the training data, and extract a dictionary of words from the training data for generating the search space. Our pilot study suggested that a bigram language model is sufficient for this task.

$$Util(W) = \ln(P(W)) - |W| * K \quad (4)$$

Character-based segmenter We use an order-1 linear conditional random field to label a character sequence. Following Xue (2003), we use the four-tag scheme "BIES". We use the tool CRF++[3]. The features that we use are character n-grams within the neighboring 5-character window and tag bigrams. Given a character c_0 in the character sequence $c_{-2}c_{-1}c_0c_1c_2$, we extract the following features: character unigrams c_{-2}, c_{-1}, c_0, c_1, c_2, bigrams $c_{-1}c_0$ and c_0c_1. L2 regularization is applied in learning.

As can be seen, we build a word-based segmenter that uses only word level features, and a character-based segmenter that uses only character level features. These two segmenters by no means satisfy the conditionally independence assumption, but we have the hope that they are not too correlated as they use different levels of information and these

[3] http://crfpp.googlecode.com/svn/trunk/doc/index.html

different levels of information have been shown to be complementary in literature. Also the effectiveness of these two segmenters has been demonstrated in literature and will be shown again in our results in Section 4. Finally, both segmenters can decode and be trained pretty quickly. In our implementation, running on a Xeon 2.93GHz CPU with 4G of memory, it takes less than 30 seconds to build a word-based segmenter and less than 1 hour to build a character-based segmenter with the SIGhan PKU training data, and it takes less than 20 seconds to apply the word-based segmenter or less than 5 seconds to apply the character-based segmenter to the PKU testing data.

3.2 Co-Training

We follow the framework in Figure 2 for the co-training setup. We do not use the cache C, but directly label the whole unlabelled data set U, because in our experiment setup (see Section 4) U is not huge and computationally we can afford to label the whole set. The stopping criteria we use is when U is empty. Following Wang et al. (2007) and Guz et al. (2007), we use disagreement-based data selection. In every iteration, we pick some sentences that are segmented by the character-based model with high confidence but are segmented by the word-based model with low confidence to add to the training data of the word-based model, and vice versa. Confidence score is normalized with regard to the length of the sentence (i.e. number of characters) to avoid biasing towards short sentences. Confidence scores between the two segmenters, however, are not directly comparable. Thus we rank the sentences by their confidence scores in each segmenter respectively, and calculate the rank difference between the two segmenters. This rank difference is used as the indication of the gap of the confidence between the two segmenters. The sentences of highest rank difference are assigned to the training data of the word-based segmenter, with the segmentations from the character-based model; and the sentences of lowest rank difference are assigned to the training data of the character-based model, with segmentations from the word-based model.

4 Experiments

4.1 Data and Experiment Setup

We conduct a set of experiments to evaluate the performance of our co-training on semi-supervised Chinese word segmentation. Two corpora, the PKU corpus and the CU corpus, from the SIGhan Bakeoff 2005 are used. The PKU corpus contains texts of simplified Chinese characters, which include 19056 sentences in the training data and 1945 sentences in the testing data. The CU corpus contains texts of traditional Chinese characters, which include 53019 sentences in the training data and 1493 sentences in the testing data. The training data in each corpus is randomly split into 10 subsets. In each run one set is used as the labelled data S, and the other nine sets are combined and used as the unlabelled data U with segmentations removed. That is, 10% of the training data is used as segmented data, and 90% are used as unsegmented data in our semi-supervised training. This setup resembles our semi-supervised application, where there is only a small limited amount of segmented data but a relatively large amount of in-domain unsegmented data available. The final trained character-based and word-based segmenters from co-training are then evaluated on the testing data. Results we report in this paper are the average of the 10 runs. F-measure is used as the performance measurement. A 99% confidence interval is calculated as $\pm 2.56\sqrt{p(1-F)/N}$ for statistical significance evaluation, where F is the F-measure and N is the number of words. Subsequent assertions in this paper about statistical significance indicate whether or not the p-value in question exceeds 1%.

4.2 Co-Training Results

For comparison, we measure the baseline as the performance of a model trained with the 10% segmented data only (referred to as *BASIC* baselines). The *BASIC* baselines, both for the word-based model and the character-based model, however, use only the segmented data but leave out the large amount of available unsegmented data. We thus measure another baseline (referred to as *FOLD-IN*), which naively uses the unsegmented data. In the *FOLD-IN* baseline, a model is first trained with the 10% segmented data, and then this model is used

Table 1: Co-training results

	PKU		CU	
	char	word	char	word
BASIC	90.4	84.2	89.2	78.4
FOLD-IN	90.5	84.2	89.3	78.5
CEILING	94.5	93.0	94.2	88.9
CO-TRAINING	91.2	90.3	90.2	86.2

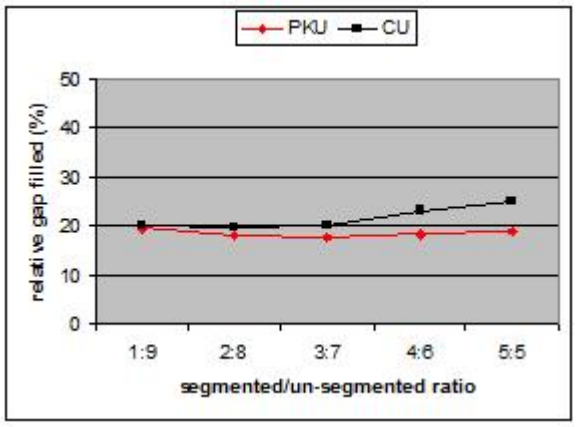

Figure 3: Gap filling with different split ratio

to label the unsegmented data. The automatic segmentation is then combined with the segmented data to build a new model. We also measure the *CEILING* as the performance of a model trained with all the training data available, i.e. we use the true segmentations of the 90% unsegmented data together with the 10% segmented data to train a model. The *CEILING* tells us the oracle performance when we have all segmented data for training, while the *BASIC* shows how much performance is dropped when we only have 10% of the segmented data. The performance of co-training will tell us how much we can fill the gap by taking advantage of the other 90% as unsegmented data in the semi-supervised training. The *FOLD-IN* baseline further verifies the effectiveness of co-training, i.e. co-training should perform better than naively folding in the unsegmented data.

Table 1 presents the results. First, we see that both the word-based and character-based models are doing a decent job under the *CEILING* condition. This confirms the effectiveness of each individual model, which is generally a requirement for running co-training. The character-based segmenter, although simple and with character-level features only, achieves the performance that is close to the state-of-the-art technologies that are much more complicated (The best performance is 95.2% for the PKU corpus and 95.1% for the CU corpus, see (Sun et al., 2009)). Second, we see that under all four conditions, the character-based segmenter performs better than the word-based model. This is not too surprising as these results are consistent with those reported in the literature. The word-based segmenter implemented in this work is less powerful, and it needs a good dictionary to achieve good performance. In our implementation, a dictionary is extracted from the segmented training set. Thus the word-based model suffers a lot when the training data is small. Third, we see that both the word-based model and the character-based model are improved by co-training, and the improvements are all statistically significant. It is not surprising for the word-based model to learn from the more accurate character-based model, which can also identify new words to add to the dictionary. More interestingly, the character-based segmenter is able to benefit from the less powerful word-based segmenter. For the character-based model, about 20% of the gap between *BASIC* and *CEILING* is filled by co-training, consistently in both the PKU and CU corpora. Finally, comparing *FOLD-IN* and *BASIC*, we see that naively using the unsegmented data does not lead to a significant improvement. This suggests that co-training provides a process that effectively makes use of the unsegmented data.

For completeness, in Figure 3 we also show the relative gap filling with different splits of the segmented vs unsegmented data. With more data moving to the segmented set, the absolute improvement of co-training over *BASIC* gets smaller, while the gap between the *BASIC* and *CEILING* also becomes smaller. The relative gap filled, i.e. the improvement relative to the difference between *BASIC* and *CEILING*, as can be seen, consistently falls inside the section of 15% and 25%.

4.3 Further Analysis

It is not surprising that the word-based segmenter benefits from co-training since it learns from the more accurate character-based segmenter. Our focus, however, is to better understand what benefit the character-based segmenter gains from the co-training procedure. The character-based segmenter treats word segmentation as a character sequence labelling problem with four tags "B I E S". Assuming that segmentation accuracy is proportional to tag accuracy, we examine the tag accuracy of the character-based segmenter before and after co-training.

If a character is labelled with tag *T0* initially before co-training and with tag *T1* after co-training, with the tag *T1* different from *T0*, there can be one of three cases: 1) *T0* is correct; 2) *T1* is correct; or 3) neither is correct. The absolute gain from co-training of switching from tag *T0* to *T1* is defined as the number of case 2 instances less case 1 instances. Absolute gain indicates the gain of tag accuracy where co-training learns to switch from *T0* to *T1*, and it contributes to the overall tag accuracy improvement. We also define *relative gain* of switching from tag *T0* to *T1* as the absolute gain divided by the total number of cases switching from tag *T0* to *T1*. Relative gain indicates how well co-training learns to switch from *T0* to *T1*.

Results are shown in Table 2. For both absolute gain and relative gain, 12 ordered switching pairs can be divided into two pools, a positive pool that has higher gain including $B \rightarrow E$, $E \rightarrow B$, $S \rightarrow B$, $S \rightarrow E$, $E \rightarrow I$, $B \rightarrow I$, $B \rightarrow S$, and a neutral pool that has lower or even negative gain including $I \rightarrow E$, $I \rightarrow S$, $I \rightarrow B$, $E \rightarrow S$, $S \rightarrow I$. The $S \rightarrow B$, $S \rightarrow E$, $B \rightarrow I$, $E \rightarrow I$ in the positive pool actually suggest that the character-based segmenter learns from co-training to combine a single-character word with it's neighbour to create a new longer word; whereas the $I \rightarrow E$, $I \rightarrow S$, $I \rightarrow B$ in the neutral pool suggest that it does not really learn how to separate a longer words into smaller units.

Table 2: Absolute Gain and Relative Gain

		Absolute Gain		Relative Gain	
T0	T1	PKU	CU	PKU	CU
B	I	678	681	0.28	0.59
B	E	2331	1727	0.41	0.46

S	I	104	47	0.22	0.28
S	E	1438	846	0.26	0.55

4.4 Feature Combination

We split the features into two sets, a character-level feature set used by the character-based segmenter and a word-level feature set used by the word-based segmenter. We have shown that these two segmenters improve each other via co-training. However, as reviewed in Section 2.1, there is active research in combining the character-level and word-level features in a segmenter. When training with the whole set of data (i.e. under the *CEILING* condition), a segmenter with combined features tends to perform better than only using one set of features. Thus we need to address two problems. First, we want to understand whether co-training, which splits the features, can actually beat the *BASIC* and *FOLD-IN* baselines of a segmenter with combined features. Second, we want to explore whether we can further improve the final co-training performance by feature combination.

To address these two problems, we adopt Weiwei Sun's character-based segmenter[4] in (Sun, 2010). We use this segmenter because it is publicly available and it performs well on both the PKU corpus and CU corpus. It models word segmentation as a character labelling problem, and solves it with a *passive-aggressive* optimization algorithm. It uses the same feature set as in (Sun et al., 2009), including both character-level features and word-level features. Character-level features include character uni-grams and bi-grams in the five character window, and whether the current character is the same as the next or the one after the next character. Word-

level features include what word uni-grams or bi-grams are anchored at the current character. Word uni-grams and bi-grams are extracted from the labeled training data. For more details, please refer to (Sun et al., 2009) and (Sun, 2010). For ease of description, we will refer to Weiwei Sun's segmenter with combined features as *Sun-Segmenter*, and the character-based segmenter used in our co-training which uses character-level features as *Char-Segmenter*.

Table 3 shows the performance of the Sun-Segmenter under the three conditions: *BASIC*, *FOLD-IN*, and *CEILING*. We see that under the *CEILING* condition, the Sun-Segmenter outperforms the Char-Segmenter by 0.3% in the PKU corpus and 0.8% in the CU corpus. However, under the *BASIC* condition when there is only 10% of training data available, the Sun-Segmenter gives no gain. This probably is due to the fact that the Sun-Segmenter uses a much larger feature set and thus correspondingly a larger training set is needed to avoid under-fitting. The Sun-Segmenter has more gain when folding in the unsegmented data than the Char-Segmenter, further suggesting that the Sun-Segmenter is benefiting from the size of data. For both corpora, however, the Char-Segmenter after co-training beats the *FOLD-IN* baseline of the Sun-Segmenter by at least 0.5%, and the improvement is statistically significant. When there is only a small amount of segmented data available, using a more advanced segmenter with combined features still under-performs compared to co-training. These results justify the split of features for running co-training.

Next we would like to explore whether we could further improve the co-training performance, given that we have a more advanced segmenter using combined features. We try two approaches. In the first approach, after all the iterations of co-training, the data are split into two sets, one set for training the word-based segmenter L1 and the other set for training the character-based segmenter L2. The segmentations of these two sets of data are probably better than the segmentations under the *FOLD-IN* condition. We thus combine the two sets of data, and use the combined data to train a new model with the Sun-Segmenter. In the second approach, we use the character-based segmenter after co-training, which has an improved performance, to relabel the set of unsegmented data U, and then combine it with the segmented data set S. We then use the combined data to train a new model with the Sun-Segmenter.

Results are shown in Table 4. In the PKU corpus, we do not see a gain using either the data combination approach or the relabelling approach compared to the performance of the Char-Segmenter after co-training, probably because the Sun-Segmenter just modestly improves over the Char-Segmenter under the *CEILING* condition. However, in the CU corpus, where under the *CEILING* condition the Sun-Segmenter has a much bigger gain over the Char-Segmenter, there is 0.7% improvement by using the data combination approach and 0.8% by using the relabelling approach, and the improvement is statistically significant. Overall, using co-training with feature combination we are able to cut the gap between the *BASIC* baseline and *CEILING* of the Sun-Segmenter by 20% in the PKU corpus and 31% in the CU corpus.

5 Discussion

There has been some research on semi-supervised Chinese word segmentation. For example, Liang (2005) derive word cluster features and mutual information features from unlabelled data, and add them to supervised discriminative training; Li and Sun (2009) use punctuation as implicit annotations of a character starting a word (the character after a punctation) or ending a word (the character before a punctuation) in a large unlabelled data set to augment supervised data; Sun and Xu (2011) derive a large set of features from unlabelled data, includ-

ing mutual information, accessor variety and punctuation variety to augment the character and word features derived from labelled data. These research works aim to use huge amount of unsegmented data to further improve the performance of an already well-trained supervised model.

In this paper, we assume a much limited amount of segmented data available, and try to boost up the performance by using in-domain unsegmented data. Chinese word segmentation is domain-sensitive or application sensitive. For example, a CRF segmenter trained on the SIGhan MSR training data, which achieves an F-measure of 96.5% in the MSR testing data, only has 83.8% when applied to the PKU testing data; and the same CRF segmenter trained on the PKU training data achieves 94.5% on the PKU testing data. When one starts a new application that requires word segmentation in a new domain, it is likely that there is only a very small amount of segmented data available.

We propose the approach of co-training for Chinese word segmentation for the semi-supervised setting where there is only a limited amount of human-segmented data available, but there exists a relatively large amount of in-domain unsegmented data. We split the feature set into character-level features and word-level features, and then build a character-based segmenter with character-level features and a word-based segmenter with word-level features, using the limited amount of available segmented data. These two segmenters then iteratively educate and improve each other by making use of the large amount of unsegmented data. Finally we combine the word-level and character-level features with an advanced segmenter to further improve the co-training performance. Our experiments show that using 10% data as segmented data and the other 90% data as unsegmented data, co-training reaches 20% performance improvement achieved by supervised training with all data in the SIGHAN 2005 PKU corpus and 31% in the CU corpus.

Ubertagging: Joint segmentation and supertagging for English

Rebecca Dridan
Institutt for Informatikk
Universitetet i Oslo
rdridan@ifi.uio.no

Abstract

A precise syntacto-semantic analysis of English requires a large detailed lexicon with the possibility of treating multiple tokens as a single meaning-bearing unit, a *word-with-spaces*. However parsing with such a lexicon, as included in the English Resource Grammar, can be very slow. We show that we can apply supertagging techniques over an ambiguous token lattice without resorting to previously used heuristics, a process we call ubertagging. Our model achieves an ubertagging accuracy that can lead to a four to eight fold speed up while improving parser accuracy.

1 Introduction and Motivation

Over the last decade or so, supertagging has become a standard method for increasing parser efficiency for heavily lexicalised grammar formalisms such as LTAG (Bangalore and Joshi, 1999), CCG (Clark and Curran, 2007) and HPSG (Matsuzaki et al., 2007). In each of these systems, fine-grained lexical categories, known as supertags, are used to prune the parser search space prior to full syntactic parsing, leading to faster parsing at the risk of removing necessary lexical items. Various methods are used to configure the degree of pruning in order to balance this trade-off.

The English Resource Grammar (ERG; Flickinger (2000)) is a large hand-written HPSG-based grammar of English that produces fine-grained syntacto-semantic analyses. Given the high level of lexical ambiguity in its lexicon, parsing with the ERG should therefore also benefit from supertagging, but while various attempts have shown possibilities (Blunsom, 2007; Dridan et al., 2008; Dridan, 2009), supertagging is still not a standard element in the ERG parsing pipeline. There are two main reasons for this. The first is that the ERG lexicon does not assign simple atomic categories to words, but instead builds complex structured *signs* from information about lemmas and lexical rules, and hence the shape and integration of the supertags is not straightforward. Bangalore and Joshi (2010) define a supertag as a primitive structure that contains all the information about a lexical item, including argument structure, and where the arguments should be found. Within the ERG, that information is not all contained in the lexicon, but comes from different places. The choice, therefore, of what information may be predicted prior to parsing and how it should be integrated into parsing is an open question.

The second reason that supertagging is not standard with ERG processing is one that is rarely considered when processing English, namely ambiguous segmentation. In most mainstream English parsing, the segmentation of parser input into tokens that will become the leaves of the parse tree is considered a fixed, unambiguous process. While recent work (Dridan and Oepen, 2012) has shown that producing even these tokens is not a solved problem, the issue we focus on here is the ambiguous mapping from these tokens to meaning-bearing units that we might call *words*. Within the ERG lexicon are many multi-token lexical entries that are sometimes referred to as *words-with-spaces*. These multi-token entries are added to the lexicon where the grammarian finds that the semantics of a fixed expression is non-compositional and has the distributional properties of other single word entries. Some examples include an adverb-like *all of a sudden*, a preposition-like *for example* and an adjective-like *over and done with*. Each of these entries create an segmentation ambiguity between treating the whole expression as a single unit, or allowing analyses comprising en-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1201–1212,
Seattle, Washington, USA, 18-21 October 2013.

tries triggered by the individual tokens. Previous supertagging research using the ERG has either used the gold standard tokenisation, hence making the task artificially easier, or else tagged the individual tokens, using various heuristics to apply multi-token tags to single tokens. Neither approach has been wholly satisfactory.

In this work we avoid the heuristic approaches and learn a sequential classification model that can simultaneously determine the most likely segmentation and supertag sequences, a process we dub ubertagging. We also experiment with more fine-grained tag sets than have been previously used, and find that it is possible to achieve a level of ubertagging accuracy that can improve both parser speed and accuracy for a precise semantic parser.

2 Previous Work

As stated above, supertagging has become a standard tool for particular parsing paradigms, but the definitions of a supertag, the methods used to learn them, and the way they are used in parsing varies across formalisms. The original supertags were 300 LTAG elementary trees, predicted using a fairly simple trigram tagger that provided a configurable number of tags per token, since the tagger was not accurate enough to make assigning a single tree viable parser input (Bangalore and Joshi, 1999). The C&C CCG parser uses a more complex Maximum Entropy tagger to assign tags from a set of 425 CCG lexical categories (Clark and Curran, 2007). They also found it necessary to supply more than one tag per token, and hence assign all tags that have a probability within a percentage β of the most likely tag for each token. Their standard parser configuration uses a very restrictive β value initially, relaxing it when no parse can be found. Matsuzaki et al. (2007) use a supertagger similar to the C&C tagger alongside a CFG filter to improve the speed of their HPSG parser, feeding sequences of single tags to the parser until a parse is possible. As in the ERG, category and inflectional information are separate in the automatically-extracted ENJU grammar: their supertag set consists of 1361 tags constructed by combining lexical categories and lexical rules. Figure 1 shows examples of supertags from these three tag sets, all describing the simple transitive use of *lends*.

(b) CCG

[NP.nom<V.bse>NP.acc]-singular3rd_verb_rule

(c) ENJU HPSG

Figure 1: Examples of supertags from LTAG, CCG and ENJU HPSG, for the word *lends*.

The ALPINO system for parsing Dutch is the closest in spirit to our ERG parsing setup, since it also uses a hand-written HPSG-based grammar, including multi-token entries in its lexicon. Prins and van Noord (2003) use a trigram HMM tagger to calculate the likelihood of up to 2392 supertags, and discard those that are not within τ of the most likely tag. For their multi-token entries, they assign a constructed category to each token, so that instead of assigning `preposition` to the expression *met betrekking tot* ("with respect to"), they use `(1,preposition)`, `(2,preposition)`, `(3,preposition)`. Without these constructed categories, they would only have 1365 supertags.

Most previous supertagging attempts with the ERG have used the grammar's lexical types, which describe the coarse-grained part of speech, and the subcategorisation of a word, but not the inflection. Hence both *lends* and *lent* have a possible lexical type `v_np*_pp*_to_le`, which indicates a verb, with optional noun phrase and prepositional phrase arguments, where the preposition has the form *to*. The number of lexical types changes as the grammar grows, and is currently just over 1000. Dridan (2009) and Fares (2013) experimented with other tag types, but both found lexical types to be the optimal balance between predictability and efficiency. Both used a multi-tagging approach dubbed selective tagging to integrate the supertags into the parser. This involved only applying the supertag filter when the tag probability is above a configurable threshold, and not pruning otherwise.

For multi-token entries, both Blunsom (2007) and

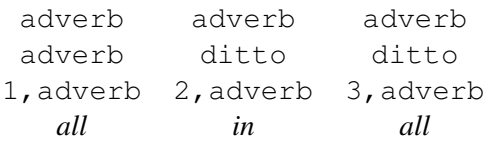

Figure 2: Options for tagging parts of the multi-token adverb *all in all* separately.

Dridan (2009) assigned separate tags to each token, with Blunsom (2007) assigning a special `ditto` tag all but the initial token of a multi-token entry, while Dridan (2009) just assigned the same tag to each token (leading to *example* in the expression *for example* receiving `p_np_i_le`, a preposition-type category). Both of these solutions (demonstrated in Figure 2), as well as that of Prins and van Noord (2003), in some ways defeat one of the purposes of treating these expressions as fixed units. The grammarian, by assigning the same category to, for example, *all of a sudden* and *suddenly*, is declaring that these two expressions have the same distributional properties, the properties that a sequential classifier is trying to exploit. Separating the tokens loses that information, and introduces extra noise into the sequence model.

Ytrestøl (2012) and Fares (2013) treat the multi-entry tokens as single expressions for tagging, but with no ambiguity. Ytrestøl (2012) manages this by using gold standard tokenisation, which is, as he states, the standard practice for statistical parsing, but is an artificially simplified setup. Fares (2013) is the only work we know about that has tried to predict the final segmentation that the ERG produces. We compare segmentation accuracy between our joint model and his stand-alone tokeniser in Section 6.

Looking at other instances of joint segmentation and tagging leads to work in non-whitespace separated languages such as Chinese (Zhang and Clark, 2010) and Japanese (Kudo et al., 2004). While at a high level, this work is solving the same problem, the shape of the problems are quite different from a data point of view. Regular joint morphological analysis and segmentation has much greater ambiguity in terms of possible segmentations but, in most cases, less ambiguity in terms of labelling than our situation. This also holds for other lemmatisation and morphological research, such as Toutanova and Cherry (2009). While we drew inspiration from this

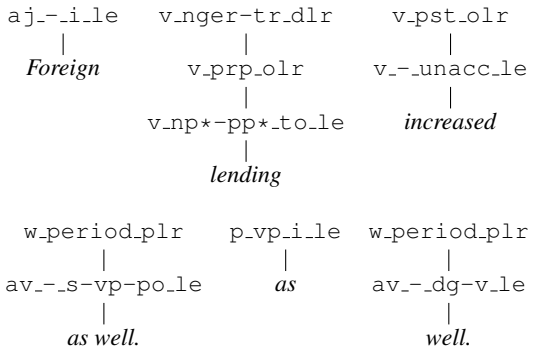

Figure 3: A selection from the 70 **lexitems** instantiated for *Foreign lending increased as well.*

related area, as well as from the speech recognition field, differences in the relative frequency of observations and labels, as well as in segmentation ambiguity mean that conclusions found in these areas did not always hold true in our problem space.

3 The Parser

The parsing environment we work with is the PET parser (Callmeier, 2000), a unification-based chart parser that has been engineered for efficiency with precision grammars, and incorporates subsumption-based ambiguity packing (Oepen and Carroll, 2000) and statistical model driven selective unpacking (Zhang et al., 2007). Parsing in PET is divided in two stages. The first stage, lexical parsing, covers everything from tokenising the raw input string to populating the base of the parse chart with the appropriate lexical items, ready for the second — syntactic parsing — stage. In this work, we embed our ubertagging model between the two stages. By this point, the input has been segmented into what we call `internal tokens`, which broadly means splitting at whitespace and hyphens, and making *'s* a separate token. These tokens are subject to a morphological analysis component which proposes possible inflectional and derivational rules based on word form, and then are used in retrieving possible lexical entries from the lexicon. The results of applying the appropriate lexical rules, plus affixation rules triggered by punctuation, to the lexical entries form a lexical item object, that for this work we dub a **lexitem**.

Figure 3 shows some examples of **lexitems** instantiated after the lexical parsing stage when

analysing *Foreign lending increased as well.* The pre-terminal labels on these subtrees are the lexical types that have previously been used as supertags for the ERG. For uninflected words, with no punctuation affixed, the lexical type is the only element in the **lexitem**, other than the word form (e.g. *Foreign*, *as*). In this example, we also see **lexitems** with inflectional rules (`v_prp_olr`, `v_pst_olr`), derivational rules (`v_nger-tr_dlr`) and punctuation affixation rules (`w_period_plr`).

These **lexitems** are put in to a chart, forming a lexical lattice, and it is over this lattice that we apply our ubertagging model, removing unlikely **lexitems** before they are seen by the syntactic parsing stage.

4 The Data

The primary data sets we use in these experiments are from the 1.0 version of DeepBank (Flickinger et al., 2012), an HPSG annotation of the Wall Street Journal text used for the Penn Treebank (PTB; Marcus et al. (1993)). The current version has gold standard annotations for approximately 85% of the first 22 sections. We follow the recommendations of the DeepBank developers in using Sections 00–19 for training, Section 20 (WSJ_{20}) for development and Section 21 (WSJ_{21}) as test data.

In addition, we use two further sources of training data: the training portions of the LinGO Redwoods Treebank (Oepen et al., 2004), a steadily growing collection of gold standard HPSG annotations in a variety of domains; and the Wall Street Journal section of the North American News Corpus (NANC), which has been parsed, but *not* manually annotated. This builds on observations by Prins and van Noord (2003), Dridan (2009) and Ytrestøl (2012) that even uncorrected parser output makes very good training data for a supertagger, since the constraints in the parser lead to viable, if not entirely correct sequences. This allows us to use much larger training sets than would be possible if we required manually annotated data.

In final testing, we also include two further data sets to observe how domain affects the contribution of the ubertagging. These are both from the test portion of the Redwoods Treebank: CatB, an essay about open-source software;[1] and WeScience_{13}, text from Wikipedia articles about Natural Language Processing from the WeScience project (Ytrestøl et al., 2009). Table 1 summarises the vital statistics of the data we use.

With the focus on multi-token **lexitems**, it is instructive to see just how frequent they are. In terms of **type** frequency, almost 10% of the approximately 38500 lexical entries in the current ERG lexicon have more than one token in their canonical form.[2] However, while this is a significant percentage of the lexicon, they do not account for the same percentage of **tokens** during parsing. An analysis of $\text{WSJ}_{00:19}$ shows that approximately one third of the sentences had at least one multi-token **lexitem** in the unpruned lexical lattice, and in just under half of those, the gold standard analysis included a multi-word entry. That gives the multi-token **lexitems** the awkward property of being rare enough to be difficult for a statistical classifier to accurately detect (just under 1% of the leaves of gold parse trees contain multiple tokens), but too frequent to ignore. In addition, since these multi-token expressions have often been distinguished because they are non-compositional, failing to detect the multi-word usage can lead to a disproportionately adverse effect on the semantic analysis of the text.

5 Ubertagging Model

Our ubertagging model is very similar to a standard trigram Hidden Markov Model (HMM), except that the states are not all of the same length. Our states are based on the **lexitems** in the lexical lattice produced by the lexical parsing stage of PET, and as such, can be partially overlapping. We formalise this be defining each state by its start position, end position, and tag. This turns out to make our model equivalent to a type of Hidden semi-Markov Model called a segmental HMM in Murphy (2002). In a segmental HMM, the states are segments with a tag (t) and a length in frames (l). In our setup, the frames are the ERG internal tokens and the segments are the **lexitems**, which are the potential candidates

[1] `http://catb.org/esr/writings/cathedral-bazaar/` by Eric S. Raymond

[2] While the parser has mechanisms for handling words unknown to the lexicon, with the current grammar these mechanisms will never propose a multi-token **lexitem**, and so only the multi-token entries explicitly in the lexicon will be recognised as such.

to become leaves of the parse tree. As indicated above, the majority of segments (over 99%) will be one frame long, but segments of up to four frames are regularly seen in the training data.

A standard trigram HMM has a transition probability matrix A, where the elements A_{ijk} represent the probability $P(k|ij)$, and an emission probability matrix B whose elements B_{jo} record the probabilities $P(o|j)$. Given these matrices and a vector of observed frames, O, the posterior probabilities of each state at frame v are calculated as:[3]

$$P(q_v = q_y|O) = \frac{\alpha_v(q_y)\beta_v(q_y)}{P(O)} \quad (1)$$

where $\alpha_v(q_y)$ is the forward probability at frame v, given a current state q_y (i.e. the probability of the observation up to v, given the state):

$$\alpha_v(q_y) \equiv P(O_{0:v}|q_v = q_y) \quad (2)$$

$$= \sum_{q_x} \alpha_v(q_x q_y) \quad (3)$$

$$\alpha_v(q_x q_y) = B_{q_y o_v} \sum_{q_w} \alpha_{v-1}(q_w q_x) A_{q_w q_x q_y} \quad (4)$$

$\beta_v(q_y)$ is the backwards probability at frame v, given a current state q_y (the probability of the observation from v, given the state):

$$\beta_v(q_y) \equiv P(O_{v+1:V}|q_v = q_y) \quad (5)$$

$$= \sum_{q_x} \beta_v(q_x q_y) \quad (6)$$

$$\beta_v(q_x q_y) = \sum_{q_z} \beta_{v+1}(q_y q_z) A_{q_x q_y q_z} B_{q_z o_{v+1}} \quad (7)$$

and the probability of the full observation sequence is equal to the forward probability at the end of the sequence, or the backwards probability at the start of the sequence:

$$P(O) = \alpha_V(\langle \mathcal{E} \rangle) = \beta_0(\langle \mathcal{S} \rangle) \quad (8)$$

In implementation, our model varies only in what we consider the previous or next states. While v still indexes frames, q_v now indicates a state that *ends* with frame v, and we look forwards and backwards to adjacent states, not frames, formally designated in terms of l, the length of the state. Hence, we modify equation (4):

$$\alpha_v(q_x q_y) = B_{q_y O_{v-l+1:v}} \sum_{q_w} \alpha_{v-l}(q_w q_x) A_{q_w q_x q_y} \quad (9)$$

where $v-l$ indexes the frame before the current state *starts*, and hence we are summing over all states that lead directly to our current state. An equivalent modification to equation (7) gives:

$$\beta_v(q_x q_y) = \sum_{\substack{q_z \\ \in Q_n}} \sum_{l(q_z)} \beta_{v+l}(q_y q_z) A_{q_x q_y q_z} B_{q_z O_{v+1:v+l}} \quad (10)$$

[3] Since we will require per-state probabilities for integration to the parser, we focus on the calculation of posterior probabilities, rather than determing the single best path.

Type	Example	#Tags

FULL	v_np-pp*_to_le:v_pas_odlr:w_period_plr	21866

Figure 4: Possible tag types and their tag set size, with examples derived from the **lexitem** on the right.

where Q_n is the set of states that start at $v + 1$ (i.e., the states immediately following the current state), and $l(q_z)$ is the length of state q_z.

We construct the transition and emission probability matrices using relative frequencies directly observed from the training data, where we make the simplifying assumption that $P(q_k|q_iq_j) \equiv P(t(q_k)|t(q_i)t(q_k))$. Which is to say, while **lexitems** with the same tag, but different length will trigger distinct states with distinct emission probabilities, they will have the same transition probabilities, given the same proceeding tag.[4] Even with our large training set, some tag trigrams are rare or unseen. To smooth these probabilities, we use deleted interpolation to calculate a weighted sum of the trigram, bigram and unigram probabilities, since it has been successfully used in effective PoS taggers like the TnT tagger (Brants, 2000). Future work will look more closely at the effects of different smoothing methods.

6 Intrinsic Ubertag Evaluation

In order to develop and tune the ubertagging model, we first looked at segmentation and tagging performance in isolation over the development set. We looked at three tag granularities: lexical types (LTYPE) which have previously been shown to be the optimal granularity for supertagging with the ERG, inflected types (INFL) which encompass inflectional and derivational rules applied to the lexical type, and the full lexical item (FULL), which also includes affixation rules used for punctuation handling. Examples of each tag type are shown in Figure 4, along with the number of tags of each type seen in the training data.

[4]Since the multi-token lexical entries are defined because they have the same properties as the single token variants, there is no reason to think the length of a state should influence the tag sequence probability.

LTYPE	99.40	93.03	93.27	38.12

Table 2: Segmentation and tagging performance of the best path found for each model, measured per segment in terms of F_1, and also as complete sentence accuracy.

Single sequence results Table 2 shows the results when considering the best path through the lattice. In terms of segmentation, our sentence accuracy is comparable to that of the stand-alone segmentation performance reported by Fares et al. (2013) over similar data.[5] In that work, the authors used a binary CRF classifier to label points between objects they called micro-tokens as either SPLIT or NOSPLIT. The CRF classifier used a less informed input (since it was external to the parser), but a much more complex model, to produce a best single path sentence accuracy of 94.06%. Encouragingly, this level of segmentation performance was shown in later work to produce a viable parser input (Fares, 2013).

Switching to the tagging results, we see that the F_1 numbers are quite good for tag sets of this size.[6] The best tag accuracy seen for ERG LTYPE-style tags was 95.55 in Ytrestøl (2012), using gold standard segmentation on a different data set. Dridan (2009) experimented with a tag granularity similar to our INFL (letype+morph) and saw a tag accuracy of 91.51, but with much less training data. From other formalisms, Kummerfeld et al. (2010)

[5]Fares et al. (2013) used a different section of an earlier version of DeepBank, but with the same style of annotation.

[6]We need to measure F_1 rather than tag accuracy here, since the number of tokens tagged will vary according to the segmentation.

report a single tag accuracy of 95.91, with the smaller CCG supertag set. Despite the promising tag F_1 numbers however, the sentence level accuracy still indicates a performance level unacceptable for parser input. Comparing between tag types, we see that, possibly surprisingly, the more fine-grained tags are more accurately assigned, although the differences are small. While instinctively a larger tag set should present a more difficult problem, we find that this is mitigated both by the sparse lexical lattice provided by the parser, and by the extra constraints provided by the more informative tags.

Multi-tagging results The multi-tagging methods from previous supertagging work becomes more complicated when dealing with ambiguous tokenisation. Where, in other setups, one can compare tag probabilities for all tags for a particular token, that no longer holds directly when tokens can partially overlap. Since ultimately, the parser uses **lexitems** which encompass segmentation and tagging information, we decided to use a simple integration method, where we *remove* any **lexitem** which our model assigns a probability below a certain threshold (ρ). The effect of the different tag granularities is now mediated by the relationship between the states in the ubertagging lattice and the **lexitems** in the parser's lattice: for the FULL model, this is a one-to-one relationship, but states from the models that use coarser-grained tags may affect multiple **lexitems**. To illustrate this point, Figure 5 shows some **lexitems** for the token *forecast,*, where there are multiple possible analyses for the comma. A FULL tag of `v_cp_le:v_pst_olr:w_comma_plr` will select only **lexitem** (b), whereas an INFL tag `v_cp_le:v_pst_olr` will select (b) and (c) and the LTYPE tag `v_cp_le` picks out (a), (b) and (c). On the other hand, where there is no ambiguity in inflection or affixation, an LTYPE tag of `n_-_mc_le` may relate to only a single **lexitem** ((f) in this case).

Since we are using an absolute, rather than relative, threshold, the number needs to be tuned for each model[7] and comparisons between models can only be made based on the effects (accuracy or pruning power) of the threshold. Table 3 shows how a selection of threshold values affect the accuracy

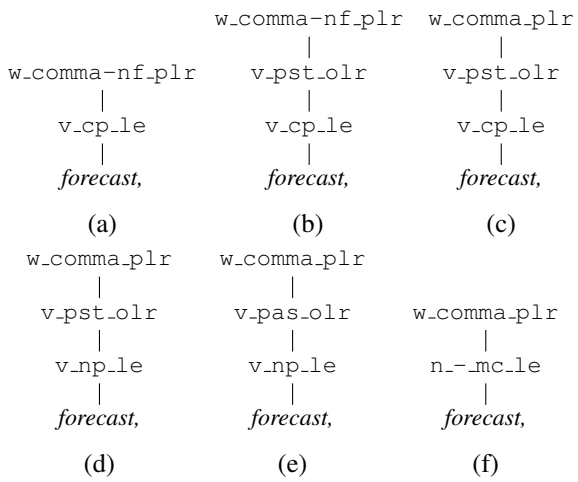

Figure 5: Some of the **lexitems** triggered by *forecast,* in *Despite the gloomy forecast, profits were up.*

Tag Type	ρ	Acc.	Lexitems Kept	Lexitems Ave.

Table 3: Accuracy and ambiguity after pruning **lexitems** in WSJ_{20}, at a selection of thresholds ρ for each model. Accuracy is measured as the percentage of gold **lexitems** remaining after pruning, while ambiguity is presented both as a percentage of **lexitems** kept, and the average number of **lexitems** per initial token still remaining.

[7] A tag set size of 1028 will lead to higher probabilities in general than a tag set size of 21866.

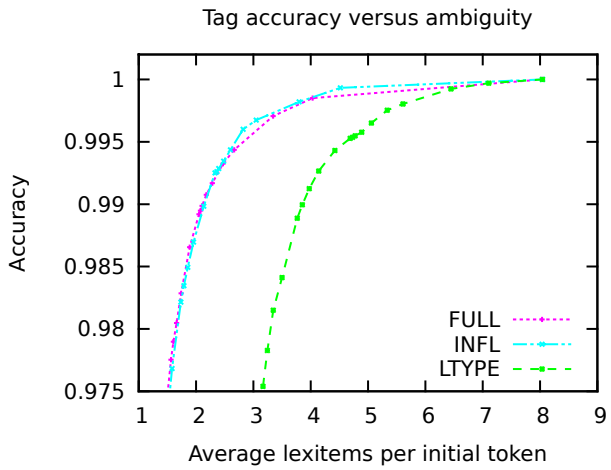

Figure 6: Accuracy over gold **lexitems** versus average **lexitems** per initial token over the development set, for each of the different ubertagging models.

and pruning impact of our different disambiguation models, where the accuracy is measured in terms of percentage of gold **lexitems** retained. The pruning effect is given both as percentage of **lexitems** retained after pruning, and average number of **lexitems** per initial token.[8] Comparison between the different models can be more easily made by examining Figure 6. Here we see clearly that the LTYPE model provides much less pruning for any given level of **lexitem** accuracy, while the performance of the other models is almost indistinguishable.

Analysis The current state-of-the-art POS tagging accuracy (using the 45 tags in the PTB) is approximately 97.5%. The most restrictive ρ value we report for each model was selected to demonstrate that level of accuracy, which we can see would lead to pruning over 80% of **lexitems** when using FULL tags, an average of 1.56 tags per token. While this level of accuracy has been sufficient for statistical treebank parsing, previous work (Dridan, 2009) has shown that tag accuracy cannot directly predict parser performance, since errors of different types can have very different effects. This is hard to quantify without parsing, but we made a qualitative analysis at the **lexitems** that were incorrectly being pruned. For all models, the most difficult **lexitems** to get correct were proper nouns, particular those that are also used as common nouns (e.g. *Bank*, *Airline*, *Report*). While capitalisation provides a clue here, it is not always deterministic, particularly since the treebank incorporates detailed decisions regarding the distinction between a name and a capitalised common noun that require real world knowledge, and are not necessarily always consistent. Almost two thirds of the errors made by the FULL and INFL models are related to these decisions, but only about 40% for the LTYPE model. The other errors are predominately over noun and verb type **lexitems**, as the open classes, with the only difference between models being that the FULL model seems marginally better at classifying verbs. The next section describes the end-to-end setup and results when parsing the development set.

7 Parsing

With encouraging ubertagging results, we now take the next step and evaluate the effect on end-to-end parsing. Apart from the issue of different error types having unpredictable effects, there are two other factors that make the isolated ubertagging results only an approximate indication of parsing performance. The first confounding factor is the statistical parsing disambiguation model. To show the effect of ubertagging in a realistic configuration, we only evaluate the first analysis that the parser returns. That means that when the unrestricted parser does not rank the gold analysis first, errors made by our model may not be visible, because we would never see the gold analysis in any case. On the other hand, it is possible to improve parser accuracy by pruning incorrect **lexitems** that were in a top ranked, non-gold analysis.

The second new factor that parser integration brings to the picture is the effect of resource limitations. For reasons of tractability, PET is run with per sentence time and memory limits. For treebank creation, these limits are quite high (up to four minutes), but for these experiments, we set the timeout to a more practical 60 seconds and the memory limit to 2048Mb. Without lexical pruning, this leads to approximately 3% of sentences not receiving an analysis. Since the main aim of ubertagging is to in-

[8] The average number of **lexitems** per token for the unrestricted parser is 8.03, although the actual assignment is far from uniform, with up to 70 **lexitems** per token seen for the very ambiguous tokens.

Tag Type	ρ	F_1 Lexitem	Bracket	Time
No Pruning		94.06	88.58	6.58
FULL	0.00001	95.62	89.84	3.99

LTYPE	0.05	93.36	87.26	0.88

Table 4: **Lexitem** and bracket F_1over WSJ_{20}, with average per sentence parsing time in seconds.

crease efficiency, we would expect to regain at least some of these unanalysed sentences, even when a **lexitem** needed for the gold analysis has been removed.

Table 4 shows the parsing results at the same threshold values used in Table 3. Accuracy is calculated in terms of F_1 both over **lexitems**, and PARSEVAL-style labelled brackets (Black et al., 1991), while efficiency is represented by average parsing time per sentence. We can see here that an ubertagging F_1 of below 98 (cf. Table 3) leads to a drop in parser accuracy, but that an ubertagging performance of between 98 and 99 can improve parser F_1 while also achieving speed increases up to 8-fold.

From the table we confirm that, contrary to earlier pipeline supertagging configurations, tags of a finer granularity than LTYPE can deliver better performance, both in terms of accuracy and efficiency. Again, comparing graphically in Figure 7 gives a clearer picture. Here we have graphed labelled bracket F_1 against parsing time for the full range of threshold values explored, with the unpruned parsing results indicated by a cross.

From this figure, we see that the INFL model, despite being marginally less accurate when measured in isolation, leads to slightly more accurate parse results than the FULL model at all levels of efficiency.

Looking at the same graph for different samples of the development set (not shown) shows some

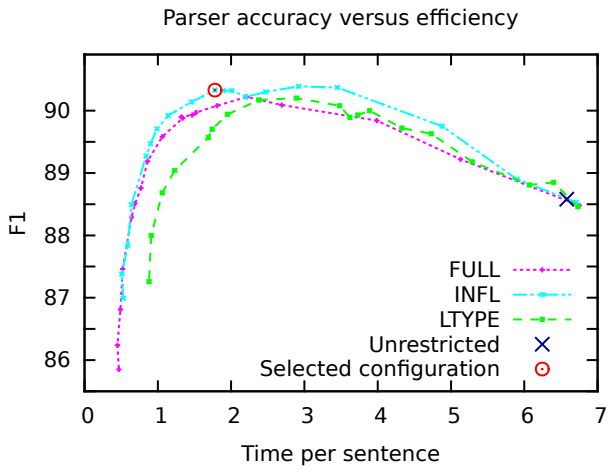

Figure 7: Labelled bracket F_1 versus parsing time per sentence over the development set, for each of the different ubertagging models. The cross indicates unpruned performance, while the circle pinpoints the configuration we chose for the final test runs.

variance in which threshold value gives the best F_1, but the relative differences and basic curve shape remains the same. From these different views, using the guideline of maximum efficiency without harming accuracy we selected our final configuration: the INFL model with a threshold value of 0.001 (marked with a circle in Figure 7). On the development set, this configuration leads to a 1.75 point improvement in F_1 in 27% of the parsing time.

8 Final Results

Table 5 shows the results obtained when parsing using the configuration selected on the development set, over our three test sets. The first, WSJ_{21} is from the same domain as the development set. Here we see that the effect over the WSJ_{21} set fairly closely mirrored that of the development set, with an F_1 increase of 1.81 in 29% of the parsing time.

The Wikipedia domain of our $WeScience_{13}$ test set, while very different to the newswire domain of the development set could still be considered in domain for the parsing and ubertagging models, since there is Wikipedia data in the training sets. With an average sentence length of 15.18 (compared to 18.86 in WSJ_{21}), the baseline parsing time is faster than for WSJ_{21}, and the speedup is not quite as large

	Baseline		Pruned	
Data Set	**F_1**	**Time**	**F_1**	**Time**
WSJ_{21}	88.12	6.06	89.93	1.77
$WeScience_{13}$	86.25	4.09	87.14	1.48
CatB	86.31	5.00	87.11	1.78

Table 5: Parsing accuracy in terms of labelled bracket F_1 and average time per sentence when parsing the test sets, without pruning, and then with lexical pruning using the INFL model with a threshold of 0.001.

but still welcome, at 36% of the baseline time. The increase is accuracy is likewise smaller (due to less issues with resource exhaustion in the baseline), but as our primary goal is to not *harm* accuracy, the results are pleasing.

The CatB test set is the standard out-of-domain test for the parser, and is also out of domain for the ubertagging model. The average sentence length is not much below that of WSJ_{21}, at 18.61, but the baseline parsing speed is still noticeably faster, which appears to be a reflection of greater structural ambiguity in the newswire text. We still achieve a reduction in parsing time to 35% of the baseline, again with a small improvement in accuracy.

The across-the-board performance improvement on all our test sets suggests that, while tuning the pruning threshold could help, it is a robust parameter that can provide good performance across a variety of domains. This means that we finally have a robust supertagging setup for use with the ERG that doesn't require heuristic shortcuts and can be reliably applied in general parsing.

9 Conclusions and Outlook

In this work we have demonstrated a lexical disambiguation process dubbed ubertagging that can assign fine-grained supertags over an ambiguous token lattice, a setup previously ignored for English. It is the first completely integrated supertagging setup for use with the English Resource Grammar, which avoids the previously necessary heuristics for dealing with ambiguous tokenisation, and can be robustly configured for improved performance without loss of accuracy. Indeed, by learning a joint segmentation and supertagging model, we have been able to achieve usefully high tagging accuracies for very fine-grained tags, which leads to potential parser speedups of between 4 and 8 fold.

Analysis of the tagging errors still being made have suggested some possibly avoidable inconsistencies in the grammar and treebank, which have been fed back to the developers, hopefully leading to even better results in the future.

In future work, we will investigate more advanced smoothing methods to try and boost the ubertagging accuracy. We also intend to more fully explore the domain adaptation potentials of the lexical model that have been seen in other parsing setups (see Rimell and Clark (2008) for example), as well as examine the limits on the effects of more training data. Finally, we would like to explore just how much the statistic properties of our data dictate the success of the model by looking at related problems like morphological analysis of unsegmented languages such as Japanese.

Acknowledgements

I am grateful to my colleagues from the Oslo Language Technology Group and the DELPH-IN consortium for many discussions on the issues involved in this work, and particularly to Stephan Oepen who inspired the initial lattice tagging idea. Thanks also to three anonymous reviewers for their very constructive feedback which improved the final version. Large-scale experimentation and engineering is made possible though access to the TITAN high-performance computing facilities at the University of Oslo, and I am grateful to the Scientific Computating staff at UiO, as well as to the Norwegian Metacenter for Computational Science and the Norwegian tax payer.

Automatic Knowledge Acquisition for Case Alternation between the Passive and Active Voices in Japanese

Ryohei Sasano[1] **Daisuke Kawahara**[2] **Sadao Kurohashi**[2] **Manabu Okumura**[1]

Abstract

We present a method for automatically acquiring knowledge for case alternation between the passive and active voices in Japanese. By leveraging several linguistic constraints on alternation patterns and lexical case frames obtained from a large Web corpus, our method aligns a case frame in the passive voice to a corresponding case frame in the active voice and finds an alignment between their cases. We then apply the acquired knowledge to a case alternation task and prove its usefulness.

1 Introduction

Predicate-argument structure analysis is one of the fundamental techniques for many natural language applications such as recognition of textual entailment, information retrieval, and machine translation. In Japanese, the relationship between a predicate and its argument is usually represented by using case particles[1] (Kawahara and Kurohashi, 2006; Taira et al., 2008; Yoshikawa et al., 2011). However, since case particles vary depending on the voices, we have to take case alternation into account to represent predicate-argument structure. There are thus two major types of representations: one uses surface cases, and the other uses normalized-cases for the base form of predicates. For example, while the Kyoto University Text Corpus (Kawahara et al., 2004), one of the major Japanese corpora that contains annotations of predicate-argument structures, adopts the former representation, the NAIST Text Corpora (Iida et al., 2007), another major Japanese corpus, adopts the latter representation.

Examples (1) and (2) describe the same event in the passive and active voices, respectively. When we use surface cases to represent the relationship between the predicate and its argument in Example (1), the case of "女 (woman)" is *ga*[2] and the case of "男 (man)" is *ni*.[2] On the other hand, when we use the normalized-cases for the base form, the case of "女 (woman)" is *wo*[2] and the case of "男 (man)" is *ga*, which are the same as the surface cases in the active voice as in Example (2).

(1) 女が (woman-*ga*) 男に (man-*ni*) 突き落とされた. (was pushed down)
(A woman was pushed down by a man.)

(2) 男が (man-*ga*) 女を (woman-*wo*) 突き落とした. (pushed down)
(A man pushed down a woman.)

Both representations have their own advantages. Surface case analysis is easier than normalized-case analysis, especially when we consider omitted arguments, which are also called zero anaphors (Nagao and Hasida, 1998). In Japanese, zero anaphora frequently occurs, and the omitted unnormalized-case of a zero anaphor is often the same as the surface case of its antecedent (Sasano and Kurohashi, 2011). Therefore, surface case analysis suits zero anaphora resolution. On the other hand, when

[1] Japanese is a head-final language. Word order does not mark syntactic relations. Instead, postpositional case particles function as case markers.

[2] *Ga*, *wo*, and *ni* are typical Japanese postpositional case particles. In most cases, they indicate nominative, accusative, and dative, respectively.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1213–1223,
Seattle, Washington, USA, 18-21 October 2013.

we focus on the resulting predicate argument structures, the normalized-case structure is more useful. Specifically, since a normalized-case structure represents the same meaning in the same representation, normalized-case analysis is useful for recognizing textual entailment and information retrieval.

Therefore, we need a system that first analyzes surface cases and then alternates the surface cases with normalized-cases. In particular, we focus on the transformation of the passive voice into the active voice in this paper. Passive-to-active voice transformation in English can be performed systematically, which does not depend on lexical information in most cases. However, in Japanese, the method of transformation depends on lexical information. For example, while the case particle *ni* in Example (1) is alternated with *ga* in the active voice, the case particle *ni* in Example (3) is not alternated in the active voice as in Example (4) even though both their predicates are "突き落とされた (be pushed down)."

(3) 女が 海に 突き落とされた.
woman-*ga* sea-*ni* was pushed down
(A woman was pushed down into the sea.)

(4) 女を 海に 突き落とした.
woman-*wo* sea-*ni* pushed down
(ϕ pushed down a woman into the sea.)

The *ni* case in Example (1) indicates *agent*. On the other hand, the *ni* case in Example (3) indicates *direction*. To determine the difference is important for many NLP applications including machine translation. In fact, Google Translate (GT)[3] translates Examples (1) and (3) as "Woman was pushed down in the man" and "Woman was pushed down in the sea," respectively, which may be because GT cannot distinguish between the roles of *ni* in Examples (1) and (3).

(5) 賞が 男に 贈られた.
prize-*ga* man-*ni* was awarded
(A prize was awarded to a man.)

In example (5), although the *ni*-case argument "男 (man)" is the same as in Example (1), the case particle *ni* indicates *recipient* and is not alternated in the active voice. These examples show that case alternation between the passive and active voices in Japanese depends on not only predicates but also arguments, and we have to consider their combinations. Since it is impractical to manually describe the case alternation rules for all combinations of predicates and arguments, we have to acquire such knowledge automatically.

Thus, in this paper, we present a method for acquiring the knowledge for case alternation between the passive and active voices in Japanese. Our method leverages several linguistic constraints on alternation patterns and lexical case frames obtained from a large Web corpus, which are constructed for each meaning and voice of each predicate.

2 Related Work

Levin (1993) grouped English verbs into classes on the basis of their shared meaning components and syntactic behavior, defined in terms of diathesis alternations. Hence, diathesis alternations have been the topic of interest for a number of researchers in the field of automatic verb classification, which aims to induce possible verb frames from corpora (e.g., McCarthy 2000; Lapata and Brew 2004; Joanis et al. 2008; Schulte im Walde et al. 2008; Li and Brew 2008; Sun and Korhonen 2009; Theijssen et al. 2012). Baroni and Lenci (2010) used distributional slot similarity to distinguish between verbs undergoing the causative-inchoative alternations, and verbs that do not alternate.

There is some work on passive-to-active voice transformation in Japanese. Baldwin and Tanaka (2000) empirically identified the range and frequency of basic verb alternation, including active-passive alternation, in Japanese. They automatically extracted alternation types by using hand-crafted case frames but did not evaluate the quality. Kondo et al. (2001) dealt with case alternation between the passive and active voices as a subtask of paraphrasing a simple sentence. They manually introduced case alternation rules on the basis of verb types and case patterns and transformed passive sentences into active sentences.

Murata et al. (2006) developed a machine-learning-based method for Japanese case alternation. They extracted 3,576 case particles in passive sentences from the Kyoto University Text Corpus

Case particle	Grammatical function
ga	nominative
wo	accusative
ni	dative
de	locative, instrumental
kara	ablative
no	genitive

Table 1: Examples of Japanese postpositional case particles and their typical grammatical functions.

and tagged their cases in the active voice. Then, they trained SVM classifiers using the tagged corpus. Their features for training SVM were made by using several lexical resources such as IPAL (IPA, 1987), the Japanese thesaurus *Bunrui Goi Hyo* (NLRI, 1993), and the output of Kondo et al.'s method.

3 Lexicalized Case Frames

To acquire knowledge for case alternation, we exploit lexicalized case frames that are automatically constructed from 6.9 billion Web sentences by using Kawahara and Kurohashi (2002)'s method. In short, their method first parses the input sentences, and then constructs case frames by collecting reliable modifier-head relations from the resulting parses.

These case frames are constructed for each predicate like PropBank frames (Palmer et al., 2005), for each meaning of the predicate like FrameNet frames (Fillmore et al., 2003), and for each voice. However, neither pseudo-semantic role labels such as Arg1 in PropBank nor information about frames defined in FrameNet are included in these case frames. Each case frame describes surface cases that each predicate has and instances that can fill a case slot, which is fully lexicalized like the subcategorization lexicon VALEX (Korhonen et al., 2006).

We list some Japanese postpositional case particles with their typical grammatical functions in Table 1 and show examples of case frames in Table 2.[4] Ideally, one case frame is constructed for each meaning and voice of the target predicate. However, since Kawahara and Kurohashi's method is unsupervised, several case frames are actually constructed

[4] *Niyotte* in Table 2 is a Japanese functional phrase that indicates *agent* in this case. We treat *niyotte* as a case particle in this paper for the sake of simplicity.

Case Frame: "突き落とされる-4 (be pushed down-4)"
{ 女性 (woman):5, 僕 (I):2, 女 (woman):2, · · · }-*ga*
{ 海 (sea):229, 川 (bottom):115, 池 (pond):51, · · · }-*ni*
{ 継母(stepmother):2, ペガサス(Pegasus):2, · · · }-*niyotte*
· · ·

Case Frame: "突き落とされる-5 (be pushed down-5)"
{ 京子 (Kyoko):3, 監督 (manager):1, · · · }-*ga*
{ 誰か (someone):143, 何者か (somebody):85, · · · }-*ni*
{ 階段 (stair):20, 船 (ship):7, 崖 (cliff):7, · · · }-*kara*
· · ·

Case Frame: "突き落とす-2 (push down-2)"
{ 男 (man):14, 獅子 (lion):5, 虎 (tiger):3, · · · }-*ga*
{ 子(child):316, 子供(child):81, 人(person):51, · · · }-*wo*
{ 海 (sea):580, 谷 (ravine):576, 川 (river):352 · · · }-*ni*
· · ·

Case Frame: "突き落とす-4 (push down-4)"
{ 誰か (someone):14, ライオン (lion):5, · · · }-*ga*
{ 人 (person):257, 私 (I):214, 子 (child):137, · · · }-*wo*
{ 崖 (cliff):53, 階段 (stair):28, · · · }-*kara*
· · ·

Table 2: Examples of case frames for "突き落とされる (be pushed down)" and "突き落とす (push down)." Words in curly braces denote instances that can fill corresponding cases and the numbers following these words denote their frequency in the corpus.

for each meaning and voice. For example, 59 and eight case frames were respectively constructed for the predicate in the passive voice "突き落とされる (be pushed down)" and in the active voice "突き落とす (push down)" from 6.9 billion Web sentences. Table 2 shows the 4th and 5th case frames for "突き落とされる (be pushed down)" and the 2nd and 4th case frames for "突き落とす (push down)."

Table 3 shows an example of case frames for "殴る (hit)," which includes *no*-case. Here, the Japanese postpositional case particle "*no*" roughly corresponds to "of," that is, "*X no Y*" means "Y of X," and thus *no*-case is not an argument of the target predicate. While Kawahara and Kurohashi's method basically collects arguments of the target predicate, the phrase of *no*-case that modifies the direct object of the predicate is also collected as *no*-case. This is because, as we will show in the next section, this phrase can be represented as *ga*-case in the passive voice.

Case Frame: “殴る-2 (hit-2)”
{ 男 (man):51, 拳 (fist):30, 誰か (someone):23, · · · }-*ga*
{ 自分 (myself):360, 私 (I):223, · · · }-*no*
{ 頭 (head):5424, 顔 (face):3215, · · · }-*wo*
{ 拳 (fist):316, 平手 (palm):157, 拳骨 (fist):126, · · · }-*de*
· · ·

Table 3: An example of case frames for “殴る (hit).”

4 Passive-Active Transformation in Japanese

Morphologically speaking, the passive voice in Japanese is expressed by using the auxiliary verbs “れる (*reru*)” and “られる (*rareru*),” whose past forms are “れた (*reta*)” and “られた (*rareta*),” respectively. For example, the verb in the base form “突き落とす (*tsukiotosu*, push down)” is transformed into the past passive form “突き落とされた (*tsukiotosa-reta*, was pushed down).” Case alternations accompany passive-active transformation in Japanese. There are only two case alternations at most in passive-active transformation. One is the case represented as *ga* in the passive voice, and the other is the case represented as *ga* in the active voice.

Japanese passive sentences can be classified into three types in accordance with what is represented as *ga*-case in the passive voice: **direct passive**, **indirect passive**, and **possessor passive**.

In **direct passive** sentence, the object of the predicate in the active voice is represented as *ga*-case. Examples (1), (3), and (5) are all direct passive sentences. The case that is represented as *ga* in the active voice is usually represented as *ni*, *niyotte*, *kara*, or *de* in the passive sentence. In the first sentence of Examples (6) and (7),[5] *ga*-cases in the active voice are represented as *niyotte* and *kara*, respectively. On the other hand, *ga*-case in the passive sentence is alternated with *wo* or *ni* as shown with broken lines in the second sentence of Examples (6) and (7).

(6) P: 原因が 男によって 特定された.
cause-*ga* man-*niyotte* was identified
(The cause was identified by a man.)

A: 男が 原因を 特定した.
man-*ga* cause-*wo* identified
(A man identified the cause.)

[5]“P” denotes a passive sentence and “A” denotes the corresponding active sentence in these examples.

(7) P: 男が 女から 話しかけられた.
man-*ga* woman-*kara* was talked to
(A man was talked to by a woman.)

A: 女が 男に 話しかけた.
woman-*ga* man-*ni* talked to
(A woman talked to a man.)

Indirect passive is also called adversative passive, in which an indirectly influenced agent is represented with *ga*. For example, “私 (I),” the argument represented with *ga* in the first sentence of Example (8), does not appear in the active voice, i.e. the second sentence of Example (8). In the case of indirect passive, *ga*-case in the active sentence is always alternated with *ni*-case in the passive sentence as shown with solid lines in Examples (8).

(8) P: 私が 子供に 泣かれた.
I-*ga* child-*ni* was cried
(I’ve got a child crying.)

A: 子供が 泣いた. (A child cried.)
child-*ga* cried

Possessor passive is similar to indirect passive in that the argument represented with *ga*-case does not appear as an argument of the predicate in the active voice. Therefore, possessor passive is sometimes treated as a kind of indirect passive. However, in the case of possessor passive, the argument appears in the active sentence as a possessor of the direct object. For example, the *ga*-case argument “女 (woman)” in the passive sentence of Example (9) does not appear as an argument of the predicate “殴った (hit)” in the active sentence but appears in the phrase that modifies the direct object “頭 (head)” with the case particle *no*, which indicates that “女 (woman)” is the possessor of “頭 (head).”

(9) P: 女が 男に 頭を 殴られた.
woman-*ga* man-*ni* head-*wo* was hit
(A woman was hit on the head by a man.)

A: 男が 女の 頭を 殴った.
man-*ga* woman-*no* head-*wo* hit
(A man hit the head of a woman.)

In conclusion, the number of case alternation patterns accompanying passive-active transformation in Japanese is limited. *Ga*-case in the passive voice can

be alternated only with either *wo*, *ni*, or *no*, or does not appear in the active voice. *Ga*-case in the active voice can be represented only by *ni*, *niyotte*, *kara*, or *de* in the passive voice. Hence, it is sufficient to consider only their combinations.

5 Knowledge Acquisition for Case Alternation

5.1 Task Definition

Our objective is to acquire knowledge for case alternation between the passive and active voices in Japanese. We leverage lexical case frames obtained from a large Web corpus by using Kawahara and Kurohashi (2002)'s method and align cases of a case frame in the passive voice and cases of a case frame in the active voice. As described in Section 2, several case frames are constructed for each voice of each predicate. Our task consists of the following two subtasks:

1. Identify a corresponding case frame in the active voice.
2. Find an alignment between cases of case frames in the passive and active voice.

Figure 1 shows the overview of our task. If a case frame in the passive voice is input, we identify a corresponding case frame in the active voice, and find an alignment between cases by using the algorithm described in Section 5.3. In this example, an active case frame "突き落とす-4 (push down-4)" is identified as a corresponding case frame for the input passive case frame "突き落とされる-5 (be pushed down-5)" and *ga*, *ni*, and *kara*-cases in the passive case frame are aligned to *wo*, *ga*, and *kara*-cases in the active case frame, respectively.

5.2 Clues for Knowledge Acquisition

We exploit three clues for corresponding case frame identification and case alignment as follows:

1. Semantic similarity between the instances of the aligned cases: sim_{SEM}.
2. Case distribution similarity between the corresponding case frames: sim_{DIST}.
3. Preference of alternation patterns: f_{PP}.

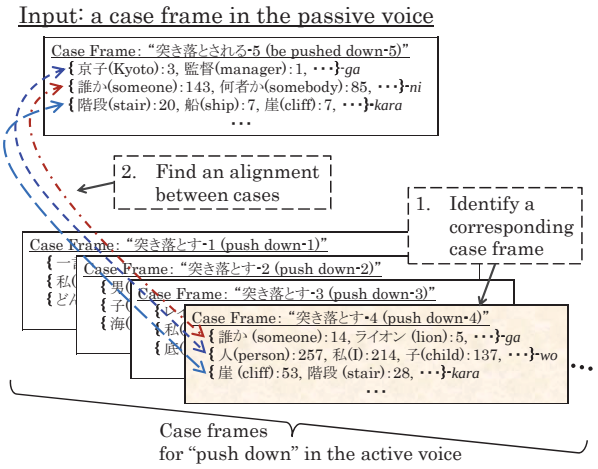

Figure 1: The overview of our task.

Semantic similarity The instances of the aligned cases should be similar. For example, the instances of the *ga*-case of the case frame "突き落とされる-5 (be pushed down-5)" and the *wo*-case of the case frame "突き落とす-4 (push down-4)," which are considered to be aligned and represent *patient*, are similar. Thus, we exploit semantic similarity sim_{SEM} between the instances of the corresponding cases.

We first define an asymmetric similarity measure between C_1 and C_2, each of which is a set of case slot instances, as follows:

$$\mathrm{sim}_a(C_1, C_2) = \frac{1}{|C_1|} \sum_{i_1 \in C_1} \max_{i_2 \in C_2} (\mathrm{sim}(i_1, i_2)),$$

where $\mathrm{sim}(i_1, i_2)$ is the similarity between instances. In this study, we apply a distributional similarity measure (Lin, 1998), which was computed from the Web corpus used to construct the case frames. We next define a symmetric similarity measure between C_1 and C_2 as an average of $\mathrm{sim}_a(C_1, C_2)$ and $\mathrm{sim}_a(C_2, C_1)$.

$$\mathrm{sim}_s(C_1, C_2) = \frac{1}{2}(\mathrm{sim}_a(C_1, C_2) + \mathrm{sim}_a(C_2, C_1)).$$

Then we define semantic similarity of a case alignment A between case frames CF_1 and CF_2.

$$\mathrm{sim}_{SEM}(A) = \frac{1}{N} \sum_{i=1}^{N} \mathrm{sim}_s(C_{1,i}, C_{2,a(i)}),$$

where N denotes the number of case slots of CF_1, $C_{1,i}$ denotes a set of instances of the i-th case slot of CF_1, and $C_{2,a(i)}$ denotes the set of the aligned case instances of CF_2. A denotes the alignment $\{c_{1,1} \rightarrow c_{2,a(1)}, c_{1,2} \rightarrow c_{2,a(2)}, \ldots, c_{1,N} \rightarrow c_{2,a(N)}\}$ where $c_{n,i}$ denotes the case name that corresponds to $C_{n,i}$.

Case distribution similarity Although arguments are often omitted in Japanese, arguments that are usually mentioned explicitly in the passive voice will be also explicitly mentioned in the active voice. Hence, the frequency distribution of cases can be a clue for case alignment. In this study, we exploit the following cosine similarity of frequency distribution as case distribution similarity:

$$\mathrm{sim}_{DIST}(A) = \cos((|C_{1,1}|, \ldots, |C_{1,N}|), (|C_{2,a(1)}|, \ldots, |C_{2,a(N)}|)).$$

As an example, consider the alignment between a passive case[6] "選ばれる-1 (be selected-1)" and the corresponding active case frame "選ぶ-13 (select-13)" in Table 4. The alignment $A_1 = \{ga \rightarrow wo, ni \rightarrow ni, \mathrm{NIL} \rightarrow ga\}$ is considered to be correct. However, if we consider only the semantic similarity, an alignment $A_2 = \{ga \rightarrow ni, ni \rightarrow ga, wo \rightarrow wo\}$ is selected, because the alignment A_2 has the highest semantic similarity. On the other hand, the case distribution similarity

$$\mathrm{sim}_{DIST}(A_1) = \cos((17722, 122273, 0), (33338, 800, 382)) \approx 0.167$$

is much larger than

$$\mathrm{sim}_{DIST}(A_2) = \cos((17722, 122273, 96), (800, 382, 33338)) \approx 0.016.$$

Thus, the alignment A_1 would be selected by considering the case distribution similarity.

Preference of alternation patterns Some alternation patterns often appear, and others do not. For example, as Murata et al. (2006) reported, whereas 96.47% of *ga*-case is alternated with *wo*-case in passive-active transformation in Japanese, only 27.38% of *ni*-case is alternated with *ga*-case. Therefore, when we can use development data, we exploit a weighting factor $f_{PP}(A)$ that is determined on the development data and takes into account the preference of alternation patterns. We define $f_{PP}(A)$ as follows:

$$f_{PP}(A) = w(ga \rightarrow c_{ga\_to}) \times w(c_{to\_ga} \rightarrow ga), \quad \text{(i)}$$

where c_{ga_to} is the case in the active voice to which *ga*-case in the passive voice is aligned, c_{to_ga} is the case in the passive voice which is aligned to *ga*-case in the active voice, and $w(c_1 \rightarrow c_2)$ denotes the weight of the case alternation "$c_1 \rightarrow c_2$."

Case Frame: "選ばれる-1 (be selected-1)"
{ 選手 (player):1119, 作品 (work):983, $\cdots$ }-*ga*:17722
{ 代表 (representative):18295, $\cdots$ }-*ni*:122273
{ 作品 (work):5, 市長 (mayor):3, $\cdots$ }-*wo*:96
$\cdots$

Case Frame: "選ぶ-13 (select-13)"
{ 私 (I):14, 先生 (teacher):18, $\cdots$ }-*ga*:382
{ 優秀賞 (award):42, シングル (single):17, $\cdots$ }-*ni*:800
{ 曲 (tune):16666, 作品 (work):9967, $\cdots$ }-*wo*:33338
$\cdots$

Table 4: Case frames "選ばれる-1 (be selected-1)" and "選ぶ-13 (select-13)." The numbers following case names denote the total numbers of case slot instances.

5.3 Algorithm

Algorithm 1 presents our algorithm for identifying a corresponding case frame and finding an alignment between cases in pseudo-code. Our algorithm first makes all possible combinations of a case frame in the active voice (cf_{active}), a case in the active voice to which *ga*-case in the passive voice is aligned (c_{ga_to}), and a case in the passive voice which is aligned to *ga*-case in the active voice (c_{to_ga}) on the basis of the linguistic constraints, and then evaluates the score for the combinations $\{cf_{active}, c_{ga\_to}, c_{to\_ga}\}$ by the following equation:

$$score = \mathrm{sim}_{SEM}(A) \times \mathrm{sim}_{DIST}(A)^{\alpha} \times f_{PP}(A), \quad \text{(ii)}$$

where α is a parameter that controls the impact of the case distribution similarity.[7] When we can use

[6] This case frame should not have *wo*-case. However, since we constructed case frames automatically, some case frames have improper cases.

[7] Since $f_{PP}(A)$ is defined with a set of weights of case alternation patterns, $f_{PP}(A)$ contains these weights implicitly, and thus there is only a single explicit weight in equation (ii).

Algorithm 1: Identifying a corresponding case frame and finding an alignment between cases.

Input: a case frame in the passive voice: $cf_{passive}$, and a set of case frames in the active voice: CFS_{active}
Output: a case frame and an alignment between cases: A

1: $max\_score = 0$, $A = ()$
2: **for each** $cf_{active} \in CFS_{active}$
3: **for each** $c_{ga\_to} \in$ {*wo*, *ni*, *no*, NIL}
4: **for each** $c_{to\_ga} \in$ {*ni*, *niyotte*, *kara*, *de*, NIL}
5: **if** (!occur(c_{ga_to}, c_{to_ga})) **then continue**
6: $A' = (cf_{active}, c_{ga\_to}, c_{to\_ga})$
7: $score = \text{sim}_{SEM}(A') \times \text{sim}_{DIST}(A')^{\alpha} \times f_{PP}(A')$
8: **if** ($score > max\_score$) **then**
9: $(max\_score, A) = (score, A')$
10: **end for**
11: **end for**
12: **end for**

development data, we tune α on the development data; otherwise we set $\alpha = 1$. Since some combinations of c_{ga_to} and c_{to_ga} never occur, our algorithm filters them out in line 5 of the algorithm. After checking all combinations, the combination with the highest score is output.

6 Evaluation of the Acquired Knowledge

We applied our algorithm to the case frames that are automatically constructed from a corpus consisting of about 6.9 billion Japanese sentences from the Web. Of course, these case frames contain improper ones, that is, several frames mix several meanings or usages of the predicates. Thus, it is difficult to evaluate the acquired knowledge itself. Instead, we evaluate the usefulness of the acquired knowledge on a case alternation task between the passive and active voices.

6.1 Setting and Algorithm for Case Alternation

We basically used the same data as Murata et al. (2006). As mentioned in Section 2, they extracted 3,576 case particles in passive sentences from the Kyoto University Text Corpus, and tagged their cases in the active voice. Since they treated possessor passive as a kind of indirect passive, they did not adopt the case alternation between *ga* and *no*. In addition, their data included some annotation errors. We thus modified 21 annotations,[8] five of which were changed to the case alternation between *ga* and *no*. Note that there were some cases where multiple possible case particles were tagged to one instance. We adopted evaluation metrics called "Eval. B" by Murata et al., that is, we judged the output to be correct when the output was included in possible answers. We performed experiments on the following three types of data settings.

1. Experiments without either development or training data.

2. Experiments with development data.

3. Experiments with training data.

Experiments without either development or training data In the first setting, we aligned the input passive case frame to one of the active case frames of the same predicate only by using sim_{SEM} and sim_{DIST} with the parameter $\alpha = 1$. Therefore, this setting is fully unsupervised. In this setting, the input surface cases are alternated as follows:

1. If a passive sentence is input, perform syntactic and surface case structure analysis by using Kawahara and Kurohashi (2006)'s model.[9] Their model identified a proper case frame for each predicate, and assigned arguments in the input sentence to case slots of the case frame.

2. By using the acquired knowledge for case alternation, alternate input surface cases with cases in the active voice.

We call this model Model 1. For example, if Example (10) is input, the *ga*-case argument is assigned to the *ga*-case of the case frame "突き落とされる-5 (be pushed down-5)." Since this case is aligned to the *wo*-case of the case frame "突き落とす-4 (push down-4)" as shown in Figure 1, this *ga*-case is alternated with *wo*-case.

(10) 女が　突き落とされた.
woman-*ga* was pushed down
(A woman was pushed down.)

[8] The modified version of the data is publicly available at http://alaginrc.nict.go.jp/case/src/kaku1.1.tar.gz.

Algorithm 2: Pseudo-code of the hill-climbing algorithm for tuning the parameter vector $\mathbf{x}$.

$\mathbf{x} = (1.0, 1.0, \ldots, 1.0)$
$acc = f_{accuracy}(\mathbf{x}), pre\_acc = 0$
while $acc > pre\_acc$
  $pre\_acc = acc$
  for $i \in \{0, \ldots, |\mathbf{x}| - 1\}$
    $acc_+ = f_{accuracy}(x_0, \ldots, x_i + 0.1, \ldots, x_{|\mathbf{x}|-1})$
    $acc_- = f_{accuracy}(x_0, \ldots, x_i - 0.1, \ldots, x_{|\mathbf{x}|-1})$
    if $acc_+ > acc$ **and** $acc_+ > acc_-$ **then** $x_i = x_i + 0.1$
    else if $acc_- > acc$ **then** $x_i = x_i - 0.1$
    $acc = f_{accuracy}(\mathbf{x})$
  end for
end while

	Model			Accuracy
	sim_{SEM}	sim_{DIST}	Parameter tuning	
Model 1_S	✓			0.902 (3,224/3,576)
Model 1_D		✓		0.857 (3,063/3,576)
Model 1	✓	✓		0.906 (3,239/3,576)
Model 2_S	✓		✓	0.928 (3,320/3,576)
Model 2_D		✓	✓	0.927 (3,314/3,576)
Model 2	✓	✓	✓	0.938 (3,353/3,576)
Baseline				0.883 (3,159/3,576)

Table 5: Experimental results of case alternation without training data.

Experiments with development data In the second setting, we aligned the input passive case frame to one of the active case frames of the same predicate by using sim_{SEM}, sim_{DIST}, and f_{PP} with α tuned on the development data. In advance, we divided the tagged data into two parts just as Murata et al. (2006) did, both of which contained 1,788 case particles, and performed 2-fold cross-validation. We used one part for development and the other for testing, and vice versa.

We tuned $w(ga \rightarrow c_{ga\_to})$, $w(c_{to\_ga} \rightarrow ga)$ in Equation (i), and α in Equation (ii) by a simple hill-climbing strategy. Since the candidate cases for c_{ga_to} are *ni*, *niyotte*, *kara*, *de*, and NIL, and the candidate cases for c_{to_ga} are *wo*, *ni*, *no*, and NIL, we defined parameter vector $\mathbf{x}$ as follows:

$$\mathbf{x} = (w(ga \rightarrow ni), w(ga \rightarrow niyotte), w(ga \rightarrow kara), w(ga \rightarrow de), w(ga \rightarrow \text{NIL}), w(wo \rightarrow ga), w(ni \rightarrow ga), w(wo \rightarrow no), w(\text{NIL} \rightarrow ga), \alpha).$$

Algorithm 2 shows the hill-climbing algorithm for tuning the parameter vector $\mathbf{x}$, where $f_{accuracy}(\mathbf{x})$ is a function that returns the case alternation accuracy on the development data with parameter $\mathbf{x}$. This algorithm varies one parameter at a time with a step-size of 0.1 until there is no accuracy improvement in the development data. After acquiring knowledge for case alternation with the tuned parameter, we applied the same method for case alternation as the first setting. We call this model Model 2.

Experiments with training data In the third setting, we also performed 2-fold cross validation, that is, we used one part of the divided tagged corpus for training and the other for testing, and vice versa. Although we basically applied Murata et al. (2006)'s method, which is based on SVMs, we added the output of Model 2 as a new feature.

Specifically, we first tuned the parameter vector $\mathbf{x}$ on the training data and acquired the knowledge for case alternation with the tuned parameter. By using the acquired knowledge, we alternated the input cases in both the training and test data and obtained the resulting case of Model 2. Note that, we did not use any annotations for the test data in this process. We then trained the SVMs on the training data and applied them to the test data using the resulting case as a new feature. We call this model Model 3.

6.2 Results and Discussion

Table 5 shows the results of the experiments without training data. Baseline is a system that outputs the most frequently alternated cases in the development data, which was also used by Murata et al. (2006). The baseline score was higher than that reported by Murata et al. because we modified 21 annotations. We also performed experiments without using case distribution similarity or semantic similarity. We call these models in the first setting Model 1_S and Model 1_D, and these models in the second setting Model 2_S and Model 2_D, respectively.

Although Models 1_S, 1_D, and 1 were fully unsupervised models, Models 1_S and 1 significantly[10] outperformed the baseline model (p-values of McNemar (1947)'s test were smaller than 0.00001). On the other hand, the difference between Models 1_S

[10] In this paper, we call a difference significant if the p-value of McNemar (1947)'s test is less than 0.01.

Model	Accuracy
(Murata et al., 2006)	0.944 (3,376/3,576)
Model 3	0.956 (3,417/3,576)

Table 6: Comparison between Murata et al. (2006)'s method and our method with training data.

and 1 is not statistically significant, and thus the effect of the case distribution similarity was not confirmed by these experiments.

Models 2_S, 2_D, and 2 were models with parameter tuning. Parameter tuning significantly improved the performance. In addition, the difference between Models 2_S and 2 and the difference between Models 2_D and 2 were both significant (p-values of McNemar's test were 0.00032 and 0.00039, respectively), and thus we confirmed the usefulness of the two similarity measures. The parameter α that controls the impact of the case distribution similarity was tuned to 0.3, which means semantic similarity between the instances of the aligned cases is more important than case distribution similarity for this task.

Table 6 compares Murata et al.'s method and our method with training data. We used Murata et al.'s method without feature selection because it achieved the highest performance on this setting. Their method's score was higher than that they reported, again due to the corpus modification. The difference between their method and our method was significant (p-value of McNemar's test was 0.00011), and we confirmed the usefulness of the acquired knowledge for case alternation.

Table 7 shows an example of case alternation between the passive and active voices. When the passive sentence was input, the argument "松樹さんが(Mr. Matsuki-*ga*)" was first assigned to *ga*-case of the case frame "殴られる-2 (be hit-2)." Since this case was aligned to *no*-case of the case frame "殴る-2 (hit-2)," the input *ga*-case was alternated with *no*-case. On the other hand, the cases of the other arguments "バットで (bat-*de*)" and "頭を (head-*wo*)" were output as they were in the passive sentence.

We now list three error causes observed in our experiments of the case alternation task:

1) The passive voice in Japanese is expressed by using the auxiliary verbs "れる (*reru*)" and "られる (*rareru*)." However, these auxiliary verbs can represent several other meanings, such as honorific and possibility. Since Kawahara and Kurohashi (2002)'s method does not distinguish between these meanings, our case frames sometimes contain improper cases such as *wo*-case in case frame "選ばれる-1 (be selected-1)" in Table 4.

Input Text:
· · · 松樹さんが　金属バットで　頭を　殴られ、· · ·
Mr. Matsuki-*ga* metal bat-*de* head-*wo* was hit
(. . . Mr. Matsuki was hit on the head with a metal bat . . .)

Identified passive case frame:
Case Frame: "殴られる-2 (be hit-2)"
{ 何者か (someone):2, 部員 (member):1, · · · }-*niyotte*
{ 女性 (woman):5, 女児 (girl)):4, · · · }-***ga***
{ 頭 (head):3944, 顔 (face):1186, · · · }-*wo*
{ 鈍器 (blunt weapon):84, バット (bat):45, · · · }-*de*
· · ·

Corresponding active case frame and case alignment:
Case alignment: {*niyotte*→*ga*, ***ga*** **→*no***, *wo*→*wo*, *de*→*de*}
Case Frame: "殴る-2 (hit-2)"
{ 男 (man):51, 拳 (fist):30, 誰か (someone):23, · · · }-*ga*
{ 自分 (myself):360, 私 (I):223, · · · }-***no***
{ 頭 (head):5424, 顔 (face):3215, · · · }-*wo*
{ 拳 (fist):316, 平手 (palm):157, 拳 (fist):43, · · · }-*de*
· · ·

Table 7: An example of case alternation. The input *ga*-case was alternated with *no*-case.

2) In some passive sentences, there are two surface *ni*-cases as in Example (11). However, our method does not assume such sentences, and thus cannot deal with them properly.

(11) 男に (man-*ni*) オフィスに (office-*ni*) 派遣された. (was sent)
(ϕ was sent to the office by a man.)

3) *Agent* of a predicate can be represented by using several types of case particles in the passive voice. For example, "会社 (company)" in Example (12) is the *agent* of "雇用した (employed)," which can be represented by either of *ni*, *niyotte*, and *kara* in the passive voice. Since Kawahara and Kurohashi (2002)'s method can not recognize the exchangeablity of case particles, some case frames contain several cases of the same semantic role. However, since our method enforces a one-to-one alignments, only one of these cases is properly aligned to the corresponding case in the active voice.

(12) 会社 が　　男を　　雇用した.
company-*ga* man-*wo* employed
(The company employed a man.)

6.3 Application to Alternation between the Causative and Active Voices

To confirm the applicability of our framework to other types of alternation than the active-passive alternation, we applied our framework to case alternation between the causative and active voices. The causative voice in Japanese is a grammatical voice and is expressed by using the auxiliary verbs "せる (*seru*)" and "させる (*saseru*)." We basically used the same algorithm as Algorithm 1 for acquiring the knowledge for case alternation, but used different constraints on case alternation patterns because possible case alternation patterns are different from those of active-passive alternation. Specifically, we replaced the third and fourth lines of Algorithm 1 with "for each $c_{to\_ga} \in \{\text{NIL}, ni\}$" and "for each $c_{ga\_to} \in \{wo, ni\}$," respectively, based on linguistic analysis of active-causative alternation in Japanese.

We used a part of the data created by Murata and Isahara (2003) to evaluate the usefulness of the acquired knowledge. Their data consists of 4,671 case particles in passive or causative sentences from the Kyoto University Text Corpus with their cases in the active voice. We first extracted 524 case particles that were extracted from causative sentences. Since the annotation quality was not very high, we manually checked all tags and modified inappropriate ones. We then performed 2-fold cross validation experiments. Table 8 shows experimental results. Baseline is a system that outputs the most frequently alternated cases in the training data. The difference between Murata et al. (2006)'s model[11] and our method was significant (p-value of McNemar's test was 0.0019), and we confirmed the applicability of our framework to active-causative alternation.

Model	Accuracy
Baseline	0.781 (409/524)
Murata et al. (2006)'s model	0.836 (438/524)
Our method with training data	0.872 (457/524)

Table 8: Experimental results of case alternation between the causative and active voices.

7 Conclusions and Future Directions

We have presented a method for automatically acquiring knowledge for case alternation between the passive and active voices in Japanese. Our method aligned an input case frame in the passive voice to a corresponding case frame in the active voice and found an alignment between their cases. We then applied the acquired knowledge to a case alternation task and proved its usefulness.

The knowledge we have to manually construct is only the knowledge of linguistic constraints on case alternation patterns. The other types of knowledge are automatically acquired from a large raw corpus. Thus, although this paper focused on the active-passive alternation in Japanese, our framework is applicable to the other types of case alternation and to other languages, especially similar languages such as Korean. We plan to apply our framework to other types of case alternation such as case alternation between intransitive and transitive verbs.

[11] In this experiment, we used the same features as those used by Murata and Isahara (2003).

Exploiting Multiple Sources for Open-domain Hypernym Discovery

Abstract

Hypernym discovery aims to extract such noun pairs that one noun is a hypernym of the other. Most previous methods are based on lexical patterns but perform badly on open-domain data. Other work extracts hypernym relations from encyclopedias but has limited coverage. This paper proposes a simple yet effective distant supervision framework for Chinese open-domain hypernym discovery. Given an entity name, we try to discover its hypernyms by leveraging knowledge from multiple sources, i.e., search engine results, encyclopedias, and morphology of the entity name. First, we extract candidate hypernyms from the above sources. Then, we apply a statistical ranking model to select correct hypernyms. A set of novel features is proposed for the ranking model. We also present a heuristic strategy to build a large-scale noisy training data for the model without human annotation. Experimental results demonstrate that our approach outperforms the state-of-the-art methods on a manually labeled test dataset.

1 Introduction

Hypernym discovery is a task to extract such noun pairs that one noun is a hypernym of the other (Snow et al., 2005). A noun H is a hypernym of another noun E if E is an instance or subclass of H. In other word, H is a semantic class of E. For instance, "actor" is a hypernym of "Mel Gibson"; "dog" is a hypernym of "Caucasian sheepdog"; "medicine" is a hypernym of "Aspirin". Hypernym discovery is an important subtask of semantic relation extraction and has many applications in ontology construction (Suchanek et al., 2008), machine reading (Etzioni et al., 2006), question answering (McNamee et al., 2008), and so on.

Some manually constructed thesauri such as WordNet can also provide some semantic relations such as hypernyms. However, these thesauri are limited in its scope and domain, and manual construction is knowledge-intensive and time-consuming. Therefore, many researchers try to automatically extract semantic relations or to construct taxonomies.

Most previous methods on automatic hypernym discovery are based on lexical patterns and suffer from the problem that such patterns can only cover a small part of complex linguistic circumstances (Hearst, 1992; Turney et al., 2003; Zhang et al., 2011). Other work tries to extract hypernym relations from large-scale encyclopedias like Wikipedia and achieves high precision (Suchanek et al., 2008; Hoffart et al., 2012). However, the coverage is limited since there exist many infrequent and new entities that are missing in encyclopedias (Lin et al., 2012). We made similar observation that more than a half of entities in our data set have no entries in the encyclopedias.

This paper proposes a simple yet effective distant supervision framework for Chinese open-domain hypernym discovery. Given an entity name, our goal is to discover its hypernyms by leveraging knowledge from multiple sources. Considering the case where a person wants to know the meaning of an unknown entity, he/she may search it in a search engine and then finds out the answer after going through the search results. Furthermore, if he/she finds an entry about the entity in an authentic web site, such as Wikipedia, the information will help him/her under-

Seattle, Washington, USA, 18-21 October 2013.

stand the entity. Also, the morphology of the entity name can provide supplementary information. In this paper, we imitate the process. The evidences from the above sources are integrated in our hypernym discovery model.

Our approach is composed of two major steps: hypernym candidate extraction and ranking. In the first step, we collect hypernym candidates from multiple sources. Given an entity name, we search it in a search engine and extract high-frequency nouns as its main candidate hypernyms from the search results. We also collect the category tags for the entity from two Chinese encyclopedias and the head word of the entity as the candidates.

In the second step, we identify correct hypernyms from the candidates. We view this task as a ranking problem and propose a set of effective features to build a statistical ranking model. For the parameter learning of the model, we also present a heuristic strategy to build a large-scale noisy training data without human annotation.

Our contributions are as follows:

- We are the first to discover hypernym for Chinese open-domain entities by exploiting multiple sources. The evidences from different sources can authenticate and complement each other to improve both precision and recall.
- We manually annotate a dataset containing 1,879 Chinese entities and their hypernyms, which will be made publicly available. To the best of our knowledge, this is the first dataset for Chinese hypernyms.
- We propose a set of novel and effective features for hypernym ranking. Experimental results show that our method achieves the best performance.

Furthermore, our approach can be easily ported from Chinese to English and other languages, except that a few language dependent features need to be changed.

The remainder of the paper is organized as follows: Section 2 discusses the related work. Section 3 introduces our method in detail. Section 4 describes the experimental setup. Section 5 shows the experimental results. Conclusion and future work are presented in Section 6.

2 Related Work

Previous methods for hypernym discovery can be summarized into two major categories, i.e., pattern-based methods and encyclopedia-based methods.

Pattern-based methods make use of manually or automatically constructed patterns to mine hypernym relations from text corpora. The pioneer work by Hearst (1992) finds that linking two noun phrases (NPs) via certain lexical constructions often implies hypernym relations. For example, NP_1 is a hypernym of NP_2 in the lexical pattern "such NP_1 as NP_2". Similarly, succeeding researchers follow her work and use handcrafted patterns to extract hypernym pairs from corpora (Caraballo, 1999; Scott and Dominic, 2003; Ciaramita and Johnson, 2003; Turney et al., 2003; Pasca, 2004; Etzioni et al., 2005; Ritter et al., 2009; Zhang et al., 2011).

Evans (2004) considers the web data as a large corpus and uses search engines to identify hypernyms based on lexical patterns. Given an arbitrary document, he takes each capitalized word sequence as an entity and aims to find its potential hypernyms through pattern-based web searching. Suppose `X` is a capitalized word sequence. Some pattern queries like "such as `X`" are threw into the search engine. Then, in the retrieved documents, the nouns that immediately precede the pattern are recognized as the hypernyms of `X`. This work is most related to ours. However, the patterns used in his work are too strict to cover many low-frequency entities, and our experiments show the weakness of the method.

Snow et al. (2005) for the first time propose to automatically extract large numbers of lexico-syntactic patterns and then detect hypernym relations from a large newswire corpus. First, they use some known hypernym-hyponym pairs from WordNet as seeds and collect many patterns from a syntactically parsed corpus in a bootstrapping way. Then, they consider all noun pairs in the same sentence as potential hypernym-hyponym pairs and use a statistical classifier to recognize the correct ones. All patterns corresponding to the noun pairs in the corpus are fed into the classifier as features. Their method relies on accurate syntactic parsers and it is difficult to guarantee the quality of the automatically extracted patterns. Our experiments show that their method is inferior to ours.

Encyclopedia-based methods extract hypernym relations from encyclopedias like Wikipedia (Suchanek et al., 2008; Hoffart et al., 2012). The user-labeled information in encyclopedias, such as category tags in Wikipedia, is often used to derive hypernym relations.

In the construction of the famous ontology YAGO, Suchanek et al. (2008) consider the title of each Wikipedia page as an entity and the corresponding category tags as its potential hypernyms. They apply a shallow semantic parser and some rules to distinguish the correct hypernyms. Heuristically, they find that if the head of the category tag is a plural word, the tag is most likely to be a correct hypernym. However, this method cannot be used in Chinese because of the lack of plurality information.

The method of Suchanek et al. (2008) cannot handle the case when the entity is absent in Wikipedia. To solve this problem, Lin et al. (2012) connect the absent entities with the entities present in Wikipedia sharing common contexts. They utilize the Freebase semantic types to label the present entities and then propagate the types to the absent entities. The Freebase contains most of entities in Wikipedia and assigns them semantic types defined in advance. But there are no such resources in Chinese.

Compared with previous work, our approach tries to identify hypernyms from multiple sources. The evidences from different sources can authenticate and complement each other to improve both precision and recall. Our experimental results show the effectiveness of our method.

3 Method

Our method is composed of two steps. First, we collect candidate hypernyms from multiple sources for a given entity. Then, a statistical model is built for hypernym ranking based on a set of effective features. Besides, we also present a heuristic strategy to build a large-scale training data.

3.1 Candidate Hypernym Collection from Multiple Sources

In this work, we collect potential hypernyms from four sources, i.e., search engine results, two encyclopedias, and morphology of the entity name.

We count the co-occurrence frequency between the target entities and other words in the returned snippets and titles, and select top N nouns (or noun phrases) as the main candidates. As the experiments show, this method can find at least one hypernym for 86.91% entities when N equals 10 (see Section 5.1). This roughly explains why people often can infer semantic meaning of unknown entities after going through several search results.

Furthermore, the user-generated encyclopedia category tags are important clues if the entity exists in a encyclopedia. Thus we add these tags into the candidates. In this work, we consider two Chinese encyclopedias, Baidubaike and Hudongbaike[1], as hypernym sources.

In addition, the head words of entities are also their hypernyms sometimes. For example, the head word of "皇帝企鹅 (Emperor Penguin)" indicates that it's a kind of "企鹅 (penguins)". Thus we put head words into the hypernym candidates. In Chinese, head words are often laid after their modifiers. Therefore, we try to segment a given entity. If it can be segmented and the last word is a noun, we take the last word as the head word. In our data set, the head words of 41.35% entities are real hypernyms (see Section 5.1).

We combine all of these hypernym candidates together as the input of the second stage. The final coverage rate reaches 93.24%.

3.2 Hypernym Ranking

After getting the candidate hypernyms, we then adopt a ranking model to determine the correct hypernym. In this section, we propose several effective features for the model. The model needs training data for learning how to rank the data in addition to parameter setting. Considering that manually annotating a large-scale hypernym dataset is costly and time-consuming, we present a heuristic strategy to collect training data. We compare three hypernym ranking models on this data set, including Support Vector Machine (SVM) with a linear kernel, SVM with a radial basis function (RBF) kernel and Logistic Regression (LR).

[1]Baidubaike (`http://baike.baidu.com`) and Hudongbaike (`http://www.baike.com`) are two largest Chinese encyclopedias containing more than 6.26 million and 7.87 million entries respectively, while Chinese Wikipedia contains about 0.72 million entries until September, 2013.

Feature	Comment	Value Range
Prior	the prior probability of a candidate being a potential hypernym	[0, 1]
Is_Tag	whether a candidate is a category tag in the encyclopedia page of the entity if it exists	0 or 1
Is_Head	whether a candidate is the head word of the entity	0 or 1
In_Titles	some binary features based on the frequency of occurrence of a candidate in the document titles in the search results	0 or 1
Synonyms	the ratio of the synonyms of the candidate in the candidate list of the entity	[0, 1]
Radicals	the ratio of the radicals of characters in a candidate matched with the last character of the entity	[0, 1]
Source_Num	the number of sources where the candidate is extracted	1, 2, 3, or 4
Lexicon	the hypernym candidate itself and its head word	0 or 1

Table 1: The features for ranking

3.2.1 Features for Ranking

The features for hypernym ranking are shown in Table 1. We illustrate them in detail in the following.

Hypernym Prior: Intuitively, different words have different probabilities as hypernyms of some other words. Some are more probable as hypernyms, such as *animal*, *plant* and *fruit*. Some other words such as *sun*, *nature* and *alias*, are not usually used as hypernyms. Thus we use a prior probability to express this phenomenon. The assumption is that if the more frequent that a noun appears as category tags, the more likely it is a hypernym. We extract category tags from 2.4 million pages in Baidubaike, and compute the prior probabilities $prior(w)$ for a word w being a potential hypernym using Equation 1. $count_{CT}(w)$ denotes the times a word appeared as a category tag in the encyclopedia pages.

$$prior(w) = \frac{count_{CT}(w)}{\sum_{w'} count_{CT}(w')} \quad (1)$$

In Titles: When we enter a query into a search engine, the engine returns a search result list, which contains document titles and their snippet text. The distributions of hypernyms and non-hypernyms in titles are compared with that in snippets respectively in our training data. We discover that the average frequency of occurrence of hypernyms in titles is 15.60 while this number of non-hypernyms is only 5.18, while the difference in snippets is very small (Table 2). Thus the frequency of candidates in titles can be used as features. In this work the frequency is divided into three cases: greater than 15.60, less than 5.18, and between 5.18 and 15.60. Three binary features are used to represent these cases.

	Avg. Frequency in titles	Avg. Frequency in snippets
Hypernym	15.60	33.69
Non-Hypernym	5.18	30.61

Table 2: Distributions of candidate hypernyms in titles and snippets

Synonyms: If there exist synonyms of a candidate hypernym in the candidate list, the candidate is probably correct answer. For example, when "药品 (medicine)" and "药物 (medicine)" both appear in the candidate list of an entity, the entity is probably a kind of medicine. We get synonyms of a candidate from a Chinese semantic thesaurus – Tongyi Cilin (Extended) (CilinE for short)[2] and compute the score as a feature using Equation 2.

$$ratio_{syn}(h, l_e) = \frac{count_{syn}(h, l_e)}{len(l_e)} \quad (2)$$

Given a hypernym candidate h of an entity e and the list of all candidates l_e, we compute the ratio of the synonyms of h in l_e. $count_{syn}(h, l_e)$ denotes the count of the synonyms of h in l_e. $len(l_e)$ is the total count of candidates.

[2]CilinE contains synonym and hypernym relations among 77 thousand words, which is manually organized as a hierarchy of five levels.

Radicals: Chinese characters are a form of ideogram. By far, the bulk of Chinese characters were created by linking together a character with a related meaning and another character to indicate its pronunciation. The character with a related meaning is called radical. Sometimes, it is a important clue to indicate the semantic class of the whole character. For example, the radical "虫" means insects, so it hints "蜻蜓 (dragonfly)" is a kind of insects. Similarly "疒" hints "淋巴癌 (lymphoma)" is a kind of diseases. Thus we use radicals as a feature the value of which is computed by using Equation 3.

$$radical(e,h) = \frac{count_{RM}(e,h)}{len(h)} \quad (3)$$

Here $radical(e,h)$ denotes the ratio of characters radical-matched with the last character of the entity e in the hypernym h. $count_{RM}(e,h)$ denotes the count of the radical-matched characters in h. $len(h)$ denotes the total count of the characters in h.

3.2.2 Training Data Collection

Now training data is imperative to learn the weights of the features in Section 3.2.1. Hence, we propose a heuristic strategy to collect training data from encyclopedias.

Firstly, we extract a number of open-domain entities from encyclopedias randomly. Then their hypernym candidates are collected by using the method proposed in Section 3.1. We select positive training instances following two principles:

- Principle 1: Among the four sources used for candidate collection, the more sources from which the hypernym candidate is extracted, the more likely it is a correct one.
- Principle 2: The higher the prior of the candidate being a hypernym is, the more likely it is a correct one.

We select the best candidates following Principle 1 and then select the best one in them as a positive instance following Principle 2. And we select a candidate as a negative training instance when it is from only one source and its prior is the lowest. If there are synonyms of training instances in the candidates list, the synonyms are also extended into the training set.

Domain	# of entities	
	Dev.	Test
Biology	72	351
Health Care	61	291
Food	75	303
Movie	51	204
Industry	56	224
Others	35	136
Total	350	1529

Table 3: The evaluation data

In this way, we collect training data automatically, which are used to learn the feature weights of the ranking models.

4 Experimental Setup

In this work, we use Baidu[3] search engine, the most popular search engine for Chinese, and get the top 100 search results for each entity. The Chinese segmentation, POS tagging and dependency parsing is provided by an open-source Chinese language processing platform LTP[4] (Che et al., 2010).

4.1 Experimental Data

In our experiments, we prepare open-domain entities from dictionaries in wide domains, which are published by a Chinese input method editor software Sogou Pinyin[5]. The domains include biology, health care, food, movie, industry, and so on. We sample 1,879 entities from these domain dictionaries and randomly split them into 1/5 for development and 4/5 for test (Table 3). We find that only 865 (46.04%) entities exist in Baidubaike or Hudongbaike. Then we extract candidate hypernyms for the entities and ask two annotators to judge each hypernym relation pair true or false manually. A pair `(E, H)` is annotated as true if the annotators judge "`E` is a (or a kind of) `H`" is true. Finally, we get 12.53 candidate hypernyms for each entity on average in which about 2.09 hypernyms are correct. 4,330 hypernym relation pairs are judged by both the annotators. We measure the agreement of the judges using the Kappa coefficient (Siegel and Castellan Jr, 1988). The

[3] http://www.baidu.com
[4] http://ir.hit.edu.cn/demo/ltp/
[5] http://pinyin.sogou.com/dict/

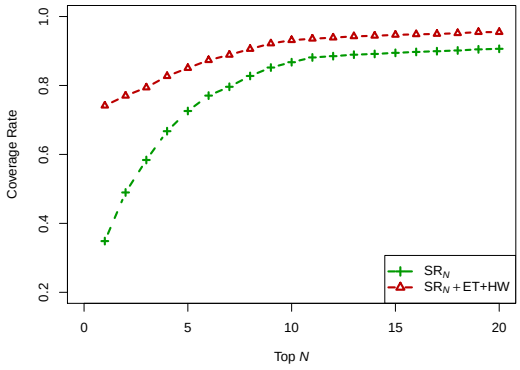

Figure 1: Effect of candidate hypernym coverage rate while varying N

Kappa value is 0.79.

Our training data, containing 11,481 positive instances and 18,378 negative ones, is extracted from Baidubaike and Hudongbaike using the heuristic strategy proposed in Section 3.2.2.

4.2 Experimental Metrics

The evaluation metrics for our task include:

Coverage Rate: We evaluate coverage rate of the candidate hypernyms. Coverage rate is the number of entities for which at least one correct hypernym is found divided by the total number of all entities.

Precision@1: Our method returns a ranked list of hypernyms for each entity. We evaluate precision of top-1 hypernyms (the most probable ones) in the ranked lists, which is the number of correct top-1 hypernyms divided by the number of all entities.

R-precision: It is equivalent to Precision@R where R is the total number of candidates labeled as true hypernyms of an entity.

Precision, Recall, and F-score: Besides, we can convert our ranking models to classification models by setting thresholds. Varying the thresholds, we can get different precisions, recalls, and F-scores.

5 Results and Analysis

5.1 The Coverage of Candidate Hypernyms

In this section, we evaluate the coverage rate of the candidate hypernyms. We check the candidate hypernyms of the whole 1,879 entities in the development and test sets and see how many entities we can collect at least one correct hypernym for.

Source	Coverage Rate	Avg. #
SR_{10}	0.8691	9.44*
ET	0.3938	3.07
HW	0.4135	0.87†
SR_{10} + ET	0.8909	12.02
SR_{10} + HW	0.9117	9.75
ET + HW	0.7073	3.92
SR_{10} + ET + HW	0.9324	12.53

Table 4: Coverage evaluation of the candidate hypernym extraction

There are four different sources to collect candidates as described in Section 3.1, which can be divided into three kinds: search results (SR for short), encyclopedia tags (ET) and head words (HW). For SR, we select top N frequent nouns (SR_N) in the search results of an entity as its hypernym candidates. The effect of coverage rate while varying N is shown in Figure 1. As we can see from the figure, the coverage rate is improved significantly by increasing N until N reaches 10. After that, the improvement becomes slight. When the candidates from all sources are merged, the coverage rate is further improved.

Thus we set N as 10 in the remaining experiments. The detail evaluation is shown in Table 4. We can see that top 10 frequent nouns in the search results contain at least one correct hypernym for 86.91% entities in our data set. This coincides with the intuition that people usually can infer the semantic classes of unknown entities by searching them in web search engines.

The coverage rate of ET merely reaches 39.38%. We find the reason is that more than half of the entities have no encyclopedia pages. The average number of candidate hypernyms from ET is 3.07. Note that the number is calculated among all the entities. We also calculate the average number only for the present entities in encyclopedias. The number reaches 6.68. The reason is that for many present entities, the category tags include not only hypernyms

*For some of entities are rare, there may be less than 10 nouns in the search results. So the average count of candidates is less than 10.

†Not all of the entities can be segmented. We cannot get the head words of the ones that cannot be segmented.

Method	Present Entities		Absent Entities		All Entities	
	P@1	R-Prec	P@1	R-Prec	P@1	R-Prec
$M_{Pattern}$	0.5542	0.4937	0.4306	0.3638	0.5229	0.4608

M_{Prior}	0.7339	0.5483	0.3940	0.3531	0.5494	0.4423
$M_{SVM-linear}$	0.8569	0.6899	0.6157	0.5837	0.7260	0.6322
$M_{SVM-rbf}$	0.8484	0.6940	0.6241	0.5901	0.7266	0.6376
M_{LR}	**0.8612**	**0.7052**	**0.6807**	**0.6258**	**0.7632**	**0.6621**

Table 5: Precision@1 and R-Precision results on the test set. Here the present entities mean the entities existing in the encyclopedias. The absent entities mean the ones not existing in the encyclopedias.

but also related words. For example, "布拉德利中心 (Bradley Center)" in Baidubaike have 5 tags, i.e., "NBA", "体育 (sports)", "体育运动 (sports)", "篮球 (basketball)", and "场馆 (arena)". Among them, only "场馆 (arena)" is a proper hypernym whereas the others are some related words indicating merely thematic vicinity. Comparing the results of SR_{10} and SR_{10} + ET, we can see that collecting candidates from ET can improve coverage, although many incorrect candidates are added in at the same time.

The HW source provides 0.87 candidates on average with 41.35% coverage rate. That is to say, for these entities, people can infer the semantic classes when they see the surface lexicon.

At last, we combine the candidates from all of the three sources as the input of the ranking methods. The coverage rate reaches 93.24%.

We also compare with the manually constructed semantic thesaurus CilinE mentioned in Section 3.2.1. Only 29 entities exist in CilinE (coverage rate is only 1.54%). That is why we try to automatically extract hypernym relations.

5.2 Evaluation of the Ranking

5.2.1 Overall Performance Comparison

In this section, we compare our proposed methods with other methods. Table 5 lists the performance measured by precision at rank 1 and R-precision of some key methods. The precision-recall curves of all the methods are shown in Figure 2. Table 7 lists the maximum F-scores.

$M_{Pattern}$ refers to the pattern-based method of Hearst (1992). We craft Chinese Hearst-style patterns (Table 6), in which E represents an entity and H represents one of its hypernyms. Following Evans (2004), we combine each pattern and each entity and submit them into the Baidu search engine. For example, for an entity E, we search "E 是一个 (E is a)", "E 等 (E and other)", and so on. We select top 100 search results of each query and get 1,285,209 results in all for the entities in the test set. Then we use the patterns to extract hypernyms from the search results. The result shows that 508 correct hypernyms are extracted for 568 entities (1,529 entities in total). Only a small part of the entities can be extracted hypernyms for. This is mainly because only a few hypernym relations are expressed in these fixed patterns in the web, and many ones are expressed in more flexible manners. The hypernyms are ranked based on the count of evidences where the hypernyms are extracted.

Pattern	Translation
E 是(一个/一种) H	E is a (a kind of) H
E (、)等 H	E(,) and other H
H (，)叫(做) E	H(,) called E
H (，)(像)如 E	H(,) such as E
H (，)特别是 E	H(,) especially E

Table 6: Chinese Hearst-style lexical patterns

M_{Snow} is the method originally proposed by Snow et al. (2005) for English but we adapt it for Chinese. We consider the top 100 search results for each known hypernym-hyponym pairs as a corpus to extract lexico-syntactic patterns. Then, an LR classifier is built based on this patterns to recognize hypernym relations. This method considers all nouns co-occurred with the focused entity in the same sentences as candidate hypernyms. So the number of candidates is huge, which causes inefficiency. In

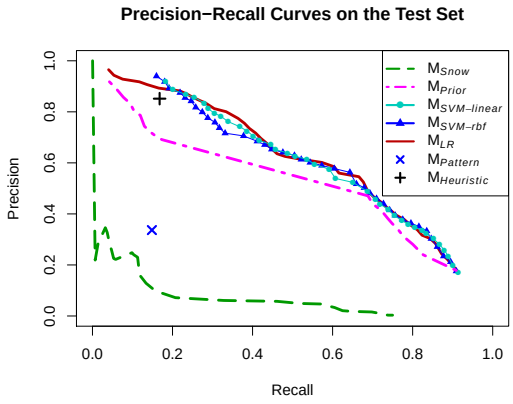

Figure 2: Precision-Recall curves on the test set

our corpus, there are 652,181 candidates for 1,529 entities (426.54 for each entity on average), most of which are not hypernyms. One possible reason is that this method relies on an accurate syntactic parser and it is difficult to guarantee the quality of the automatically extracted patterns. Even worse, the low quality of the language in the search results may make this problem more serious.

M_{Prior} refers to the ranking method based on only the prior of a candidate being a hypernym. As Table 5 shows, it outperforms M_{Snow} and achieves comparable results with $M_{Pattern}$ on Precision@1 and R-Precision.

Based on the features proposed in Section 3.2.1, we train several statistical models based on SVM and LR on the training data. $M_{SVM-linear}$ and $M_{SVM-rbf}$ refer to the SVM models based on linear kernels and RBF kernels respectively. M_{LR} refers to the LR model. The probabilities[6] output by the models are used to rank the candidate hypernyms. All of the parameters which need to be set in the models are selected on the development set. Table 5 shows the best models based on each algorithm. These supervised models outperform the previous methods. M_{LR} achieves the best performance.

The precision-recall plot of the methods on the test set is presented in Figure 2. $M_{Heuristic}$ refers to the heuristic approach, proposed in Section 3.2.2, to collect training data. Because this method cannot provide ranking information, it is not listed in Table 5. For fair comparison of R-precision and recall, we add the extra correct hypernyms from $M_{Pattern}$ and M_{Snow} to the test data set. The models based on SVM and LR still perform better than the other methods. $M_{Pattern}$ and M_{Snow} suffer from low recall and precision. $M_{Heuristic}$ get a high precision but a low recall, because it can only deal with a part of entities appearing in encyclopedias. The precision of $M_{Heuristic}$ reflects the quality of our training data. We summarize the maximum F-score of different methods in Table 7.

[6]The output of an SVM is the distance from the decision hyper-plane. Sigmoid functions can be used to convert this uncalibrated distance into a calibrated posterior probability (Platt, 1999).

Method	Max. F-score
$M_{Pattern}$	0.2061
M_{Snow}	0.1514
$M_{Heuristic}$	0.2803
M_{Prior}	0.5591
$M_{SVM-linear}$	0.5868
$M_{SVM-rbf}$	**0.6014**
M_{LR}	0.5998

Table 7: Summary of maximum F-score on the test set

Feature	P@1	R-Prec	Max. F-score
All	**0.7632**	**0.6621**	**0.5998**
– Prior	0.7534	0.6546	0.5837

Table 8: Performance of LR models with different features on the test set

5.2.2 Feature Effect

Table 8 shows the impact of each feature on the performance of LR models. When we remove any one of the features, the performance is degraded more or less. The most effective features are Is_Tag and Is_Head. The last line in Table 8 shows the performance when we remove all features about the source information, i.e., Is_Tag, Is_Head, and

Entity	Top-1 Hypernym	Entity	Top-1 Hypernym
头孢哌酮钠(cefoperazone sodium)	药品(drug)	圆舵鲣(bullet tuna)	鱼类(fish)
佛手卷(finger citron rolls)	小吃(snack)	锆英石(zirconite)	矿石(ore)
复仇者联盟(The Avengers)	电影(movie)	费利克斯托(Felixstowe)	港口(port)
套叠鞭(mastigium)	基准(datum)	基节臼(coxal cavity)	植物(plant)
乙醇胺磷酸转移酶 (Ethanolamine phosphotransferase)	生物 (organism)	彗发 (coma)	知识 (knowledge)

Table 10: Examples of entity-hypernym pairs extracted by M_{LR}

Domain	P@1	R-Prec	Max. F-score
Biology	0.8165	0.7203	0.6424
Health Care	0.7354	0.5962	0.6061
Food	0.7450	0.6634	0.6938
Movie	0.9310	0.8069	0.7031
Industry	0.6286	0.5841	0.4624
Others	0.6324	0.4936	0.4318

Table 9: Performance of M_{LR} in various domains

Source_Num. The performance is degraded sharply. This indicates the importance of the source information for hypernym ranking.

5.2.3 The Performance in Each Domain

In this section, we evaluate the performance of M_{LR} method in various domains. We can see from Table 9 that the performance in movie domain is best while the performance in industry domain is worst. That is because the information about movies is abundant on the web. Furthermore, most of movies have encyclopedia pages. It is easy to get the hypernyms. In contrast, the entities in industry domain are more uncommon. On the whole, our method is robust for different domains. In Table 10, some instances in various domains are presented.

5.3 Error Analysis

The uncovered entities[7] and the false positives[8] are analyzed after the experiments. Some error examples are shown in Table 10 (in red font).

[7]Uncovered entities are entities which we do not collect any correct hypernyms for in the first step.

[8]False positives are hypernyms ranked at the first places, but actually are not correct hypernyms.

Uncovered entities: About 34% of the errors are caused by uncovered entities. It is found that many of the uncovered entities are rare entities. Nearly 36% of them are very rare and have only less than 100 search results in all. When we can't get enough information of an unknown entity from the search engine, it's difficult to know its semantic meaning, such as "套叠鞭 (mastigium)", "基节臼 (coxal cavity)", "彗发 (coma)". The identification of their hypernyms requires more human-crafted knowledge. The ranking models we used are unable to select them, as the true synonyms are often below rank 10.

False positives: The remained 66% errors are false positives. They are mainly owing to the fact that some other related words in the candidate lists are more likely hypernyms. For example, "生物 (organism)" is wrongly recognized as the most probable hypernym of "乙醇胺磷酸转移酶 (Ethanolamine phosphotransferase)", because the entity often co-occurs with word "生物 (organism)" and the latter is often used as a hypernym of some other entities. The correct hypernyms actually are "酶 (enzyme)", "化学物质 (chemical substance)", and so on.

6 Conclusion

This paper proposes a novel method for finding hypernyms of Chinese open-domain entities from multiple sources. We collect candidate hypernyms with wide coverage from search results, encyclopedia category tags and the head word of the entity. Then, we propose a set of features to build statistical models to rank the candidate hypernyms on the training data collected automatically. In our experiments, we show that our method outperforms the state-of-the-art methods and achieves the best preci-

sion of 76.32% on a manually labeled test dataset. All of the features which we propose are effective, especially the features of source information. Moreover, our method works well in various domains, especially in the movie and biology domains. We also conduct detailed analysis to give more insights on the error distribution. Except some language dependent features, our approach can be easily transfered from Chinese to other languages. For future work, we would like to explore knowledge from more sources to enhance our model, such as semantic thesauri and infoboxes in encyclopedias.

A Semantically Enhanced Approach to Determine Textual Similarity

Eduardo Blanco and **Dan Moldovan**

Abstract

This paper presents a novel approach to determine textual similarity. A layered methodology to transform text into logic forms is proposed, and semantic features are derived from a logic prover. Experimental results show that incorporating the semantic structure of sentences is beneficial. When training data is unavailable, scores obtained from the logic prover in an unsupervised manner outperform supervised methods.

1 Introduction

The task of Semantic Textual Similarity (Agirre et al., 2012) measures the degree of semantic equivalence between two sentences. Unlike textual entailment (Giampiccolo et al., 2007), textual similarity is symmetric, and unlike both textual entailment and paraphrasing (Dolan and Brockett, 2005), textual similarity is modeled using a graded score rather than a binary decision. For example, sentence pair (1) below is very similar [5 out of 5], (2) is somewhat similar [3 out of 5] and (3) is not similar at all [0 out of 5]:

1. Someone is removing the scales from the fish.
   A person is descaling a fish.
2. A woman is chopping an herb.
   A man is finely chopping a green substance.
3. A cat is playing with a watermelon on a floor.
   A man is pouring oil into a pan.

State-of-the-art systems to determine textual similarity (Bär et al., 2012; Šarić et al., 2012; Banea et al., 2012) do not account for the semantic structure of sentences, and mostly rely on word pairings and knowledge derived from large corpora, e.g., Wikipedia. Regardless of details, each word in sent_1 is paired with the word in sent_2 that is most similar according to some similarity measure. Then, all similarities are added and normalized by the length of sent_1 to obtain the similarity score from sent_1 to sent_2. The process is repeated to obtain the similarity score from sent_2 to sent_1, and both scores are then averaged to determine the overall textual similarity. Several word-to-word similarity measures are often combined with other shallow features, e.g., n-gram overlap, syntactic dependencies, to obtain the final similarity score.

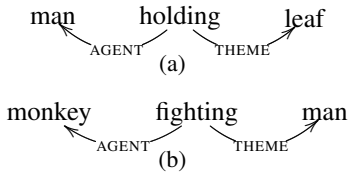

Figure 1: Semantic representation of 1(a) *A man is holding a leaf* and 1(b) *A monkey is fighting a man*.

Consider sentences 1(a) *A man is holding a leaf* and 1(b) *A monkey is fighting a man*. These two sentences are very dissimilar, the only commonality is the concept '*man*'. Any approach that blindly searches for the word in 1(b) that is the most similar to word '*man*' in 1(a) will find '*man*' from 1(b) to be a perfect match. One of three content words is a match and thus the estimated similarity will be much higher than it actually is.

Consider now the semantic representations for sentences 1(a) and 1(b) in Figure 1. '*man*' plays the role of AGENT in 1(a), and THEME in 1(b). While in both sentences the word '*man*' encodes the same concept, their semantic functions with respect to other concepts are different. Intuitively, it seems reasonable to penalize the similarity score based on the role discrepancy.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1235–1245,
Seattle, Washington, USA, 18-21 October 2013.

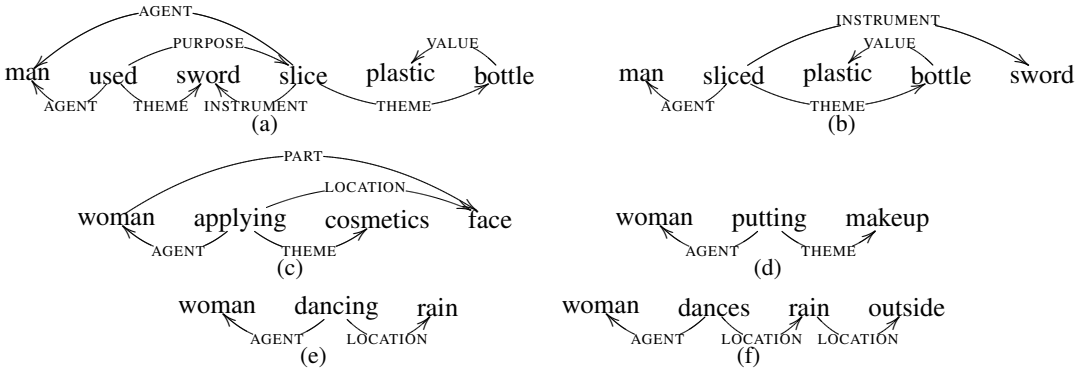

Figure 2: Semantic representations of 2(a) *The man used a sword to slice a plastic bottle*, 2(b) *A man sliced a plastic bottle with a sword*, 2(c) *A woman is applying cosmetics to her face*, 2(d) *A woman is putting on makeup*, 2(e) *A woman is dancing in the rain*, and 2(f) *A woman dances in the rain outside*. Pairs (a, b), (c, d) and (e, f) are highly similar even though concepts and relations only match partially.

This paper proposes a novel approach to determine textual similarity. Semantic representations of sentences are exploited, syntactic features omitted and the only external resource used in WordNet (Miller, 1995). The main novelties of our approach are: it (1) derives semantic features from a logic prover to be used in a machine learning framework; (2) uses three logic form transformations capturing different levels of knowledge; and (3) incorporates semantic representations extracted automatically.

1.1 Matching Semantic Representations and Determining Textual Similarity

Throughout this paper, the semantic representation of a sentence comprises the concepts in it, semantic relations linking those concepts and named entities qualifying them. First, we note that existing tools to extract semantic relations and named entities are not perfect, thus any system relying on them will suffer from incomplete and incorrect representations. Second, even if flawless representations were readily available, the problem of determining textual similarity cannot be reduced to matching semantic representations: partial matches may correspond to completely similar sentences. The rest of this section illustrates this point with the examples in Figure 2. Our approach (Section 3) copes with the inherent errors made by tools used to obtain semantic representations and learns which parts of a representation are important to determine textual similarity.

Consider sentences 2(a) *The man used a sword to slice a plastic bottle* and 2(b) *A man sliced a plastic bottle with a sword*. Both sentences have high similarity [5 out of 5], and yet their semantic representations only match partially. In this example, the verb '*used*' in 2(a) and its semantic links are somewhat semantically superfluous. Note that in other cases, missing a semantic relation signals lower similarity, e.g., *I had fun [at the party]*$_{\text{LOCATION}}$ and *I had fun*, while similar, do not convey the same meaning.

Sentence 2(c) *A woman is applying cosmetics to her face* and 2(d) *A woman is putting on makeup* are highly similar even though the latter specifies neither the LOCATION where the '*makeup*' is applied nor the fact that a PART of the '*woman*' is her '*face*'. Similarly, sentences 2(e) *A woman is dancing in the rain* and 2(f) *A woman dances in the rain outside* are semantically equivalent since '*rain*' always has LOCATION '*outside*': missing this information does not carry loss of meaning.

2 Related Work

Determining similarity between text snippets is relevant to information retrieval (Hatzivassiloglou et al., 1999), paraphrase recognition (Madnani and Dorr, 2010), grading answers to questions (Mohler et al., 2011) and many others. We focus on recent work and emphasize the differences from our approach.

The SemEval 2012 Task 6: A Pilot on Semantic Textual Similarity (Agirre et al., 2012) brought together 35 teams that competed against each other. The top 3 performers (Bär et al., 2012; Šarić et al., 2012; Banea et al., 2012), followed a ma-

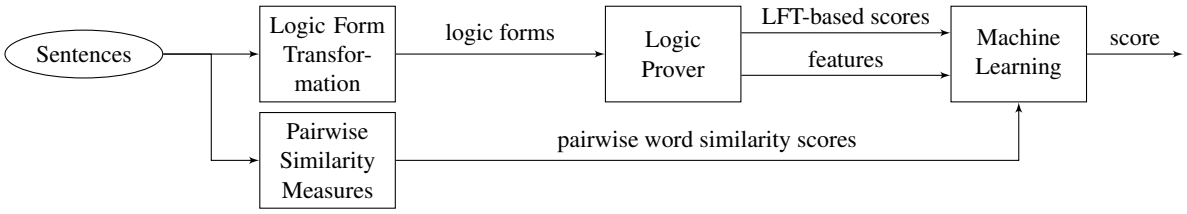

Figure 3: Main components of our system to determine textual similarity.

chine learning approach with features that do not take into account the semantic structure of sentences, e.g., n-grams, word overlap, evaluation measures for machine translation, pairwise word similarities, syntactic dependencies. All three used WordNet, Wikipedia and other large corpora. In particular, Banea et al. (2012) obtained models from 6 million Wikipedia articles and more than 9.5 million hyperlinks; Bär et al. (2012) used Wiktionary[1], which contains over 3 million entries; and Šarić et al. (2012) used The New York Times Annotated Corpus (Sandhaus, 2008), which contains over 1.8 million news articles, and Google n-grams (Lin et al., 2012), which consists of approximately 24GB of compressed text files. Our approach only uses WordNet, by far the smallest external resource with less than 120,000 synsets.

Participants that incorporated information about the semantic structure of sentences (Glinos, 2012; Rios et al., 2012)[2] did not perform at the top. Out of 88 runs, they were ranked 16, 36 and 64. We believe this is because they use semantic relations to calculate some ad-hoc similarity score. In contrast, our approach derives features from semantic representations encoded using logic, and combine these features using machine learning. Moreover, we use three logic form transformations capturing different levels of knowledge, from only content words to semantic structure. In turn, this allows us to boost performance by relying on semantics when simpler shallow methods fail.

A few logic-based approaches to recognize textual entailment are similar to the work presented here. Bos and Markert (2006) extract semantic representations with Boxer (Bos et al., 2004) and incorporate background knowledge from external resources. They use a standard theorem prover and extract 8 features that are later combined using machine learning. Raina et al. (2005) use a logic form transformation derived from dependency parses and named entities. They use abductive reasoning and define an assumption cost model to account for partial entailments. Unlike them, we define three logic from transformations, use a modified resolution step and extract hundreds of features from the proofs. Tatu and Moldovan (2005) use a modified logic prover that drops predicates when a proof cannot be found. Unlike us, they do not drop unbound predicates and use a single logic form transformation. Another key difference is that they assign fixed weights to predicates a priori instead of using machine learning to determine them.

3 Approach

Our approach to determine textual similarity (Figure 3) is grounded on using semantic features derived from a logic prover that are later combined in a standard supervised machine learning framework. First, sentences are transformed into logic forms (lft_1, lft_2). Then, a modified logic prover is used to find a proof in both directions (lft_1 to lft_2 and lft_2 to lft_1). The prover yields similarity scores based on the number of predicates dropped and features characterizing the proofs. Additional similarity scores are obtained using standard pairwise word similarity measures. Finally, all scores and features are combined using machine learning to yield the final textual similarity score.

If training data is unavailable, only the LFT-based and individual pairwise word similarity scores apply, the machine learning component is the only one supervised. The rest of this section details each component and exemplifies it with 2(e) *A woman is dancing in the rain* and 2(f) *A woman dances in the rain outside*.

[1] http://www.wiktionary.org/

[2] A third team, *spirin2*, submitted results but a description paper could not be found in the ACL anthology.

	sent$_1$: *A woman is dancing in the rain.*
	semantic relations extracted: AGENT(*dancing*, *woman*), LOCATION(*dancing*, *rain*)
Basic	woman_N(x_1) & dance_V(x_2) & rain_N(x_3)
SemRels	woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2,x_1) & rain_N(x_3) & LOCATION_SR(x_2,x_3)
Full	woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2,x_1) & rain_N(x_3) & LOCATION_SR(x_2,x_3)
	sent$_2$: *A woman dances in the rain outside.*
	semantic relations extracted: AGENT(*dances*, *woman*), LOCATION(*dances*, *rain*)
Basic	woman_N(x_1) & dance_V(x_2) & rain_N(x_3) & outside_M(x_4)
SemRels	woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2,x_1) & rain_N(x_3) & LOCATION_SR(x_2,x_3)
Full	woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2,x_1) & rain_N(x_3) & LOCATION_SR(x_2,x_3) & outside_M(x_4)

Table 1: Examples of logic from transformation using modes *Basic*, *SemRels* and *Full*.

3.1 Logic Form Transformation

The logic form transformation (LFT) of a sentence is derived from the concepts in it, the semantic relations linking them and named entities. Unlike other LFT proposals (Zettlemoyer and Collins, 2005; Poon and Domingos, 2009), transforming sentences into logic forms is a straightforward step, the quality of the logic forms is determined by the output of standard NLP tools.

We distinguish six types of predicates:

- N for nouns, e.g., *woman*: woman_N(x_1).
- V for verbs, e.g., *dances*: dance_V(x_2).
- M for adjectives and adverbs, e.g., *outside*: outside_M(x_3).
- O for concepts encoded by other POS tags.
- NE for named entities, e.g., *guitar*: guitar_N(x_4) & instrument_NE(x_4).
- SR for semantic relations, e.g., *A woman dances*: woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2,x_1).

In order to overcome semantic relation extraction errors, we have experimented with three logic form transformation modes. Each mode captures different levels of knowledge:

Basic generates predicates for all nouns, verbs, modifiers and named entities. This logic form is parallel to accounting for content words, their POS tags and named entity types.

SemRels generates predicates for all semantic relations, concepts that are arguments of relations and named entities qualifying those concepts. This mode ignores concepts not linked to other concepts through a relation and might miss key concepts if some relations are missing. If no semantic relations are found, this mode backs off to *Basic* to avoid empty logic forms.

Full generates predicates for all concepts, all semantic relations and all named entities. It is equivalent to *SemRels* after adding predicates for concepts that are not arguments of a semantic relation.

Table 1 exemplifies the three logic form modes. If perfect semantic relations were always available, *SemRels* would be the preferred mode. However, this is often not the case and combining the three logic forms yields better performance (Section 4). Note that since relation LOCATION(*rain*, *outside*) is not extracted from sent$_2$, predicate outside_M(x_4) is not present in mode *SemRels*.

3.2 Modified Logic Prover

Textual similarity is symmetric and therefore we find proofs in both directions (from lft_1 to lft_2 and from lft_2 to lft_1). The logic prover uses a modified resolution procedure to calculate a similarity score and features derived from the proof. The rest of this section exemplifies one direction, lft_1 to lft_2. The logic prover is a modification of OTTER[3] (McCune and Wos, 1997), an automated theorem prover for first-order logic. For the textual similarity task, we load lft_1 and $\neg lft_2$ to the *set of support* and lexical chain axioms to the *usable list*. Then, the logic prover begins its search for a proof. Two scenarios are possible: (1) a contradiction is found, i.e., a proof is found; or (2) a contradiction cannot be found. The modifications to the standard resolution

[3] http://www.cs.unm.edu/~mccune/otter/

sent$_1$: *A woman plays an electric guitar*			sent$_2$: *A man is cutting a potato*	
lft_1: woman_N(x_1) & play_V(x_2) & AGENT_SR(x_2, x_1) & electric_M(x_3) & guitar_N(x_4) & instrument_NE(x_4) & VALUE_SR(x_4, x_3) & THEME_SR(x_2, x_4)				
$\neg lft_2$: ¬man_N(x_1) ∨ ¬cut_V(x_2) ∨ ¬AGENT_SR(x_2, x_1) ∨ ¬potato_N(x_3) ∨ ¬THEME_SR(x_2, x_3)				
Step	Predicate dropped (regular)	Score	Predicate dropped (unbound)	Score
1	woman_N(x_1)	0.875	n/a	0.875
2	play_V(x_2)	0.750	AGENT_SR(x_2, x_1)	0.625
3	electric_M(x_3)	0.500	n/a	0.500
4	guitar_N(x_4)	0.375	instrument_NE(x_4), VALUE_SR(x_4, x_3), THEME_SR(x_2, x_4)	0.000

Table 2: Example of predicate dropping step by step. Predicates AGENT_SR(x_2, x_1) and THEME_SR(x_2, x_4) would not be dropped if unbound predicates were not dropped, yielding a score of 0.250 instead of 0.000.

procedure are used in scenario (2), when a proof cannot be found. In this case, predicates from *lft*$_1$ are dropped until a proof is found. The worst case occurs when all predicates in *lft*$_1$ are dropped. The goal of the dropping mechanism is to force the prover to always find a proof, and penalize partial proofs accordingly.

Lexical chain axioms are extracted from WordNet. Assuming each word w in sent$_1$ has the first sense, axioms $w \rightarrow c$, where c is at most distance 2 in the WordNet hierarchy are generated. For example, axioms derived from *woman* include *woman* → *female*, *woman* → *mistress*, *woman* → *widow* and *woman* → *madam*. Although simple, this WordNet expansion proved useful in our experiments.

3.2.1 Predicate Dropping Criteria

When a proof cannot be found, individual predicates from *lft*$_1$ not present in *lft*$_2$ are dropped. A greedy algorithm was implemented for this step: out of all predicates from *lft*$_1$ not present in *lft*$_2$, drop whichever occurs first.

Dropping a predicate is not done in isolation. After dropping a predicate, all predicates that become unbound are dropped as well. With our current logic form transformation, dropping a noun, verb or modifier may make a semantic relation (_SR) or named entity (_NE) predicate unbound. To avoid determining high similarity between sentences with a *common* semantic structure but *unrelated* concepts instantiating this structure, predicates encoding semantic relations and named entities are automatically dropped when they become unbound.

3.2.2 Proof Scoring Criterion

The score assigned to the proof from *lft*$_1$ to *lft*$_2$ is calculated as the ratio of number of predicates in *lft*$_1$ not dropped to find the proof over the original number of predicates in *lft*$_1$.

Note that the dropping mechanism, and in particular whether predicates that become unbound are automatically dropped, greatly impact the proof obtained and its score (Table 2). If predicates that become unbound were not automatically dropped in each step, instrument_NE(x_4) and VALUE_SR(x_4, x_3) would be dropped in steps 5 and 6, AGENT_SR(x_2, x_1) and THEME_SR(x_2, x_4) would not be dropped, and the final score would be 0.250 instead of 0.000. In plain English, dropping unbound predicates avoids matching semantic structures instantiated by unrelated concepts.

3.2.3 Feature Selection

While the proof score can be used directly as an estimator of the similarity between *lft*$_1$ and *lft*$_2$, additional features are extracted from the proof itself. Namely, for each predicate type (N, V, M, O, SR, NE), we count the number of predicates present in *lft*$_1$, the number of predicates dropped to find a proof for *lft*$_2$ and the ratio of the two counts. These three counts are also calculated for each specific semantic relation predicate (AGENT_SR, LOCATION_SR, etc.). An example of score and feature calculation in both directions is shown in Table 3.

The LFT-based scores and features are fed to a machine learning algorithm. Specifically, there are 477 features derived from the logic prover:

- 9 LFT-based scores (3×3; three scores (2 directions and average), three LFT modes)

lft_1: woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2, x_1) & rain_N(x_3) & LOCATION_SR(x_2, x_3)																
lft_2: woman_N(x_1) & dance_V(x_2) & AGENT_SR(x_2, x_1) & rain_N(x_3) & LOCATION_SR(x_2, x_3) & outside_M(x_4)																
lft_1 to lft_2	pred. dropped	none														
	score	1														
	features	n_t	n_d	n_r	v_t	v_d	v_r	m_t	m_d	m_r	ne_t	ne_d	ne_r	sr_t	sr_d	sr_r
		2	0	0	1	0	0	0	0	0	0	0	0	2	0	0
lft_2 to lft_1	pred. dropped	outside_M(x_4)														
	score	$5/6 = 0.833$														
	features	n_t	n_d	n_r	v_t	v_d	v_r	m_t	m_d	m_r	ne_t	ne_d	ne_r	sr_t	sr_d	sr_r
		2	0	0	1	0	0	1	1	1	0	0	0	2	0	0

Table 3: Two logic forms and output of logic prover in both directions. For each predicate type (n, v, m, o, ne, sr) and semantic relation type (AGENT, LOCATION, etc.) features indicate the total number of predicates, the number of predicates dropped until a proof is found and ratio of the two counts ($_t$, $_d$ and $_r$ respectively). We omit the features for predicate O and individual semantic relations because of space constraints.

- 108 features for predicates ($3 \times 6 \times 3 \times 2 = 108$; three features for each of the six predicate types, three LFT modes, two directions)

- 360 features specific to a semantic relation ($3 \times 20 \times 3 \times 2 = 360$; three features for each of the 20 semantic relations types, three LFT modes, two directions)

3.3 Pairwise Word Similarities

Pairwise word similarity measures between concepts have been long studied, and they have been used for the task of textual similarity before (Mihalcea et al., 2006). We incorporate scores derived using these measures for comparison purposes and to improve robustness in our approach.

Basically, each open-class word in $sent_1$ is paired with the open-class word in $sent_2$ that is most similar according to some similarity measure. All these individual similarities are summed and normalized by the length of $sent_1$ to find the similarity between $sent_1$ and $sent_2$. The process is repeated from $sent_2$ to $sent_1$ to obtain the similarity between $sent_2$ and $sent_1$, and both overall similarities are averaged to determine the final similarity score.

We have experimented with measures Path (distance in a taxonomy), LCH (Leacock and Chodorow, 1998), Lesk (Lesk, 1986), WUP (Wu and Palmer, 1994), Resnik (Resnik, 1995), Lin (Lin, 1998) and JCN (Jiang and Conrath, 1997), and use the WordNet::Similarity package[4].

[4] http://wn-similarity.sourceforge.net/

3.4 Machine Learning Algorithm

We follow a standard supervised machine learning framework. Instances from the training split are used to create a model that is later tested with test instances not seen during training. The model was tuned using 10-fold cross-validation over the training instances. As a learning algorithm, we use bagging with M5P decision trees (Quinlan, 1992; Wang and Witten, 1997) as implemented in the Weka software package (Hall et al., 2009).

4 Experiments and Results

Logic forms are derived from the output of state-of-the-art NLP tools developed previously and not tuned in any way to the current task or corpora. Our approach is not tied to any tool, set of named entities or relations. Any other semantic representation could be used; the only required modification would be the LFT component (Figure 3) so that it accounts for the subtleties of the representation of choice.

The named entity recognizer extracts 35 fine-grained types organized in a taxonomy (date, language, city, instrument, etc.) and was first developed for a question answering system (Moldovan et al., 2002). The implementation uses publicly available gazetteers as well as machine learning.

Semantic relations are extracted with Polaris (Moldovan and Blanco, 2012), a semantic parser that given text extracts semantic relations. Polaris is trained using FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), NomBank (Meyers et al., 2004), several SemEval corpora (Girju et al., 2007;

	Score	Sentence Pair	Notes
MSRpar (36/35) [750/750]	2.600	The unions also staged a five-day strike in March that forced all but one of Yale's dining halls to close. The unions also staged a five-day strike in March; strikes have preceded eight of the last 10 contracts.	Long sentences, difficult to parse; often several details are missing in one sentence but the pair is similar
MSRvid (13/13), [750/750]	0.000	A woman is swimming underwater. A man is slicing some carrots.	Short sentences, easy to parse
SMTeuroparl (56/21), [734/459]	4.250	Then perhaps we could have avoided a catastrophe. We would perhaps then able prevent a disaster.	One sentence often ungrammatical (SMT)
surprise.OnWN (–/16), [–/750]	1.500	the alleviation of distress a change for the better.	WN glosses, difficult to parse with standard tools
surprise.SMTnews (–/24), [–/399]	3.000	He did, but the initiative did not get very far What he has done without the initiative goes too far.	One sentence often ungrammatical (SMT)

Table 4: Examples of sentence pairs belonging to the five sources. The numbers between round (square) parenthesis indicate the average number of tokens per sentence pair (number of instances) in the train and test splits.

Pustejovsky and Verhagen, 2009; Hendrickx et al., 2010) and in-house annotations.

4.1 Corpora

We use the corpora released by SemEval 2012 Task 06: A Pilot on Semantic Textual Similarity[5] (Agirre et al., 2012). These corpora consist of pairs of sentences labeled with their semantic similarity score, ranging from 0.0 to 5.0. Sentence pairs come from five sources: (1) MSRpar, a corpus of paraphrases; (2) MSRvid, short video descriptions; (3) SMTeuroparl, output of machine translation systems and reference translations; (4) surprise.OnWN, OntoNotes (Hovy et al., 2006) and WordNet (Miller, 1995) glosses; and (5) surprise.SMTnews, output of machine translation systems in the news domain and gold translations. Examples can be found in Table 4, for more details refer to the aforementioned citation.

4.2 Results and Error Analysis

Results are reported using the same train and test splits provided by the organization of SemEval 2012 Task 6. For surprise.OnWn and surprise.SMTnews, only test data is available and supervised machine learning is not an option.

Table 5 shows results obtained with the test split not dropping and dropping unbound predicates. For comparison purposes, results of the top-3 performers and participants using the semantic structure of sentences are also shown. *LFT-score* systems output the score (average of both directions) obtained with the corresponding logic form transformation (Basic, SemRels or Full) and are unsupervised: training data with textual similarity scores is not used. The other three systems presented are supervised. *LFT-scores + features* combines the 9 LFT-scores and 468 features derived from the logic proof. *WN-scores* uses as features the 7 scores derived using pairwise word similarity measures. Finally, *All* combines the full set of 484 features. We indicate that the performance of one of our systems with respect to *LFT score Basic not dropping unbound predicates* is significant with * (confidence 99%) and † (confidence 95%).

Overall, systems that drop unbound predicates perform better than systems that do not drop them. The only noticeable exception is *LFT-score* with sentences from SMTeuroparl. However, best results for SMTeuroparl are obtained dropping unbound predicates and using *All* features. Henceforth, we comment on results dropping unbound predicates as they are higher.

Regarding logic form transformations, one can see a trend depending on the source of sentences. Polaris, the semantic parser, and the syntactic parser Polaris relies on are mostly trained in the news domain, and thus semantic representations have higher quality in that domain. For SMTeuroparl and SMTnews, the two corpora closest to the news domain, *Full* obtains better results than *Basic* and *SemRels*. The difference is most noticeable in SMTnews, where *Basic* yields 0.4616, *SemRels*

Table 5: Correlations obtained with the test split using our approach (not dropping and dropping unbound predicates), and results obtained by the top-3 performers and teams that included in their models features derived from the semantic structure of sentences. Statistically significant differences in performance between our systems and *LFT score Basic not dropping unbound predicates* are indicated with * (confidence 99%) and † (confidence 95%).

0.4796 (+0.0180) and *Full* 0.5291 (+0.0675 and +0.0495 respectively).

Outside the news domain (MSRpar, MSRvid, OnWN), *Basic* performs better than *SemRels* and *Full*, and *Full* performs better than *SemRels*. This leads to the conclusion that several semantic relations are often missing, and thus considering concepts even if they are not linked to other concepts via a semantic relation (*Full*) is more sound than ignoring them (*SemRels*).

When training data is available (MSRpar, MSRvid, SMTeuroparl), *LFT-scores + features* always outperforms the scores obtained with a single logic form transformation in an unsupervised manner. In other words, combining the scores obtained with the three logic form transformations and incorporating the additional features derived from the proofs improves performance. These results demonstrate that while a shallow logic form transformation (*Basic*) offers a strong baseline, it can be successfully complemented with logic form transformations that consider the semantic structure of sentences (*SemRels*, *Full*) and additional features characterizing the proofs. The improvements *LFT-scores + features* brings over the LFT-score obtained with *Basic* are substantial: 0.0218 (3.9%) for MSRpar, 0.0206 (2.5%) for MSRvid and 0.0283 (5.7%) for SMTeuroparl.

WN scores, which only uses as features the scores derived from pairwise word similarity measures, performs astonishingly well for some corpora. Namely, the differences in performance between *LFT scores + features* and *WN scores* in MSRvid and SMTeuroparl are minimal (−0.0055 and +0.0060). We believe this is due to the characteristics of these two corpora. Sentence pairs from MSRvid are very short with 13 tokens on average (Table 4), i.e., 6.5 tokens per sentence, and SMTeuroparl pairs are hard to parse: at least one comes from a machine translation system and is often ungrammatical.

Finally, dropping unbound predicates and using *All* features outperforms any other system. While both *LFT scores + features* and *WN scores* yield

good performance, the combination of the two outperforms them. Features extracted successfully complement each other for all corpora.

4.2.1 A Look at the ML Model

A benefit of decision trees is that one can inspect them. This section briefly gives insight about the most predictive features for *All* system.

The best features, i.e., features used in decisions closer to the root, are the LFT-scores calculated using *Basic* and *Full*. The LFT-score obtained using *SemRels* is used only when the other two cannot discriminate. Sorted by impact, the features extracted for verbs, nouns, semantic relations, named entities and modifiers follow. Towards the bottom of the tree, features for specific semantic relations (AGENT_SR, LOCATION_SR, etc.) are used. All three sources (MSRpar, MSRvid and SMTeuroparl) use features for THEME, LOCATION, AGENT and QUANTIFICATION. MSRpar also benefits from features for TIME and only SMTeuroparl benefits from TOPIC and MANNER.

4.2.2 Comparison with Previous Work

The semantic logic-based approach presented in this paper either outperforms other systems or performs in the top-3 (Table 5). Moreover, it clearly outperforms any other proposal that takes into account the semantic structure of sentences. These results lead to the conclusion that the semantic structure of sentences is worth considering and more effort should be devoted to deeper approaches.

When using sentences in the news domain (SMTeuroparl and SMTnews), i.e., when text is closer to the domain in which the NLP tools are trained, our semantic approach yields the best results known to date. For MSRvid, the system presented here performs as well as systems that use external knowledge (Section 2), the differences are minimal ($+0.0030$, -0.0089, $+0.0041$) and not statistically significant (confidence 99%). For MSRpar, the system performs amongst the top-3 even though two of these systems clearly obtained better results ($+0.0673$, $+0.0828$); both differences are statistically significant (confidence 99%).

Performance using surprise.OnWN deserves special comment. This corpus contains definitions, not sentences (Table 4). Lin's similarity measure alone yields a correlation of 0.6787, beating all systems in Table 5 except one of the top-3 performers (Šarić et al., 2012). Our semantic approach is not successful because we cannot extract valid representations, glosses are rarely a full sentence and are hard to parse with generic NLP tools like the ones we use.

5 Conclusions

This paper presents a novel approach to determine textual similarity that employs a logic prover to extract semantic features. A layered methodology to transform text into logic forms using three logic form transformations modes is presented. Each mode captures different levels of knowledge, from only content words to semantic representations automatically extracted. Best results are obtained when features derived from the logic prover are complemented with simpler pairwise word similarity measures. Features that account for the semantic structure of sentences are incorporated when needed, as the results obtained with systems *All*, *LFT scores* and *WN scores* show.

Our approach is heavily dependent on the quality of semantic representations, and unlike current top performers, does not require knowledge derived from Wikipedia or other large corpora. State-of-the-art NLP tools to extract semantic representations from text, which are far from perfect, yield promising results. Indeed, the approach outperforms previous work when the source text is relatively familiar to the tools, i.e., within the news domain, and performs in the top-3 otherwise.

Abstract

Why do certain combinations of words such as *"disadvantageous peace"* or *"metal to the petal"* appeal to our minds as interesting expressions with a sense of creativity, while other phrases such as *"quiet teenager"*, or *"geometrical base"* not as much? We present statistical explorations to understand the characteristics of lexical compositions that give rise to the perception of being original, interesting, and at times even artistic. We first examine various correlates of perceived creativity based on information theoretic measures and the connotation of words, then present experiments based on supervised learning that give us further insights on how different aspects of lexical composition collectively contribute to the perceived creativity.

1 Introduction

An essential property of natural language is the generative capacity that makes it possible for people to express indefinitely many thoughts through indefinitely many different ways of composing phrases and sentences (Chomsky, 1965). The possibility of novel, creative expressions never seems to exhaust. Various types of writers, such as novelists, journalists, movie script writers, and creatives in advertising, continue creating novel phrases and expressions that are original while befitting in expressing the desired meaning in the given situation. Consider unique phrases such as *"geological split personality"*, or *"intoxicating Shangri-La of shoes"*,[1] that continue flowing into the online text drawing attention from readers.

Writers put significant effort in choosing the perfect words in completing their compositions, as a well-chosen combination of words is impactful in readers' minds for rendering the precise intended meaning, as well as stimulating an increased level of cognitive responses and attention. Metaphors in particular, one of the quintessential forms of linguistic creativity, have been discussed extensively by studies across multiple disciplines, e.g., Cognitive Science, Psychology, Linguistics, and Literature (e.g., Lakoff and Johnson (1980), McCurry and Hayes (1992), Goatly (1997)). Moreover, recent studies based on fMRI begin to discover biological evidences that support the impact of creative phrases on people's minds. These studies report that unconventional metaphoric expressions elicit significantly increased involvement of brain processing when compared against the effect of conventional metaphors or literal expressions (e.g., Mashal et al. (2007), Mashal et al. (2009)).

Several linguistic elements, e.g., syntax, semantics, and pragmatics, are likely to be working together in order to lead to the perception of creativity. However, their underlying mechanisms by and large are yet to be investigated. In this paper, as a small step toward quantitative understanding of linguistic creativity, we present a focused study on lexical composition two content words.

Being creative, by definition, implies qualities such as being unique, novel, unfamiliar or unconventional. But not every unfamiliar combination of words would appeal as creative. For example, unfa-

[1] Examples from New York Times articles in 2013.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1246–1258,
Seattle, Washington, USA, 18-21 October 2013.

miliar biomedical terms, e.g., *"cardiac glycosides"*, are only informative without appreciable creativity. Similarly, less frequent combinations of words, e.g., *"rotten detergent"* or *"quiet teenager"*, though describing situations that are certainly uncommon, do not bring about the sense of creativity. Finally, some unique combinations of words can be just nonsensical , e.g., *"elegant glycosides"*.

Different studies assumed different definitions of linguistic creativity depending on their context and end goals (e.g., Chomsky (1976), Zhu et al. (2009), Gervás (2010), Maybin and Swann (2007), Carter and McCarthy (2004)). In this paper, as an operational definition, we consider a phrase creative if it is (a) unconventional or uncommon, and (b) expressive in an interesting, imaginative, or inspirational way.

A system that can recognize creative expressions could be of practical use for many aspiring writers who are often in need of inspirational help in searching for the optimal choice of words. Such a system can also be integrated into automatic assessment of writing styles and quality, and utilized to automatically construct a collection of interesting expressions from the web, which may be potentially useful for enriching natural language generation systems.

With these practical goals in mind, we aim to understand phrases with linguistic creativity in a broad scope. Similarly as the work of Zhu et al. (2009), our study encompasses phrases that evoke the sense of interestingness and creativity in readers' minds, rather than focusing exclusively on clearly but narrowly defined figure of speeches such as *metaphors* (e.g., Shutova (2010)), *similes* (e.g., Veale et al. (2008), Hao and Veale (2010)), and *humors* (e.g., Mihalcea and Strapparava (2005), Purandare and Litman (2006)). Unlike the study of Zhu et al. (2009), however, we concentrate specifically on how combinations of different words give rise to the sense of creativity, as this is an angle that has not been directly studied before. We leave the roles of syntactic elements as future research.

We first examine various correlates of perceived creativity based on information theoretic measures and the connotation of words, then present experiments based on supervised learning that give us further insights on how different aspects of lexical composition collectively contribute to the perceived creativity.

2 Theories of Creativity and Hypotheses

Many researchers, from the ancient philosophers to the modern time scientists, have proposed theories that attempt to explain the mechanism of creative process. In this section, we draw connections from some of these theories developed for general human creativity to the problem of quantitatively interpreting linguistic creativity in lexical composition.

2.1 Divergent Thinking and Composition

Divergent thinking (e.g., McCrae (1987)), which seeks to generate multiple unstereotypical solutions to an open ended problem has been considered as the key element in creative process, which contrasts with *convergent* thinking that find a single, correct solution (e.g., Cropley (2006)). Applying the same high-level idea to lexical composition, divergent composition that explores an unusual, unconventional set of words is more likely to be creative.

Note that the key novelty then lies in the *compositional* operation itself, i.e., the act of putting together a set of words in an unexpected way, rather than the rareness of individual words being used. In recent years there has been a swell of work on compositional distributional semantics that captures the compositional aspects of language understanding, such as sentiment analysis (e.g., Yessenalina and Cardie (2011), Socher et al. (2011)) and language modeling (e.g., Mitchell and Lapata (2009), Baroni and Zamparelli (2010), Guevara (2011), Clarke (2012), Rudolph and Giesbrecht (2010)). However, none has examined the compositional nature in quantifying creativity in lexical composition.

We consider two computational approaches to capture the notion of creative composition. The first is via various information theoretic measures, e.g., relative entropy reduction, to measure the surprisal of seeing the next word given the previous word. The second is via supervised learning, where we explore different modeling techniques to capture the statistical regularities in creative compositional operations. In particular, we will explore (1) compositional operations of vector space models, (2) kernels capturing the non-linear composition of different dimensions in the meaning space, (3) the use of

neural networks as an alternative to incorporate non-linearity in vector composition. (See §5).

2.2 Latent Memory and Creative Semantic Subspace

Although we expect that unconventional composition has a connection to creativeness of resulting phrases, that alone does not explain many counter examples where the composition itself is uncommon but the resulting expression is not creative due to lack of interestingness or imagination, e.g., *"room and water"*.[2] Therefore, we must consider additional conditions that give rise to creative phrases.

Let $\mathcal{S}$ represent the semantic space, i.e., the set of all possible semantic representation that can be expressed by a phrase that is composed of two content words.[3] Then we hypothesize that some subsets of semantic space $\{\mathcal{S}_i | \mathcal{S}_i \subset \mathcal{S}\}$ are semantically futile regions for appreciable linguistic creativity, regardless of how novel the composition in itself might be. Such regions may include technical domains such as law or pharmacology. Similarly, we expect semantically fruitful subsets of semantic space where creative expressions are more frequently found. For instance, phrases such as *"guns and roses"* and *"metal to the petal"* are semantically close to each other and yet both can be considered as interesting and creative (as opposed to one of them losing the sense of creativity due to its semantic proximity to the other).

This notion of creative semantic subspace connects to theories that suggest that latent memories serve as motives for creative ideas and that one's creativity is largely depending on prior experience and knowledge one has been exposed to (e.g., Freud (1908), Necka (1999), Glaskin (2011), Cohen and Levinthal (1990), Amabile (1997)), a point also made by Einstein: *"The secret to creativity is knowing how to hide your sources."*

Figure 5 presents visualized supports for creative semantic subspace,[4] where we observe that phrases in the neighborhood of legal terms are generally not creative, while the semantic neighborhood of *"kingdom"* and *"power"* is relatively more fruitful for composing *creative* (i.e., unique and uncommon while being imaginative and interesting, per our operational definition of creativity given in §1) word pairs, e.g., *invisible empire"*. In our empirical investigation, this notion of semantically fruitful and futile semantic subspaces are captured using distributional semantic space models under supervised learning framework (§5).

Source	# of uniq words	# of sent	Avg sent len	Entropy
QUOTES^{raw}	29498	49402	28	173.05
GLOSSES^{raw}	20869	7745	53	96.79

Table 1: Entropy of word distribution in datasets

Dataset	# of word pairs			percentage
	total	#(-)	#(+)	#(+)/total %
GLOSSES	1912	149	18	0.94
QUOTES	3298	204	35	1.06

Table 2: Distribution of creative(+)/common(-) word pairs over **GLOSSES** and **QUOTES** dataset.

2.3 Affective Language

Another angle we probe is the connection between creative expressions and the use of affective language. This idea is supported in part by previous research that explored the connection between figurative languages such as metaphors and sentiment (e.g., Fussell and Moss (1998), Rumbell et al. (2008), Rentoumi et al. (2012)). The focus of previous work was either on interpretation of the sentiment in metaphors, or the use of metaphors in the description of affect. In contrast, we aim to quantify the correlation between creative expressions (beyond metaphors) and the use of sentiment-laden words in a more systematic way. This exploration has a connection to the creative semantic subspace discussed earlier (§2.2), but pays a more direct attention to the aspect of sentiment and connotation.

3 Creative Language Dataset

We start our investigation by considering two types of naturally existing collection of sentences: (1) quotes and (2) dictionary glosses. We expect that quotes are likely to be rich in creative expressions, while dictionary glosses stand in the opposite spec-

[2] With additional context this example may turn into a creative one, but for simplicity we focus on phrases with two content words considered out of context.

[3] Investigation on recursive composition of more than two content words and the influence of syntactic packaging is left as future research.

[4] See §6 for more detailed discussion.

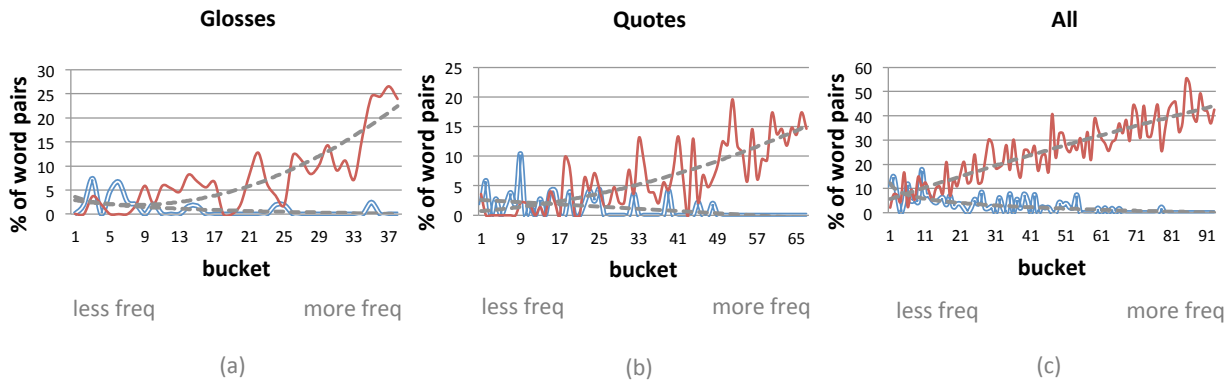

Figure 1: Distribution of *creative* (double lines in blue) versus *common* (single lines in red) word pairs with varying ranges of frequencies (x-axis) for **GLOSSES**, **QUOTES** and both datasets combined.

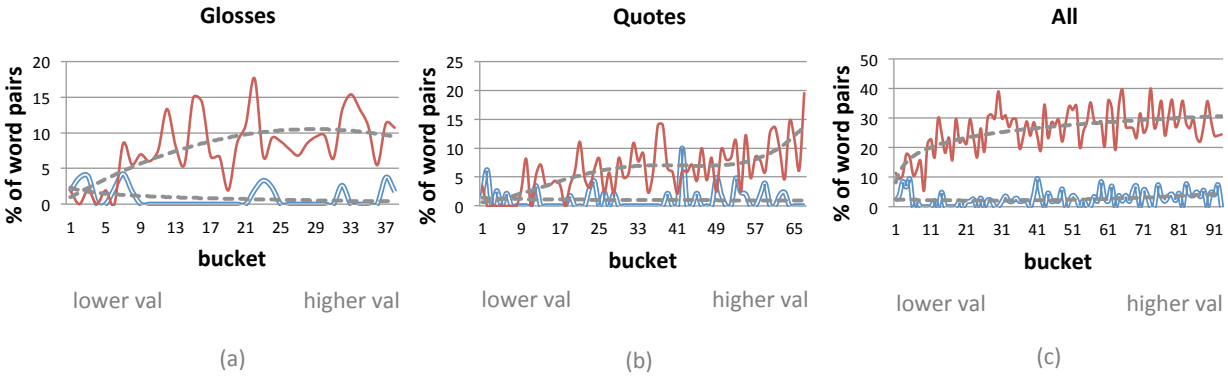

Figure 2: Distribution of *creative* (double lines in blue) versus *common* (single lines in red) word pairs with varying ranges of PMI values (x-axis) for **GLOSSES**, **QUOTES** and both datasets combined.

trum of being creative.

QUOTES^{raw}: We crawled inspirational quotes from "Brainy Quote".[5]

GLOSSES^{raw}: We collected glosses from Oxford Dictionary and Merriam-Webster Dictionary.[6] Overall we crawled about 8K definitions. Table 1 shows statistics of the dataset.[7]

Entropy of word distribution We conjecture that QUOTES and GLOSSES are different in terms of word variety, which can be quantified by the entropy of word distributions. To compute the entropy for each dataset, we use ngram statistics from the corresponding dataset to measure the probability of each word. As expected, QUOTES dataset has higher entropy than GLOSSES in Table 1.

3.1 Creative Word Pairs

We extract word pairs corresponding to the following syntactic patterns: [NN NN], [JJ NN], [NN JJ] and [JJ JJ]. Not all pairs from QUOTES^{raw} are creative, and likewise, not all pairs from GLOSSES^{raw} are uncreative. Therefore, we perform manual annotations to a subset of the collected pairs as follows. We obtain a small subset of pairs by applying stratified sampling based on bigram frequency buckets: first we sort word pairs by their bigram frequencies obtained from Web 1T corpus (Brants and Franz (2006)), group them into consecutive fre-

[5] http://www.brainyquote.com/

[6] http://oxforddictionaries.com/ and http://www.merriam-webster.com/. We only consider words appearing in both dictionaries to avoid unusual words such as compound words, e.g., "zero-base".

[7] QUOTES^{raw} contain 30K unique words and GLOSSES^{raw} has 20K unique words. QUOTES^{raw} have much arger number of sentences, while its average sentence is shorter.

quency buckets each of which containing 400 word pairs, then sample 40 word pairs from each bucket.

We label word pairs using Amazon Mechnical Turk (AMT) (e.g., Snow et al. (2008)). We ask three turkers to score each pair in 1-5 scale, where 1 is the least creative and 5 is the most creative. We then obtain the final creativity scale score by averaging the scores over 3 users. In addition, we ask turkers a series of yes/no questions to help turkers to determine whether the given pair is creative or not.[8] We determine the final label of a word pair based on two scores, creativity scale score and yes/no question-based score. If creativity scale score is 4 or 5 and question-based score is positive, we label the pair as creative. Similarly, if creativity scale score is 1 or 2 and question-based score is negative, we label the pair as common. We discard the rest from the final dataset. This filtering process is akin to the removal of neural sentiment in the early work of sentiment analysis (e.g., Pang et al. (2002)).[9] Table 2 shows the statistics of the resulting dataset.

Creative Pairs and their Frequencies: To gain insights on the stratified sample of word pairs, we plot the label ($\in \{creative, common\}$) distribution of word pairs as a function of simple statistics, such as a range (bucket) of bigram frequencies or PMI values of the given pair of words. Both bigram frequencies and PMI scores are computed based on Google Web 1T corpus Brants and Franz (2006). Figure 1 shows the results for word frequencies. As expected, word pairs with high frequencies are much more likely to be common, while word pairs with low frequencies can be either of the two. Also as expected, pairs extracted from QUOTES are relatively more likely to be creative than those from GLOSSES. In any case, it is clear that not all rare pairs are creative.

Creative Pairs and their PMI Scores: Similarly as above, Figure 2 plots the relation between the distribution of labels of word pairs and their corresponding PMI. As expected, pairs with high PMI are more likely to be common, though the trend is not as skewed as before.

Common	Creative
quiet teenager	inglorious success
constant longitude	thorny existence
watery juice	relaxed symmetry
noble political	sardonic destiny
diet cooking	dispassionate history
verbal interpretation	poetical enthusiasm
unwelcome situation	verbal beauty
migratory tuna	earth breathe
lousy businessman	disadvantageous peace
terrific marriage	alchemical marriage
solved issue	deep nonsense

Table 3: Sample Creative / Common Word Pairs

Final Dataset: From our initial annotation study, it became apparent to us that creative pairs are very rare, perhaps not surprisingly, even among infrequent pairs. In order to build the word pair corpus with as many creative pairs as possible, we focus on infrequent word pairs for further annotation, from which we construct a larger and balanced set of creative and common word pairs, with 394 word pairs for each class. The specific construction procedure is as follows: first combine all of the word pairs extracted from both QUOTES^{raw} and GLOSSES^{raw} as a single dataset, sort them by bigram frequency, group them into consecutive frequency buckets each of which has 40 word pairs; finally balance each frequency bucket, by discarding word pairs with higher frequency value from the larger class in that bucket. Examples of labeled word pairs are shown in Table 3. Hereafter we use this balanced dataset of word pairs for all experiments.[10]

4 Creativity Measures

4.1 Information Measures

In this section we explore information theoretic measures to quantify the *surprisal* aspect of creative word pairs, relating to the divergent, compositional nature of creativity discussed in §2.1.

Entropy of Context Seeing a word w changes our expectation on what might follow next. Some words have stronger selective preference (higher entropy) than others.

[8] E.g., *"is this word combination boring and not original?"* or *"does it provoke unusual imagination?"*.

[9] Cohen's Kappa and Pearson Correlation on the filtered data are 0.69 and 0.72 respectively. Corresponding scores for the unfiltered data drop to 0.26 and 0.29 respectively. All the experiments are performed on the filtered data.

[10] The resulting dataset is available at `http://www.cs.stonybrook.edu/~pkuznetsova/creativity/`

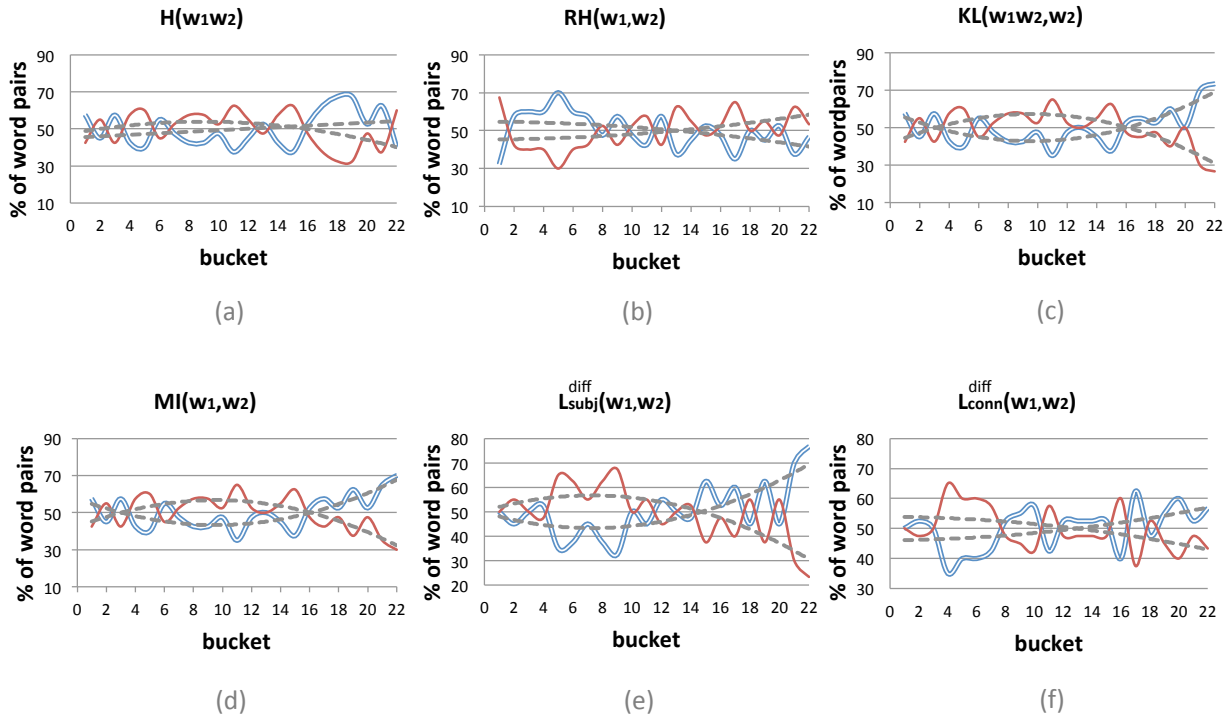

Figure 3: Distribution of *creative* (double lines in blue) versus *common* (single lines in red) word pairs with varying ranges of information or polarity measures (x-axis).

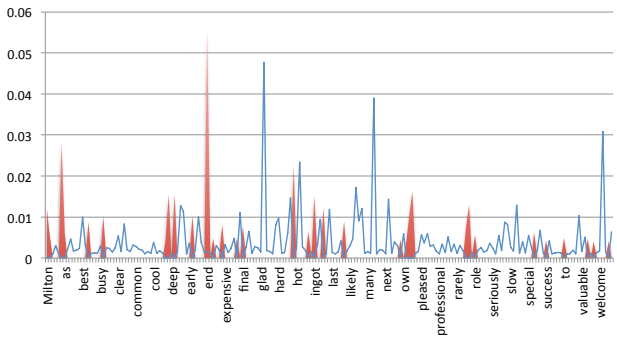

Figure 4: Conditional probability of neighboring words for "inglorious" (filled / red) and "very" (unfilled / blue).

For instance, the entropy after seeing *"very"* would be higher than that after seeing *"inglorious"*, as the former can be used in a wider variety of context than the later. Figure 4 visualizes relatively more skewed distribution of *"inglorious"*. We compute the entropy of future context conditioning on w_1, w_2 and w_1w_2, which we denote as $H(w_1)$, $H(w_2)$, $H(w_1w_2)$ respectively, latter is shown in Figure 3 – a.[11]

[11]As before, language models are drawn from Google Web 1T corpus Brants and Franz (2006).

Relative Entropy Transformation In order to focus more directly on the relative change of entropy as a result of composition, we compute Relative Entropy Transformation:

$$RH(w_1, w_2) = \frac{|H(w_1) - H(w_1w_2)|}{H(w_1) + H(w_1w_2)} \quad (1)$$

As expected (Figure 3 – b and Table 4), this relative quantity captures creativity better than the absolute measure $H(w_1w_2)$ computed above. The idea behind this measure has a connection to uncertainty reduction in psycholinguistic literature (e.g., Frank (2010), Hale (2003), Hale (2006)).

KL divergence To capture unusual combinations of words, we compare the difference between the distributional contexts of w_1 and w_1w_2 so that

$$KL(w_1w_2, w_1) = \sum_{w_i \in V} P(w_i|w_1, w_2) \log \frac{P(w_i|w_1, w_2)}{P(w_i|w_1)} \quad (2)$$

Figure (3 – c) shows that $KL(w_1w_2, w_1)$[12] is among

[12]We also compute $KL(w_1, w_2)$ in a similar manner as $KL(w_1w_2, w_1)$

the effective measures in capturing creative pairs.

Mutual Information Finally, we consider mutual information (Figure 3 – d):

$$MI(w_1, w_2) = \sum_{w_i \in V} P(w_i|w_1, w_2) \times \log \frac{P(w_i|w_1, w_2)}{P(w_i|w_1) \cdot P(w_i|w_2)} \quad (3)$$

Correlation coefficients Pearson coefficients for all measures are shown in Table 4. Interestingly, information theoretic measures that compare the distribution of word's context, such as $RH(w_1, w_2)$, $KL(w_1w_2, w_1)$ and $MI(w_1, w_2)$, capture the surprisal aspect of creativity better than simple frequencies or PMI scores that do not consider contextual changes. But even for those cases when the correlation is statistically significant, the values are not too high. We conjecture that there are two reasons for this. First, Pearson assumes linear correlations, hence not sensitive enough to capture non-linear correlations that are evident in graphs shown in Figure 3. Second, these measures only capture the surprisal aspect of creativity, missing the other important qualities: interestingness or imaginativeness.

4.2 Sentiment and Connotation

Next we investigate the connection between creativity and sentiment, as illustrated in §2.3. We consider both sentiment (more explicit) and connotation (more implicit) words,[13] and consider them with or without distinguishing the polarity (i.e., positive, negative). To determine sentiment and connotation, we use lexicons provided by OpinionFinder (Wilson et al. (2005)) and Feng et al. (2013) respectively. We denote polarity of a word w_i as $L(w_i)$.[14] When w_i has a negative polarity $L(w_i)$ is assigned a value of -1, and when w_i is positive $L(w_i)$ is equal to 1. We assume that a word is neutral when it is not in the lexicon, assigning 0 to $L(w_i)$. For a word pair w_1w_2 we compute absolute difference $L^{diff}(w_1, w_2)$ between polarities of tokens in a word pair in order to catch examples such as *"inglorious success"*.

[13]E.g., expressions such as *"blue sky"* or *"white sand"* are not sentiment-laden, but do have positive connotation.

[14]We denote polarity from OpinionFinder as L_{subj} and connotation as L_{conn}

Measure	Corr Coeff	p-value*	adj p-value**
pointwise, noncontextual			
$Freq(w_1w_2)$	0.014	0.67	0.86
$PMI(w_1, w_2)$	0.011	0.75	0.86
information theoretic, contextual			
$E(w_1)$	-0.038	0.26	0.49
$E(w_2)$	**-0.126**	0.00019	0.00083
$E(w_1, w_2)$	0.013	0.71	0.86
$RH(w_1, w_2)$	**0.113**	0.00081	0.0024
$KL(w_1w_2, w_1)$	**0.134**	7.152-05	0.00054
$KL(w_1, w_2)$	**-0.080**	0.018	0.039
$MI(w_1, w_2)$	**0.125**	0.00022	0.00083
sentiment & connotation			
$L_{subj}(w_1)$	0.006	0.87	0.87
$L_{subj}(w_2)$	0.031	0.36	0.60
$L^{diff}_{subj}(w_1, w_2)$	**0.168**	6.67e-07	1.00e-05
$L_{conn}(w_1)$	0.023	0.49	0.74
$L_{conn}(w_2)$	0.008	0.80	0.86
$L^{diff}_{conn}(w_1, w_2)$	**0.082**	0.015	0.038

Table 4: Pearson correlation between various measures and creativity of word pairs. Boldface denotes statistical significance ($p \leq 0.05$).
note *: Two-tailed p-value, 394 word pairs per class
note **: We used Benjamini-Hochberg method to adjust p-values for multiple tests

Table 4 shows Pearson coefficient for sentiment and connotation based measures. It turns out that polarity of each word on its own does not have a high impact on the creativity of a word pair. Rather, it is the difference between the two words that gives rise the sense of creativity.

4.3 Learning to Recognize Creativity

Now we put together all measures explored in §4.1 and 4.2 in a supervised-learning framework. As expected, rather than either one alone, the combination of various measures leads to the best performance:

$$\vec{F}_{12} = [RH(w_1, w_2); KL(w_1, w_2); H(w_1w_2); L^{diff}_{conn}(w_1, w_2); PMI(w1, w_2); H(w_2); KL(w_1w_2, w_1); KL(w_2, w_1); L^{diff}_{subj}(w_1, w_2); MI(w_1, w_2); Freq(w_1w_2); H(w_1)]$$

Table 5 shows the performance of the above feature vector with 12 features using libsvm (Chang and Lin, 2011). We use C-Support Vector Classification (C-SVC). Performance is reported in accuracy using 5-fold cross validation.[15]

[15]Among these 12 features, the feature selection algorithm

5 Learning Creative Pairs with Distributional Semantic Vectors

The measures explored in §4 were largely uninformed of distributional semantic dimensions of each word. However, in order to pursue the conceptual aspect of creativity illustrated in §2.2, that is, the notion of semantic subspaces that are inherently futile or fruitful for creativity, we need to incorporate semantic representations more directly. We therefore explore the use of distributional vector space models. Another goal of this section will be additional learning-based investigation to the compositional nature of creative word pairs, complementing the investigation in §4, which focused on the compositional aspect of creativity described in §2.1.

With above goals in mind, in what follows, we explore three different ways to learn compositional aspect of creative word pairs: (1) learning with explicit compositional vector operations (§5.1), (2) learning nonlinear composition via kernels (§5.2), (3) learning nonlinear composition via deep learning (§5.3). Note that in all these approaches, the notion of creative semantic subspace is integrated indirectly, as the feature representation always incorporates the resulting (composed) vector representations.

Baseline & Configuration We consider the concatenation of two word vectors $[\vec{w}_1; \vec{w}_2]$ as the baseline, since it can be viewed as what simple bag-of-word features would be. Since the size of creative pair dataset is not at scale yet, we choose to work with vector space models that are in reduced dimensions. We experimented with both Non-Negative Sparse Embedding (Murphy et al. (2012)) and neural semantic vectors of Huang et al. (2012), but report experiments with the latter only as those gave us slightly better results.

5.1 Compositional Vector Operations

We consider the following compositional vector operations inspired by recent studies for compositional distributional semantics (e.g., Guevara (2011), Clarke (2012), Mitchell and Lapata (2008), Widdows (2008)).

- **ADD**: $\vec{w}_1 + \vec{w}_2$
- **DIFF**: $abs(\vec{w}_1 - \vec{w}_2)$
- **MULT**: $\vec{w}_1 .* \vec{w}_2$
- **MIN**: $\min\{\vec{w}_1, \vec{w}_2\}$
- **MAX**: $\max\{\vec{w}_1, \vec{w}_2\}$

All operations take two input vectors $\in R^n$, and output a vector $\in R^n$. Each operation is applied element-wise. We then perform binary classification over the composed vectors using linear SVM. Besides using features based on the composed vectors, we also experiment with features based on concatenating multiple composed vectors, in the hope to capture more diverse compositional operations. See Table 5 for more details and experimental results.

5.2 Learning Nonlinear Composition via Kernels

As an alternative to explicit vector compositions, we also probe implicit operations based on non-linear combinations of semantic dimensions using kernels (e.g., Schölkopf and Smola (2002), Shawe-Taylor and Cristianini (2004)), in particular:

- Polynomial: $K(x, y) = (\gamma x^T y + r)^d,\ \gamma > 0$
- RBF: $K(x, y) = \exp(-\gamma \left\|x - y\right\|^2),\ \gamma > 0$
- Laplacian: $K(x, y) = \exp(-\gamma \left\|x - y\right\|),\ \gamma > 0$

5.3 Learning Non-linear Composition via Deep Learning

Yet another alternative to model non-linear composition is deep learning. To learn the non-linear transformation of a pair of semantic vectors, we explore the use of autoencoders (e.g., Pollack (1990), Voegtlin and Dominey (2005)). We follow the formulation of vector composition proposed by Socher et al. (2011) except that we do not stack autoencoders for recursion. More specifically, given the two input words $\vec{w}_1, \vec{w}_2 \in R^n$, we want to learn a vector space representation of their combination $\vec{p} \in R^n$. The recursive auto encoder (RAE) of Socher et al. (2011) models the composition of a word pair as a non-linear transformation of their concatenation $[\vec{w}_1; \vec{w}_2]$:

$$\vec{p} = f(M_1[\vec{w}_1; \vec{w}_2] + \vec{b}_1) \quad (4)$$

where $M_1 \in R^{n \times 2n}$. After adding a bias term $\vec{b}_1 \in R^n$, a nonlinear element-wise function f such as $tanh$ is applied to the resulting vector. The representation $\vec{p}$ of the word pair is then fed into a reconstruction layer to reconstruct the two input vectors,

of Chen and Lin (2005) determines that the most two important ones are $RH(w_1, w_2)$ and $KL(w_1, w_2)$.

Methods	Accuracy
Creativity measures (§4.3)	
$\vec{F}_{12}$	62.30
Baseline: vector concatenation (no composition)	
$[\vec{w}_1; \vec{w}_2]$	67.51
Explicit vector composition (§5.1)	
$\vec{w}_1 + \vec{w}_2$	66.62
$abs(\vec{w}_1 - \vec{w}_2)$	60.03
$\min\{\vec{w}_1, \vec{w}_2\}$	66.08
$\max\{\vec{w}_1, \vec{w}_2\}$	64.97
$\vec{w}_1 .* \vec{w}_2$	56.34
$[abs(\vec{w}_1 - \vec{w}_2); \vec{w}_1; \vec{w}_2]$	**69.54**
$[\max\{\vec{w}_1, \vec{w}_2\}; \vec{w}_1; \vec{w}_2]$	68.02
Non-linear composition via kernels (§5.2)	
Polynomial	65.86
RBF	**69.16**
Laplacian	68.15
Non-linear composition via deep learning (§5.3)	
$f(M_1[\vec{w}_1; \vec{w}_2] + \vec{b}_1)$	67.25

Table 5: Performance comparison of creativity classifiers.

Incorrectly predicted word pairs	y^*	Semantically close word pairs	y^*
CONFUSION DUE TO WORD SIMILARITY (20/42)			
"entire carton"	-	*"whole angst"*	+
"outdated tax"	-	*"graconian tax"*	+
"dismissive way"	-	*"amorous way"*	+
"insidious part"	+	*"leather part"*	-
CONFUSION DUE TO SUBJECTIVE LABELING (8/42)			
"independent religion"	+	*"wonderful religion"*	-
WORD SENSE DISAMBIGUATION PROBLEMS (2/42)			
"fiscal cliff"	-	*"winding lake"*	+
"opera window"	+	*"work-shop floor"*	-

and a softmax layer to predict the probability of the word pair being creative and not creative. We initialize the word vectors using the pre-learned vector space representations in Huang et al. (2012).

5.4 Experimental Results

Table 5 shows the performance comparison of different features sets and algorithms. In all cases, parameters are tuned from the training portion of the data. We see that simple vector composition alone does not perform better than vector concatenation $[\vec{w}_1; \vec{w}_2]$. However, combining $abs(\vec{w}_1 - \vec{w}_2)$ or $max\{\vec{w}_1; \vec{w}_2\}$ with $[\vec{w}_1; \vec{w}_2]$ perform better than concatenation. Kernels with non-linear transformation of feature space generally improve performance over linear SVM, suggesting that kernels capture some of the interesting compositional aspect of creativity that is not covered by some of the explicit vector compositions considered in §5.1. We also experimented with additional features driven from the creativity measures explored in §4, but we omit their results as those did not help improving the performance. Unfortunately learning nonlinear composition with deep learning did not yield better results. We conjecture that it is due to the small dataset we were able to obtain for this study, which may have not been enough to learn the rich parameter space of the nonlinear transformation matrix.

6 Analysis and Insight

Error analysis We manually inspected a randomly chosen 42 error cases, and characterize the potential causes of those errors. Examples of three types of errors are shown in Table 6. For each incorrectly predicted word pair, we also show a semantically close word pair with the opposite true label that might have confused the learning algorithm.

Visualization To gain additional insight, we project word pairs represented in their vector concatenations onto 2-dimensional space using t-Distributed Stochastic Neighbor Embedding (van der Maaten and Hinton (2008)). Figure 5 shows some of the interesting regions of the projection: some regions are relatively futile in having creative phrases (e.g., regions involving simple adjectives such as *"good"*, *"bad"*, regions corresponding to legal terms), while some regions are relatively more fruitful (e.g., regions involving abstract adjectives such as *"infinite"*, *"universal"*, *"fundamental"*). There are also many other regions (e.g., in the vicinity of *"true"*, *"perfect"* or *"intelligent"* in Figure 5) where the separation between creative and noncreative phrases are not as prominent. In those regions, compositional aspects would play a bigger role in determining creativity than memorizing fruitful semantic subspaces.

Figure 5: Creative (blue bold) and not creative (red italic) word pairs graph.

7 Related Work

Among computational approaches that touch on linguistic creativity, many focused on *metaphor* (e.g., Dunn (2013), Krishnakumaran and Zhu (2007), Mashal et al. (2007), Rumbell et al. (2008), Rentoumi et al. (2012), Mashal et al. (2009)). Other linguistic devices and phenomena related to creativity include *irony* (e.g., Davidov et al. (2010), González-Ibáñez et al. (2011), Filatova (2012)), *neologism* (e.g., Cartoni (2008)), *humor* (e.g., Mihalcea and Strapparava (2005), Purandare and Litman (2006)), and *similes* (e.g., Hao and Veale (2010)).

Veale (2011) proposed the new task of creative text retrieval to harvest expressions that potentially convey the same meaning as the query phrase in a fresh or unusual way. Our work contributes to the retrieval process of recognizing more creative phrases. Ozbal and Strapparava (2012) explored automatic creative naming of commercial products and services, focusing on the generation of creative phrases within a specific domain. Costello (2002) investigated the cognitive process that guides people's choice of words when making up a novel noun-noun compound. In contrast, we present a data-driven investigation to quantifying creativity in lexical composition. Memorability is loosely related to linguistic creativity (Danescu-Niculescu-Mizil et al. (2012)) as some of the creative quotes may be more memorable, but not all creative phrases are memorable and vice versa.

8 Conclusion

We presented the first study that focuses on learning and quantifying creativity in lexical compositions, exploring statistical techniques motivated by three different theories and hypotheses of creativity, ranging from divergent thinking, compositional structure, creative semantic subspace, and the connection to sentiment and connotation. Our experimental results suggest the viability of learning creative language, and point to promising directions for future research.

Abstract

Assigning a positive or negative score to a word out of context (i.e. a word's prior polarity) is a challenging task for sentiment analysis. In the literature, various approaches based on SentiWordNet have been proposed. In this paper, we compare the most often used techniques together with newly proposed ones and incorporate all of them in a learning framework to see whether blending them can further improve the estimation of prior polarity scores. Using two different versions of SentiWordNet and testing regression and classification models across tasks and datasets, our learning approach consistently outperforms the single metrics, providing a new state-of-the-art approach in computing words' prior polarity for sentiment analysis. We conclude our investigation showing interesting biases in calculated prior polarity scores when word Part of Speech and annotator gender are considered.

1 Introduction

Many approaches to sentiment analysis make use of lexical resources – i.e. lists of positive and negative words – often deployed as baselines or as features for other methods (usually machine learning based) for sentiment analysis research (Liu and Zhang, 2012). In these lexica, words are associated with their prior polarity, i.e. if that word out of context evokes something positive or something negative. For example, *wonderful* has a positive connotation – prior polarity – while *horrible* has a negative one. These approaches have the advantage of not needing deep semantic analysis or word sense disambiguation to assign an affective score to a word and are domain independent (they are thus less precise but more portable).

SentiWordNet (henceforth SWN) is one of these resources and has been widely adopted since it provides a broad-coverage lexicon – built in a semi-automatic manner – for English (Esuli and Sebastiani, 2006). Given that SWN provides polarities scores for each word sense (also called 'posterior polarities'), it is necessary to derive prior polarities from the posteriors. For example, the word *cold* has a posterior polarity for the meaning "having a low temperature" – like in "*cold* beer" – that is different from the one in "*cold* person" which refers to "being emotionless". This information must be considered when reconstructing the prior polarity of *cold*.

Several formulae to compute prior polarities starting from posterior polarities scores have been used in the literature. However, their performance varies significantly depending on the adopted variant. We show that researchers have not paid sufficient attention to this *posterior-to-prior polarity* issue. Indeed, we show that some variants outperform others on different datasets and can represent a fairer state-of-the-art approach using SWN. On top of this, we attempt to outperform the state-of-the-art formula using a learning framework that combines the various formulae together.

In detail, we will address five main research questions: (*i*) is there any relevant difference in the posterior-to-prior polarity formulae performance (both in regression and classification tasks), (*ii*) is there any relevant variation in prior polarity values

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1259–1269,
Seattle, Washington, USA, 18-21 October 2013.

if we use different releases of SWN (i.e. SWN_1 or SWN_3), (*iii*) can a learning framework boost performance of such formulae, (*iv*) considering word Part of Speech (PoS), is there any relevant difference in formulae performance, (*v*) considering the gender dimension of the annotators (male/female) and the sentiment dimension (positive/negative), is there any relevant difference in SWN performance.

In Section 2 we briefly describe our approach and how it differentiates from similar sentiment analysis tasks. Then, in Sections 3 and 4, we present SentiWordNet and overview various posterior-to-prior polarity formulae based on this resource that appeared in the literature (included some new ones we identified as potentially relevant). In Section 5 we describe the learning approach adopted on prior-polarity formulae. In Section 6 we introduce the ANEW and General Inquirer resources that will be used as gold standards. Finally, in the two last sections, we present a series of experiments, both in regression and classification tasks, that give an answer to the aforementioned research questions. The results support the hypothesis that using a learning framework we can improve on state-of-the-art performance and that there are some interesting phenomena connected to PoS and annotator gender.

2 Proposed Approach

In the broad field of Sentiment Analysis we will focus on the specific problem of posterior-to-prior polarity assessment, using both regression and classification experiments. A general overview on the field and possible approaches can be found in (Pang and Lee, 2008) or (Liu and Zhang, 2012).

For the regression task, we tackled the problem of assigning affective scores (along a continuum between -1 and 1) to words using the posterior-to-prior polarity formulae. For the classification task (assessing whether a word is either *positive* or *negative*) we used the same formulae, but considering just the sign of the result. In these experiments we will also use a learning framework which combines the various formulae together. The underlying hypothesis is that by blending these formulae, and looking at the same information from different perspectives (i.e. the posterior polarities provided by SWN combined in various ways), we can give a better prediction.

The regression task is harder than binary classification, since we want to assess not only that *pretty*, *beautiful* and *gorgeous* are positive words, but also to define a partial or total order so that *gorgeous* is more positive than *beautiful* which, in turn, is more positive than *pretty*. This is fundamental for tasks such as affective modification of existing texts, where words' polarity together with their score are necessary for creating multiple graded variations of the original text (Guerini et al., 2008). Some of the work that addresses the problem of sentiment strength are presented in (Wilson et al., 2004; Paltoglou et al., 2010), however, their approach is modeled as a multi-class classification problem (*neutral*, *low*, *medium* or *high* sentiment) at the sentence level, rather than a regression problem at the word level. Other works such as (Neviarouskaya et al., 2011) use a fine grained classification approach too, but they consider emotion categories (*anger*, *joy*, *fear*, etc.), rather than sentiment strength categories. On the other hand, even if approaches that go beyond pure prior polarities – e.g. using word bigram features (Wang and Manning, 2012) – are better for sentiment analysis tasks, there are tasks that are intrinsically based on the notion of words' prior polarity. Consider copywriting, where evocative names are a key element to a successful product (Özbal and Strapparava, 2012; Özbal et al., 2012). In such cases no context is given and the brand name alone, with its perceived prior polarity, is responsible for stating the area of competition and evoking semantic associations. For example *Mitsubishi* changed the name of one of its SUV for the Spanish market, since the original name *Pajero* had a very negative prior polarity, as it meant 'wanker' in Spanish (Piller, 2003).

To our knowledge, the only work trying to address the SWN posterior-to-prior polarity issue, comparing some of the approaches appeared in the literature is (Gatti and Guerini, 2012). However, in our previous study we only considered a regression framework, we did not use machine learning and we only tested SWN_1. So, we took this work as a starting point for our analysis and expanded on it.

3 SentiWordNet

SentiWordNet (Esuli and Sebastiani, 2006) is a lexical resource in which each entry is a set of

lemma-PoS pairs sharing the same meaning, called "synset". Each synset `s` is associated with the numerical scores `Pos(s)` and `Neg(s)`, which range from 0 to 1. These scores – automatically assigned starting from a bunch of seed terms – represent the positive and negative valence (or posterior polarity) of the synset and are inherited by each lemma-PoS in the synset. According to the structure of SentiWordNet, each pair can have more than one sense and each of them takes the form of `lemma#PoS#sense-number`, where the smallest sense-number corresponds to the most frequent sense.

Obviously, different senses can have different polarities. In Table 1, the first 5 senses of `cold#a` present all possible combinations, included mixed scores (`cold#a#4`), where positive and negative valences are assigned to the same sense. Intuitively, mixed scores for the same sense are acceptable, as in "*cold* beer" (positive) vs. "*cold* pizza" (negative).

PoS	Offset	Pos(s)	Neg(s)	SynsetTerms
a	1207406	0.0	0.75	`cold#a#1`
a	1212558	0.0	0.75	`cold#a#2`
a	1024433	0.0	0.0	`cold#a#3`
a	2443231	0.125	0.375	`cold#a#4`
a	1695706	0.625	0.0	`cold#a#5`

Table 1: First five *SentiWordNet* entries for `cold#a`

In our experiments we use two different versions of SWN: SentiWordNet 1.0 (SWN_1), the first release of SWN, and its updated version SentiWordNet 3.0 (Baccianella et al., 2010) – SWN_3. In SWN_3 the annotation algorithm used in SWN_1 was revised, leading to an increase in the accuracy of posterior polarities over the previous version.

4 Prior Polarities Formulae

In this section we review the main strategies for computing prior polarities used in previous studies. All the proposed approaches try to estimate the prior polarity score from the posterior polarities of all the senses for a single lemma-PoS. Given a lemma-PoS with n senses (`lemma#PoS#n`), every formula f is independently applied to all the `Pos(s)` and `Neg(s)` . This produces two scores, $f(posScore)$ and $f(negScore)$, for each lemma-PoS. To obtain a unique prior polarity for each lemma-PoS, $f(posScore)$ and $f(negScore)$ can be mapped according to different strategies:

$$f_m = \begin{cases} f(posScore) & \text{if } f(posScore) \geq f(negScore) \\ -f(negScore) & \text{otherwise} \end{cases}$$

$$f_d = f(posScore) - f(negScore)$$

where f_m computes the absolute maximum of the two scores, while f_d computes the difference between them. It is worth noting that $f(negScore)$ is always positive by construction. To obtain a final prior polarity that ranges from -1 to 1, the negative sign is imposed. So, considering the first 5 senses of `cold#a` in Table 1, $f(posScore)$ will be derived from the `Pos(s)` values $<0.0, 0.0, 0.0, 0.125, 0.625>$, while $f(negScore)$ from $<0.750, 0.750, 0.0, 0.375, 0.0>$. Then, the final polarity strength returned will be either f_m or f_d.

The formulae (f) we tested are the following:

fs. In this formula only the first (and thus most frequent) sense is considered for the given `lemma#PoS`. This is equivalent to considering only the SWN score for `lemma#PoS#1`. Based on (Neviarouskaya et al., 2009; Agrawal and Siddiqui, 2009; Guerini et al., 2008; Chowdhury et al., 2013), this is the most basic form of prior polarities.

mean. It calculates the mean of the positive and negative scores for all the senses of the given `lemma#PoS`. This formula has been used in (Thet et al., 2009; Denecke, 2009; Devitt and Ahmad, 2007; Sing et al., 2012).

uni. Based on (Neviarouskaya et al., 2009), it considers only those senses that have a `Pos(s)` greater than or equal to the corresponding `Neg(s)`, and greater than 0 (the $stronglyPos$ set). In case $posScore$ is equal to $negScore$, the one with the highest weight is returned, where weights are defined as the cardinality of $stronglyPos$ divided by the total number of senses. The same applies for the negative senses. This is the only method, together with rnd, for which we cannot apply f_d, as it returns a positive or negative score according to the weight.

uniw. Like uni but without the weighting system.

w1. This formula weighs each sense with a geometric series of ratio 1/2. The rationale behind this choice is based on the assumption that more frequent

senses should bear more "affective weight" than rare senses when computing the prior polarity of a word. The system presented in (Chaumartin, 2007) uses a similar approach of weighted mean.

w2. Similar to the previous one, this formula weighs each lemma with a harmonic series, see for example (Denecke, 2008).

On top of these formulae, we implemented some new formulae that were relevant to our task and have not been implemented before. These formulae mimic the ones discussed previously, but they are built under a different assumption: that the saliency (Giora, 1997) of a word's prior polarity might be more related to its posterior polarities score, rather than to sense frequencies. Thus we ordered $posScore$ and $negScore$ by strength, giving more relevance to 'valenced' senses. For instance, in Table 1, $posScore$ and $negScore$ for `cold#a` become $<0.625, 0.125, 0.0, 0.0, 0.0>$ and $<0.750, 0.750, 0.375, 0.0, 0.0>$ respectively.

w1s and **w1n**. Like $w1$ and $w2$, but senses are ordered by strength (sorting Pos(s) and `Neg(s)` independently).

w1n and **w2n**. Like $w1$ and $w2$ respectively, but without considering senses that have a 0 score for both `Pos(s)` and `Neg(s)`. Our motivation is that "empty" senses are mostly noise.

w1sn and **w2sn**. Like $w1s$ and $w2s$, but without considering senses that have a 0 score for both `Pos(s)` and `Neg(s)`.

median: return the median of the senses ordered by polarity score.

All these prior polarities formulae are compared against two gold standards (one for regression, one for classification) both one by one, as in the works mentioned above, and combined together in a learning framework (to see whether combining these features – that capture different aspect of prior polarities – can further improve the results).

Finally, we implemented two variants of a prior polarity random baseline to asses possible advantages of approaches using SWN:

rnd. This formula represents the basic baseline random approach. It simply returns a random number between -1 and 1 for any given `lemma#PoS`.

swnrnd. This formula represents an advanced random approach that incorporates some "knowledge" from SWN. It takes the scores of a random sense for the given `lemma#PoS`. We believe this is a fairer baseline than rnd since SWN information can possibly constrain the values. A similar approach has been used in (Qu et al., 2008).

5 Learning Algorithms

We used two non-parametric learning approaches, Support Vector Machines (SVMs) (Shawe-Taylor and Cristianini, 2004) and Gaussian Processes (GPs) (Rasmussen and Williams, 2006), to test the performance of all the metrics in conjunction. SVMs are non-parametric deterministic algorithms that have been widely used in several fields, in particular in NLP where they are the state-of-the-art for various tasks. GPs, on the other hand, are an extremely flexible non-parametric probabilistic framework able to explicitly model uncertainty, that, despite being considered state-of-the-art in regression, have rarely been used in NLP. To our knowledge only two previous works did so (Polajnar et al., 2011; Cohn and Specia, 2013).

Both methods take advantage of the *kernel trick*, a technique used to embed the original feature space into an alternative space where data may be linearly separable. This is performed by the kernel function that transforms the input data in a new structure, called *kernel*. How it is used to produce the prediction is one of the main differences between SVMs and GPs. In classification SVMs use the geometric mean to discriminate between the positive and negative classes, while the GP model uses the posterior probability distribution over each class. Both frameworks support learning algorithms for regression and classification. An exhaustive explanation of the two methodologies can be found in (Shawe-Taylor and Cristianini, 2004) and (Rasmussen and Williams, 2006).

In the SVM experiments, we use C-SVM and ϵ-SVM implemented in the LIBSVM toolbox (Chang and Lin, 2011). The selection of the kernel (linear, polynomial, radial basis function and sigmoid) and the optimization of the parameters are carried out through grid search in 10-fold cross-validation.

GP regression models with Gaussian noise are a rare exception where the exact inference with likelihood functions is tractable, see §2 in (Rasmussen

and Williams, 2006). Unfortunately, this is not valid for the classification task – see §3 in (Rasmussen and Williams, 2006) – where an approximation method is required. In this work, we use the Laplace approximation method proposed in (Williams and Barber, 1998). Different kernels are tested (covariance for constant functions, linear with and without automatic relevance determination (ARD)[1], Matern, neural network, etc.[2]) and the linear logistic (lll) and probit regression (prl) likelihood functions are evaluated in classification. In our classification experiments we tried all possible combinations of kernels and likelihood functions, while in the regression tests we ranged only on different kernels. All the GP models were implemented using the GPML Matlab toolbox[3]. Unlike SVMs, the optimization of the kernel parameters can be performed without using grid search, but the optimal parameters can be obtained iteratively, by maximizing the marginal likelihood (or in classification, the Laplace approximation of the marginal likelihood). We fix at 100 the maximum number of iterations.

An interesting property of the GPs is their capability of weighting the features differently according to their importance in the data. This is referred to as the automatic variance determination kernel. As demonstrated in (Weston et al., 2000), SVMs can benefit from the application of feature selection techniques especially when there are highly redundant features. Since the prior polarities formulae tend to cluster in groups that provide similar results (Gatti and Guerini, 2012) – creating noise for the learner – we want to understand whether feature selection approaches can boost the performance of SVMs. For this reason, we also test feature selection prior to the SVM training. For that we used Randomized Lasso, or stability selection (Meinshausen and Bühlmann, 2010). Re-sampling of the training data is performed several times and a Lasso regression model is fit on each sample. Features that appear in a given number of samples are retained. Both the fraction of the data to be sampled and the threshold to select the features can be configured. In our experiments we set the sampling fraction to 75%, the selection threshold to 25% and the number of resamples to 1,000. We refer to these as *SVMfs*.

[1] $linone$ and $linard$ in the result tables, respectively.

[2] More detailed information on the available kernels are in §4 (Rasmussen and Williams, 2006)

6 Gold Standards

To assess how well prior polarity formulae perform, a gold standard with word polarities provided by human annotators is needed. There are many such resources in the literature, each with different coverage and annotation characteristics. ANEW (Bradley and Lang, 1999) rates the valence score of 1,034 words, which were presented in isolation to annotators. The SO-CAL entries (Taboada et al., 2011) were collected from corpus data and then manually tagged by a small number of annotators with a multi-class label. These ratings were further validated through crowdsourcing. Other resources, such as the General Inquirer lexicon (Stone et al., 1966), provide a binomial classification (either *positive* or *negative*) of sentiment-bearing words. The resource presented in (Wilson et al., 2005) uses a similar binomial annotation for single words; another interesting resource is WordNetAffect (Strapparava and Valitutti, 2004) but it labels words senses and it cannot be used for the prior polarity validation task.

In the following we describe in detail the two resources we used for our experiments, namely ANEW for the regression experiments and the General Inquirer (GI) for the classification ones.

6.1 ANEW

ANEW (Bradley and Lang, 1999) is a resource developed to provide a set of normative emotional ratings for a large number of words (roughly 1 thousand) in the English language. It contains a set of words that have been rated in terms of pleasure (affective valence), arousal, and dominance. In particular for our task we considered the valence dimension. Since words were presented to subjects in isolation (i.e. no context was provided) this resource represents a human validation of prior polarities scores for the given words, and can be used as a gold standard. For each word ANEW provides two main metrics: $anew_{\mu}$, which correspond to the average of annotators votes, and $anew_{\sigma}$, which gives the variance in annotators scores for the given word. In the same way these metrics are also provided for

the male/female annotator groups.

6.2 General Inquirer

The Harvard General Inquirer dictionary is a widely used resource, built for automatic text analysis (Stone et al., 1966). Its latest revision[4] contains 11789 words, tagged with 182 semantic and pragmatic labels, as well as with their part of speech. Words and their categories were initially taken from the Harvard IV-4 Psychosociological Dictionary (Dunphy et al., 1974) and the Lasswell Value Dictionary (Lasswell and Namenwirth, 1969). For this paper we consider the `Positiv` and `Negativ` categories (1,915 words the former, 2,291 words the latter, for a total of 4,206 affective words).

7 Experiments

In order to use the ANEW dataset to measure prior polarities formulae performance, we had to assign a PoS to all the words to obtain the SWN `lemma#PoS` format. To do so, we proceeded as follows: for each word, check if it is present among both SWN_1 and SWN_3 lemmas; if not, lemmatize the word with the TextPro tool suite (Pianta et al., 2008) and check if the lemma is present instead[5]. If it is not found (i.e., the word cannot be aligned automatically), remove the word from the list (this was the case for 30 words of the 1,034 present in ANEW). The remaining 1,004 lemmas were then associated with all the PoS present in SWN to get the final `lemma#PoS`. Note that a lemma can have more than one PoS, for example, *writer* is present only as a noun (`writer#n`), while *yellow* is present as a verb, a noun and an adjective (`yellow#v`, `yellow#n`, `yellow#a`). This gave us a list of 1,484 words in the `lemma#PoS` format.

In a similar way we pre-processed the GI words that uses the generic `modif` label to indicate either adjective or adverb (`noun` and `verb` PoS were instead consistently used). Finally, all the sense-disambiguated words in the `lemma#PoS#n` format were discarded (1,114 words out of the 4,206 words with positive or negative valence).

After the two datasets were built this way, we removed the words for which the $posScore$ and $negScore$ contained all 0 in both SWN_1 and SWN_3 (523 `lemma#PoS` for ANEW and 484 for the GI dataset), since these words are not informative for our experiments. The final dataset included 961 entries for ANEW and 2,557 for GI. For each `lemma#PoS` in GI and ANEW, we then applied the prior polarity formulae described in Section 4, using both SWN_1 and SWN_3 and annotated the results.

According to the nature of the human labels (real numbers or -1/1), we ran several regression and classification experiments. In both cases, each dataset was randomly split into 70% for training and the remaining for test. This process was repeated 5 times to generate different splits. For each partition, optimization of the learning algorithm parameters was performed on the training data (in 10-fold cross-validation for SVMs). Training and test sets were normalized using the z-score.

To evaluate the performance of our regression experiments on ANEW we used the Mean Absolute Error (MAE), that averages the error over a given test set. Accuracy was used for the classification experiments on GI instead. We opted for accuracy – rather than F1 – since for us True Negatives have same importance as True Positives. For each experiments we reported the average performance and the standard deviation over the 5 random splits. In the following sections, to check if there was a statistically significant difference in the results, we used Student's t-test for regression experiments, while an approximate randomization test (Yeh, 2000) was used for the classification experiments.

In Tables 2 and 3, the results of regression experiments over the ANEW dataset, using SWN_1 and SWN_3, are presented. The results of the classification experiments over the GI dataset, using SWN_1 and SWN_3 are shown in Tables 4 and 5. For the sake of interpretability, results are divided according to the main approaches: randoms, posterior-to-prior formulae, learning algorithms. Note that for classification we report the generics f and not the f_m and f_d variants. In fact, both versions always return the same classification answer (we are classifying according to the sign of f result and not its strength). For the GPs, we report the two best configurations only.

[4] `http://www.wjh.harvard.edu/~inquirer/`

[5] We did not lemmatize everything to avoid duplications (for example, if we lemmatize the ANEW entry *addicted*, we obtain *addict*, which is already present in ANEW).

8 General Discussion

In this section we sum up the main results of our analysis, providing an answer to the various questions we introduced at the beginning of the paper:

SentiWordNet improves over random. One of the first things worth noting – in Tables 2, 3, 4 and 5 – is that the random approach (*rnd*), as expected, is the worst performing metric, while all other approaches, based on *SWN*, have statistically significant improvements both for MAE and for Accuracy ($p < 0.001$). So, using *SWN* for posterior-to-prior polarity computation brings benefits, since it increases the performance above the baseline in words' prior polarity assessment.

SWN$_3$ is better than SWN$_1$. With respect to SWN_1, using SWN_3 enhances performance, both in regression (MAE μ 0.398 vs. 0.366, $p < 0.001$) and classification (Accuracy μ 0.710 vs. 0.771, $p < 0.001$) tasks. Since many of the approaches described in the literature use SWN_1 their results should be revised and SWN_3 should be used as standard. This difference in performance can be partially explained by the fact that, even after preprocessing, for the ANEW dataset 137 `lemma#PoS` have all senses equal to 0 in SWN_1, while in SWN_3 they are just 48. In the GI lexicon the numbers are 233 for SWN_1 and 69 for SWN_3.

Not all formulae are created equal. The formulae described in Section 4 have very different results, along a continuum. While inspecting every differ-

Table 5: Accuracy results for classification using SWN_3

ence in performance is out of the scope of the present paper, we can see that there is a strong difference between best and worst performing formulae both in regression (in Table 2 $w2n_m$ is better than $uniw_m$, in Table 3 $w2n_m$ is better than max_m) and classification (in Table 4 $w1sn_m$ is better than fs_m,in Table 5 $w2_m$ is better than fs_m) and these differences are all statistically significant ($p < 0.001$). Again, these results indicate that the previous experiments in the literature that use SWN as a baseline should be revised to take these results into account. Furthermore, the new formulae we introduced, based on the "posterior polarities saliency" hypothesis, proved to be among the best performing in all experiments. This entails that there is room for inspecting new formulae variants other than those already proposed in the literature.

Selecting just one sense is not a good choice. On a side note, the approaches that rely on only one sense polarity (namely fs, $median$ and max) have similar results which do not differ significantly from $swnrnd$ (for max_m, fs_d and fs_m in Table 2, and for max_m in Table 3). These same approaches are also far from the best performing formulae: in Table 3, $median_d$ differs from $w2n_m$ ($p < 0.05$), as do max_m, max_d, fs_m and fs_d ($p < 0.001$); in Table 3, fs, max and $median$ in both their f_m and f_d variants are significantly different from the best performing $w2n_m$ ($p < 0.001$). For classification, in Table 4 and 5 the difference between the corresponding best performing formula and the single senses formulae is always significant (at least $p < 0.01$). Among other things, this finding entails, surprisingly, that taking the first sense of a `lemma#PoS` in some cases has no improvement over taking a random sense, and that in all cases it is one of the worst approaches with SWN. This is surprising since in many NLP tasks, such as word sense disambiguation, algorithms based on most frequent sense represent a very strong baseline[6].

Learning improvements. Combining the formulae in a learning framework further improves the results over the best performing formulae, both in regression (MAEμ with SWN_1 0.366 vs. 0.391, $p < 0.001$; MAEμ with SWN_3 0.333 vs. 0.359, $p < 0.001$) and in classification (Accuracyμ for SWN_1 is 0.743 vs. 0.719, $p < 0.001$; Accuracyμ for SWN_3 is 0.792 vs. 0.781, not significant $p = 0.07$). Another thing worth noting is that, in regression, GPs are outperformed by both versions of

[6]In SemEval 2010, only 5 participants out of 29 performed better than the most frequent threshold (Agirre et al., 2010).

SVM ($p < 0.001$), see Tables 2 and 3. This is in contrast with the results presented in (Cohn and Specia, 2013), where GPs on the single task are on average better than SVMs. In classification, GPs have similar performance to SVM without feature selection, and in some cases (see Table 5) even slightly better. Analyzing the selected kernels for GPs and SVMs, we notice that in most of the splits SVMs prefer the radial based function, while the best performance with the GPs are obtained with linear kernels with and without ARD. There is no significant difference in using linear logistic and probit regression likelihoods. In all our experiments, SVM with feature selection leads to the best performance. This is not surprising due the high level of redundancy in the formulae scores. Interestingly, inspecting the most frequent selected features by $SVMfs$, we see that features from different groups are selected, and even the worst performing formulae can add information, confirming the idea that viewing the same information from different perspectives (i.e. the posterior polarities provided by SWN combined in various ways) can give better predictions.

To sum up: the new state-of-the-art performance level in prior-polarity computation is represented by the $SVMfs$ approach using SWN_3, and this should be used as the reference from now on.

9 PoS and Gender Experiments

Next, we wanted to understand if the performance of our approach, using SWN_3, was consistent across word PoS. In Table 6 we report the results for the best performing formulae and learning algorithm on the GI PoS classes. In particular for ADJ there are 1,073 words, 922 for NOUN and 508 for VERB. We discarded adverbs since the class was too small to allow reliable evaluation and efficient learning (only 54 instances). The results show a greater accuracy for adjectives ($p < 0.01$), while performance for nouns and verbs are similar.

	SVMfs		$best\_f$	
	Acc. μ	Acc. σ	Acc. μ	Acc. σ
ADJ	0.829	0.019	0.821	0.016
NOUN	0.784	0.021	0.765	0.023
VERBS	0.782	0.052	0.744	0.046

Table 6: Accuracy results for PoS using SWN_3

Finally we test against the male and female ratings provided by ANEW. As can be seen from Table 7, SWN approaches are far more precise in predicting Male judgments rather than Female ones (MAEμ goes from 0.392 to 0.323 with the best formula and from 0.369 to 0.292 with $SVMfs$, both differences are significant $p < 0.001$). Instead, in Table 8 – which displays the results along gender and polarity dimensions – there is no statistically significant difference in MAE on positive words between male and female, while there is a strong statistical significance for negative words ($p < 0.001$).

Interestingly, there is also a large difference between positive and negative affective words (both for male and female dimensions). This difference is maximum for male scores on positive words compared to female scores on negative words (0.283 vs. 0.399, $p < 0.001$). Recent work by Warriner et al. (2013) inspected the differences in prior polarity assessment due to gender.

At this stage we can only note that prior polarities calculated with SWN are closer to ANEW male annotations than female ones. Understanding why this happens would require an accurate examination of the methods used to create WordNet and SWN (which will be the focus of our future work).

	Male		female	
	MAE μ	MAE σ	MAE μ	MAE σ
SVMfs	0.292	0.020	0.369	0.008
best_f	0.323	0.022	0.392	0.010

Pos	0.283	0.022	0.340	0.009
Neg	0.301	0.029	0.399	0.013

Table 8: MAE for Male/Female - Pos/Neg using SWN_3

10 Conclusions

We have presented a study on the posterior-to-prior polarity issue, i.e. the problem of computing words' prior polarity starting from their posterior polarities. Using two different versions of SentiWordNet and 30 different approaches that have been proposed in the literature, we have shown that researchers have not paid sufficient attention to this issue. Indeed, we

showed that the better variants outperform the others on different datasets both in regression and classification tasks, and that they can represent a fairer state-of-art baseline approach using SentiWordNet. On top of this, we also showed that these state-of-the-art formulae can be further outperformed using a learning framework that combines the various formulae together. We conclude our analysis with some experiments investigating the impact of word PoS and annotator gender in gold standards, showing interesting phenomena that requires further investigation.

Abstract

Building search engines that can respond to spoken queries with spoken content requires that the system not just be able to find useful responses, but also that it know when it has heard enough about what the user wants to be able to do so. This paper describes a simulation study with queries spoken by non-native speakers that suggests that indicates that finding relevant content is often possible within a half minute, and that combining features based on automatically recognized words with features designed for automated prediction of query difficulty can serve as a useful basis for predicting when that useful content has been found.

1 Introduction

Much of the early work on what has come to be called "speech retrieval" has focused on the use of text queries to rank segments that are automatically extracted from spoken content. While such an approach can be useful in a desktop environment, half of the world's Internet users can access the global information network only using a voice-only mobile phone. This raises two challenges: 1) in such settings, both the query and the content must be spoken, and 2) the language being spoken will often be one for which we lack accurate speech recognition.

The Web has taught us that the "ten blue links" paradigm can be a useful response to short queries. That works because typed queries are often fairly precise, and tabular responses are easily skimmed. However, spoken queries, and in particular open-domain spoken queries for unrestricted spoken content, pose new challenges that call for new thinking about interaction design. This paper explores the potential of a recently proposed alternative, in which the spoken queries are long, and only one response can be played at a time by the system. This approach, which has been called Query by Babbling, requires that the user ramble on about what they are looking for, that the system be able to estimate when it has found a good response, and that the user be able to continue the search interaction by babbling on if the first response does not fully meet their needs (Oard, 2012).

One might question whether users actually will "babble" for extended periods about their information need. There are two reasons to believe that some users might. First, we are particularly interested in ultimately serving users who search for information in languages for which we do not have usable speech recognition systems. Speech-to-speech matching in such cases will be challenging, and we would not expect short queries to work well. Second, we seek to principally serve users who will be new to search, and thus not yet conditioned to issue short queries. As with Web searchers, we can expect them to explore initially, then to ultimately settle on query strategies that work well enough to meet their needs. If longer queries work better for them, it seems reasonable to expect that they would use longer queries. Likewise, if systems cannot effectively use longer queries to produce useful results, then people will not use them.

To get a sense for whether such an interaction modality is feasible, we performed a simulation

Seattle, Washington, USA, 18-21 October 2013.

study for this paper in which we asked people to babble on some topic for which we already have relevance judgments results. We transcribe those babbles using automatic speech recognition (ASR), then note how many words must be babbled in each case before an information retrieval system is first able to place a relevant document in rank one. From this perspective, our results show that people are indeed often able to babble usefully; and, moreover, that current information retrieval technology could often place relevant results at rank one within half a minute or so of babbling even with contemporary speech recognition technology.

The question then arises as to whether a system can be built that would recognize when an answer is available at rank one. Barging in with an answer before that point wastes time and disrupts the user; barging in long after that point also wastes time, but also risks user abandonment. We therefore want a "Goldilocks" system that can get it just about right. To this end, we introduce an evaluation measure that differentially penalizes early and late responses. Our experiments using such a measure show that systems can be built that, on average, do better than could be achieved by any fixed response delay.

The remainder of this paper is organized as follows: We begin in Section 2 with a brief review of related work. Section 3 then describes the design of the ranking component of our experiment; Section 4 follows with some exploratory analysis of the ranking results using our test collection. Section 6 completes the description of our methods with an explanation of how the stopping classifier is built; Section 7 then presents end-to-end evaluation results using a new measure designed for this task. Section 8 concludes the paper with some remarks on future work.

2 Background

The rapid adoption of remarkably inexpensive mobile telephone services among low-literacy users in developing and emerging markets has generated considerable interest in so-called "spoken forum" projects (Sherwani et al., 2009; Agarwal et al., 2010; Medhi et al., 2011; Mudliar et al., 2012). It is relatively straightforward to collect and store spoken content regardless of the language in which it is spoken; organizing and searching that content is, however, anything but straightforward. Indeed, the current lack of effective search services is one of the key inhibitors that has, to date, limited spoken forums to experimental settings with at most a few hundred users. If a "spoken web" is to achieve the same degree of impact on the lives of low-literacy users in the developing world that the World Wide Web has achieved over the past decade in the developed world, we will need to develop the same key enabler: an effective search engine.

At present, spoken dialog systems of conventional design, such as Siri, rely on complex and expensive language-specific engineering, which can easily be justified for the "languages of wealth" such as English, German, and Chinese; but perhaps not for many of the almost 400 languages that are each spoken by a million or more people.[1] An alternative would be to adopt more of an "information retrieval" perspective by directly matching words spoken in the query with words that had been spoken in the content to be searched. Some progress has been made on this task in the MediaEval benchmark evaluation, which has included a spoken content matching task each year since 2011 (Metze et al., 2012). Results for six low-resource Indian and African languages indicate that miss rates of about 0.5 can be achieved on individual terms, with false alarm rates below 0.01, by tuning acoustic components that had originally been developed for languages with reasonably similar phonetic inventories. Our goal in this paper is to begin to explore how such capabilities might be employed in a complete search engine for spoken forum content, as will be evaluated for the first time at MediaEval 2013.[2] The principal impediment to development in this first year of that evaluation is the need for relevance judgments, which are not currently available for spoken content of the type we wish to search. That consideration has motivated our design of the simulation study reported in this paper.

[2] http://www.multimediaeval.org/mediaeval2013/qa4sw2013/

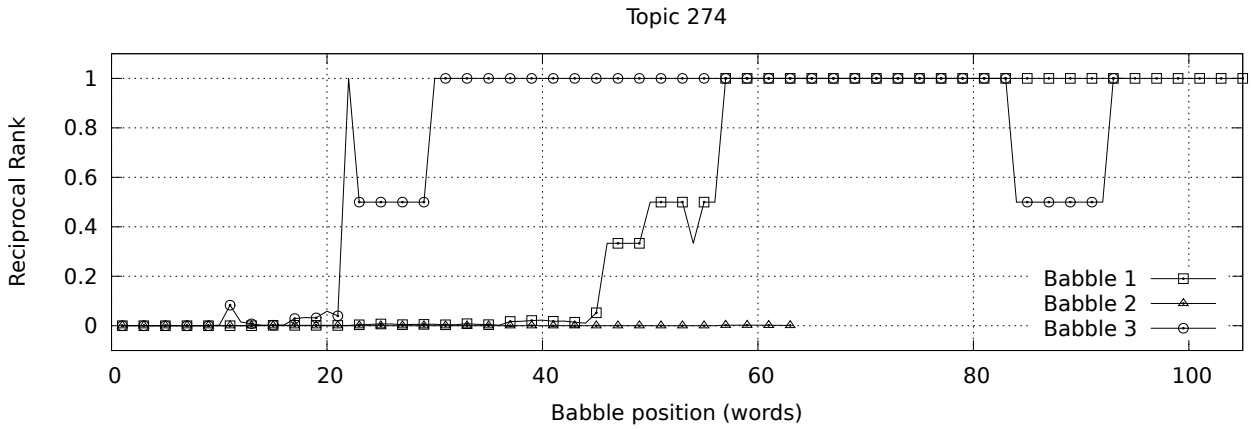

Figure 1: Reciprocal ranks at for each query making up a given babble. When retrieving results, a babbler either "latches" on to a relevant document (Babble 1), moves back-and-forth between relevant documents (Babble 3), or fails to elicit a relevant document at all (Babble 2).

3 Setup and Method

The approach taken in this paper is to simulate, as closely as possible, babbling about topics for which we a) already have relevance judgments available, and b) have the ability to match partial babbles with potential answers in ways that reflect the errors introduced by speech processing. To this end, we chose to ask non-native English speakers to babble, in English, about an information need that is stimulated by an existing English Text Retrieval Conference (TREC) topic for which we already have relevance judgments. An English Automatic Speech Recognition (ASR) system was then used to generate recognized words for those babbles. Those recognized words, in turn, have been used to rank order the (character-coded written text) news documents that were originally used in TREC, the documents for which we have relevance judgments. Our goal then becomes twofold: to first rank the documents in such a way as to get a relevant document into rank one; and then to recognize when we have done so.

Figure 1 is a visual representation of retrieval results as a person babbles. For three different babbles prompted by TREC Topic 274, it shows the reciprocal rank for the query that is posed after each additional word is recognized. We are primarily interested in cases where the reciprocal rank is one.[3] In these three babbles we see all cases that the retrieval system must take into account: babbles that never yield a relevant first-ranked document (Babble 2); babbles that eventually yield a relevant first-rank document, and that continue to do so as the person speaks (Babble 1); and babbles that alternate between good and bad results as the speaker continues (Babble 3).

3.1 Acquiring Babbles

Ten TREC-5 Ad Hoc topics were selected for this study: 255, 257, 258, 260, 266, 271, 274, 276, 287, and 297 based on our expectation of which of the 50 TREC 5 topics would be most suitable for prompted babbles. In making this choice, we avoided TREC topics that we felt would require specialized domain knowledge, experience with a particular culture, or detailed knowledge of an earlier time period, such as when the topics had been crafted. For each topic, three babbles were created by people speaking at length about the same information need that the TREC topic reflected. For convenience, the people who created the babbles were second-language speakers of English selected from information technology companies. There were a total of ten babblers; each recorded, in English, babbles for three topics, yielding a total of thirty babbles. We maintained a balance across topics when assigning topic

[3] A reciprocal rank of one indicates that a known relevant document is in position one; a reciprocal rank of 0.5 indicates that the most highly ranked known relevant document is in position two; 0.33 indicates position three; and so on.

So long time back one of my friend had a Toyota Pryus it uses electric and petrol to increase the to reduce the consumption and increase the mileage I would now want to get information about why car operators manufacturers or what do they think about electric vehicles in the US well this is what the stories say that the car lobby made sure that the electric vehicles do not get enough support and the taxes are high by the government but has it changed now are there new technologies that enable to lower cost and also can increase speed for electric vehicles I am sure something is being done because of the rising prices of fuel these days	So long time at one of my friends headed towards the previous accuses electric in petrol to increase the to reduce the consumption and increase the minutes and would now want to get information about why car operator manufacturers on what to think about electric vehicles in the us versus what the story said that the car lobby make sure that the electric vehicles to not get enough support to an attack and I try to comment but has changed now arctic new technologies that enabled to cover costs and also can increase speak for electric vehicles I'm sure some clinton gore carls junior chef

Table 1: Text from an example babble (274-1). The left is transcribed through human comprehension; the right is the output from an automatic speech recognition engine.

numbers to babblers. All babblers had more than sixteen years of formal education, had a strong command on the English language, and had some information about the topics that they selected. They were all briefed about our motivation for collecting this data, and about the concept of query by babbling.

The babbles were created using a phone interface. Each subject was asked to call an interactive voice response (IVR) system. The system prompted the user for a three digit topic ID. After obtaining the topic ID, the system then prompted the user to start speaking about what they were looking for. TREC topics contain a short title, a description, and a narrative. The title is generally something a user might post as an initial Web query; the description is something one person might say to another person who might then help them search; the narrative is a few sentences meant to reflect what the user might jot down as notes to themselves on what they were actually looking for. For easy reference, the system provided a short description—derived from the description and narrative of the TREC topics—that gave the user the context around which to speak. The user was expected to begin speaking after hearing a system-generated cue, at which time their speech was recorded. Two text files were produced from the audio babbles: one produced via manual transcription,[4] and one produced by an ASR system; Table 1 presents an example. The ASR transcripts of the babbles were used by our system as a basis for ranking, and as a basis for making the decision on when to barge-in, what we call the "stopping point." The manual transcriptions were used only for scoring the Word Error Rate (WER) of the ASR transcript for each babble.

TREC Topic		WER

Table 3: Rank-1 relevance ("Rel") judgments and position of first and last scorable guesses.

3.2 System Setup

The TREC-5 Associated Press (AP) and Wall Street Journal (WSJ) news stories were indexed by Indri (Strohman et al., 2004) using the Krovetz stemmer (Krovetz, 1993), standard English stopword settings, and language model matching. Each babble was turned into a set of nested queries by sequentially concatenating words. Specifically, the first query contained only the first word from the babble, the second query only the first two words, and so on. Thus, the number of queries presented to Indri for a given babble was equivalent to the number of words in the babble, with each query differing only by the number of words it contained. The results were scored using `trec_eval` version 9.0. For evaluation, we were interested in the reciprocal rank; in particular, where the reciprocal rank was one. This measure tells us when Indri was able to place a known relevant document at rank one.

4 Working with Babbles

Our experiment design presents three key challenges. The first is ranking well despite errors in speech processing. Table 2 shows the average Word Error Rate (WER) for each topic, over three babbles. Averaging further over all thirty babbles, we see that about half the words are correctly recognized. While this may seem low, it is in line with observations from other spoken content retrieval research: over classroom lectures (Chelba et al., 2007), call center recordings (Mamou et al., 2006), and conversational telephone speech (Chia et al., 2010). Moreover, it is broadly consistent with the reported term-matching results for low density languages in MediaEval.

The second challenge lies in the scorability of the system guesses. Table 3 provides an overview of where relevance was found within our collection of babbles. It includes only the subset of babbles for which, during the babble, at least one known relevant document was found at the top of the ranked list. The table presents the number of recognized words—a proxy for the number of potential stopping points—and at how many of those potential stopping points the document ranked in position 1 is known to be relevant, known not to be relevant, or of unknown relevance. Because of the way in which TREC relevance judgments were created, unknown relevance indicates that no TREC system returned the document near the top of their ranked list. At TREC, documents with unknown relevance are typ-

ically scored as if they are not relevant;[5] we make the same assumption.

Table 3 also shows how much we would need to rely on that assumption: the "scorable" fraction for which the relevance of the top-ranked document is known, rather than assumed, ranges from 93 per cent down to 5 per cent. In the averages that we report below, we omit the five babbles with scorable fractions of 30 per cent or less. On average, over the 10 topics for which more than 30 per cent of the potential stopping points are scorable, there are 37 stopping points at which our system could have been scored as successful based on a known relevant document in position 1. In three of these cases, the challenge for our stopping classifier is extreme, with only a handful—between two and seven—of such opportunities.

A third challenge is knowing when to interrupt to present results. The ultimate goal of our work is to predict when the system should interrupt the babbler and barge-in to present an answer in which they might be interested. Table 3 next presents the word positions at which known relevant documents first and last appear in rank one ("First Rel"). This are the earliest and latest scorable successful stopping points. As can be seen, the first possible stopping point exhibits considerable variation, as does the last. For some babbles—babble 274-3, for example—almost any choice of stopping points would be fine. In other cases—babble 258-1, for example—a stopping point prediction would need to be spot on to get any useful results at all. Moreover, we can see both cases in different babbles for the same topic despite the fact that both babblers were prompted by the same topic; for example, babbles 257-1 and 257-3, which are, respectively, fairly easy and fairly hard.

Finally, we can look for interaction effects between speech processing errors and scorability. The rightmost column of Table 3 shows the measured WER for each scorable babble. Of the 10 scorable babbles for which more than 30 per cent of the potential stopping points are scorable, three turned out to be extremely challenging for ASR, with word error rates above 0.7. Overall, however, the WER for the 10 babbles on which we focus is 0.56, which is about the same as the average WER over all 30 babbles.

In addition to the 15 babbles shown in Table 3, there are another 15 babbles for which no relevant document was retrievable. Of those, only a single babble—babble 255-2, at 54 per cent scorable and a WER of 0.402—had more than 30 per cent of the potential stopping points scorable.

5 Learning to Stop

There are several ways in which we could predict when to stop the search and barge-in with an answer—in this paper, we consider a machine learning approach. The idea is that by building a classifier with enough information about known good and bad babbles, a learner can make such predictions better than other methods. Our stopping prediction models uses four types of features for each potential stopping point: the number of words spoken so far, the average word length so far, some "surface characteristics" of those words, and some query performance prediction metrics. The surface characteristics that we used were originally developed to quantify writing style—they are particularly useful for generating readability grades of a given document. Although many metrics for readability have been proposed, we choose a subset: Flesch Reading Ease (Flesch, 1948), Flesch-Kincaid Grade Level (Kincaid et al., 1975), Automated Readability Index (Senter and Smith, 1967), Coleman-Liau index (Coleman and Liau, 1975), Gunning fog index (Gunning, 1968), LIX (Brown and Eskenazi, 2005), and SMOG Grading (McLaughlin, 1969). Our expectation was that a better readability value should correspond to use of words that are more succinct and expressive, and that a larger number of more expressive words should help the search engine to get good responses highly ranked.

As post-retrieval query difficulty prediction measures, we choose three that have been prominent in information retrieval research: clarity (Cronen-Townsend et al., 2002), weighted information gain (Zhou and Croft, 2007), and normalized query commitment (Shtok et al., 2012). Although each takes a distinct approach, the methods all compare some aspect of the documents retrieved by a query

[5] On the assumption that the TREC systems together span the range of responses that are likely to be relevant.

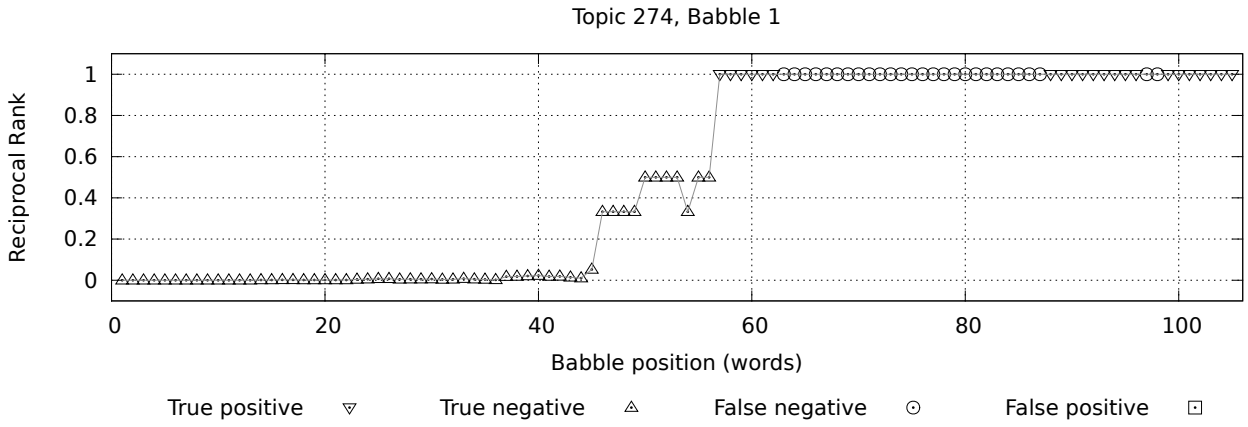

Figure 2: Predictions for babble 274-1 made by a decision tree classifier trained on 27 babbles for the nine other topics. For each point, the mean reciprocal rank is annotated to indicate the correctness of the guess made by the classifier. Note that in this case, the classifier never made a false positive. See Figure 1 for an unannotated version of this same babble.

	Confusion Matrix					
Class.	T_n	F_p	F_n	T_p	F_1	Acy.
Bayes	1288	1259	61	291	0.31	55%
Reg.	2522	25	253	99	0.42	90%
Trees	2499	48	70	282	0.83	96%

Table 4: Cross validation accuracy ("Acy.") measures for stop-prediction classifiers: naive Bayes, logistic regression, and Decision trees.

with the complete collection of documents in the collection from which that retrieval was performed. They seek to provide some measure of information about how likely a query is to have ranked the documents well when relevance judgments are not available. Clarity measures the difference in the language models induced by the retrieved results and the corpus as a whole. Weighted information gain and normalized query commitment look at the scores of the retrieved documents, the former comparing the mean score of the retrieved set with that of the entire corpus; the latter measuring the standard deviation of the scores for the retrieved set.

Features of all four types were were created for each query that was run for each babble; that is after receiving each new word. A separate classifier was then trained for each topic by creating a binary objective function for all 27 babbles for the nine other topics, then using every query for every one of those babbles as training instances. The objective function produces 1 if the query actually retrieved a relevant document at first rank, and 0 otherwise. Figure 2 shows an example of how this training data was created for one babble, and Table 4 shows the resulting hold-one-topic-out cross-validation results for intrinsic measures of classifier accuracy for three Weka classifiers[6]. As can be seen, the decision tree classifier seems to be a good choice, so in Section 7 we compare the stopping prediction model based on a decision tree classifier trained using hold-one-topic-out cross-validation with three baseline models.

6 Evaluation Design

This section describes our evaluation measure and the baselines to which we compared.

6.1 Evaluation Measure

To evaluate a stopping prediction model, the fundamental goal is to stop with a relevant document in rank one, and to do so as close in time as possible to the first such opportunity. If the first guess is bad, it would be reasonable to score a second guess, with some penalty.

Specifically, there are several things that we

[6]Naive Bayes, logistic regression, and decision trees (J48)

would like our evaluation framework to describe. Keeping in mind that ultimately the system will interrupt the speaker to notify them of results, we first want to avoid the interruption before we have found a good answer. Our evaluation measure gives no credit for such a guess. Second, we want to avoid interrupting long after finding the first relevant answer. Credit is reduced with increasing delays after the first point where we could have barged in. Third, when we do barge-in, there must indeed be a good answer in rank one. This will be true if we barge-in at the first opportunity, but if we barge-in later the good answer we had found might have dropped back out of the first position. No credit is given if we barge-in such a case. Finally, if a bad position for first barge-in is chosen, we would like at least to get it right the second time. Thus, we limit ourselves to two tries, awarding half the credit on the second try that we could have received had we barged in at the same point on the first try.

The delay penalty is modeled using an exponential distribution that declines with each new word that arrives after the first opportunity. Let q_0 be the first point within a query where the reciprocal rank is one. Let p_i be the first "yes" guess of the predictor after point q_0. The score is thus $e^{\lambda(q_0-p_i)}$, where λ is the half-life, or the number of words by which the exponential decay has dropped to one-half. The equation is scaled by 0.5 if i is the second element (guess) of p, and by 0.25 if it is the third. From Figure 1, some cases the potential stopping points are consecutive, while in others they are intermittent—we penalize delays from the first good opportunity even when there is no relevant document in position one because we feel that best models the user experience. Unjudged documents in position one are treated as non-relevant.

6.2 Stopping Prediction Baselines

We chose one deterministic and one random baseline for comparison. The deterministic baseline made its first guess at a calculated point in the babble, and continued to guess at each word thereafter. The initial guess was determined by taking the average of the first scorable point of the other 27 out-of-topic babbles.

The random baseline drew the first and second words at which to guess "yes" as samples from a uniform distribution. Specifically, drawing samples uniformly, without replacement, across the average number of words in all other out-of-topic babbles.

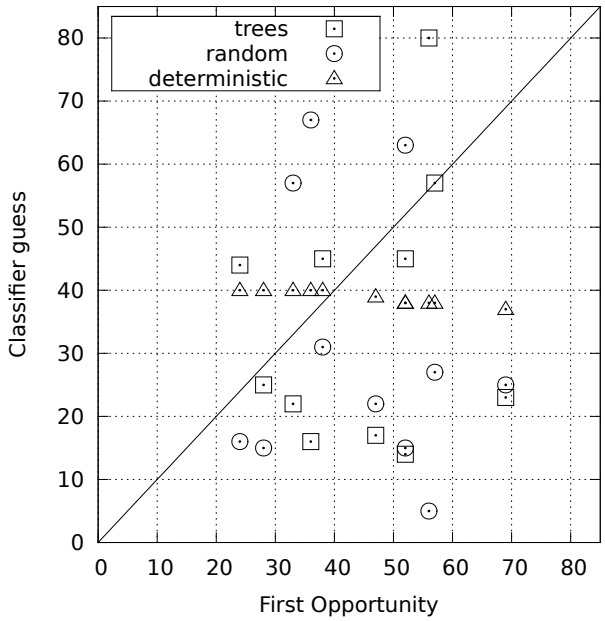

Figure 3: First guesses for various classifiers plotted against the first instance of rank one documents within a babble. Points below the diagonal are places where the classifier guessed too early; points above are guesses too late. All 11 babbles for which the decision tree classifier made a guess are shown.

7 Results

Figure 3 shows the extent to which each classifiers first guess is early, on time, or late. These points falls, respectively, below the main diagonal, on the main diagonal, or above the main diagonal. Early guesses result in large penalties from our scoring function, dropping the maximum score from 1.0 to 0.5; for late guesses the penalty depends on how late the guess is. As can be seen, our decision tree classifier ("trees") guesses early more often than it guesses late. For an additional four cases (not plotted), the decision tree classifier never makes a guess.

Figure 4 shows the results for scoring at most three guesses. These results are averaged over all eleven babbles for which the decision tree classifier made at least one guess; no guess was made on babbles 257-3, 266-2, 260-3, or 274-3. These re-

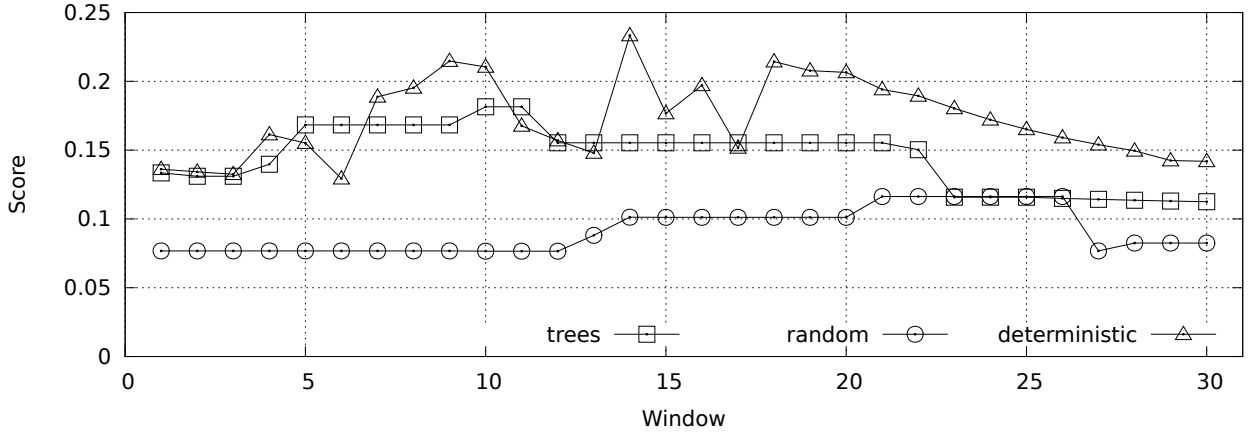

Figure 4: Evaluation using all available babbles in which the tree classifier made a guess.

sults are shown for a half-life of five words, which is a relatively steep penalty function, essentially removing all credit after about ten seconds at normal speaking rates. The leftmost point in each figure, plotted at a "window size" of one, shows the results for the stopping prediction models as we have described them. It is possible, and indeed not unusual, for our decision tree classifier to make two or three guesses in a row, however, in part because it has no feature telling it how long is has been since its most recent guess. To see whether adding a bit of patience would help, we added a deterministic period following each guess in which no additional guess would be allowed. We call the point at which this delay expires, and a guess is again allowed, the delay "window."

As can be seen, a window size of ten or eleven—allowing the next guess no sooner than the tenth or eleventh subsequent word—is optimal for the decision tree classifier when averaged over these eleven babbles. The random classifier has an optimal point between window sizes of 21 and 26, but is generally not as good as the other classifiers. The deterministic classifier displays the most variability, but for window sizes greater than 14, it is the best solution. Although it has fewer features available to it—knowing only the mean number of words to the first opportunity for other topics—it is able to outperform the decision tree classifier for relatively large window sizes.

From this analysis we conclude that our decision tree classifier shows promise; and that going forward, it would likely be beneficial to integrate features of the deterministic classifier. We can also conclude that these results are, at best, suggestive—a richer test collection will ultimately be required. Moreover, we need some approach to accommodate the four cases in which the decision tree classifier never guesses. Setting a maximum point at which the first guess will be tried could be a useful initial heuristic, and one that would be reasonable to apply in practice.

8 Conclusions and Future Work

We have used a simulation study to show that building a system for query by babbling is feasible. Moreover, we have suggested a reasonable evaluation measure for this task, and we have shown that several simple baselines for predicting stopping points can be beaten by a decision tree classifier. Our next step is to try these same techniques with spoken questions and spoken answers in a low-resource language using the test collection that is being developed for the MediaEval 2013 Question Answering for the Spoken Web task.

Another potentially productive direction for future work would be to somehow filter the queries in ways that improve the rankings. Many potential users of this technology in the actual developing region settings that we wish to ultimately serve will likely have no experience with Internet search engines, and thus they may be even less likely to fo-

cus their babbles on useful terms to the same extent that our babblers did in these experiments. There has been some work on techniques for recognizing useful query terms in long queries, but of course we will need to do that with spoken queries, and moreover with queries spoken in a language for which we have at lest limited speech processing capabilities available. How best to model such a situation in a simulation study is not yet clear, so we have deferred this question until the MediaEval speech-to-speech test collection becomes available.

In the long term, many of the questions we are exploring will also has implications for open-domain Web search in other hands- or eyes-free applications such as driving a car or operating an aircraft.

Acknowledgments

We thank Anna Shtok for her assistance with the understanding and implementation of the various query prediction metrics. We also thank the anonymous babblers who provided data that was imperative to this study. Finally, we would like to thank the reviewers, whose comments helped to improve the work overall.

Abstract

The rapid development of Web2.0 leads to significant information redundancy. Especially for a complex news event, it is difficult to understand its general idea within a single coherent picture. A complex event often contains branches, intertwining narratives and side news which are all called storylines. In this paper, we propose a novel solution to tackle the challenging problem of storylines extraction and reconstruction. Specifically, we first investigate two requisite properties of an ideal storyline. Then a unified algorithm is devised to extract all effective storylines by optimizing these properties at the same time. Finally, we reconstruct all extracted lines and generate the high-quality story map. Experiments on real-world datasets show that our method is quite efficient and highly competitive, which can bring about quicker, clearer and deeper comprehension to readers.

1 Introduction

News reports usually consist of various modalities of tremendous information, especially all kinds of textual information and visual information, which make web users dazzled and lost. The situation gets worse on complex news events. To help readers quickly grasp the general information of the news, a more concise and convenient system over multi-modality information should be provided. For example, given a large collection of texts and images related to a specified news event (e.g., *East Japan Earthquake*), such a system should present a terse and brief summarization about the event by showing different clues of its development, and thus helping readers to effectively find out "when, where, what, how and why" at a glance.

The researches (Goldstein et al., 2000) on automatic multi-document summarization (MDS) have helped a lot when we generate a description for a specific event. However, it traditionally exhibits in a very simple style like a "0-dimensional" point. The appearance of *Timeline* (Allan et al., 2001) brings about a visual progress for massive documents analyses. Readers can not only get the most important ideas, but also browse the story evolution in chronological order. Previous news summarization systems with structured output (Yan et al., 2011) have focused on timeline generation. Timeline becomes a "1-dimensional" line. This style of summarization only works for simple stories, which are linear in nature. However, the structure of complex stories usually turns out to be non-linear. These stories branch into storylines, dead ends, intertwining narratives and side news. To explore these lines, we need a map to reorganize all the information. Therefore, a "2-dimensional" story map is in bad need. Figure 1 shows a part of the story map generated by our system for representing *East Japan Earthquake*. We notice that the whole event evolves into 4 branches. Each of them focuses on a specific sub-topic and is distinct from other lines. Figure 2 takes a close look at the 4 nodes from different lines, and they differ a lot from each other as expected.

Text information is more precise and exquisite when compared with images. Nevertheless, as the

Seattle, Washington, USA, 18-21 October 2013.

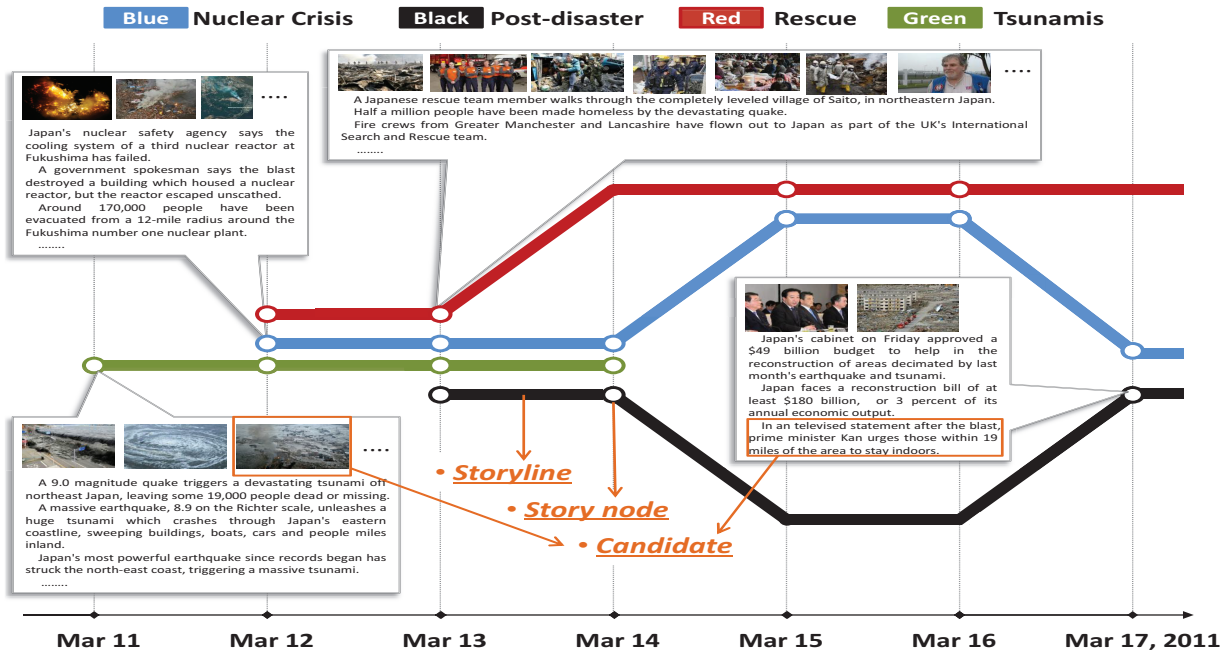

Figure 1: Four storylines are obtained in the story map of "East Japan Earthquake". They focus on *Tsunamis*, *Nuclear Crisis*, *Rescue* and *Post-disaster* respectively.

saying goes, "a picture paints a thousand words", an image could provide far more information than words do. In fact, a summarization including both texts and images will absolutely yield a more powerful and intuitive description about the news event. Under this motivation, we study on extracting and reconstructing tracks with different sub-topics for a complex event. To the best of our knowledge, the exploration and analysis of 2-dimensional cross-modal summarization is academically novel.

We are faced with two main problems. The first is how to select the most important sentences and images to make up the final story map. The previous work by Shahaf et al. presents a 2-D story map called "metro map", which summarizes the complex topics (Shahaf et al., 2012). They study on the document-level, and use the entire news document as one story node. But on real web, this may confront some difficulties. On one hand, news articles may report the event from different perspectives, especially those reviews or retrospective reports. This kind of documents contains many useful saliency information of different sub-topics, but they cannot be further subdivided to help understand each better. On the other hand, some documents, such as

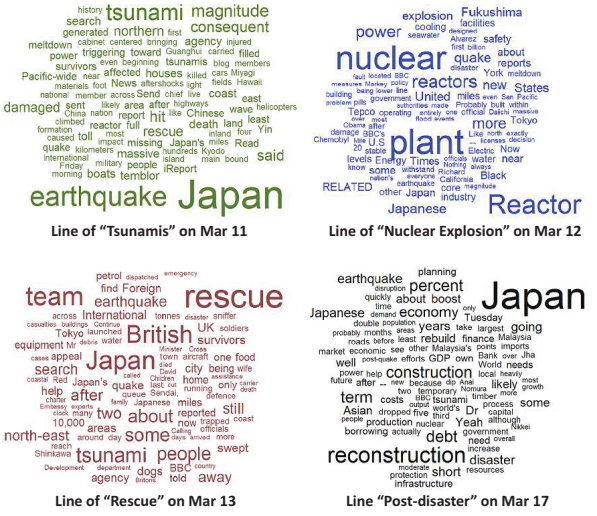

Figure 2: Word distributions vary a lot among nodes in different storylines

cover news and interviewing reports, contain one or two famous remarks. Since these documents also include too much useless information, it's inappropriate to use the whole document as a story node. So our work, the sentence-level story map extraction, is just aimed at this brand new problem. The second problem is the way to utilize the cross-modal

information suitably. Our goal is not only to fuse sentences and images together, but also to provide a unified framework to improve them mutually.

In this paper, we introduce a novel solution for the story map summarization problem. All the sentences and images are the candidates for making up the final map. The analysis of complicated information usually requires a semantic-level knowledge study. We address this in the pre-processing of data in Section 3.1. The key task of our research is the extraction of storylines. We reveal two fundamental properties of an ideal storyline, and propose an optimization algorithm in Section 3.2. A highly compatible MDS sub-algorithm is also fused in and offers help to the sentences/images selection. In Section 3.3, the extracted storylines are reconstructed as a final story map. The experimental results conducted on four real datasets show that our approach can perform effectively.

The rest of this paper is organized as follows. Some related researches are demonstrated in Section 2. We introduce our methodology in Section 3. The experimental results in Section 4 prove the effectiveness of our approach. Finally, we conclude this paper and present our future work in Section 5.

2 Related Work

Generally speaking, multi-document summarization can be either extractive or abstractive. Researchers mainly focus on the former which extracts the information deemed most important to the summary. Various techniques have been used for this type of MDS (Haghighi and Vanderwende, 2009; Contractor et al., 2012). Graph-based text summarization techniques have been widely used for years. The algorithms, used in TextRank (Mihalcea and Tarau, 2005) and LexPageRank (Radev et al., 2004), which are meant to compute sentence importance, are similar to those in PageRank and HITS.

Recently, timeline becomes a popular style to present a schedule of events and attracts many researchers consequently. For example, Yan et al. make use of timestamps to generate an evolutionary timeline (Yan et al., 2011). Shahaf et al. present a 2-D story map called "metro map" to summarize the complex topic (Shahaf et al., 2012). But previous work only studies on the document level, which inevitably brings about much information redundancy.

Previous studies show that the use of visual materials not only leads to the conservation of information but also promotes comprehension (Panjwani et al., 2009). Thus the cross-modal fusion is necessary. Wu et al. propose a framework of multimodal information fusion for multimedia data analysis by learning the optimal combination of multimodal information with the superkernel fusion (Wu et al., 2004). Borrowing the idea of recommendation in heterogeneous network into the cross-modal news summarization is also a convincing research. Xu et al. tackle this task and bring out an 1-D cross-media timeline generation framework (Xu et al., 2013).

Summarization of multimedia involves researches on information retrieval of multimedia. Since textual and visual information are quite different from each other, how to make a good transformation to mine latent knowledge from unannotated images is of great concern. Feng and Lapata (2010) use visual words to describe visual features and then propose a probabilistic model based on the assumption that images and their co-occurring textual data are generated by mixtures of latent topics.

However, to the best of our knowledge, no existing research manages to generate a 2-dimensional story map automatically and integrate images and texts into a unified framework at the same time.

3 Methodology

The original data of one event is a collection of news documents on different days, or in a finer granularity, a set of sentences and images with different timestamps. Each item in the data collection is a candidate for selection to form the final map. We denote the data collection as C, and $C = C_s \cup C_v$, where C_s is the subset containing all sentences and C_v contains all images. In the following elaboration of our method, dateset C is the important knowledge base. As the ultimate goal for a specific event, we would like to generate the "2-D" story map $\mathcal{M}$, whose main component is a set of "1-D" storylines $\mathcal{L} = \{L_1, L_2, \ldots\}$. Each storyline $L \in \mathcal{L}$ is made up of a set of "0-D" story nodes, $L = \{I_1, I_2, \ldots\}$, each of which is composed of a set of candidates sharing the same timestamp $I = \{c_1, c_2, \ldots\}$. For more concise, our method can be scheduled with the

following three steps:

1. Prepare semantic knowledge for each candidate, and then purify data collection C by eliminating the noisy candidates;

2. Conduct OPT-LSH algorithm to extract $\mathcal{L}$ that contains all qualified storylines;

3. Reconstruct the storylines as the final map $\mathcal{M}$.

3.1 Pre-processing

Before we extract the storylines, we have to solve two problems first. Since our work is cross-modal, the semantic knowledge under the literal and visual surface is basically required. Recall from Section 2, there exist many effective ways to dig into the semantic level of image and text. In this paper, we employ the approach proposed by Jiang and Tan (2006). They present a convincing approach which employs a multilingual retrieval model to apply knowledge mining on semantic level. The first is the sentence feature vector generation. With the preprocessing such as stemming and stop words removal, they extract the textual TF-IDF feature Vec_s of each sentence. The second, also the challenging part, is the image feature vector generation. In this step, for each region they extract visual features that are consisting of 6 color features and 60 gabor features which have been proven to be useful in many applications. Color features are the means and variances of the RGB color spaces. Gabor features are extracted by calculating the means and variations of the filtered image regions on 6 orientations. After the visual feature vectors of the image regions are extracted, all image regions are clustered using the k-means algorithm. The generated clusters, called "visterms" or "visual words", are treated as a vocabulary for the images. Besides visual features, they also utilize the context textual feature of each image as the semantic supplement to generate to final feature vector Vec_v.

Based on these feature vector of each cantidate, they further calculating the intra-modal similarity with classical IR methods, they obtain the inter-modal similarity through the vague transformation (Mandl T, 1998). We also note that translation tools such as VIPS (Cai et al., 2003) and WebKit[1] can help us to segment web documents and pick those text blocks whose coordinates are neighboring to each specified image. In this way we can successfully obtain images, text contexts and content sentences. Three kinds of semantic similarity are now ready. They are uniformly denoted as $sim(c_i, c_j)$, representing the similarity between two candidates. c_i and c_j can be any type of modalities.

Another problem is the noise from irregular data. We would like to utilize the sentences and images of high quality. The intuitive assumption is that a good candidate should have substance in speech, and be coherent with other good candidates. Fortunately, many useful measures are now available. They can be used to choose better candidates. Inspired by the analysis analogy to information retrieval, we extend the idea of the classical *PageRank* algorithm to estimate the authority for each candidate. The similarity between two candidates is regarded as the weighted "link" between them.

Inspired by the idea of classic "update summarization" task, we try to avoid those chronologically ordered documents sets focusing on a constant topic. Therefore, given the particularity of our task, we also have to develop the weighting function Γ with the temporal factor before starting the ranking algorithm. Our fundamental assumption is that the inter-date and inter-modal "links" have different influence comparing with the intra ones. Therefore the core formula calculating the authority of c_i is adapted as follows to make it become weight-compatible:

$$Auth(c_i) = \frac{1-q}{|C|} + q \cdot [\, \alpha \sum_{c_j \in C'} \Gamma(c_i, c_j) \cdot \frac{Auth(c_j)}{O(c_j)} + (1-\alpha) \sum_{c_k \in C''} \Gamma(c_i, c_k) \cdot \frac{Auth(c_k)}{O(c_k)} \,]$$

C' is the subset of C which only includes the candidates of the same modality with c_i, and C'' is the cross-modal candidates subset. $O(c_j)$ denotes the out-degree of c_j, and smoothing parameter q is set as the common value 0.85. Parameter α is used to balance the biases of intra- and inter-modal impact. If α is set to 1, it means the cross-modal information is abandoned, and vice versa. $\Gamma(c_i, c_j)$ contains two terms as follows:

$$\Gamma(c_i, c_j) = sim(c_i, c_j) \cdot e^{\frac{-\|c_i.t - c_j.t\|}{2\sigma^2}}$$

[1] http://www.webkit.org

The second term of Γ's formula is Gaussian Kernel (Aliguliyev R, 2009), which is used to measure the temporal gap between two candidates ($*.t$ denotes the date-based timestamp). Note that the similarity metric is content-based and time-independent, since the time decay function is only used to adjust the ranking impact strength. In this way, we can give higher authority to the more informative and coherent candidates. The optimal value of σ, which controls the spread of kernel curves, is sensitive to datasets and will be discussed later.

We eliminate the candidates whose authority goes under threshold. The data collection C is then significantly downsized and purified for later work. Authority is also used to determine the presentation sequence inside each story node of final map.

3.2 Extraction: LSH-OPT Algorithm

Other traditional relative methods need to pre-decide how many sub-topics are going to be obtained, like clustering or other supervised models. They fail in the unsupervised automatic storylines extraction problem. In this Section, we propose a concrete algorithm to extract storyline set $\mathcal{L}$ from C. Our proposed LSH-based algorithm can automatically optimize the number of storylines according to their self-evaluation.

3.2.1 Task Formalization

Let's investigate the storyline first. We may think of some basic attributes as well as many extension properties. The number of nodes in the storyline L (denoted as $|L|$) is intuitively one of its basic attributes. We would like to define another basic attribute called the SUPPORT of L. In detail, $Support(L) = \min_{I_k \in L} |I_k|$, which denotes the smallest size among all the story nodes it has.

The most challenging part is to properly model extension properties. We observe that an effective storyline should meet three key requirements: (1) **Coherence**. Within one storyline, news changes gradually as time goes and the evolution indicates consistency among component story nodes. We rely on the notion of coherence developed in *Connect-the-Dots* (Shahaf and Guestrin, 2010) and transform it to what we exactly need in this research; (2) **Diversity**. According to MMR principle (Goldstein et al., 1999), though the work is about summary, we still can draw an analogy and derive that a good storyline should be concise and contain redundant information as few as possible, i.e., two sentences providing information of similar content should not be presented in different storylines; (3) **Coverage**. The extracted storyline set $\mathcal{L}$ should keep alignment with the source collection C, which is intuitive and even proved to be significant as proposed in (Li et al., 2009). However, *Coverage* in some ways is technically redundant in front of *Diversity*. We decide to use the first two criteria in extraction process and use the last one to verify the effectiveness.

Since a storyline is composed of several nodes, we can select or abandon nodes mainly according to these two requirements. In fact, both of them involve a measurement of similarity between two story nodes, denoted by two word distributions (see Figure 2). Specifically, for story node I_i, its distribution probability of word w is estimated as $p(w|I_i) = \frac{\sum_{c \in I_i} TF(w)}{\sum_w \sum_{c \in I_i} TF(w)}$ where the denominator is used for normalization. Then *Kullback-Leibler* divergence is employed to denote the distance between two nodes I_i and I_j:

$$D_{KL}(I_i, I_j) = \sum_w p(w|I_i) \log \frac{p(w|I_i)}{p(w|I_j)}$$

In addition, we introduce the decreasing and increasing variants based on logistic functions, $D^{\flat}_{KL} = 1/(1 + e^{D_{KL}})$ and $D^{\sharp}_{KL} = e^{D_{KL}}/(1 + e^{D_{KL}})$, to map the distance into $[0, 1]$. Given the measurement, we can formulate the two properties.

For *Coherence*, a storyline L_i consists of a series of individual but correlated nodes, which do not necessarily have the serial timestamps. We would like to choose such a set of nodes $\{I_1, I_2, \ldots\}$, and at the same time guarantee this criterion:

$$Cor(L_i) = \frac{1}{|L_i|} \sum\nolimits_{1 \le k < |L_i|} D^{\flat}_{KL}(I_k, I_{k+1})$$

For *Diversity*, each storyline $Li \in \mathcal{L}$ should demonstrate quite different subtopics with other storylines. This is the most essential motivation for us to step into 2-dimensional field. This criterion can be used to maximize the minimum diversity value among all storylines:

$$Div(\mathcal{L}) = \min_{L_i, L_j \in \mathcal{L}} \{ \frac{\sum_{I_k \in L_i} \sum_{I_{k'} \in L_j} D^{\sharp}_{KL}(I_k, I_{k'})}{|L_i| \cdot |L_j|} \}$$

Then the problem can be transformed into the following optimization problem. Parameters θ_1, θ_2 and θ_3 denote the minimum number of nodes in each line, the smallest size of candidates in each node and the coherence lower bound respectively. The task is to extract an optimal $\mathcal{L}$ out of C, such that:

$$\forall L \in \mathcal{L},\ |L| \geq \theta_1\ \&\ Support(L) \geq \theta_2;$$
$$\forall L \in \mathcal{L},\ Cor(L) \geq \theta_3;$$
$$Div(\mathcal{L})\ is\ maximized.$$

3.2.2 Optimization Algorithm

It can be proved that finding the optimal set $\mathcal{L}$ is an NP-Complete problem (not presented due to the limited space). Thus the brute-force exhaustive approach is crashed. We develop a near-optimal algorithm based on locality sensitive hashing (OPT-LSH). The original LSH solution is a popular technique used to solve the nearest neighbor search problems in high dimensions. Its basic idea is to hash similar input items into the same bucket (i.e., uniquely definable hash signature) with high probability. All potential storylines can be targeted fast if we make good use of this idea.

LSH performs probabilistic dimension reduction of high dimensional data by projecting a higher d-dimensional vector Vec_c (recall from Section 3.1) to a lower d'-dimensional vector ($d'<<d$), such that the candidates which are in close proximity in the higher dimension get mapped into the same item in the lower dimensional space with high probability. It guarantees a lower bound on the probability that two similar input items fall into the same bucket in the projected space and also the upper bound on the probability that two dissimilar vectors fall into the same bucket (Indyk and Motwani, 1998).

One of the key requirements for good performance of LSH is the careful selection of the family of hashing functions. In OPT-LSH, we use the hashing scheme proposed by Charikar (Charikar M, 2002). In detail, d' random unit d-dimensional vectors $\vec{r_1}, \vec{r_2}, \ldots, \vec{r_{d'}}$ are generated first. Each of the d entries of $\vec{r_i}$ is drawn from a standardized normal distribution N(0,1). Then the d' hashing functions are defined as:

$$h_i(c) = \begin{cases} 1, & if\ \vec{r_i} \cdot Vec(c) \geq 0 \\ 0, & if\ \vec{r_i} \cdot Vec(c) < 0 \end{cases} \quad 1 \leq i \leq d'$$

We represent the d'-dimensional bucket feature $\mathbf{h}$ for c, $\mathbf{h}(c) := [h_1(c), \ldots, h_{d'}(c)]$. There are $2^{d'}$ different buckets at most. Each denotes a potential storyline, so we have to verify the probability of similar candidates falling into the same bucket, whose lower bound is given by Charikar (Charikar M, 2002).

Simply filtering and searching among all potential lines in single pass may lead to empty result set if in post-processing no bucket satisfies all constraints. This could probably happen because the input parameter d' is set so large that the optimal set of candidates is separated into different buckets. However, we will get a suboptimal result in turn when d' is too small. We are then motivated to tune LSH by iterative relaxation that varies d' in each iteration. Changing the value of d' balances the leverage between expected number of potential storylines and their properties. We perform a binary search between 1 and d' to identify the ideal number of hash functions to employ. Algorithm 1 shows the pseudo code of our OPT-LSH algorithm. The LSH time is bounded by $O(d'|C| \log |C|)$ since the binary search relaxation iteration runs for $\log |C|$ times in the worst case and the hashing time is $O(d'|C|)$.

3.3 Storylines Reconstruction

At last, we manage to reconstruct all the storylines in $\mathcal{L}^{opt}$. A real-world storyline may sometimes intertwine with another, educe other branches, and end its own evolvement. The way to reconstruct a more effective layout of the story map requires further study and provides a good research direction in the future. However, in this paper we order the sentences/images in each story node according to their authority scores. Next, all storylines are arranged to proceed along the timestamps, thus a storyline never turns back in the map. Then we adjust the structure to make story nodes sharing the same timestamp stay close, though they belong to different lines. Figure 1 shows the sample output of our system.

4 Experiments

4.1 Dataset

There is no existing standard evaluation data set for 2-dimensional cross-modal summarization methods. We randomly choose 4 news topics from 4 selected news websites: *New York Times*, *BBC*, *CNN* and

Algorithm 1 OPT-LSH Algorithm

Input: Candidate set C, similarity function sim, bucket dimensions d'

Output: A near-optimal storylines set $\mathcal{L}^{opt}$

// Main Algorithm

Initialize $left = 1, right = d', max = -1$
repeat
  $d' = (left + right)/2$
  $\mathcal{L} \leftarrow LSH(C, d')$
  Revise all word distributions $p(w|I)$ in $\mathcal{L}$
  if $\forall L \in \mathcal{L}$, $|L| \geq \theta_1$ **and** $Support(L) \geq \theta_2$ **and** $Cor(L) \geq \delta_3$ **then**
    if $Div(\mathcal{L}) > max$ **then**
      $\mathcal{L}^{opt} \leftarrow \mathcal{L}, max \leftarrow Div(\mathcal{L})$
    end if
    $left = d' + 1$
  else
    $right = d' - 1$
  end if
until $left > right$
return $\mathcal{L}^{opt}$

// $LSH(C, d') : Buckets$

Generate d' unit vectors randomly
for $j = 1$ to $|C|$ **do**
  for $i = 1$ to d' **do**
    if $\vec{r_i} \cdot Vec(c_j) \geq 0$ **then**
      $h_i(c_j) \leftarrow 1$
    else
      $h_i(c_j) \leftarrow 0$
    end if
  end for
  $\mathbf{h}(c_j) = [h_1(c_j), \ldots, h_{d'}(c_j)]$
end for
return $Buckets \leftarrow \{\mathbf{h}(c_j) | c_j \in C\}$

Reuters. We query each event confined to these sites and crawl webpages' html docs. Referring to Section 3.1, timestamps, text contents, images and their text contexts are extracted. Table 1 shows the details. These 4 datasets all contain massive information and complex evolutions.

4.2 Analysis of Our System

Since there is no standard for us to verify the effectiveness of our solution, we have to utilize convincing criteria based on manual evaluation of experts, and then we can compare them with other approaches. In order to setup the system, based on the optimization problem shown in Section 3.2, we assign the value of 1 to both θ_1 and θ_2, and empirically set θ_3 as 0.6 which can balance the number of potential lines and the quality of story map as well. Then the problem can be re-interpreted in natural language as follows. Given the data collection, we manage to find out a set of storylines such that every line in it contains at least one non-null story node and keeps self-coherence not less than 0.6. What's more, the diversity of the whole set is maximized. Before comparing OPT-LSH with other systems, we do some further analysis of inherent properties first.

Table 1: Statistics of Datasets.

Event (Query)	Document	Time Span	σ	α
EJE	504	Mar 11-Apr 8, 2011	3	0.9
OWS	638	Sept 17-Dec 10, 2011	12	0.7
NBA	489	July 1-Dec 28, 2011	17	0.6
ME	437	June 21-Aug 31, 2011	9	0.7

* Abbreviations EJE, OWS, NBA, ME denote *East Japan Earthquake*, *Occupy Wall Street*, *NBA Lockout* and *Murdock's Eavesdropping* respectively.

4.2.1 Compactness

The essential idea of summarization is to reduce the data size, so that a more concise representation will be generated and help users to fast grasp the main points. Therefore the *Compactness* of a story map needs to be guaranteed. In the pre-processing module, we have already excluded significant number of inferior candidates with the extended PageRank. Nevertheless what we really care is the compactness that OPT-LSH brings about. In the candidates and story nodes selection processes, only the most saliency and coherent candidates can appear in the final representation. We count the number of sentences and images in $\mathcal{L}^{opt}$, denoted as $||\mathcal{L}^{opt}||$, and then we compare it with the collection size $|C|$ (both before and after pre-processing) to test the compactness. Table 2 shows that OPT-LSH further reduces the representation scale significantly.

4.2.2 Coverage

Obviously, only the verification of compactness is far from enough. As mentioned in Section 3.2, the storyline set $\mathcal{L}$ we extract should keep alignment with the source collection, and contain informative as well as comprehensive information in C. Thus we

Table 2: The compactness of OPT-LSH

Dataset	EJE	OWS	NBA	ME
$\|C\|$-before	12049	22890	20403	10237
$\|C\|$-after	1454	2357	1187	1042
$\|\|\mathcal{L}\|\|$	87	168	113	92
Downsizing	94.0%	92.9%	90.5%	91.2%

need to verify another property of our summarization, the *Coverage*. Inspired by (Shannon C, 2001), we employ the *Information Entropy* to represent the information quantity based on solid mathematical theory. The less information quantity decreases after summarizing, the more story comprehensiveness is maintained. In this way we verify the property of coverage. Particularly, *Shannon* denotes the entropy H as follows of a discrete random variable X, which in fact is a word distribution. The base knowledge in our work is the global probability mass function $P(W_C)$ based on the entire vocabulary of C, with possible values $\{p(w_1), \ldots, p(w_{|W_C|})\}$.

$$H(X) = E\{-\log(P(W_C))\|X\} = -\sum_{w_i \in X} p(w_i)\log(p(w_i))$$

Although different word distributions may have the same H, we do not focus on the similarity of two corpora, but the difference of information quantities they are carrying. So H is an ideal criterion.

Besides the comparison of the entropies of C and $\mathcal{L}$, it gives us a chance to study different modules' contributions in our solution. There are two places that we may simplify the solution. One is the feature of temporal gap. If we set the parameter σ to $infinity$, then we can remove the second term of the calculation of Γ (i.e. $\sigma \leftarrow \infty$) and then bring out a *time-insensitive* system. The other is the cross-modal feature. We set parameter α as 1 to make the system work in one single modality, and ignore all images (only the textual sentences are available) to make up story map. The work then becomes the study with *text-bias*. We also implement the *simplest* system that blocks images as well as temporal feature. Figure 3 highlights the good performance of our system. We are maintaining information by a larger proportion of the original data collection. Considering the property of high compactness, our solution tackles the information redundancy quite well, and promisingly delivers entire knowledge with compact structure.

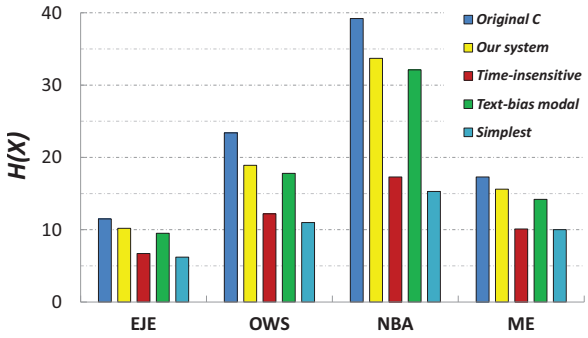

Figure 3: The y-axis denotes the entropy. And the larger H is, the richer information it brings.

During our experiments on *Coverage*, we have some interesting findings. Datasets perform differently when we take different values of σ and α, which controls the temporal decaying rate and cross-modal learning respectively. The events with short life-cycles prefer a smaller value of σ to dominate the influence from neighbors, as well as the intra-modal bias. On the contrary, long-living events prefer lager σ and more inter-modal bias to get information replenishment from different dates and modality. Due to the limited space we don't present the tuning details, but the optimal values are shown in Table 1. In fact, using the cross-modal mutual influence can, more or less, help to improve the effectiveness of information extraction and summarization.

4.3 User Study

Before we introduce other existing methods that can also tackle the cross-modal 2-dimensional summarization problem, we have to setup the appropriate standards to quantify users' evaluation.

4.3.1 Metrics

In the user study, we evaluate the effectiveness of our story maps in aiding users to integrate different aspects of multi-faceted information. (Shahaf et al., 2012) also focuses on story map generation and puts forward two convincing metrics to answer the following questions:

- *Micro-Knowledge*: Can the maps help users retrieve information faster than other methods?
- *Macro-Knowledge*: Can the maps help users understand the big picture better than other methods?

For *micro-knowledge*, we wish to see how maps help users answer specific questions. We compare the level of knowledge attained by users using our method with two other systems: *Google News* and *TDT*. Google News is a computer-generated site that aggregates headlines from news sources worldwide. News-viewing tools are dominated by portal and search approaches, and *Google News* is a typical representative of those tools. *TDT* (Nallapati et al., 2004) is a successful system which captures the rich structure and dependencies of news events.

We have noticed that making comparisons between different systems is not convincing, since the output of Google News and TDT is different both in content and in presentation (and in particular, cannot be double-blind). In order to isolate the effects of sentence selection vs. map organization, we introduce a hybrid system into the study: the system with *structureless* story map displays the same sentences and images as our system but with none of the structure. Its output is basically the same with our full system but with a single storyline and merges node content for each date. And each story nodes are sorted chronologically and displayed similarly to Google News. We implement TDT based on (Nallapati et al., 2004) (cos + TD + SimpleThresholding), and pick a representative article from each cluster. The purpose of the study is to test a single query. We also obtain the results from Google News using the same queries.

We recruit 64 volunteers to browse all the four events, and one of the four systems is assigned to each person randomly. After browsing, users are asked to answer a short questionnaire (8 questions), composed by domain experts. Users answer as many questions as possible in limited time (8 minutes). The statistics of their answers are promised to evaluate the micro-knowledge on different systems. In order to aid in comprehension, we give some examples about those asked questions. For the event of EJE, we ask that

1. *How many magnitude was initially reported by the USGS, and what about the finally report?*
2. *List at least six countries that had dispatched their rescue teams.*
3. ...

And for OWS, we ask that

Table 3: *Macro-knowledge* performance on four datasets

Dataset	Our System	Google News	TDT
EJE	56.3%	23.2%	20.5%
OWS	62.2%	22.1%	15.7%
NBA	58.3%	18.9%	22.8%
ME	47.2%	26.3%	26.5%

1. *What was the attitude of President Obama about the protesters on October?*
2. *When did the protesters begin dressing "corporate zombies" in New York?*
3. ...

These questions can effectively help us to investigate users' $micro\text{-}knowledge$ about the events.

As for *macro-knowledge*, unlike the retrieval study that evaluates users' ability to answer questions, we are interested in the use of story maps as high-level overviews, allowing users to understand the big picture. We believe that the ability to explain a certain issue is the only proof of understanding. Therefore, the 64 volunteers are then asked to write four paragraphs to summarize the four events respectively. This time, all three systems' (the structureless system presents the same content as our system) results are provided and we let users choose the sentences with complete freedom. Then we count the number of sentences they employed from each system and derive the average proportions. According to the results we can research on the macro-knowledge that different systems deliver.

4.3.2 Results

We take the time cost and the average numbers of correct answers of different systems to evaluate on the micro-knowledge. Figure 4 shows the results.

We can find out that our system outperforms the others significantly when users taking less time to learn the knowledge. The failure of structureless system proves that our work of storyline reconstruction makes lots of advantages to help reading.

On the other hand, Table 3 analyzes the statistics of macro-knowledge. It's also obvious that users would like to refer to the sentences that our system provides. A reasonable explanation is that the story maps we generate can clarify users' thoughts and views on the complicated events.

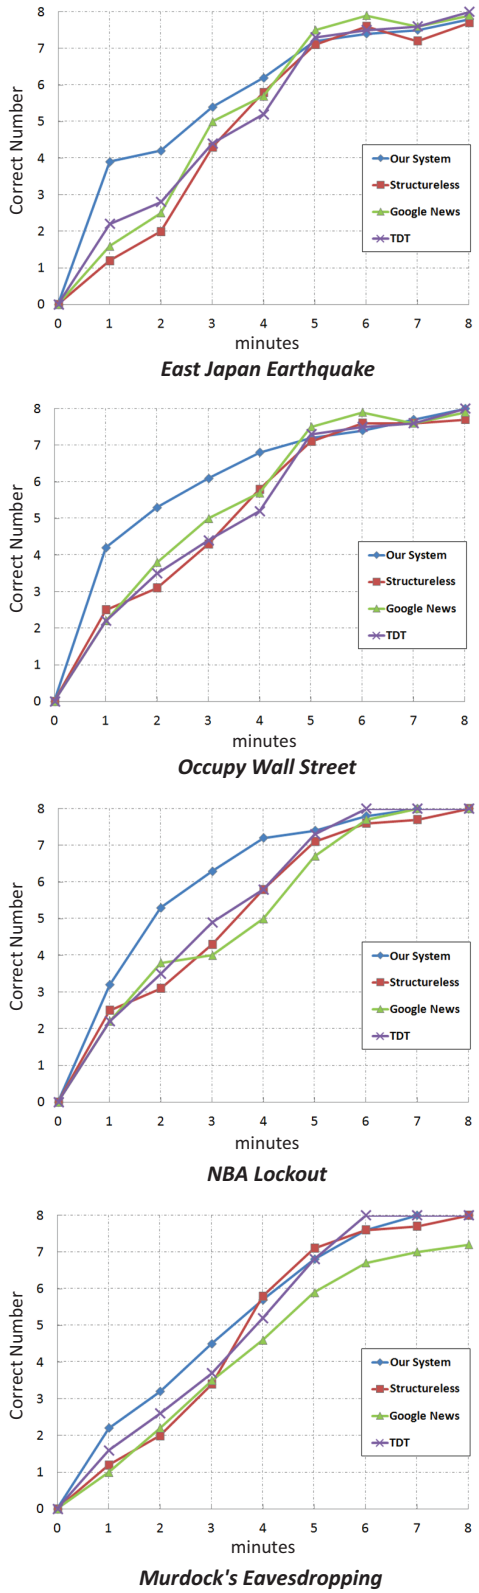

Figure 4: *Micro-knowledge* performance on four datasets

Table 4: Average runtime of different datasets

Dataset	EJE	OWS	NBA	ME
$\|C\|$	1454	2357	1187	1042
Iterations	3.5	4.7	5.4	3.7
Runtime (ms)	1582	3214	3089	1314

4.4 Runtime Analysis

At last, we analyze the time performance of our OPT-LSH algorithm on a PC server (16G RAM, 2.67GHz 4-processors CPU). The average iterations for different initial value of d' and the runtime are shown in Table 4. The results are acceptable.

5 Conclusions

In this paper, we study the feasibility of automatically generating cross-modal story maps and present a novel solution to this challenging problem. Our works mainly tackle the problems of storylines extraction and reconstruction. Specifically, we investigate two requisite properties of an ideal storyline, *Coherence* and *Diversity*. Then the convincing criteria are devised to model both. We formalize the task as an optimization problem and design an algorithm to solve it. Classical IR and text analyzing techniques like PageRank are fused into the unified framework, and a near-optimal solution is employed to deal with the NP-complete problem. Experiments on web datasets show that our method is quite efficient and competitive. We also verify that it brings quicker, clearer and deeper comprehension to users.

As a future work, we plan to adapt parameters automatically on the basis of different types of datasets. Improving the layout quality of story map by concerning the interactivity of different media (e.g. images order) is also significant. Furthermore, our framework is universal, so that the media other than text and image can be adopted as well.

Acknowledgments

We sincerely thank all the anonymous reviewers for their valuable comments, which have helped to improve this paper greatly.

Image Description using Visual Dependency Representations

Abstract

Describing the main event of an image involves identifying the objects depicted and predicting the relationships between them. Previous approaches have represented images as unstructured bags of regions, which makes it difficult to accurately predict meaningful relationships between regions. In this paper, we introduce visual dependency representations to capture the relationships between the objects in an image, and hypothesize that this representation can improve image description. We test this hypothesis using a new data set of region-annotated images, associated with visual dependency representations and gold-standard descriptions. We describe two template-based description generation models that operate over visual dependency representations. In an image description task, we find that these models outperform approaches that rely on object proximity or corpus information to generate descriptions on both automatic measures and on human judgements.

1 Introduction

Humans are readily able to produce a description of an image that correctly identifies the objects and actions depicted. Automating this process is useful for applications such as image retrieval, where users can go beyond keyword-search to describe their information needs, caption generation for improving the accessibility of existing image collections, story illustration, and in assistive technology for blind and partially sighted people. Automatic image description presents challenges on a number of levels: recognizing the objects in an image and their attributes are difficult computer vision problems; while determining how the objects interact, which relationships hold between them, and which events are depicted requires considerable background knowledge.

Previous approaches to automatic description generation have typically tackled the problem using an object recognition system in conjunction with a natural language generation component based on language models or templates (Kulkarni et al., 2011; Li et al., 2011). Some approaches have utilised the visual attributes of objects (Farhadi et al., 2010), generated descriptions by retrieving the descriptions of similar images (Ordonez et al., 2011; Kuznetsova et al., 2012), relied on an external corpus to predict the relationships between objects (Yang et al., 2011), or combined sentence fragments using a tree-substitution grammar (Mitchell et al., 2012).

A common aspect of existing work is that an image is represented as a bag of image regions. Bags of regions encode which objects co-occur in an image, but they are unable to express how the regions relate to each other, which makes it hard to describe what is happening. As an example, consider Figure 1a, which depicts a man riding a bike. If the man was instead repairing the bike, then the bag-of-regions representation would be the same, even though the image would depict a different action and would have to be described differently. This type of co-occurrence of regions indicates the need for a more structured image representation; an image description system that has access to structured repre-

Figure 1: (a) Image with regions marked up: BIKE, CAR, MAN, ROAD, TREES; (b) human-generated image description; (c) visual dependency representation expressing the relationships between MAN, BIKE, and ROAD aligned to the syntactic dependency parse of the first sentence in the human-generated description (b).

sentations would be able to correctly infer the action that is taking place, such as the distinction between repairing or riding a bike, which would greatly improve the descriptions it is able to generate.

In this paper, we introduce *visual dependency representations* (VDRs) to represent the structure of images. This representation encodes the geometric relations between the regions of an image. An example can be found in Figure 1c, which depicts the VDR for Figure 1a. It encodes that the MAN is above the BIKE, and that the BIKE is on the ROAD. These relationships make it possible to infer that the man is riding a bike down the road, which corresponds to the first sentence of the human-generated image description in Figure 1b.

In order to test the hypothesis that structured image representations are useful for description generation, we present a series of template-based image description models. Two of these models are based on approaches in the literature that represent images as bags of regions. The other two models use visual dependency representations, either on their own or in conjunction with gold-standard image descriptions at training time.

We find that descriptions generated using the VDR-based models are significantly better than those generated using bag-of-region models in automatic evaluations using smoothed BLEU scores and in human judgements. The BLEU score improvements are found at bi-, tri-, and four-gram levels, and humans rate VDR-based image descriptions 1.2 points above the next-best model on a 1–5 scale.

Finally, we also show that the benefit of the visual dependency representation is maintained when image descriptions are generated from automatically parsed VDRs. We use a modified version of the edge-factored parser of McDonald et al. (2005) to predict VDRs over a set of annotated object regions. This result reaffirms the potential utility of this representation as a means to describe events in images. Note that throughout the paper, we work with gold-standard region annotations; this makes it possible to explore the effect of structured image representations independently of automatic object detection.

2 Visual Dependency Representation

In analogy to dependency grammar for natural language syntax, we define *Visual Dependency Grammar* to describe the spatial relations between pairs of image regions. A directed arc between two regions is labelled with the spatial relationship between those regions, defined in terms of three geometric properties: pixel overlap, the angle between regions, and the distance between regions. Table 1 presents a detailed explanation of the spatial relationships defined in the grammar.

A visual dependency representation of an image is constructed by creating a directed acyclic graph

 X $\overrightarrow{on}$ Y	More than 50% of the pixels of region X overlap with region Y.[1]
 X $\overrightarrow{surrounds}$ Y	The entirety of region X overlaps with region Y.
 X $\overrightarrow{beside}$ Y	The angle between the centroid of X and the centroid of Y lies between 315° and 45° or 135° and 225°.
 X $\overrightarrow{opposite}$ Y	Similar to *beside*, but used when there X and Y are at opposite sides of the image.
 X $\overrightarrow{above}$ Y	The angle between X and Y lies between 225° and 315°.
 X $\overrightarrow{below}$ Y	The angle between X and Y lies between 45° and 135°.
 X $\overrightarrow{infront}$ Y	The Z-plane relationship between the regions is dominant.
 X $\overrightarrow{behind}$ Y	Identical to *infront* except X is behind Y in the Z-plane.

Table 1: Visual Dependency Grammar defines eight relations between pairs of annotated regions. To simplify explanation, all regions are circles, where *X* is the grey region and *Y* is the white region. All relations are considered with respect to the centroid of a region and the angle between those centroids. We follow the definition of the unit circle, in which 0° lies to the right and a turn around the circle is counter-clockwise.

over the set of regions in an image using the spatial relationships in the Visual Dependency Grammar. It is created from a region-annotated image and a corresponding image description by first identifying the central actor of the image. The central actor is the person or object carrying out the depicted action; this typically corresponds to the subject of the sentence describing the image. The region corresponding to the central actor is attached to the ROOT node of the graph. The remaining regions are then attached based on their relationship with either the actor or the other regions in the image as they are mentioned in the description. Each arc introduced is labelled with one of the spatial relations defined in the grammar, or with no label if the region is not described in relation to anything else in the image.

As an example of the output of this annotation process, consider Figure 1a, its description in 1b, and its VDR in 1c. Here, the MAN is the central actor in the image, as he is carrying out the depicted action (riding a bike). The region corresponding to MAN is therefore attached to ROOT without a spatial relation. The BIKE region is then attached to the MAN region using the $\overrightarrow{above}$ relation and BIKE is attached to the ROAD with the $\overrightarrow{on}$ relation. In the second sentence of the description, CAR and TREES are mentioned without a relationship to anything else in the image, so they are attached to the ROOT node. If these regions were attached to other regions, such as CAR $\overrightarrow{above}$ ROAD then this would imply structure in the image that is not conveyed in the description.

2.1 Data

Our data set uses the images from the PASCAL Visual Object Classification Challenge 2011 action recognition taster competition (Everingham et al., 2011). This is a closed-domain data set containing images of people performing ten types of actions, such as making a phone call, riding a bike, and taking a photo. We annotated the data set in a three-step process: (1) collect a description for each image; (2) annotate the regions in the image; and (3) create a visual dependency representation of the image. Note that Steps (2) and (3) are dependent on the image description, as both the region labels and the relations between them are derived from the description.

2.2 Image Descriptions

We collected three descriptions of each image in our data set from Amazon Mechanical Turk. Workers were asked to describe an image in two sentences. The first sentence describes the action in the image, the person performing the action and the region involved in the action; the second sentence describes any other regions in the image not directly involved in the action. An example description is given in Figure 1b.

A total of 2,424 images were described by three workers each, resulting in a total of 7,272 image de-

[1] As per the PASCAL VOC definition of overlap in the object detection task (Everingham et al., 2011).

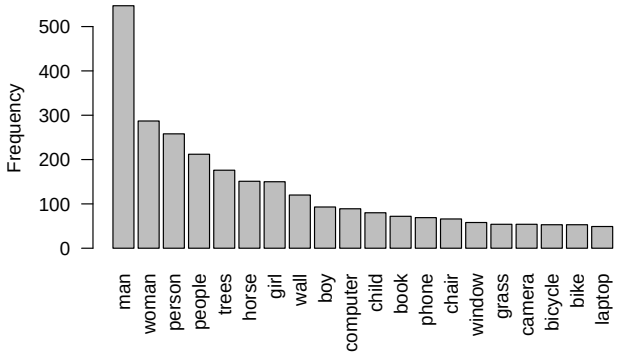

Figure 2: Top 20 annotated regions.

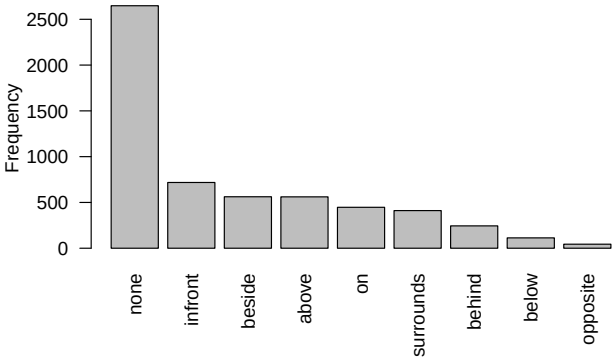

Figure 3: Distribution of the spatial relations.

scriptions. The workers, drawn from those registered in the US with a minimum HIT acceptance rate of 95%, described an average of 145 $\pm$ 93 images; they were encouraged to describe fewer than 300 images each to ensure a linguistically diverse data set. They were paid \$0.04 per image and it took on average 67 $\pm$ 123 seconds to describe a single image. The average length of a description was 19.9 $\pm$ 6.5 words in a range of 8–50 words. Dependency parses of the descriptions were produced using the MST-Parser (McDonald et al., 2005) trained on sections 2-21 of the WSJ portion of the Penn Treebank.

2.3 Region Annotations

We trained two annotators to draw polygons around the outlines of the regions in an image using the LabelMe annotation tool (Russell et al., 2008). The regions annotated for a given image were limited to those mentioned in the description paired with the image. Region annotation was performed on a subset of 341 images and resulted in a total of 5,034 annotated regions with a mean of 4.19 $\pm$ 1.94 annotations per image. A total of 496 distinct labels were used to label regions. Figure 2 shows the distribution of the top 20 region annotations in the data; people-type regions are the most commonly annotated regions. Given the prevalence of labels referring to the same types of regions, we defined 26 sets of equivalent labels to reduce label sparsity (e.g., BIKE was considered equivalent to BICYCLE). This normalization process reduced the size of the region label vocabulary from 496 labels to 362 labels. Inter-annotator agreement was 74.3% for region annotations, this was measured by computing polygon overlap over the annotated regions.

2.4 Visual Dependency Representations

The same two annotators were trained to construct gold-standard visual dependency representations for annotated image–description pairs. The process for creating a visual dependency representation of an image is described earlier in this section of the paper. The 341 region-annotated images resulted in a set of 1,023 visual dependency representations. The annotated data set comprised a total of 5,748 spatial relations, corresponding to a mean of 4.79 $\pm$ 3.51 relations per image. Figure 3 shows the distribution of spatial relation labels in the data set. It can be seen that the majority of regions are attached to the ROOT node, i.e., they have the relation label *none*. Inter-annotator agreement on a subset of the data was measured at 84% agreement for labelled dependency accuracy and 95.1% for unlabelled dependency accuracy. This suggests the task of generating visual dependency representations can be performed reliably by human annotators. We induced an alignment between the annotated region labels and words in the image description using simple lexical matching augmented with WordNet hyponym lookup. See Figure 1c for an example of the alignments.

3 Image Description Models

We present four template-based models for generating image descriptions in this section. Table 2

	Regions	VDR	External Corpus	Parallel text
PROXIMITY	✓			
CORPUS	✓		✓	
STRUCTURE	✓	✓		
PARALLEL	✓	✓		✓

Table 2: The data available to each model at training time.

T_1	DT O_i AUX REL DT O_j. T_5?
T_2	There AUX also $\{\text{DT } O_i\}_{i=1}^{\lvert unrelated \rvert}$ in the image.
T_3	DT O_i AUX REL DT O_j REL DT O_k. T_5?
T_4	REL DT O_j.
T_5	PRP AUX $\{\text{REL DT } O_i\}_{i=1}^{\lvert dependents \rvert}$.

Table 3: The language generation templates.

presents an overview of the amount of information available to each model at training time, ranging from only the annotated regions of an image to using visual dependency representation of an image aligned with the syntactic dependency representation of its description. At test time, all models have access to image regions and their labels, and use these to generate image descriptions. Two of the models also have access to VDRs at test time, allowing us to test the hypothesis that image structure is useful for generating good image descriptions.

The aim of each model is to determine what is happening in the image, which regions are important for describing it, and how these regions relate to each other. Recall that all our images depict actions, and that the gold-standard annotation was performed with this in mind. A good description therefore is one that relates the main actors depicted in the image to each other, typically through a verb; a mere enumeration of the regions in the image is not sufficient. All models attempt to generate a two-sentence description, as per the gold standard descriptions.

In the remainder of this section, we will use Figure 1 as a running example to demonstrate the type of language each model is capable of generating. All models share the set of templates in Table 3.

3.1 PROXIMITY

PROXIMITY is based on the assumption that people describe the relationships between regions that are near each other. It has access to only the annotated image regions and their labels.

Region–region relationships that are potentially relevant for the description are extracted by calculating the proximity of the annotated regions. Here, o_i is the subject region, o_j is the object region, and s_{ij} is the spatial relationship between the regions. Let $R = \{(o_i, s_{ij}, o_j), \dots\}$ be the set of possible region–region relationships found by calculating the nearest neighbour of each region in Euclidean space between the centroids of the polygons that mark the region boundaries. The tuple with the subject closest to the centre of the image is used to describe what is happening in the image, and the remaining regions are used to describe the background.

The first sentence of the description is realised with template T_1 from Table 3. o_i is the label of the subject region and o_j is the label of the object region. DT is a simple determiner chosen from {the, a}, depending on whether the region label is a plural noun; AUX is either {is, are}, depending on the number of the region label; and REL is a word to describe the relationship between the regions. For this model, REL is the spatial relationship between the centroids chosen from {above, below, beside}, depending on the angle formed between the region centroids, using the definitions in Table 1. The second sentence of the description is realised with template T_2 over the subjects o_i in R that were not used in the first sentence. An example of the language generated is:

(1) The man is beside the bike. There is also a road, a car, and trees in the image.

With the exception of visual attributes to describe size, colour, or texture, this model is based on the approach described by Kulkarni et al. (2011).

3.2 CORPUS

The biggest limitation of PROXIMITY is that regions that are near each other are not always in a relevant relationship for a description. For example, in Figure 1, the BIKE and the CAR regions are nearest neighbours but they are unlikely to be described as being in an relationship by a human annotator. The model CORPUS addresses this issue by using an

external text corpus to determine which pairs of regions are likely to be in a describable relationship. Furthermore, CORPUS can generate verbs instead of spatial relations between regions, leading to more human-like descriptions. CORPUS is based on Yang et al. (2011), except we do not use scene type (indoor, outdoor, etc.) as part of the model. At training time, the model has access to the annotated image regions and labels, and to the dependency-parsed version of the English Gigaword Corpus (Napoles et al., 2012). The corpus is used to extract subject–verb–object subtrees, which are then used to predict the best pairs of regions, as well as the verb that relates the regions.

The set of region–region relationships $\mathrm{R} = \{(\mathrm{o}_i, \mathrm{v}_{ij}, \mathrm{o}_j), \dots\}$ is determined by searching for the most likely o_j^*, v^* given an o_i over a set of verbs $\mathcal{V}$ extracted from the corpus and the other regions in the image. This is shown in Equation 1.

$$o_j^*, v^* | o_i = \arg\max_{o_j, v} p(o_i) \cdot p(v|o_i) \cdot p(o_j|v, o_i) \quad (1)$$

We can easily estimate $p(o_i)$, $p(v|o_i)$, and $p(o_j|v, o_i)$ directly from the corpus. If we cannot find an o_j^*, v^* for a region, we back-off to the spatial relationship calculation as defined in PROXIMITY. When we have found the best pairs of regions, we select the most probable pair and generate the first sentence of the description using that pair an template T_1. The second sentence is realised with template T_2 over the subjects in R not used in generating the first sentence. An example of the language generated is:

(2) The man is riding the bike. There is also a car, a road, and trees in the image.

In comparison to PROXIMITY, this model will only describe pairs of regions that have observed relations in the external corpus. The corpus also provides a verb that relates the regions, which produces descriptions that are more in line with human-generated text. However, since noun co-occurrence in the corpus controls which regions can be mentioned in the description, this model will be prone to relating regions simply because their labels occur together frequently in the corpus.

3.3 STRUCTURE

The model STRUCTURE exploits the visual dependency representation of an image to generate language for only the relationships that hold between pairs of regions. It has access to the image regions, the region labels, and the visual dependency representation of an image.

Region–region relationships are generated during a depth-first traversal of the VDR using templates T_1, T_3, T_4, and T_5. The VDR of an image is traversed and language fragments are generated and then combined depending on the number of children of a node in the tree. If a node has only one child then we use T_1 to generate text for the head-child relationship. If a node has more than one child, we need to decide how to order the language generated by the model. We generate sentence fragments using T_4 for each child independently and combine them later. In STRUCTURE, the sentence fragments are sorted by the Euclidean distance of the children from the parent. In order to avoid problematic descriptions such as *"The woman is above the horse is above the field is beside the house"*, we include a special case for when a node has more than one child. In these cases, the nearest region is realized in direct relation to the head using either T_3 (two children) or T_1 (more than two children), and the remaining regions form a separate sentence using T_5. This sorting and combing process would result in *"The woman is above the horse. She is above field and beside the house"* for the case mentioned above.

An example of the type of description that can be generated during a traversal is:

(3) The man is above the bike above the road. There is also a car and trees in the image.

In comparison to PROXIMITY, this model can exploit a representation of an image that encodes the relationships between regions in an image (the VDR). However, it is limited to generating spatial relations, because it cannot predict verbs to relate regions.

3.4 PARALLEL

The model PARALLEL is an extension of STRUCTURE that uses the image descriptions available to

predict verbs that relate regions in parent-child relationships in a VDR. At training time it has access to the annotated regions and labels, the visual dependency representations, and the gold-standard image descriptions. Recall from Section 2.1 that the descriptions were dependency-parsed using the parser of McDonald et al. (2005) and alignments were calculated between the nodes in the VDRs and the words in the parsed image descriptions.

We estimate two distributions from the image descriptions using the alignments: $p(verb|o_{head}, o_{child}, rel_{head-child})$ and $p(verb|o_{head}, o_{child})$. The second distribution is used as a backoff when we do not observe the arc label between the regions in the training data. The generation process is similar to that used in STRUCTURE, with two exceptions: (1) it can generate verbs during the generation steps, and (2) when a node has multiple dependents, the sentence fragments are sorted by the probability of the verb associated with them. This sorting step governs which child is in a relationship with its parent. When the model generates text, it only generates a verb for the most probable sentence fragment. The remaining fragments revert back to spatial relationships to avoid generating language that places the subject region in multiple relationships with other regions. An example of the language generated is:

(4) The man is riding the bike on the road. There is also a car and trees in the image.

In comparison to CORPUS, this model generates descriptions in which the relations between the regions determined by the image itself and not by an external corpus. In comparison to PROXIMITY and STRUCTURE, this model generates descriptions that express meaningful relations between the regions and not simple spatial relationships.

4 Image Parsing

The STRUCTURE and PARALLEL models rely on visual dependency representations, but it is unrealistic to assume gold-standard representations will always be available because they are expensive to construct. In this section we describe an image parser that can induce VDRs automatically from region-annotated images, providing the input for the STRUCTURE-PARSED and PARALLEL-PARSED models at test time.

The parser is based on the arc-factored dependency parsing model of McDonald et al. (2005). This model generates a dependency representation by maximizing the score s computed over all edges of the representation. In our notation, $\mathbf{x}_{vis}$ is the set of annotated regions and y_{vis} is a visual dependency representation of the image; (i, j) is a directed arc from node i to node j in $\mathbf{x}_{vis}$, $\mathbf{f}(i, j)$ is a feature representation of the arc (i, j), and $\mathbf{w}$ is a vector of feature weights to be learned by the model. The overall score of a visual dependency representation is:

$$s(\mathbf{x}_{vis}, y_{vis}) = \sum_{(i,j) \in y_{vis}} \mathbf{w} \cdot \mathbf{f}(i, j) \quad (2)$$

The features in the model are defined over region labels in the visual dependency representation as well as the relationship labels. As our dependency representations are unordered, none of the features encode the linear order of region labels, unlike the feature set of the original model. Unigram features describe how likely individual region labels are to appear as either heads or arguments and bigram feature captures which region labels are in head-argument relationships. All features are conjoined with the relationship label.

We evaluate our parser on the 1,023 visual dependency representations from the data set. The evaluation is run over 10 random splits into 80% training, 10% development, and 10% test data.[2] Performance is measured with labelled and unlabelled directed dependency accuracy. The parser achieves 58.2% $\pm$ 3.1 labelled accuracy and 65.5% $\pm$ 3.3 unlabelled accuracy, significantly better than the baseline of 51.6% $\pm$ 2.5 for both labelled and unlabelled accuracy (the baseline was calculated by attaching all image regions to the root node; this is the most frequent form of attachment in our data).

5 Language Generation Experiments

We evaluate the image description models in an automatic setting and with human judgements. In

[2]Different visual dependency representations of the same image are never split between the training and test data.

	Automatic Evaluation				Human Judgements		
	BLEU-1	BLEU-2	BLEU-3	BLEU-4	Grammar	Action	Scene
PARALLEL-PARSED	45.4 ± 2.0	$\mathbf{16.1 \pm 0.9}$	$\mathbf{6.4 \pm 0.7}$	$\mathbf{2.7 \pm 0.5}$	4.2 ± 1.3	$\mathbf{3.3 \pm 1.7}$	3.5 ± 1.3
PROXIMITY	45.1 ± 0.8	$10.2 \pm 1.0^\star$	$2.1 \pm 0.6^\star$	$0.4 \pm 0.2^\star$	$3.7 \pm 1.5^\star$	$2.1 \pm 0.3^\star$	$3.0 \pm 1.4^\star$
CORPUS	46.1 ± 1.1	$12.4 \pm 1.3^\star$	$3.1 \pm 0.8^\star$	$0.7 \pm 0.3^\star$	4.4 ± 1.1	$2.2 \pm 1.3^\star$	3.4 ± 1.3
STRUCTURE	$40.2 \pm 3.0^\star$	$11.5 \pm 1.2^\star$	$3.5 \pm 0.5^\star$	$0.3 \pm 0.1^\star$	4.1 ± 1.4	$2.1 \pm 1.4^\star$	$3.0 \pm 1.4^\star$
STRUCTURE-PARSED	$41.1 \pm 2.1^\star$	$12.2 \pm 0.9^\star$	$3.6 \pm 0.4^\star$	$0.4 \pm 0.2^\star$	4.0 ± 1.4	$1.6 \pm 1.3^\star$	3.2 ± 1.3
PARALLEL	44.6 ± 3.1	16.0 ± 1.5	6.8 ± 1.0	2.9 ± 0.7	$4.5 \pm 1.0^\star$	3.4 ± 1.6	3.7 ± 1.3
GOLD	-	-	-	-	$4.8 \pm 0.4^\star$	$4.8 \pm 0.6^\star$	$4.6 \pm 0.7^\star$

Table 4: Automatic evaluation results averaged over 10 random test splits of the data, and human judgements on the median scoring BLEU-4 test split for PARALLEL. We find significant differences ($^\star p < 0.05$) in the descriptions generated by PARALLEL-PARSED compared to models that operate over an unstructured bag of image regions representation. **Bold** means PARALLEL-PARSED is significantly better than PROXIMITY, CORPUS, and STRUCTURE.

the automatic setting, we follow previous work and measure how close the model-generated descriptions are to the gold-standard descriptions using the BLEU metric. Human judgements were collected from Amazon Mechanical Turk.

5.1 Methodology

The task is to produce a description of an image. The PROXIMITY and CORPUS models have access to gold-standard region labels and region boundaries at test time. The STRUCTURE and PARALLEL models have additional access to the visual dependency representation of the image. These representations are either the gold-standard, or in the case of STRUCTURE-PARSED and PARALLEL-PARSED, produced by the image parser described in Section 4. Table 2 provides a reminder of the information the different models have access to at training time.

Our data set of 1,023 image–description–VDR tuples was randomly split into 10 folds of 80% training data, 10% development data, and 10% test data. The results we report are means computed over the 10 splits. The image parser used for models STRUCTURE-PARSED and PARALLEL-PARSED is trained on the gold-standard VDRs of the training splits, and then predicts VDRs on the development and test splits. Significant differences were measured using a one-way ANOVA with PARALLEL-PARSED as the reference[3], with differences between pairs of mean checked with a Tukey HSD test.

5.2 Automatic Evaluation

The model-generated descriptions are compared against the human-written gold-standard descriptions using the smoothed BLEU measure (Lin and Och, 2004). BLEU is commonly used in machine translation experiments to measure the effective overlap between a reference sentence and a proposed translation sentence. Table 4 shows the results on the test data and Figure 4 shows sample outputs for two images. PARALLEL, the model with access to both image structure and aligned image descriptions at training time outperforms all other models on higher-order BLEU measures. One reason for this improvement is that PARALLEL can formulate sentence fragments that relate the subject, a verb, and an object without trying to predict the best object, unlike CORPUS. The probability associated with each fragment generated for nodes with multiple children also tends to lead to a more accurate order of mentioning image regions. It can also be seen that PARALLEL-PARSED remains significantly better than the other models when the VDRs of images are predicted by an image parser, rather than being gold-standard.

[3]Recall that PARALLEL uses gold-standard VDRs and PARALLEL-PARSED uses the output of the image parser described in Section 4.

The weakest results are obtained from a model that relies on the proximity of regions to generate descriptions. PROXIMITY achieves competitive BLEU-1 scores but this is mostly due to it correctly generating region names and determiners. CORPUS is better than PROXIMITY at correctly producing higher-order n-grams than because it has a better model of the region–region relationships in an image. However, it has difficulties guessing the correct verb for a description, as it relies on corpus co-occurrences for this (see the second example in Table 4). STRUCTURE uses the VDR of an image to generate the description, which this leads to an improvement over PROXIMITY on some of the BLEU metrics; however, it is not sufficient to outperform CORPUS.

5.3 Human Judgements

We conducted a human judgement study on Mechanical Turk to complement the automatic evaluation. Workers were paid $0.05 to rate the quality of an image–description pair generated by one of the models using three criteria on a scale from 1 to 5:

1. Grammaticality: give high scores if the description is correct English and doesn't contain any grammatical mistakes.
2. Action: give high scores if the description correctly describes what people are doing in the image.
3. Scene: give high scores if the description correctly describes the rest of the image (background, other objects, etc).

A total of 101 images were used for this evaluation and we obtained five judgments for each image-description pair, resulting in a total of 3,535 judgments. To ensure a fair evaluation, we chose the images from the split of the data that gave median BLEU-4 accuracy for PARALLEL, the best performing model in the automatic evaluations.

The right side of Table 4 shows the mean judgements for each model for across the three evaluation criteria. The gold-standard descriptions elicited judgements around five, and were significantly better than the model outputs on all aspects. Furthermore, all models produce highly grammatical output, with mean ratings of between 3.7 and 4.5. This can be explained by the fact that the models all relied on templates to ensure grammatical output.

The ratings of the action descriptions reveal the usefulness of structural information. PROXIMITY, CORPUS, and STRUCTURE all perform badly with mean judgements around two, PARALLEL, which uses both image structure and aligned descriptions, significantly outperforms all other models with the exception of PARALLEL-PARSED, which has very similar performance. The fact that PARALLEL and PARALLEL-PARSED perform similarly on all three human measures confirms that automatically parsed VDRs are as useful for image description as gold-standard VDRs.

When we compare the quality of the scene descriptions, we notice that all models perform similarly, around the middle of the scale. This is probably due to the fact that they all have access to gold-standard region labels, which enables them to correctly refer to regions in the scene most of the time. The additional information about the relationships between regions that STRUCTURE and PARALLEL have access to does not improve the quality of the background scene description.

6 Related Work

Previous work on image description can be grouped into three approaches: description-by-retrieval, description using language models, and template-based description. Ordonez et al. (2011), Farhadi et al. (2010), and Kuznetsova et al. (2012) generate descriptions by retrieving the most similar image from a large data set of images paired with descriptions. These approaches are restricted to generating descriptions that are only present in the training set; also, they typically require large amounts of training data and assume images that share similar properties (scene type, objects present) should be described in a similar manner.

Kulkarni et al. (2011) and Li et al. (2011) generate descriptions using n-gram language models trained on a subset of Wikipedia. Both approaches first determine the attributes and relationships between regions in an image as region–preposition–region triples. The disadvantage of relying on region–preposition–region triples is that they cannot distinguish between the main event of the image and the

PROXIMITY	A man is beside a phone. There is also a wall and a sign in the image.
CORPUS	A man is holding a sign. There is also a wall and a phone in the image.
STRUCTURE	A wall is above a wall. A man is beside a sign.
PARALLEL	A man is holding a phone. A wall is beside a sign.

PROXIMITY	A beach is above a beach. There are also horses, a woman, and a man in the image.
CORPUS	A woman is outnumbering a man. There are also horses and beaches in the image.
STRUCTURE	A man is beside a woman above a horse. A horse is beside a woman beside a beach.
PARALLEL	A man is riding a horse above a beach. A horse is beside a beach beside a woman.
GOLD	There is a man and women both on horses. They are on a beach during the day.

Figure 4: Some example descriptions produced by PROXIMITY, CORPUS, STRUCTURE and PARALLEL.

background regions. Kulkarni et al. (2011) is closely related to our PROXIMITY baseline.

Yang et al. (2011) fill in a sentence template by selecting the likely objects, verbs, prepositions, and scene types based on a Hidden Markov Model. Verbs are generated by finding the most likely pairing of object labels in an external corpus. This model is closely related to our CORPUS baseline. Mitchell et al. (2012) over-generates syntactically well-formed sentence fragments and then recombines these using a tree-substitution grammar.

Previous research has relied extensively on automatically detecting object regions in an image using state-of-the art object detectors (Felzenszwalb et al., 2010). We use gold-standard region annotations to remove this noisy component from the description generation pipeline, allowing us to focus on the utility of image structure for description generation.

7 Conclusion

In this paper we introduced a novel representation of an image as a set of dependencies over its annotated regions. This *visual dependency representation* encodes which regions are related to each other in an image, and can be used to infer the action or event that is depicted. We found that image description models based on visual dependency representations significantly outperform competing models in both automatic and human evaluations. We showed that visual dependency representations can be induced automatically using a standard dependency parser and that the descriptions generated from the induced representations are as good as the ones generated from gold-standard representations. Future work will focus on improvements to the image parser, on exploring this representation in open-domain data sets, and on using the output of an object detector to obtain a fully automated model.

Abstract

In current dependency parsing models, conventional features (i.e. base features) defined over surface words and part-of-speech tags in a relatively high-dimensional feature space may suffer from the data sparseness problem and thus exhibit less discriminative power on unseen data. In this paper, we propose a novel semi-supervised approach to addressing the problem by transforming the base features into high-level features (i.e. meta features) with the help of a large amount of automatically parsed data. The meta features are used together with base features in our final parser. Our studies indicate that our proposed approach is very effective in processing unseen data and features. Experiments on Chinese and English data sets show that the final parser achieves the best-reported accuracy on the Chinese data and comparable accuracy with the best known parsers on the English data.

1 Introduction

In recent years, supervised learning models have achieved lots of progress in the dependency parsing task, as can be found in the CoNLL shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). The supervised models take annotated data as training data, utilize features defined over surface words, part-of-speech tags, and dependency trees, and learn the preference of features via adjusting feature weights.

In the supervised learning scenarios, many previous studies explore rich feature representation that leads to significant improvements. McDonald and Pereira (2006) and Carreras (2007) define second-order features over two adjacent arcs in second-order graph-based models. Koo and Collins (2010) use third-order features in a third-order graph-based model. Bohnet (2010) considers information of more surrounding words for the graph-based models, while Zhang and Nivre (2011) define a set of rich features including the word valency and the third-order context features for transition-based models. All these models utilize richer and more complex feature representations and achieve better performance than the earlier models that utilize the simpler features (McDonald et al., 2005; Yamada and Matsumoto, 2003; Nivre and Scholz, 2004). However, the richer feature representations result in a high-dimensional feature space. Features in such a space may suffer from the data sparseness problem and thus have less discriminative power on unseen data. If input sentences contain unknown features that are not included in training data, the parsers can usually give lower accuracy.

Several methods have been proposed to alleviate this problem by using large amounts of unannotated data, ranging from self-training and co-training (McClosky et al., 2006; Sagae and Tsujii, 2007) to more complex methods that collect statistical information from unannotated sentences and use them as additional features (Koo et al., 2008; Chen et al., 2009).

In this paper, we propose an alternative approach to semi-supervised dependency parsing via feature transformation (Ando and Zhang, 2005). More

specifically, we transform base features to a higher-level space. The base features defined over surface words, part-of-speech tags, and dependency trees are high dimensional and have been explored in the above previous studies. The higher-level features, which we call meta features, are low dimensional, and newly defined in this paper. The key idea behind is that we build connections between known and unknown base features via the meta features. From another viewpoint, we can also interpret the meta features as a way of doing feature smoothing.

Our feature transfer method is simpler than that of Ando and Zhang (2005), which is based on splitting the original problem into multiple auxiliary problems. In our approach, the base features are grouped and each group relates to a meta feature. In the first step, we use a baseline parser to parse a large amount of unannotated sentences. Then we collect the base features from the parse trees. The collected features are transformed into predefined discrete values via a transformation function. Based on the transformed values, we define a set of meta features. Finally, the meta features are incorporated directly into parsing models.

To demonstrate the effectiveness of the proposed approach, we apply it to the graph-based parsing models (McDonald and Nivre, 2007). We conduct experiments on the standard data split of the Penn English Treebank (Marcus et al., 1993) and the Chinese Treebank Version 5.1 (Xue et al., 2005). The results indicate that the approach significantly improves the accuracy. In summary, we make the following contributions:

- We define a simple yet useful transformation function to transform base features to meta features automatically. The meta features build connections between known and unknown base features, and relieve the data sparseness problem.
- Compared to the base features, the number of meta features is remarkably small.
- We build semi-supervised dependency parsers that achieve the best accuracy on the Chinese data and comparable accuracy with the best known systems on the English data.

The rest of this paper is organized as follows. Section 2 introduces the graph-based parsing model. Section 3 describes the meta features and meta parser. Section 4 describes the experiment settings and reports the experimental results on English and Chinese data sets. Section 5 discusses related work. Finally, in Section 6 we summarize the proposed approach.

2 Baseline parser

In this section, we introduce a graph-based parsing model proposed by McDonald et al. (2005) and build a baseline parser.

2.1 Graph-based parsing model

Given an input sentence, dependency parsing is to build a dependency tree. We define X as the set of possible input sentences, Y as the set of possible dependency trees, and $D = (x_1, y_1), ..., (x_i, y_i), ..., (x_n, y_n)$ as a training set of n pairs of $x_i \in X$ and $y_i \in Y$. A sentence is denoted by $x = (w_0, w_1, ..., w_i, ..., w_m)$, where w_0 is ROOT and does not depend on any other word and w_i refers to a word.

In the graph-based model, we define ordered pair $(w_i, w_j) \in y$ as a dependency relation in tree y from word w_i to word w_j (w_i is the head and w_j is the dependent), G_x as a graph that consists of a set of nodes $V_x = \{w_0, w_1, ..., w_i, ..., w_m\}$ and a set of arcs (edges) $E_x = \{(w_i, w_j) | i \neq j, w_i \in V_x, w_j \in (V_x - \{w_0\})\}$. The parsing model of McDonald et al. (2005) is to search for the maximum spanning tree (MST) in graph G_x. We denote $Y(G_x)$ as the set of all the subgraphs of G_x that are valid dependency trees (McDonald and Nivre, 2007) for sentence x.

We define the score of a dependency tree $y \in Y(G_x)$ to be the sum of the subgraph scores,

$$score(x, y) = \sum_{g \in y} score(x, g) \quad (1)$$

where g is a spanning subgraph of y, which can be a single arc or adjacent arcs. In this paper we assume the dependency tree to be a spanning projective tree. The model scores each subgraph using a linear representation. Then scoring function $score(x, g)$ is,

$$score(x, g) = \mathbf{f}(x, g) \cdot \mathbf{w} \quad (2)$$

where $\mathbf{f}(x, g)$ is a high-dimensional feature vector based on features defined over g and x and $\mathbf{w}$ refers to the weights for the features.

The maximum spanning tree is the highest scoring tree in $Y(G_x)$. The task of decoding algorithms in the parsing model for an input sentence x is to find y^*, where

$$\begin{aligned} y^* &= \arg\max_{y \in Y(G_x)} score(x, y) \\ &= \arg\max_{y \in Y(G_x)} \sum_{g \in y} score(x, g) \\ &= \arg\max_{y \in Y(G_x)} \sum_{g \in y} \mathbf{f}(x, g) \cdot \mathbf{w} \end{aligned} \quad (3)$$

In our system, we use the decoding algorithm proposed by Carreras (2007), which is a second-order CKY-style algorithm (Eisner, 1996) and feature weights **w** are learned during training using the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; McDonald et al., 2005).

2.2 Base features

Previous studies have defined different sets of features for the graph-based parsing models, such as the first-order features defined in McDonald et al. (2005), the second-order parent-siblings features defined in McDonald and Pereira (2006), and the second-order parent-child-grandchild features defined in Carreras (2007). Bohnet (2010) explorers a richer set of features than the above sets. We further extend the features defined by Bohnet (2010) by introducing more lexical features as the base features. The base feature templates are listed in Table 1, where h, d refer to the head, the dependent respectively, c refers to d's sibling or child, b refers to the word between h and d, $+1$ (-1) refers to the next (previous) word, w and p refer to the surface word and part-of-speech tag respectively, $[wp]$ refers to the surface word or part-of-speech tag, $d(h, d)$ is the direction of the dependency relation between h and d, and $d(h, d, c)$ is the directions of the relation among h, d, and c. We generate the base features based on the above templates.

2.3 Baseline parser

We train a parser with the base features as the Baseline parser. We define $\mathbf{f}_b(x, g)$ as the base features and $\mathbf{w}_b$ as the corresponding weights. The scoring function becomes,

$$score(x, g) = \mathbf{f}_b(x, g) \cdot \mathbf{w}_b \quad (4)$$

3 Meta features

In this section, we propose a semi-supervised approach to transform the features in the base feature space (F_B) to features in a higher-level space (F_M) with the following properties:

- The features in F_M are able to build connections between known and unknown features in F_B and therefore should be highly informative.
- The transformation should be learnable based on a labeled training set and an automatically parsed data set, and automatically computable for the test sentences.

The features in F_M are referred to as meta features. In order to perform the feature transformation, we choose to define a simple yet effective mapping function. Based on the mapped values, we define feature templates for generating the meta features. Finally, we build a new parser with the base and meta features.

3.1 Template-based mapping function

We define a template-based function for mapping the base features to predefined discrete values. We first put the base features into several groups and then perform mapping.

We have a set of base feature templates T_B. For each template $T_i \in T_B$, we can generate a set of base features F_i from dependency trees in the parsed data, which is automatically parsed by the Baseline parser. We collect the features and count their frequencies. The collected features are sorted in decreasing order of frequencies. The mapping function for a base feature f_b of F_i is defined as follows,

$$\Phi(f_b) = \begin{cases} H_i & \text{if } R(f_b) \leq \text{TOP10} \\ M_i & \text{if TOP10} < R(f_b) \leq \text{TOP30} \\ L_i & \text{if TOP30} < R(f_b) \\ O_i & \text{Others} \end{cases}$$

where $R(f_b)$ is the position number of f_b in the sorted list, "Others" is defined for the base features that are not included in the list, and TOP10 and TOP 30 refer to the position numbers of top 10% and top 30% respectively. The numbers, 10% and 30%, are tuned on the development sets in the experiments. For a base feature generated from template T_i, we have four possible values: H_i, M_i, L_i, and O_i. In

Table 1: Base feature templates

total, we have $4 \times N(T_B)$ possible values for all the base features, where $N(T_B)$ refers to the number of the base feature templates, which is usually small. We can obtain the mapped values of all the collected features via the mapping function.

3.2 Meta feature templates

Based on the mapped values, we define meta feature templates in F_M for dependency parsing. The meta feature templates are listed in Table 2, where f_b is a base feature of F_B, h_p refers to the part-of-speech tag of the head and h_w refers to the surface word of the head. Of the table, the first template uses the mapped value only, the second and third templates combine the value with the head information. The number of the meta features is relatively small. It has $4 \times N(T_B)$ for the first type, $4 \times N(T_B) \times N(POS)$ for the second type, and $4 \times N(T_B) \times N(WORD)$ for the third one, where $N(POS)$ refers to the number of part-of-speech tags, $N(WORD)$ refers to the number of words. We remove any feature related to the surface form if the word is not one of the Top-N most frequent words in the training data. We used N=1000 for the experiments for this paper. This method can reduce the size of the feature sets. The empirical statistics of the feature sizes at Section 4.2.2 shows that the size of meta features is only 1.2% of base features.

$[\Phi(f_b)]$
$[\Phi(f_b)], h_p$
$[\Phi(f_b)], h_w$

Table 2: Meta feature templates

3.3 Generating meta features

We use an example to demonstrate how to generate the meta features based on the meta feature templates in practice. Suppose that we have sentence "I ate the meat with a fork." and want to generate the meta features for the relation among "ate", "meat", and "with", where "ate" is the head, "meat" is the dependent, and "with" is the closest left sibling of "meat". Figure 1 shows the example.

We demonstrate the generating procedure using template T_k = "$h_w, d_w, c_w, d(h, d, c)$" (the second template of Table 1-(c)), which contains the surface forms of the head, the dependent, its sibling, and the directions of the dependencies among h, d, and c. We can have a base feature "ate, meat, with, RIGHTSIB", where "RIGHTSIB" refers to the parent-siblings structure with the right direction. In the auto-parsed data, this feature occurs 200 times and ranks between TOP10 and TOP30. Accord-

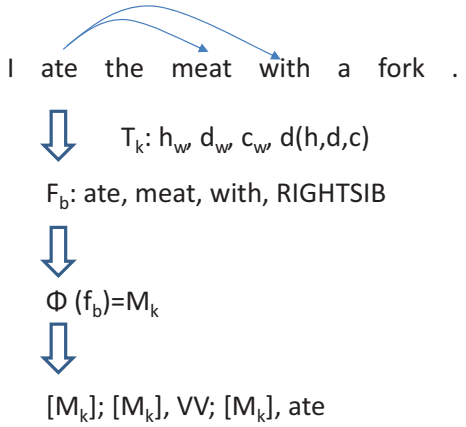

Figure 1: An example of generating meta features

ing to the mapping function, we obtain the mapped value M_k. Finally, we have the three meta features "$[M_k]$", "$[M_k], VV$", and "$[M_k], ate$", where VV is the part-of-speech tag of word "ate". In this way, we can generate all the meta features for the graph-based model.

3.4 Meta parser

We combine the base features with the meta features by a new scoring function,

$$score(x, g) = \mathbf{f}_b(x, g) \cdot \mathbf{w}_b + \mathbf{f}_m(x, g) \cdot \mathbf{w}_m \quad (5)$$

where $\mathbf{f}_b(x, g)$ refers to the base features, $\mathbf{f}_m(x, g)$ refers to the meta features, and $\mathbf{w}_b$ and $\mathbf{w}_m$ are their corresponding weights respectively. The feature weights are learned during training using MIRA (Crammer and Singer, 2003; McDonald et al., 2005). Note that $\mathbf{w}_b$ is also retrained here.

We use the same decoding algorithm in the new parser as in the Baseline parser. The new parser is referred to as the meta parser.

4 Experiments

We evaluated the effect of the meta features for the graph-based parsers on English and Chinese data.

4.1 Experimental settings

In our experiments, we used the Penn Treebank (PTB) (Marcus et al., 1993) for English and the Chinese Treebank version 5.1 (CTB5) (Xue et al., 2005) for Chinese. The tool "Penn2Malt"[1] was used to convert the data into dependency structures with the English head rules of Yamada and Matsumoto (2003) and the Chinese head rules of Zhang and Clark (2008). We followed the standard data splits as shown in Table 3. Following the work of Koo et al. (2008), we used a tagger trained on training data to provide part-of-speech (POS) tags for the development and test sets, and used 10-way jackknifing to generate part-of-speech tags for the training set. We used the MXPOST (Ratnaparkhi, 1996) tagger for English and the CRF-based tagger for Chinese. We used gold standard segmentation in the CTB5. The data partition of Chinese were chosen to match previous work (Duan et al., 2007; Li et al., 2011; Hatori et al., 2011).

	train	dev	test
PTB (sections)	2-21	22	23
CTB5 (files)	001-815 1001-1136	886-931 1148-1151	816-885 1137-1147

Table 3: Standard data splits

For the unannotated data in English, we used the BLLIP WSJ corpus (Charniak et al., 2000) containing about 43 million words.[2] We used the MXPOST tagger trained on the training data to assign part-of-speech tags and used the Baseline parser to process the sentences of the Brown corpus. For the unannotated data in Chinese, we used the Xinhua portion of Chinese Gigaword[3] Version 2.0 (LDC2009T14) (Huang, 2009), which has approximately 311 million words. We used the MMA system (Kruengkrai et al., 2009) trained on the training data to perform word segmentation and POS tagging and used the Baseline parser to parse the sentences in the Gigaword data.

In collecting the base features, we removed the features which occur only once in the English data and less than four times in the Chinese data. The feature occurrences of one time and four times are based on the development data performance.

We measured the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of to-

[1] http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html

[2] We ensured that the text used for building the meta features did not include the sentences of the Penn Treebank.

[3] We excluded the sentences of the CTB data from the Gigaword data.

kens (excluding all punctuation tokens) with the correct HEAD. We also reported the scores on complete dependency trees evaluation (COMP).

4.2 Feature selection on development sets

We evaluated the parsers with different settings on the development sets to select the meta features.

4.2.1 Different models vs meta features

In this section, we investigated the effect of different types of meta features for the models trained on different sizes of training data on English.

There are too many base feature templates to test one by one. We divided the templates into several categories. Of Table 1, some templates are only related to part-of-speech tags (P), some are only related to surface words (W), and the others contain both part-of-speech tags and surfaces (M). Table 4 shows the categories, where numbers $[1-4]$ refer to the numbers of words involved in templates. For example, the templates of N3WM are related to three words and contain the templates of W and M. Based on different categories of base templates, we have different sets of meta features.[4]

Category	Example
N1P	$h_p, d(h,d)$
N1WM	$h_w, d(h,d)$; $h_w, h_p, d(h,d)$
N2P	$h_p, d_p, d(h,d)$
N2WM	$h_w, d_w, d(h,d)$; $h_w, d_p, d(h,d)$
N3P	$h_p, d_p, c_p, d(h,d,c)$
N3WM	$h_w, d_w, c_w, d(h,d,c)$; $d_w, d_{+1p}, c_p, d(h,d,c)$
N4P	$h_p, h_{+1p}, c_p, c_{+1p}, d(h,d,c)$
N4WM	$h_w, h_{+1w}, c_w, c_{+1w}, d(h,d,c)$; $h_w, h_{+1p}, c_p, c_{+1p}, d(h,d,c)$

Table 4: Categories of base feature templates

We randomly selected 1% and 10% of the sentences respectively from the training data. We trained the POS taggers and Baseline parsers on these small training data and used them to process the unannotated data. Then, we generated the meta features based on the newly auto-parsed data. The meta parsers were trained on the different subsets of the training data with different sets of meta features. Finally, we have three meta parsers: MP1, MP10, MPFULL, which were trained on 1%, 10% and 100% of the training data.

	MP1	MP10	MPFULL
Baseline	82.22	89.50	93.01
+N1P	82.42	89.48	93.08
+N1WM	82.80	89.42	93.19
+N2P	81.29	89.01	93.02
+N2WM	82.69	90.10	93.23
+N3P	83.32	89.73	93.05
+N3WM	84.47	90.75	93.80
+N4P	82.73	89.48	93.01
+N4WM	84.07	90.42	93.67
OURS	85.11	91.14	93.91

Table 5: Effect of different categories of meta features

Table 5 shows the results, where we add each category of Table 4 individually. From the table, we found that the meta features that are only related to part-of-speech tags did not always help, while the ones related to the surface words were very helpful. We also found that MP1 provided the largest relative improvement among the three settings. These suggested that the more sparse the base features were, the more effective the corresponding meta features were. Thus, we built the final parsers by adding the meta features of N1WM, N2WM, N3WM, and N4WM. The results showed that OURS achieved better performance than the systems with individual sets of meta features.

4.2.2 Different meta feature types

In Table 2, there are three types of meta feature templates. Here, the results of the parsers with different settings are shown in Table 6, where CORE refers to the first type, WithPOS refers to the second one, and WithWORD refers to the third one. The results showed that with all the types the parser (OURS) achieved the best. We also counted the numbers of the meta features. Only 327,864 (or 1.2%) features were added into OURS. Thus, we used all the three types of meta features in our final meta parsers.

[4]We also tested the settings of dividing WM into two subtypes: W and M. The results showed that both two sub-types provided positive results. To simplify, we merged W and M into one category WM.

OURS	+327,864	93.91

Table 6: Numbers of meta features

4.3 Main results on test sets

We then evaluated the meta parsers on the English and Chinese test sets.

4.3.1 English

The results are shown in Table 7, where MetaParser refers to the meta parser. We found that the meta parser outperformed the baseline with an absolute improvement of 1.01 points (UAS). The improvement was significant in McNemar's Test ($p < 10^{-7}$).

	UAS	COMP
Baseline	92.76	48.05
MetaParser	93.77	51.36

Table 7: Main results on English

4.3.2 Chinese

	UAS	COMP
Baseline	81.01	29.71
MetaParser	83.08	32.21

Table 8: Main results on Chinese

The results are shown in Table 8. As in the experiment on English, the meta parser outperformed the baseline. We obtained an absolute improvement of 2.07 points (UAS). The improvement was significant in McNemar's Test ($p < 10^{-8}$).

In summary, Tables 7 and 8 convincingly show the effectiveness of our proposed approach.

4.4 Different sizes of unannotated data

Here, we considered the improvement relative to the sizes of the unannotated data used to generate the meta features. We randomly selected the 0.1%, 1%, and 10% of the sentences from the full data. Table 9 shows the results, where P0.1, P1, and P10 correspond to 0.1%, 1%, and 10% respectively. From the table, we found that the parsers obtained more benefits as we used more raw sentences. We also tried generating the meta features from the training data only, shown as TrainData in Table 9. However, the results shows that the parsers performed worse than the baselines. This is not surprising because only the known base features are included in the training data.

4.5 Comparison with previous work

4.5.1 English

Table 10 shows the performance of the previous systems that were compared, where McDonald06 refers to the second-order parser of McDonald and Pereira (2006), Koo10 refers to the third-order parser with model1 of Koo and Collins (2010), Zhang11 refers to the parser of Zhang and Nivre (2011), Li12 refers to the unlabeled parser of Li et al. (2012), Koo08 refers to the parser of Koo et al. (2008), Suzuki09 refers to the parser of Suzuki et al. (2009), Chen09 refers to the parser of Chen et al. (2009), Zhou11 refers to the parser of Zhou et al. (2011), Suzuki11 refers to the parser of Suzuki et al. (2011), and Chen12 refers to the parser of Chen et al. (2012).

The results showed that our meta parser outperformed most of the previous systems and obtained the comparable accuracy with the best result of Suzuki11 (Suzuki et al., 2011) which combined the clustering-based word representations of Koo et al. (2008) and a condensed feature representation. However, our approach is much simpler than theirs and we believe that our meta parser can be further improved by combining their methods.

4.5.2 Chinese

Table 11 shows the comparative results, where Li11 refers to the parser of Li et al. (2011), Hatori11 refers to the parser of Hatori et al. (2011), and Li12 refers to the unlabeled parser of Li et al. (2012). The reported scores on this data were produced by the supervised learning methods and our Baseline (supervised) parser provided the comparable accuracy. We found that the score of our meta parser for this data was the best reported so far and significantly higher than the previous scores. Note that we used the auto-assigned POS tags in the test set to match the above previous studies.

4.6 Analysis

Here, we analyzed the effect of the meta features on the data sparseness problem.

We first checked the effect of unknown features on the parsing accuracy. We calculated the number of unknown features in each sentence and computed the average number per word. The average numbers were used to eliminate the influence of varied sentence sizes. We sorted the test sentences in increasing orders of these average numbers, and divided equally into five bins. BIN 1 is assigned the sentences with the smallest numbers and BIN 5 is with the largest ones. Figure 2 shows the average accuracy scores of the Baseline parsers against to the bins. From the figure, we found that for both two languages the Baseline parsers performed worse while the sentences contained more unknown features.

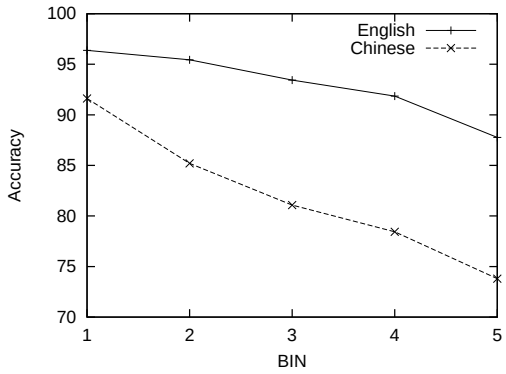

Figure 2: Accuracies relative to numbers of unknown features (average per word) by Baseline parsers

Then, we investigated the effect of the meta features. We calculated the average number of **active meta features** per word that were transformed from the unknown features for each sentence. We sorted the sentences in increasing order of the average numbers of active meta features and divided them into five bins. BIN 1 is assigned the sentences with the smallest numbers and BIN 5 is with the largest ones. Figures 3 and 4 show the results, where "Better" is for the sentences where the meta parsers provided better results than the baselines and "Worse" is for those where the meta parsers provided worse results. We found that the gap between "Better" and "Worse" became larger while the sentences contain more active meta features for the unknown features. The gap means performance improvement. This indicates that the meta features are very effective in processing the unknown features.

5 Related work

Our approach is to use unannotated data to generate the meta features to improve dependency parsing.

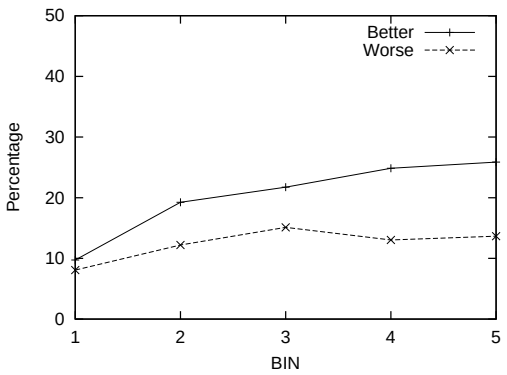

Figure 3: Improvement relative to numbers of active meta features on English (average per word)

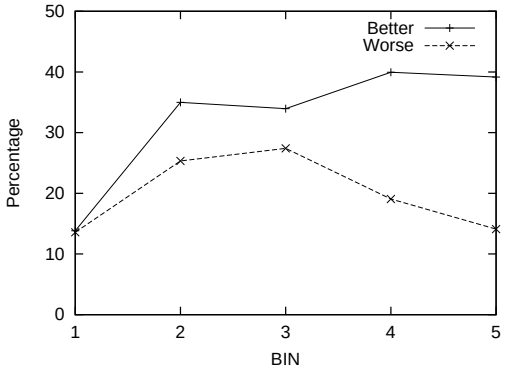

Figure 4: Improvement relative to numbers of active meta features on Chinese (average per word)

Several previous studies relevant to our approach have been conducted.

Koo et al. (2008) used a word clusters trained on a large amount of unannotated data and designed a set of new features based on the clusters for dependency parsing models. Chen et al. (2009) extracted subtree structures from a large amount of data and represented them as the additional features to improve dependency parsing. Suzuki et al. (2009) extended a Semi-supervised Structured Conditional Model (SS-SCM) of Suzuki and Isozaki (2008) to the dependency parsing problem and combined their method with the word clustering feature representation of Koo et al. (2008). Chen et al. (2012) proposed an approach to representing high-order features for graph-based dependency parsing models using a dependency language model and beam search. In future work, we may consider to combine their methods with ours to improve performance.

Several previous studies used co-training/self-training methods. McClosky et al. (2006) presented a self-training method combined with a reranking algorithm for constituency parsing. Sagae and Tsujii (2007) applied the standard co-training method for dependency parsing. In their approaches, some automatically parsed sentences were selected as new training data, which was used together with the original labeled data to retrain a new parser. We are able to use their approaches on top of the output of our parsers.

With regard to feature transformation, the work of Ando and Zhang (2005) is similar in spirit to our work. They studied semi-supervised text chunking by using a large projection matrix to map sparse base features into a small number of high level features. Their project matrix was trained by transforming the original problem into a large number of auxiliary problems, obtaining training data for the auxiliary problems by automatically labeling raw data and using alternating structure optimization to estimate the matrix across all auxiliary tasks. In comparison with their approach, our method is simpler in the sense that we do not request any intermediate step of splitting the prediction problem, and obtain meta features directly from self-annotated data. The training of our meta feature values is highly efficient, requiring the collection of simple statistics over base features from huge amount of data. Hence our method can potentially be useful to other tasks also.

6 Conclusion

In this paper, we have presented a simple but effective semi-supervised approach to learning the meta features from the auto-parsed data for dependency parsing. We build a meta parser by combining the meta features with the base features in a graph-based model. The experimental results show that the proposed approach significantly improves the accuracy. Our meta parser achieves comparable accuracy with the best known parsers on the English data (Penn English Treebank) and the best accuracy on the Chinese data (Chinese Treebank Version 5.1) so far. Further analysis indicate that the meta features are very effective in processing the unknown features. The idea described in this paper is general and can be applied to other NLP applications, such as part-

of-speech tagging and Chinese word segmentation, in future work.

Abstract

Topic segmentation classically relies on one of two criteria, either finding areas with coherent vocabulary use or detecting discontinuities. In this paper, we propose a segmentation criterion combining both lexical cohesion and disruption, enabling a trade-off between the two. We provide the mathematical formulation of the criterion and an efficient graph based decoding algorithm for topic segmentation. Experimental results on standard textual data sets and on a more challenging corpus of automatically transcribed broadcast news shows demonstrate the benefit of such a combination. Gains were observed in all conditions, with segments of either regular or varying length and abrupt or smooth topic shifts. Long segments benefit more than short segments. However the algorithm has proven robust on automatic transcripts with short segments and limited vocabulary reoccurrences.

1 Introduction

Topic segmentation consists in evidentiating the semantic structure of a document: Algorithms developed for this task aim at automatically detecting frontiers which define topically coherent segments in a text.

Various methods for topic segmentation of textual data are described in the literature, e.g., (Reynar, 1994; Hearst, 1997; Ferret et al., 1998; Choi, 2000; Moens and Busser, 2001; Utiyama and Isahara, 2001), most of them relying on the notion of lexical cohesion, i.e., identifying segments with a consistent use of vocabulary, either based on words or on semantic relations between words. Reoccurrences of words or related words and lexical chains are two popular methods to evidence lexical cohesion. This general principle of lexical cohesion is further exploited for topic segmentation with two radically different strategies. On the one hand, a measure of the *lexical cohesion* can be used to determine coherent segments (Reynar, 1994; Moens and Busser, 2001; Utiyama and Isahara, 2001). On the other hand, shifts in the use of vocabulary can be searched for to directly identify the segment frontiers by measuring the *lexical disruption* (Hearst, 1997).

Techniques based on the first strategy yield more accurate segmentation results, but face a problem of over-segmentation which can, up to now, only be solved by providing prior information regarding the distribution of segment length or the expected number of segments. In this paper, we propose a segmentation criterion combining both cohesion and disruption along with the corresponding algorithm for topic segmentation. Such a criterion ensures a coherent use of vocabulary within each resulting segment, as well as a significant difference of vocabulary between neighboring segments. Moreover, the combination of these two strategies enables regularizing the number of segments found without resorting to prior knowledge.

This piece of work uses the algorithm of Utiyama and Isahara (2001) as a starting point, a versatile and performing topic segmentation algorithm cast in a statistical framework. Among the benefits of this algorithm are its independency to any particular domain and its ability to cope with thematic segments

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1314–1324,
Seattle, Washington, USA, 18-21 October 2013.

of highly varying lengths, two interesting features to obtain a generic solution to the problem of topic segmentation. Moreover, the algorithm has proven to be up to the state of the art in several studies, with no need of a priori information about the number of segments (contrary to algorithms in (Malioutov and Barzilay, 2006; Eisenstein and Barzilay, 2008) that can attain a higher segmentation accuracy). It also provides an efficient graph based implementation of which we take advantage.

To account both for cohesion and disruption, we extend the formalism of Isahara and Utiyama using a Markovian assumption between segments in place of the independence assumption of the original algorithm. Keeping unchanged their probabilistic measure of lexical cohesion, the Markovian assumption enables to introduce the disruption between two consecutive segments. We propose an extended graph based decoding strategy, which is both optimal and efficient, exploiting the notion of generalized segment model or semi hidden Markov models. Tests are performed on standard textual data sets and on a more challenging corpus of automatically transcribed broadcast news shows.

The seminal idea of this paper was partially published in (Simon et al., 2013) in the French language. The current paper significantly elaborates on the latter, with a more detailed description of the algorithm and additional contrastive experiments including more data sets. In particular, new experiments clearly demonstrate the benefit of the method in a realistic setting with statistically significant gains.

The organization of the article is as follows. Existing work on topic segmentation is presented in Section 2, emphasizing the motivations of the model we propose. Section 3 details the baseline method of Utiyama and Isahara before introducing our algorithm. Experimental protocol and results are given in Section 4. Section 5 summarizes the finding and concludes with a discussion of future work.

2 Related work

Defining the concept of theme precisely is not trivial and a large number of definitions have been given by linguists. Brown and Yule (1983) discuss at length the difficulty of defining a topic and note: *"The notion of 'topic' is clearly an intuitively satisfactory way of describing the unifying principle which makes one stretch of discourse 'about' something and the next stretch 'about' something else, for it is appealed to very frequently in the discourse analysis literature. Yet the basis for the identification of 'topic' is rarely made explicit"*. To skirt the issue of defining a topic, they suggest to focus on topic-shift markers and to identify topic changes, what most current topic segmentation methods do.

Various characteristics can be exploited to identify thematic changes in text data. The most popular ones rely either on the lexical distribution information to measure lexical cohesion (i.e., word reoccurrences, lexical chains) or on linguistic markers such as discourse markers which indicate continuity or discontinuity (Grosz and Sidner, 1986; Litman and Passonneau, 1995). Linguistic markers are however often specific to a type of text and cannot be considered in a versatile approach as the one we are targeting, where versatility is achieved relying on the sole lexical cohesion.

The key point with lexical cohesion is that a significant change in the use of vocabulary is considered to be a sign of topic shift. This general idea translates into two families of methods, local ones targeting a local detection of lexical disruptions and global ones relying on a measure of the lexical cohesion to globally find segments exhibiting coherence in their lexical distribution.

Local methods (Hearst, 1997; Ferret et al., 1998; Hernandez and Grau, 2002; Claveau and Lefèvre, 2011) locally compare adjacent fixed size regions, claiming a boundary when the similarity between the adjacent regions is small enough, thus identifying points of high lexical disruption. In the seminal work of Hearst (1997), a fixed size window divided into two adjacent blocks is used, consecutively centered at each potential boundary. Similarity between the adjacent blocks is computed at each point, the resulting similarity profile being analyzed to find significant valleys which are considered as topic boundaries.

On the contrary, global methods (Reynar, 1994; Choi, 2000; Utiyama and Isahara, 2001; Ji and Zha, 2003; Malioutov and Barzilay, 2006; Misra et al., 2009) seek to maximize the value of the lexical cohesion on each segment resulting from the segmentation globally on the text. Several approaches have

been taken relying on self-similarity matrices, such as dot plots, or on graphs. A typical and state-of-the-art algorithm is that of Utiyama and Isahara (2001) whose principle is to search globally for the best path in a graph representing all possible segmentations and where edges are valued according to the lexical cohesion measured in a probabilistic way.

When the lengths of the respective topic segments in a text (or between two texts) are very different from one another, local methods are challenged. Finding out an appropriate window size and extracting boundaries become critical with segments of varying length, in particular when short segments are present. Short windows will render comparison of adjacent blocks difficult and unreliable while long windows cannot handle short segments. The lack of a global vision also makes it difficult to normalize properly the similarities between blocks and to deal with statistics on segment length. While global methods override these drawbacks, they face the problem of over-segmentation due to the fact that they mainly rely on the sole lexical cohesion. Short segments are therefore very likely to be coherent which calls for regularization introduced as priors on the segments length.

These considerations naturally lead to the idea of methods combining lexical cohesion and disruption to make the best of both worlds. While the two criteria rely on the same underlying principle of lexical coherence (Grosz et al., 1995) and might appear as redundant, the resulting algorithms are quite different in their philosophy. A first (and, to the best of our knowledge, unique) attempt at capturing a global view of the local dissimilarities is described in Malioutov and Barzilay (2006). However, this method assumes that the number of segments to find is known beforehand which makes it difficult for real-world usage.

3 Combining lexical cohesion and disruption

We extend the graph-based formalism of Utiyama and Isahara to jointly account for lexical cohesion and disruption in a global approach. Clearly, other formalisms than the graph-based one could have been considered. However, graph-based probabilistic topic segmentation has proven very accurate and versatile, relying on very minimal prior knowledge on the texts to segment. Good results at the state-of-the-art have also been reported in difficult conditions with this approach (Misra et al., 2009; Claveau and Lefèvre, 2011; Guinaudeau et al., 2012).

We briefly recall the principle of probabilistic graph-based segmentation before detailing a Markovian extension to account for disruption.

3.1 Probabilistic graph-based segmentation

The idea of the probabilistic graph-based segmentation algorithm is to find the segmentation into the most coherent segments constrained by a prior distribution on segments length. This problem is cast into finding the most probable segmentation of a sequence of t basic units (i.e., sentences or utterances composed of words) $W = u_1^t$ among all possible segmentations, i.e.,

$$\hat{S} = \arg\max_S P[W|S]P[S] \ . \qquad (1)$$

Assuming that segments are mutually independent and assuming that basic units within a segment are also independent, the probability of a text W for a segmentation $S = S_1^m$ is given by

$$P[W|S_1^m] = \prod_{i=1}^{m} \prod_{j=1}^{n_i} P[w_j^i|S_i] \ , \qquad (2)$$

where n_i is the number of words in the segment S_i, w_j^i is the j^{th} word in S_i and m the number of segments. The probability $P[w_j^i|S_i]$ is given by a Laplace law where the parameters are estimated on S_i, i.e.,

$$P[w_j^i|S_i] = \frac{f_i(w_j^i) + 1}{n_i + k} \ , \qquad (3)$$

where $f_i(w_j^i)$ is the number of occurrences of w_j^i in S_i and k is the total number of distinct words in W, i.e., the size of the vocabulary $\mathcal{V}$. This probability favors segments that are homogeneous, increasing when words are repeated and decreasing consistently when they are different. The prior distribution on segment length is given by a simple model, $P[S_1^m] = n^{-m}$, where n is the total number of words, exhibiting a large value for a small number of segments and conversely.

The optimization of Eq. 1 can be efficiently implemented as the search for the best path in a

weighted graph which represents all the possible segmentations. Each node in the graph corresponds to a possible frontier placed between two utterances (i.e., we have a node between each pair of utterances), the arc between nodes i and j representing a segment containing utterances u_{i+1} to u_j. The corresponding arc weight is the generalized probability of the words within segment $S_{i \to j}$ according to

$$v(i,j) = \sum_{k=i+1}^{j} ln(P[u_k|S_{i \to j}]) - \alpha ln(n)$$

where the probability is given as in Eq. 3. The factor α is introduced to control the trade-off between the segments length and the lexical cohesion.

3.2 Introduction of the lexical disruption

Eq. 2 derives from the assumption that each segment S_i is independent from the others, which makes it impossible to consider disruption between two consecutive segments. To do so, the weight of an arc corresponding to a segment S_i should take into account how different this segment is from S_{i-1}. This is typically handled using a Markovian assumption of order 1. Under this assumption, Eq. 2 is reformulated as

$$P[W|S_1^m] = P[W|S_1] \prod_{i=2}^{m} P[W|S_i, S_{i-1}] \ ,$$

where the notion of disruption can be embedded in the term $P[W|S_i, S_{i-1}]$ which explicitly mentions both segments. Formally, $P[W|S_i, S_{i-1}]$ is defined as a probability. However, arbitrary scores which do not correspond to probabilities can be used instead as the search for the best path in the graph of possible segmentations makes no use of probability theory. In this study, we define the score of a segment S_i given S_{i-1} as

$$\ln P[W|S_i, S_{i-1}] = \ln P[W_i|S_i] - \lambda \Delta(W_i, W_{i-1}) \quad (4)$$

where W_i designates the set of utterances in S_i and the rightmost part reflects the disruption between the content of S_i and of S_{i-1}. Eq. 4 clearly combines the measure of lexical cohesion with a measure of the disruption between consecutive segments: $\Delta(W_i, W_{i-1}) > 0$ measures the coherence between S_i and S_{i-1}, the substraction thus accounting for disruption by penalizing consecutive coherent segments. The underlying assumption is that the bigger $\Delta(W_i, W_{i-1})$, the weaker the disruption between the two segments. Parameter λ controls the respective contributions of cohesion and disruption.

We initially adopted a probabilistic measure of disruption based on cross probabilities, i.e., $P[W_i|S_{i-1}]$ and $P[W_{i-1}|S_i]$, which proved to have limited impact on the segmentation. We therefore prefer to rely on a cosine similarity measure between the word vectors representing two adjacent segments, building upon a classical strategy of local methods such as TextTiling (Hearst, 1997). The cosine similarity measure is calculated between vectors representing the content of resp. S_i and S_{i-1}, denoted $\mathbf{v}_i$ and $\mathbf{v}_{i-1}$, where $\mathbf{v}_i$ is a vector containing the (tf-idf) weight of each term of $\mathcal{V}$ in S_i. The cosine similarity is classically defined as

$$\cos(\mathbf{v}_{i-1}, \mathbf{v}_i) = \frac{\sum\limits_{v \in \mathcal{V}} \mathbf{v}_{i-1}(v) \ \mathbf{v}_i(v)}{\sqrt{\sum\limits_{v \in \mathcal{V}} \mathbf{v}_{i-1}^2(v) \ \sum\limits_{v \in \mathcal{V}} \mathbf{v}_i^2(v)}} \ . \quad (5)$$

$\Delta(W_i, W_{i-1})$ is calculated from the cosine similarity measure as

$$\Delta(W_i, W_{i-1}) = (1 - \cos(\mathbf{v}_{i-1}, \mathbf{v}_i))^{-1} \ , \quad (6)$$

thus yielding a small penalty in Eq. 4 for highly disrupting boundaries, i.e., corresponding to low similarity measure.

Given the quantities defined above, the algorithm boils down to finding the best scoring segmentation as given by

$$\hat{S} = \arg\max_S \sum_{i=1}^{m} ln(P[W_i|S_i]) - \lambda \sum_{i=2}^{m} \Delta(W_i, W_{i-1}) - \alpha m ln(n) \ . \quad (7)$$

3.3 Segmentation algorithm

Translating Eq. 7 into an efficient algorithm is not straightforward since all possible combinations of adjacent segments need be considered. To do so in a graph based approach, one needs to keep separated the paths of different lengths ending in a given node. In other words, only paths of the same length ending

at a given point, with different predecessors, should be recombined so that disruption can be considered properly in subsequent steps of the algorithm. Note that, in standard decoding as in Utiyama and Isahara's algorithm, only one of such paths, the best scoring one, would be retained. We employ a strategy inspired from the decoding strategy of segment models or semi-hidden Markov model with explicit duration model (Ostendorf et al., 1996; Delakis et al., 2008).

Search is performed through a lattice $L = \{V, E\}$, with V the set of nodes representing potential boundaries and E the set of edges representing segments, i.e., a set of consecutive utterances. The set V is defined as

$$V = \{n_{ij} | 0 \leq i, j \leq N\} \quad ,$$

where n_{ij} represents a boundary after utterance u_i reached by a segment of length j utterances and $N = t+1$. In the lattice example of Fig. 1, it is trivial to see that for a given node, all incoming edges cover the same segment. For example, the node n_{42} is positioned after $u4$ and all incoming segments contain the two utterances $u3$ and $u4$. Edges are defined as

$$E = \{e_{ip,jl} | 0 \leq i, p, j, l \leq N; \\ i < j; i = j - l; L_{\text{min}} \leq l \leq L_{\text{max}}\} \quad ,$$

where $e_{ip,jl}$ connects n_{ip} and n_{jl} with the constraint that $l = j - i$ and $L_{\text{min}} \leq l \leq L_{\text{max}}$. Thus, an edge $e_{ip,jl}$ represents a segment of length l containing utterances from u_{i+1} to u_j, denoted $S_{i \to j}$. In Fig. 1, $e_{01,33}$ represents a segment of length 3 from n_{01} to n_{33}, covering utterances u_1 to u_3. To avoid explosion of the lattice, a maximum segment length L_{max} is defined. Symmetrically, a minimum segment size can be used.

The property of this lattice, where, by construction, all edges out of a node have the same segment as a predecessor, makes it possible to weight each edge in the lattice according to Eq. 4. Consider a node n_{ij} for which all incoming edges encompass utterances u_{i-j} to u_i. For each edge out of n_{ij}, whatever the target node (i.e., the edge length), one can therefore easily determine the lexical cohesion as defined by the generalized probability of Eq. 3 and the disruption with respect to the previous segment as defined by Eq. 6.

Algorithm 1 Maximum probability segmentation

Step 0. Initialization
$q[0][j] = 0 \quad \forall j \in [L_{\text{min}}, L_{\text{max}}]$
$q[i][j] = -\infty \quad \forall i \in [1, N], j \in [L_{\text{min}}, L_{\text{max}}]$

Step 1. Assign best score to each node
for $i = 0 \to t$ **do**
  for $j = L_{\text{min}} \to L_{\text{max}}$ **do**
    for $k = L_{\text{min}} \to L_{\text{max}}$ **do**
      /* extend path ending after u_i with a segment of length j with an arc of length k */

$$q[i+k][k] = \max \begin{cases} q[i+k][k], \\ q[i][j] + \\ \text{Cohesion}(u_{i+1} \to u_{i+k}) - \\ \lambda \Delta(u_{i-j} \to u_i; u_{i+1} \to u_{i+k}) \end{cases}$$

    end for
  end for
end for

Step 2. Backtrack from n_{Nj} with best score $q[N][j]$

Given the weighted decoding graph, the solution to Eq. 7 is obtained by finding out the best path in the decoding lattice, which can be done straightforwardly by scanning nodes in topological order. The decoding algorithm is summarized in Algorithm 1 with an efficient implementation in $o(NL_{\text{max}}^2)$ which does not require explicit construction of the lattice.

4 Experiments

Experiments are performed on three distinct corpora which exhibit different characteristics, two containing textual data and one spoken data. We first present the corpora before presenting and discussing results on each.

4.1 Corpora

The artificial data set of Choi (2000) is widely used in the literature and enables comparison of a new segmentation method with existing ones. Choi's data set consist of 700 documents, each created by concatenating the first z sentences of 10 articles randomly chosen from the Brown corpus, assuming each article is on a different topic. Table 1 provides

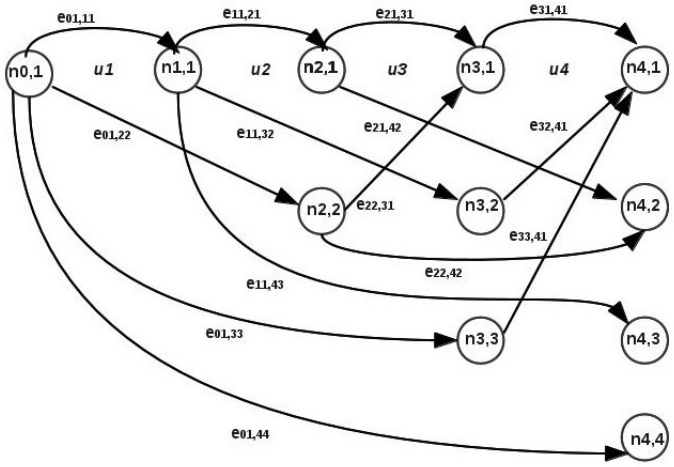

Figure 1: An example of a lattice L.

$z =$	3–11	3–5	6–8	9–11
# samples	400	100	100	100

Table 1: Number of documents in Choi's corpus (Choi, 2000).

the corpus statistics, where z=3–11 means z is randomly chosen in the range $[3, 11]$. Hence, Choi's corpus is adapted to test the ability of our model to deal with variable segments length, z=3–11 being the most difficult condition. Moreover, Choi's corpus provides a direct comparison with results reported in the literature.

One of the main criticism of Choi's data set is the presence of abrupt topic changes due to the artificial construction of the corpus. We therefore report results on a textual corpus with more natural topic changes, also used in (Eisenstein and Barzilay, 2008). The data set consists of 277 chapters selected from (Walker et al., 1990), a medical textbook, where each chapter—considered here as a document—was divided by its author into thematically coherent sections. The data set has a total of 1,136 segments with an average of 5 segments per document and an average of 28 sentences per segment. This data set is used to study the impact of smooth, natural, topic changes.

Finally, results are reported on a corpus of automatic transcripts of TV news spoken data. The data set consists of 56 news programs (≈1/2 hour each), broadcasted in February and March 2007 on the French television channel France 2, and transcribed by two different automatic speech recognition (ASR) systems, namely IRENE (Huet et al., 2010) and LIMSI (Gauvain et al., 2002), with respective word error rates (WER) around 36 % and 30 %. Each news program consists of successive reports of short duration (2-3 min), possibly with consecutive reports on different facets of the same news. The reference segmentation was established by associating a topic with each report, i.e., placing a boundary at the beginning of a report's introduction (and hence at the end of the closing remarks). The TV transcript data set, which corresponds to some real-world use cases in the multimedia field, is very challenging for several reasons. On the one hand, segments are short, with a reduced number of repetitions, synonyms being frequently employed. Moreover, smooth topic shifts can be found, in particular at the beginning of each program with different reports dedicated to the headline. On the other hand, transcripts significantly differ from written texts: no punctuation signs or capital letters; no sentence structure but rather utterances which are only loosely syntactically motivated; presence of transcription errors which may imply an accentuated lack of word repetitions.

All data were preprocessed in the same way: Words were tagged and lemmatized with TreeTag-

ger[1] and only the nouns, non modal verbs and adjectives were retained for segmentation. Inverse document frequencies used to measure similarity in Eq. 5 are obtained on a per document basis, referring to the number of sentences in textual data and of utterances in spoken data.

4.2 Results

Performance is measured by comparison of hypothesized frontiers with reference ones. Alignment assumes a tolerance of 1 sentence on texts and of 10 seconds on transcripts, which corresponds to standard values in the literature. Results are reported using recall, precision and F1-measure. Recall refers to the proportion of reference frontiers correctly detected; Precision corresponds to the ratio of hypothesized frontiers that belong to the reference segmentation; F1-measure combines recall and precision in a single value. These evaluation measures were selected because recall and precision are not sensitive to variations of segment length contrary to the *Pk* measure (Beeferman et al., 1997) and do not favor segmentations with a few number of frontiers as *WindowDiff* (Pevzner and Hearst, 2002) (see (Niekrasz and Moore, 2010) for a rigorous analytical explanation of the biases of *Pk* and *WindowDiff*).

Several configurations were considered in the experiments; due to space constraints, only the most salient experiments are presented here. In Eq. 7, the parameter α, which controls the contribution of the prior model with respect to the lexical cohesion and disruption, allows for different trade-offs between precision and recall. For any given value of λ, α is thus varied, providing the range of recall/precision values attainable. Results are compared to a baseline system corresponding to the application of the original algorithm of Utiyama and Isahara (i.e., setting $\lambda = 0$). This baseline has been shown to be a high-performance algorithm, in particular with respect to local methods that exploit lexical disruption. Differences in F1-measure between this baseline and our system presented below are all statistically significant at the level of $p < 0.01$ (paired t-test).

Choi's corpus. Figure 2 reports results obtained on Choi's data set, each graphic corresponding to a specific variation in the size of the thematic segments forming the documents (e.g., 9 to 11 sentences for the top left graphic). Results are provided for different values of λ in terms of F1-measure boxplots, i.e., variations of the F1-measure when α varies (same range of variation for α considered for each plot), where the leftmost boxplot, denoted by UI, corresponds to the baseline. Box and whisker plots graphically depicts the distribution of the F1-measures that can be attained by varying α, plotting the median value, the first and third quartile and the extrema.

z	τ	F1 gain	Confidence interval 95 % UI	Confidence interval 95 % Combined
3-5	0	-0.2	[66.6,74.26]	[75.23,78.08]
3-5	1	0.7	[72.25,83.4]	[87.88,92.13]
3-11	1	0.23	[68.5,79.3]	[86.6,87.43]
6-8	1	0.4	[68.48,80.99]	[76.9,85.17]
9-11	0	1.6	[64.35,75.16]	[81.31,84.86]
9-11	1	1.4	[68.39,80.39]	[84.37,88.9]

Table 2: Gain in F1-measure for Choi's corpus when using lexical cohesion and disruption, and the corresponding 95 % confidence intervals for the F1-measure. Results are reported for different tolerance τ. UI denotes the baseline and Combined the proposed model.

Figure 2 shows that, whatever the segments length, results globally improve according to the importance given to the disruption (λ variable). Moreover, the variation in F1-measure diminishes when disruption is considered, thus indicating the influence of the prior model diminishes. When the segments size decreases (see Figs. 2(b), 2(c), 2(d)), the difference in the maximum F1-measure between our results and that of the baseline lowers, however still in favor of our model. This can be explained by the fact that our approach is based on the distribution of words, thus more words better help discriminate between potential thematic frontiers. Finally, using too large values for λ can lead to under-segmentation, as can be seen in Fig. 2(d) where, for $\lambda = 3$, the variation of F1-measure increases and the distribution becomes negatively skewed (i.e., the median is closer to the third quartile than to the first).

These results are confirmed by Table 2 which presents the gain in F1-measure (i.e., the difference between the highest F1-measure obtained when

[1] http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger

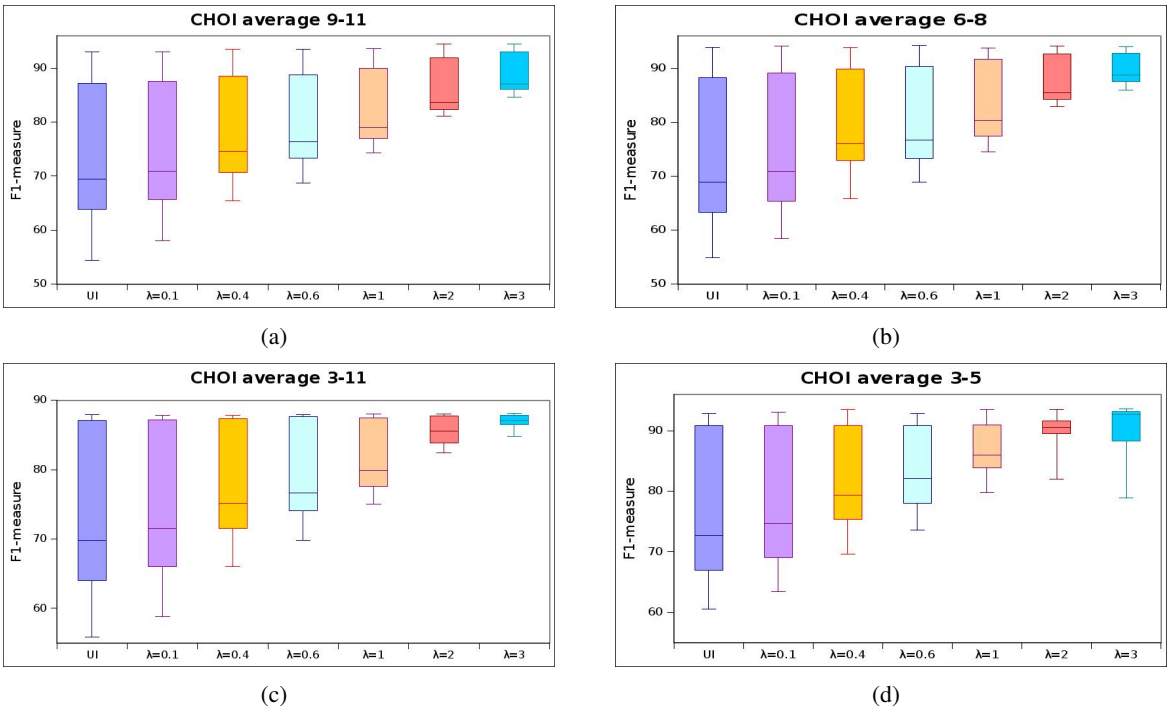

Figure 2: F1-measure variation obtained on Choi's corpus. In each graphic, the leftmost boxplot UI corresponds to results obtained by using the sole lexical cohesion (baseline), while the λ value is the importance given to the lexical disruption in our approach. Results are provided for the same range of variation of factor α, allowing a tolerance of 1 sentence between the hypothesized and reference frontiers.

combining lexical cohesion and disruption and the highest value for the baseline) for each of the four sets of documents in Choi's corpus, together with the 95 % confidence intervals: The effect of using the disruption is higher when segment size is longer, whether evaluation allows or not for a tolerance τ between the hypothesized frontiers and the reference ones. A qualitative analysis of the segmentations obtained confirmed that employing disruption helps eliminate wrong hypothesis and shift hypothesized frontiers closer to the reference ones (explaining the higher gain at tolerance 0 for 9-11 data set). When smaller segments—thus few word repetitions—and no tolerance are considered (e.g., 3–5), disruption cannot improve segmentation. Our model is globally stable with respect to segment length, with relatively similar gain for 3–11 and 6–8 data sets in which the average number of words (distinct or repeated) is close.

Results discussed up to now are optimistic as they correspond to the best F1 value attainable computed a posteriori. Stability of the results was confirmed

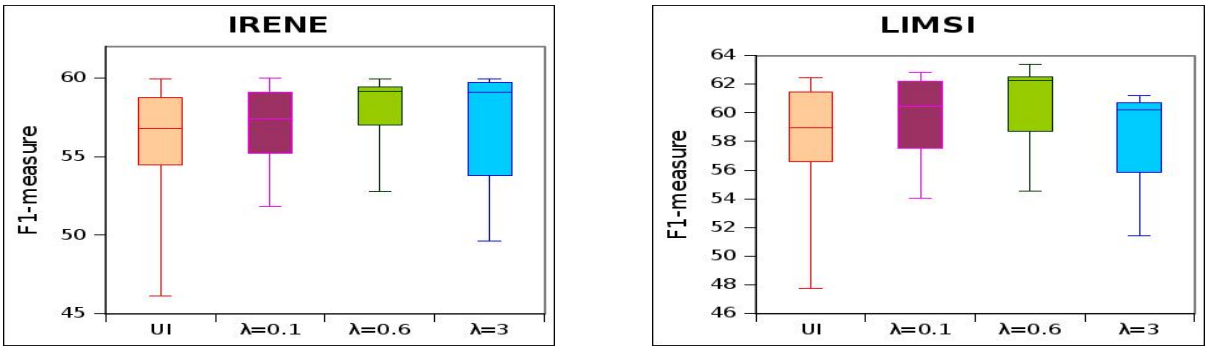
$z =$	3–5	3–11	6–8	9–11
UI	91.9	87.0	93.1	92.8
Combined	92.9	87.5	93.5	94.0

Table 3: F1 results using cross-validation on Choi's data set.

using cross-validation with 5 folds (10 folds for z=3–11): Parameters λ and α maximizing the F1-measure are determined on all but one fold, this last fold being used for evaluation. Results, averaged over all folds, are reported in Tab. 3 for the baseline and the method combining cohesion and disruption.

Medical textbook corpus. The medical textbook corpus was previously used for topic segmentation by Eisenstein and Barzilay (2008) with their algorithm BayesSeg[2]. We thus compare our results with those obtained by BayesSeg and by the baseline. When considering the best F1-measure (i.e., the best F1-measure which can be achieved by varying α and

[2]The code and the data set are available at http://groups.csail.mit.edu/rbg/code/bayesseg/



(a) (b)

Figure 3: Boxplots showing F1-measure variation on transcripts obtained using IRENE and LIMSI automatic speech recognition systems.

λ), we achieved an improvement of 2.2 with respect to BayesSeg when no tolerance is allowed, and of 0.5 when the tolerance is of 1 sentence. The corresponding figures with respect to the baseline are 0.6 and 0.4. When considering the F1-measure value for which the number of hypothesized frontiers is the closest to the number of reference boundaries, improvement is of resp. 1.5 and 0.5 with respect to BayesSeg, -0.1 and 0.4 with respect to the baseline. These results show that our model combining lexical cohesion and disruption is also able to deal with topic segmentation of corpora from a homogeneous domain, with smooth topic changes and segments of regular size.

One can argue that the higher number of free parameters in our method explains most of the gain with respect to BayesSeg. While BayesSeg has only one free parameter (as opposed to two in our case), the number of segments is assumed to be provided as prior knowledge. This assumption can be seen as an additional free parameter, i.e., the number of segments, and is a much stronger constraint than we are using. Moreover, cross-validation experiments on the Choi data set show that improvement is not due to over-fitting of the development data thanks to an additional parameter. Gains on development set with parameters tuned on the development set itself and with parameters tuned on a held-out set in cross-validation experiments are in the same range.

TV news transcripts corpus Figure 3 provides results, in terms of F1-measure variation, for TV news transcripts obtained with the two ASR systems. On this highly challenging corpus, with short segments, wrongly transcribed spoken words, and thus few word repetitions, the capabilities of our model to overcome the baseline system are reduced. Yet, an improvement of the quality of the segmentation of these noisy data is still observed, and general conclusions are quite similar—though a bit weaker—to those already made for Choi's corpus. Results are confirmed in Table 4 which presents the gain in F1-measure of our model together with the 95 % confidence interval, where F1-measure values correspond to that of segmentations with a number of hypothesized frontiers the closest to the reference. The two first lines show that the gain is smaller for IRENE transcripts which have a higher WER, thus fewer words available to discriminate between segments belonging to different topics. The impact of transcription errors is illustrated in the last three lines, when segmenting six TV news for which manual reference transcripts were available (line 3), where the higher the WER, the smaller the F1-measure gain.

5 Conclusions

We have proposed a method to combine lexical cohesion and disruption for topic segmentation. Experimental results on various data sets with various characteristics demonstrate the impact of taking into account disruption in addition to lexical cohesion. We observed gains both on data sets with segments of regular length and on data sets exhibiting segments of highly varying length within a document. Unsurprisingly, bigger gains were observed on doc-

Corpus	F1 gain	Confidence interval 95 % UI	Combined
IRENE	0.3	[54.4,57.6]	[56.92,59]
LIMSI	0.86	[56.7,60.2]	[59.44,61.95]
MANUAL (6)	0.77	[70.39,72.29]	[71.7,73.29]
IRENE (6)	0.2	[56.81,60.94]	[59.51,63.43]
LIMSI (6)	0.5	[64.27,68.64]	[67.7,71.56]

Table 4: Gain in F1-measure for TV news corpus automatic and manual transcripts when using lexical cohesion and disruption, and the corresponding 95 % confidence intervals. Last three rows report results on only 6 shows for which manual reference transcripts are available.

uments containing relatively long segments. However the segmentation algorithm has proven to be robust on automatic transcripts with short segments and limited vocabulary reoccurrences. Finally, we tested both abrupt topic changes and smooth ones with good results on both. Further work can be considered to improve segmentation of documents characterized by small segments and few words repetitions, such as using semantic relations or vectorization techniques to better exploit implicit relations not considered by lexical reoccurrence.

Abstract

We propose a Laplacian structured sparsity model to study computational branding analytics. To do this, we collected customer reviews from Starbucks, Dunkin' Donuts, and other coffee shops across 38 major cities in the Midwest and Northeastern regions of USA. We study the brand related language use through these reviews, with focuses on the brand satisfaction and gender factors. In particular, we perform three tasks: automatic brand identification from raw text, joint brand-satisfaction prediction, and joint brand-gender-satisfaction prediction. This work extends previous studies in text classification by incorporating the dependency and interaction among local features in the form of structured sparsity in a log-linear model. Our quantitative evaluation shows that our approach which combines the advantages of *graphical modeling* and *sparsity modeling* techniques significantly outperforms various standard and state-of-the-art text classification algorithms. In addition, qualitative analysis of our model reveals important features of the language uses associated with the specific brands.

1 Introduction

In marketing science, branding is a modern marketing strategy of creating a unique image for a product in the customers' mind. Establishing the brand in the broad social context is just as important as building a good product (Makens, 1965; Lederer and Hill, 2001; Kim et al., 2013). In fact, blind taste test experiments have frequently shown how branding directly leads to the success of products and companies. Most notably is a continued study sponsored by Pepsi, known as the Pepsi Challenge[1], where Pepsi demonstrates how even though people preferred the taste of Pepsi, Coca-Cola's branding has made it more popular. Even now, Microsoft uses similar blind taste tests[2] to compare search engines, Bing and Google, showing that although participants prefer Bing's results, Google's brand might have strengthened over the years. These studies all suggest that brand and its associations play important roles in the customers' perceptions and decisions.

To accommodate the market change, companies frequently adjust branding strategies by analyzing how their customers receive and respond to branding messages. So far, such analysis is often done by using surveys and focus groups (Moon and Quelch, 2006), which is expensive and not time-efficient. Recently, with the advance of machine learning techniques, researchers from the chemistry and vision communities started to pay attention to the problem of automatic brand identification from smell (Luo et al., 2004) and images (Pelisson et al., 2003). In contrast, even though textual data that contains hidden branding information is abundantly available in many forms over the Web, automatic discovery and computational analysis on such data are not well studied in the past.

Computational branding analytics (CBA) seeks to extract information, trends, and demographics about a brand on the basis of free-form text, e.g. from blogs, Twitter comments, reviews, or forum posts. As described in Section 3, in this study we use a sub-

set of online Yelp reviews that discuss coffee shops. The main reason is that this source has the advantage of providing ground truth of multi-labeled data: each review has meta-information defining a 5-star rating, the object of the review, and the reviewer's name (from which we infer gender). For the purpose of this paper we decompose CBA into three sub-problems.

- How well can the brand being discussed be identified by the raw text?
- How well can the joint value of brand and rating be predicted?
- How well can the joint value of brand, rating, and gender be predicted?

There are two reasons why one may want to construct text-based classifiers of brand, rating, and gender, when such information is present in the review header. The first is that trained classifiers can then be applied to other data sources, such as blogs, where what is available is only the review itself. The second is that by "opening the hood" to the classifier one can examine which words exhibit high affiliation with the predicted variables. This can be done, for example, to contrast the preferences of males and females with respect to evaluating the qualities of a coffee shop. Examples of such insights are provided in Section 5.5.

In this paper, we propose a Laplacian structured sparsity model for computational branding analytics. Our main contributions are two-fold: first, in the novel task of automatic brand identification from text, we show that by incorporating the dependency structure and graphical interactions among local features, our model significantly outperforms various text classification algorithms such as the standard logistic regression, principle component analysis (PCA), linear kernel support vector machine (SVM), sparse, non-sparse, and mixed-penalty log-linear models. These improvements could also be seen from a joint brand-satisfaction prediction task and a gender-specific joint brand-satisfaction prediction task. In addition, our Laplacian augmented L_1-ball projection experiment shows that the advantage of Laplacian structured sparsity is robust across different parameter settings in a L_1-constrained problem. Secondly, the qualitative analysis of our machine learning model shows the interesting features and language use that relate to brand and its associated pragmatics.

In the next section, we outline related work in CBA, sparsity, and spectral graph learning. In Section 3, we describe the corpus in this study. The Laplacian structured sparsity model is introduced in Section 4. The experimental setup and results are presented in Section 5. A short discussion is followed in Section 6 and we conclude in Section 7.

2 Related Work

Early work on statistical brand analysis in the marketing community dates back to the work of Kuehn (1962), where he first hypothesizes that brand choice could be described as a learning process. Guadagni and Little (1983) further empirically tested the hypothesis by building a calibrated multinomial logistic regression model to predict the purchase of ground coffee, using the data from the optical scanning of product code in supermarkets. Outside the marketing community, statistical brand analysis is rarely seen. More recently, a study (Luo et al., 2004) applies neural networks to identify cigarette brands, with the hope of detecting illegal cigarettes from smell features. In image processing, researchers have studied the problem of brand identification from image using histogram comparison (Pelisson et al., 2003). However, to the best of our knowledge, even though textual data is vastly available, the problems of automatic brand identification from raw text and computational branding analytics, are new.

Although the domain of our data is on branding, our work also aligns with previous work in text and language classification. Over the years, logistic regression and linear kernel SVM have shown to be very successful in various regression and classification tasks in NLP (Chahuneau et al., 2012; Biadsy et al., 2011). Recently, sparse discriminative methods that model the sparse nature of text become attractive, because unlike dense models, they are less likely to overfit to the training data, easier to interpret, and often lead to state-of-the-art results. For example, Eisenstein et al. (2011b) use the $L_{1,\infty}$ sparsity model to discover sociolinguistic patterns. Wang et al. (2012a) compare lasso, ridge, and elastic net models to predict impoliteness behaviors in teenager conversations. Martins et al. (2011) investigate the tree-structured overlapping group lasso for

structured prediction problems. Chen et al. (2013) study the use of element-wise, group-wise, and hierarchical sparsity models for dialogue act classification. Sparse inducing priors are also investigated and shown to be effective in generative models for topic modeling (Eisenstein et al., 2011a; Wang et al., 2012b; Paul and Dredze, 2012).

Besides lacking sparsity, since the traditional discriminative methods in NLP often use interdependent features such as n-grams tokens, and part-of-speech tags, they also suffer from the problem of not explicitly modeling the complex dependency structure and interaction of local features from a global perspective. To solve this problem, graph methods seem to be a good solution, because they are simple, generalizable, and are often used to model such complex dependency structures (Cohen, 2012). However, combining the sparse modeling and spectral graphical modeling approaches in a principled way is challenging. Belkin et al. (2006) and Weinberger et al. (2007) are among the first to investigate graph Laplacians as a manifold regularization method for statistical learning. Recently, Gao et al. (2012) propose a histogram intersection based kNN method to construct a Laplacian matrix for a least-square sparse coding problem in image processing. Unfortunately, this method might be too specific to the SIFT-based image coding tasks, thus might not be applicable to the text classification problem that utilizes n-gram lexical features.

3 Datasets

We collected Yelp reviews from 1,860 Starbucks, Dunkin' Donuts[3], and other coffee shops all over the Midwest and Northeast regions in the period of 2009. A detail statistics of our data can be found in Table 1. The Midwest region includes 12 states[4] and 19 major cities, and the Northeast region includes 9 states[5] and 19 major cities. For each region, we divide the coffee shops into 60% training, 20% development, and 20% test, and there are no overlaps of coffee shops among these subsets. There are three values for the brand label: Starbucks, Dunkin' Donuts, and all other coffee shop brands. The majority class is "all other coffee shop brands", and the majority baseline is shown in Table 2. In the task of joint brand-satisfaction prediction, we utilize the review scores to approximate user satisfaction: scores 1-2 as the unsatisfactory label, 3 as moderate, and 4-5 as satisfactory. Since the Yelp reviews do not reveal the reviewer's gender, we use a similar method that U.S. Census Bureau used (OConnell and Gooding, 2006): we first automatically match the first name of the reviewer with the prior name-gender distributions in the census records, then manually examine the no-match cases and a subsample of the matched cases. For those who we cannot determine the gender, the review will be dropped from the gender-specific brand-satisfaction prediction task. After filtering, there are 8,528 documents for training, 2,928 for development, and, 3,046 for testing. Since the focus of this paper is not on feature engineering, we use unigram features to represent each review. Below is an example of positive review from a male Starbucks customer from Midwest.

	Coffee Shops			Reviews		
	Train	Dev.	Test	Train	Dev.	Test
1	451	150	150	3,513	1,087	1,424
2	665	222	222	6,982	2,530	2,358
T.	1,116	372	372	10,495	3,617	3,782

Table 1: Dataset statistics. *1: midwest region. 2: northeast region. T.: total.*

> *My favorite place for my iced vanilla lattes. They have screwed up my order before: instead of a grande, I got a venti. Not a fan of their pastries though. I got a donut once, and ended up feeding it to a pigeon in city garden. Friendly and fast service. Not open Sundays.*

The coffee shop dataset is freely available[6] for research purposes.

4 Our Approach

4.1 Problem Formulation and Predictive Tasks

The automatic brand identification problem could be considered as a traditional multiclass classifica-

[3]We chose these two brands because they are reported as the leading coffee shops by WSJ (Ovide, 2011) and Forbes (DiCarlo, 2004).

[4]IL, WI, SD, ND, MN, MO, OH, NE, KS, IA, IN, and MI.

[5]CT, ME, MA, NH, RI, VT, NJ, NY and PA.

[6]http://www.cs.cmu.edu/~yww/data/emnlp2013.zip

tion problem where the estimated label $\hat{Y}$ could be drawn from $Mult(\Gamma)$, where Γ is the parameter for the multinomial distribution. To solve this, a simple but accurate solution is to decompose the multiclass problem into multiple binary classification problems (Rifkin and Klautau, 2004) by training k one-vs-all binary classifiers, and then use the argmax criteria to select the best hypothesis from the k posteriors. As for a binary classifier, we need to infer the posterior from a Bernoulli distribution that is parametrized by $\hat{\theta}_y$. Similarly, we can derive k binary classifiers:

$$\hat{\theta}_y^{(1)}, \hat{\theta}_y^{(2)}, ..., \hat{\theta}_y^{(k)}. \quad (1)$$

So, instead of drawing $\hat{Y}$ from a multinomial distribution $Mult(\Gamma)$, we can draw the final label $\hat{Y}$ that has the largest posterior across all k classifiers:

$$\hat{Y} = \underset{Y,i=1,2,...,k}{\operatorname{argmax}} \Pr(Y|\hat{\theta}_y^{(i)}, \vec{X}_t) \quad (2)$$

where $\vec{X}_t$ is the testing vector, and $\Pr(Y|\hat{\theta}_y^{(i)}, \vec{X}_t)$ is the posterior probability given the learned classifiers and the testing vector.

In this paper, we investigate three multiclass classification tasks: first, we perform a 3-way classification task for automatic brand identification. In the task of brand-satisfaction prediction, we model the brand and the satisfaction label at the same time (Chahuneau et al., 2012): we perform the task of jointly predicting aggregate brand-satisfaction score for a review using 9-way classification. Similarly, we perform 18-way classification for the gender-specific joint brand-satisfaction prediction task.

4.2 The Log-Linear Framework and Its Regularized Variants

If we consider the standard logistic regression model as the binary classifier in this log-linear framework[7], then each classifier can be written as:

$$\hat{\theta}_y = \frac{\exp\left(\vec{W}^\top \vec{X}_j\right)}{1 + \exp\left(\vec{W}^\top \vec{X}_j\right)} \quad (3)$$

here, $\vec{X}_j$ is the j-th observed feature vector, label $y \in \{0, 1\}$, and $\vec{W}$ is a vector of the coefficients. To estimate the model parameters in equation (3), we only need to set the weights $\vec{W}$. We can obtain the following log likelihood, and its gradient function by taking the first-order partial derivative of $\vec{W}$:

$$\ell = \sum_j y_j \log \hat{\theta}_{y_j} + (1 - y_j) \log(1 - \hat{\theta}_{y_j}) \quad (4)$$

$$\frac{\partial \ell}{\partial \vec{W}} = \sum_j \left(\frac{\partial \hat{\theta}_{y_j}}{\partial \vec{W}}\right)\left(\frac{y_j}{\hat{\theta}_{y_j}} - \frac{1 - y_j}{1 - \hat{\theta}_{y_j}}\right) \quad (5)$$

$$\frac{\partial \hat{\theta}_{y_j}}{\partial \vec{W}} = \left(\hat{\theta}_{y_j} - (\hat{\theta}_{y_j})^2\right)\vec{X}, \quad (6)$$

since the log likelihood objective function (4) is concave, using standard gradient ascent with maximum likelihood estimation can solve the problem. However, this model does not penalize the noisy features and unreliable features that might overfit to the training data. To address this issue, we introduce the L_1 norm from lasso technique (Tibshirani, 1996) to regularize the above likelihood function. Thus, instead of maximizing the likelihood, we can minimize the loss function of the negative log-likelihood with a linear penalty:

$$\min\Big(-\ell + \lambda_1 ||\vec{W}||\Big) \quad (7)$$

where λ_1 is the regularization coefficient. The benefit of L_1 penalty in a discriminative model is similar to the double exponential distribution of the sparse priors in generative models (Eisenstein et al., 2011a): they both push the weights of many noisy features into zeros, revealing only the important features. However, since the L_1 penalty can introduce discontinuities to the original convex function, we can also consider an alternative non-sparse ridge estimator (Le Cessie and Van Houwelingen, 1992) with log loss and L_2 norm, and has the convex property:

$$\min\Big(-\ell + \lambda_2 ||\vec{W}||^2\Big) \quad (8)$$

Another option that balances the sparsity and smoothness would be the elastic net model (Zou and Hastie, 2005) that uses the composite penalty:

$$\min\Big(-\ell + \lambda_1 ||\vec{W}|| + \lambda_2 ||\vec{W}||^2\Big) \quad (9)$$

4.3 The Laplacian Structured Sparsity Model

So far, none of the above element-wise penalty models in the previous subsection takes into account the

[7] We thank Jacob Eisenstein for the initial derivation of the logistic regression model.

dependency structure of the local features. Inspired by Gao et al.(2012), we group the local features that have similar distributions together. The intuition is that, for features that have very similar empirical distributions in the training set, their weights should not be drastically different after the learning process in the same task. In our new objective function, it is desirable to introduce a new component that structurally penalize these cases where features that are very similar to each other, but have learned completely different weights, probably due to the noise or the data sparsity issue in the training data.

The Objective Function: To do this, we first define an inter-feature affinity matrix A, where $A_{(p,q)}$ measures the similarity between a pair of features p and q. In the spectral graph theory, this affinity matrix can be viewed as a weighted undirected graph $G = (V, E)$, where each node V_p denotes a feature p, and each edge $E_{(p,q)}$ indicates the closeness among the features p and q. We also introduce a weighted diagonal degree matrix D, of which each element in the diagonal $D_{(p,p)}$ is the sum of all weighted connections of node V_p: $D_{(p,p)} = \sum_{q=1}^{Q} A_{(p,q)}$. We propose the following objective function:

$$\min \Big(-\ell + \lambda_1 ||\vec{W}|| + \lambda_2 ||\vec{W}||^2 \tag{10}$$

$$+ \alpha \sum_{(p,q)} ||\vec{W}_p - \vec{W}_q||^2 A_{(p,q)} \Big) \tag{11}$$

We then denote a graph Laplacian matrix $L = D - A$ (Belkin and Niyogi, 2001), and rewrite the objective function as:

$$\min \Big(-\ell + \lambda_1 ||\vec{W}|| + \lambda_2 ||\vec{W}||^2 \tag{12}$$

$$+ \alpha (\vec{W}^\top L \vec{W}) \Big) \tag{13}$$

where α is the regularization parameter for the Laplacian structured sparsity term. Intuitively, the objective function can be interpreted as the sum of a negative log loss function, the sparsity-inducing penalty, the quadratic penalty, and the Laplacian structured penalty. Or, another view of this new model could be seen as a Laplacian augmented elastic net model where structured sparsity and feature interaction are considered.

The Laplacian Matrix: In this model, a key aspect is to derive the Laplacian matrix L. We propose the following three steps to learn the Laplacian matrix:

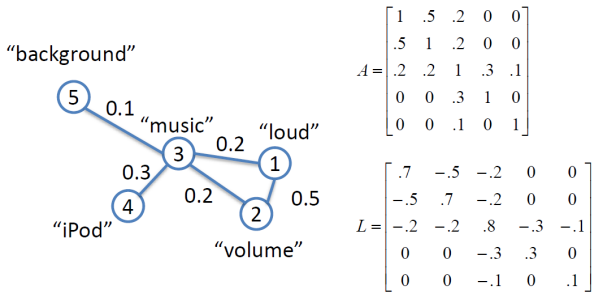

Figure 1: An example of the graph G, the corresponding affinity matrix A, and the corresponding Laplacian matrix L.

1. **Construct the distance matrix** $Dist$**.** To construct the distance matrix between each feature, we first transpose the instance-feature matrix, $I = \sum_j \vec{X}_j$, and assume that each feature (e.g. unigram in our task) is a random variable that has a multinomial distribution over the instances in the training set. Then, we compare each pair of features, and calculate the inter-feature distance matrix $Dist$ with Euclidean distance as a measure, and use the k-nearest neighbors (kNN) method (Beyer et al., 1999) to select the top neighbors of each feature.

2. **Derive the affinity matrix** A**.** To assign the weight on the edge $E_{(p,q)}$ for each connected nodes (the kNN of V in $Dist$), we use the cosine similarity $cosine(V_p, V_q)$ metric (Wang and Hirschberg, 2011).

3. **Generate the degree matrix** D **and Laplacian matrix** L**.** As discussed earlier, we sum up the symmetric affinity matrix by row, and obtain a diagonal degree matrix D, and we further define a Laplacian matrix $L = D - A$.

To calculate the above matrices in an efficient manner, we partition the covariate into blocks, and process each block in parallel (Chen et al., 2011). An intuitive example of the graph G, its associated affinity matrix A, and Laplacian matrix L, is shown in Figure 1.

Parameter Estimation: Regarding the optimization of objective function in (12-13), a notable problem is that the sparsity inducing L_1 term is non-differentiable, whereas this is not the case for the L_2 norm and the Laplacian structured sparsity term. If we first take the derivative of the latter two terms,

and we can derive the following gradient components:

$$\frac{\partial(\lambda_2||\vec{W}||^2 + \alpha(\vec{W}^\top L\vec{W}))}{\partial\vec{W}} \tag{14}$$

$$= 2\lambda_2\vec{W} + \alpha(\vec{W}^\top L^\top + \vec{W}^\top L) \tag{15}$$

$$= 2\lambda_2\vec{W} + \alpha(L^\top + L)\vec{W} \tag{16}$$

since our Laplacian matrix is symmetric, we can rewrite (16) as

$$2(\lambda_2\vec{W} + \alpha L\vec{W}) \tag{17}$$

Then, we combine the gradient of the log loss function in (5) with (17), and apply a bound-constrained re-formulation (Schmidt et al., 2007) and the limited memory BFGS (L-BFGS) method (Liu and Nocedal, 1989) to solve the L_1 regularized problem. The L-BFGS method has relatively low space complexity, and does not require the calculation of full Hessian matrix, thus it is often used for L_1 optimization problems.

Augmented Laplacian for an L_1-Constrained Problem: Instead of formulating the L_1-regularized problem by adding the L_1 norm, an alternative solution is to formulate a L_1-constrained problem by fixing the sum of all weights τ in the weight vector $\vec{W}$. The reason is because adding the L_1 norm will make the objective function not continuously differentiable, where as the L_1 constraint could be just a simple linear constraint (Lee et al., 2006). Thus, the alternative L_1-constrained problem could be defined as:

$$\min(-\ell), s.t. \sum_p \vec{W}_p \leq \tau \tag{18}$$

To test the robustness of Laplacian structured sparsity term in the setup of a L_1-constrained problem, we can incorporate the Laplacian penalty term into the above formula, and derive:

$$\min\Big(-\ell + \alpha(\vec{W}^\top L\vec{W})\Big), s.t. \sum_p \vec{W}_p \leq \tau \tag{19}$$

Note that the Laplacian matrix is positive-semidefinite,

$$\vec{W}^\top L\vec{W} = \vec{W}^\top \sum_{(p,q)} L_{(p,q)}\vec{W} \tag{20}$$

$$= \sum_{(p,q)} \vec{W}^\top L_{(p,q)}\vec{W} \tag{21}$$

$$= \sum_{(p,q)} ||\vec{W}_p - \vec{W}_q||^2 A_{(p,q)} \tag{22}$$

because this graph Laplacian penalty can be viewed as a quadratic term, and the objective function in equation 19 is now convex differentiable and will produce sparse estimates, so that we are able to use a limited-memory projected quasi-Newton method (Schmidt et al., 2009) to solve the dual form of this problem. The Lagrangian dual form of the problem in equation 19 can be written as:

$$\mathcal{L}(\vec{W}, \xi) = -\ell + \alpha(\vec{W}^\top L\vec{W}) \tag{23}$$

$$+ \beta\left(\sum_p \vec{W}_p - \tau\right) - \xi\vec{W} \tag{24}$$

where $\beta \in \mathbb{R}$ is a Lagrange multiplier, and $\xi \in \mathbb{R}^p_+$ is a p-dimensional vector of non-negative Lagrange multipliers. And then we can take first-order partial derivative with regard to $\vec{W}$, and set it to zero to derive the optimality:

$$\frac{\partial\mathcal{L}}{\partial\vec{W}} = -\sum_j \left(\hat{\theta}_{y_j} - (\hat{\theta}_{y_j})^2\right)\vec{X}\left(\frac{y_j}{\hat{\theta}_{y_j}} - \frac{1-y_j}{1-\hat{\theta}_{y_j}}\right) \tag{25}$$

$$+ 2\alpha L\vec{W} + \beta - \xi = 0 \tag{26}$$

To speed up the training, we use the linear-time L_1-ball projection method from Duchi et al. (2008) in our implementation.

5 Experiments

We first compare our model to various baselines in the 3-way automatic brand identification task. Besides the logistic regression, lasso, ridge and elastic net model that we introduced in Section 4.2, we also compare with a PCA-based logistic regression model where the dimensions of the feature space is reduced in half before the classification. A state-of-the-art linear kernel SVM model (Chang and Lin, 2011) is also taken into the comparison. In the second part, we perform 9-way joint classification of the brand-satisfaction labels. Similarly, we also perform a 18-way joint classification of the brand-gender-satisfaction labels. To test the robustness of our model, we vary the levels of sparsity of our Laplacian augmented method in a L_1-constrained problem. Finally, we analyze the identified features for CBA. Throughout this section, we use classification accuracy to report the results. We tune the regularization parameters of log-linear models and

the cost parameter of the SVM on the development set, and report results on both the development set and the held-out test set. The parameter for kNN was set to 5 according to previous literature (Gao et al., 2012). A paired two-tailed t-test is used to test the statistical differences among various models.

5.1 Automatic Brand Identification from Text

Given any piece of raw text from the Web (e.g. blogs, tweets, news, or forum posts), the first task for CBA is to identify which brand this text is related to. Our customer review data set is useful for this task, because the ground truth of the brand label is attached to each review. Table 2 shows the result of our model in this automatic brand identification task. In this 3-way classification task, the overall results indicate that it is relatively easy to identify the related brand from customer reviews. When evaluating our Laplacian structured sparsity model, our proposed model obtains the best performances of 93.17% and 92.44%, which are statistically better than the second best results ($p < .001$) in both datasets.

5.2 Joint Brand-Satisfaction Prediction

In our training data set, we observe a subtle correlation between the brand and satisfaction labels ($r = 0.09$, $p < .001$), which suggests us that it might be interesting to perform a joint prediction task for the brand-satisfaction labels. This task is also attractive from the business perspective, because it would be very useful for the companies to directly identify user's level of satisfaction about their brands. Table 3 shows that we achieve 69.56% accuracy on the development set, and 67.32% accuracy on the test set using our proposed Laplacian structured model ($p < .001$ comparing to the second best results).

Method	Dev.	Test
Majority class	28.24	27.68

Laplacian structured sparsity	**41.22***	**40.22***

Table 4: The joint brand-gender-satisfaction prediction (18-way) performances. The best result is highlighted in **bold**. * indicates $p < .001$ comparing to the second best result.

5.3 Joint Brand-Gender-Satisfaction Prediction

Another big interest in the marketing community is to predict subgroup preferences of specific brands. In this direction, we perform a 18-way joint brand-gender-satisfaction prediction using the gender labels that we described in Section 3. Table 4 shows that our proposed Laplacian structured sparsity model obtains a test accuracy of 40.22%, significantly better than the second best result ($p < .001$).

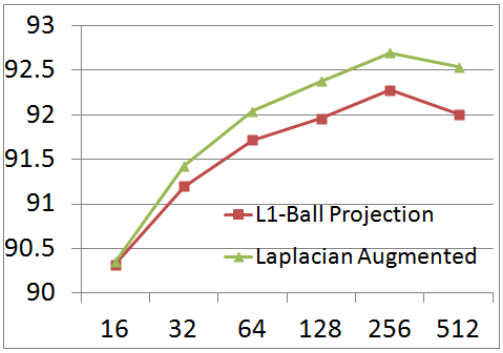

Figure 2: Automatic brand identification test performance varying the level of sparsity τ in a L_1 constrained problem.

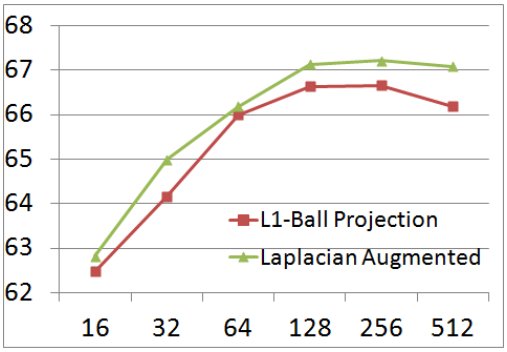

Figure 3: Joint brand-satisfaction prediction test performance varying the level of sparsity τ in a L_1 constrained problem.

5.4 Varying the Level of Sparsity in a L_1-Constrained Problem

To test the robustness of the Laplacian structured sparsity component, we exponentially increase the sum of weights τ to vary the level of sparsity in a L_1-constrained setup. When τ increases, the non-zero weights in the model also increases. Figures 2 and 3 show that the Laplacian augmented L_1-ball projection statistically outperform the L_1-ball projection baseline in all levels of sparsity ($p < .001$). In Figure 4, Laplacian augmented L_1-ball projection is also statistically better than the L_1-ball projection ($p < .001$), except when $\tau = 32$ and $\tau = 64$.

5.5 Exploratory Data Analysis

We outline the top 15 keywords from the Laplacian structured sparsity model that are associated with the Starbucks and Dunkin' Donuts brands in the automatic brand identification task in the Table 5. First of all, it is observed that our model has discovered synonyms for both brands: "sbux", "dd", "dds".

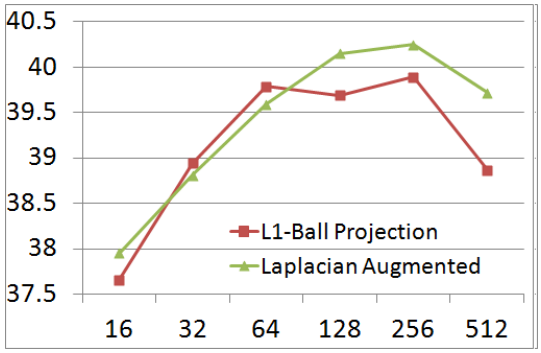

Figure 4: Joint brand-gender-satisfaction prediction test performance varying the level of sparsity τ in a L_1 constrained problem.

Also, the results imply that Starbucks' unique cup size branding strategy, "venti", "grande", "tall", has resonated with their customers as the words prominently show up as top features in reviews. Aligned with previous study in marketing science (Moon and Quelch, 2006), an informative set of features related to Starbucks store decorations showed up in our model: "store", "restroom", "public", "bathroom", and "spacious". In contrast, these features stopped to show up on the list of Dunkin' Donuts. Instead, TV and game (sports), which are indeed important features of dining at Dunkin' Donut, appeared. Note that Baskin-Robbins, which is a sub-brand of Dunkin' Brands Group, Inc., also appeared as informative features to predict Dunkin' Donuts.

To understand the preferences of different gender subgroups towards the two brands, we contrast in Table 6 and Table 7 the top features that identify the satisfied **female** and **male** customers in the joint brand-gender-satisfaction prediction task.

Interestingly, it seems that the female customers identify Starbucks as a place for "studying", with "fireplace" as the top preference of the spots in the store, and "winter" is also a high-ranked feature. Also, the adjective "super" was frequently mentioned by the female Starbucks customers (but not the males). As for Dunkin' Donuts, the top-ranked keywords are still mainly associated with its names, but it seems the snack "Munchkins" is highly preferred by the female customers. Not surprisingly, the cue words that the male customers identify the Starbucks brand do not always agree with those of the females. For example, instead of "fireplace", they prefer staying at the "patio", and drink the coffee from the "clover" brewing system. Interestingly,

Starbucks	weight	Dunkin'	weight

Table 5: Top features that identify the Starbucks and Dunkin' Donuts brands from the best model.

.

on the Dunkin's side, "munchkins" also disappeared and replaced by "glazed" (donuts). However, both males and females agreed that "fast" or "quick" service was an important feature of creating satisfaction, which echoes with the result from self-reported customer surveys (Moon and Quelch, 2006).

The word "**name**" is a prominent indicator for the female customers of Starbucks: at first we were puzzled, but after we digged into the database, we found reviews such as:

- *"... and the baristas are one of the nicest they always ask for your **name**, so you never end up with coffee meant for the guy behind you."*
- *"... she asked me my name and i told her and she excidetly proclaimed melissa and wrote my **name** on the cup. This place was probably one of the better starbucks ive been to."*
- *"... all of their employees are really friendly, and embarrassingly enough most know me by **name** and know my typical drink order grande nonfat misto with a flavor shot of white mocha. This is actually very helpful."*

The above examples show how our system effectively serves as a salient keyword spotter. And that as a keyword spotter one can use it to extract surrounding context and feed that through to the next stage of analysis, including examination by humans. This is extremely practical and useful, because it provides actionable items. For example, analysts can advise managers to revise their training manual and tell store employees to *remember the names of your frequent female customers*.

Table 7: Top features that jointly identify the satisfied **male** customers and the Starbucks and Dunkin' Donuts brands from the best model.

6 Discussions

In our preliminary experiments, we have also experimented with the setup where the two keywords "starbucks" and "dunkin" were removed from the list of features. This change resulted in a uniformed 2% decrease in performances across all the models in Table 2, which did not affect the comparisons.

However, we kept these two keywords in our final experiments, because the reviewers sometimes mention "Dunkin" in Starbucks reviews, and vice versa. Removing the two keywords could be problematic, since it changes the natural distribution of the data.

Regarding the alternative problem setups, our preliminary experiments showed that instead of using one-vs-all binary classifiers, a direct 9-way multi-class classification of joint brand-satisfaction labels using logistic regression only resulted an accuracy of 62%. We also did not adopt the hierarchical classification pipeline, where instead of performing joint classification, multiple layers of classifiers could be trained to classify brand, gender, and satisfaction labels incrementally. This is because the hierarchical classifiers suffered from the error propagation problem, and the second/third layer classifier could not correct the errors from the previous layers (Bennett and Nguyen, 2009).

Our proposed method to generate inter-feature affinity matrix captures interesting dependency of features in this dataset. For example, although the words "frappuccino" and "slurping", "furniture" and "mismatched' are semantically very different, our method actually group them together due to the subtle interactions of these word pairs in our tasks. The example in Figure 1 is also very specific to our dataset. This is very useful, because the word semantic similarity might be context-dependent, and our method learns and adapts the semantic similarity on the fly, hinges on the particular training set. On the other end of the spectrum, even though our method is desirable in our task, one might need to be cautious when working on very small data sets with only a handful of samples. This is because small samples typically have large variances in feature distributions, and that the generated Laplacian matrix might not be as reliable as in our study. To alleviate this potential problem, one might consider building the Laplacian matrix using external resources such as WordNet or FrameNet, even though this approach could also introduce biases due to the mismatched task domains.

We also observed that the accuracy of the automatic brand identification task was high, indicating the promising future of CBA for hidden brand information from other genres of text over the Web. Although the performances of joint brand-satisfaction and joint brand-gender-satisfaction predictions are relatively lower, there is still much room for improvements: for example, using the syntactic, semantic, and meta-data features could potentially enrich the proposed model. Also, it is possible to consider the higher order n-gram features for better exploratory data analysis. However, since the focus of this paper is a proof of concept for Laplacian structured sparsity models and computational branding analytics, we have not yet explored various multi-view representations to augment our model.

Why does Laplacian structured sparsity model work better in these classication tasks? Similar to the application in image classifcation (Gao et al., 2010), one advantage of Laplacian regularization in text classification is that our model can explicitly model the dependency of local features. Another reason is the expressiveness of our model: our model allows one to express the feature interactions in a structured manner. Thirdly, by embedding the structure in the regularization term, our model is more flexible: one can now control the structured penalty by tuning the regularization parameter on the development set.

7 Conclusions

We introduce a Laplacian structured sparsity model for computational branding analytics (CBA). In the automatic brand identification, our model achieves the best result, dominating many competitive baselines. We also introduce the tasks of joint brand-satisfaction and brand-gender-satisfaction predictions, and show that the Laplacian structured sparsity do well in these tasks. A closer evaluation that varying the levels of sparsity in a L_1 constrained problem also indicates that the Laplacian augmented L_1-ball projection model can provide state-of-the-art results. By examining the weights of the derived Laplacian structured sparsity model, interesting indicators of brands and theirs gender-specific customer satisfaction associations are also discovered. In the future, we would like to investigate other methods for generating robust inter-feature Laplacians that include deep syntactic and semantic features.

Abstract

Hot trends are likely to bring new business opportunities. For example, "Air Pollution" might lead to a significant increase of the sales of related products, e.g., mouth mask. For e-commerce companies, it is very important to make rapid and correct response to these hot trends in order to improve product sales. In this paper, we take the initiative to study the task of how to identify trend related products. The major novelty of our work is that we automatically learn commercial intents revealed from microblogs. We carefully construct a data collection for this task and present quite a few insightful findings. In order to solve this problem, we further propose a graph based method, which jointly models relevance and associativity. We perform extensive experiments and the results showed that our methods are very effective.

1 Introduction

A trend is a hot topic (e.g., the release of a popular movie) which is being widely discussed by the public. Hot trends usually attract much attention from the public, and they are likely to bring new business opportunities. Consider the following e-shopping scenario. A user in Beijing would like to buy something to reduce the health impacts of Beijing air pollution[1]. Different from traditional e-shopping stories, in this case the user may not have a clear idea of what she should buy, and cannot even formulate the purchase needs into a clear query. Faced with trend-driven business opportunities, e-commerce companies typically ask workers to manually identify related products and make heuristic rules to match user queries (e.g., incorporating trending keywords into related product titles).

To improve trend-driven e-commerce, in this paper, we propose to study the novel task of *automatically identifying trend related products*. Why is it compelling to understand and study trend-driven product purchase? Because hot trends are closely related to business opportunities directly or indirectly. As a case of direct causal relationship, the worldwide popularity of the movie series "Harry Potter" created the great success of the original novels of "Harry Potter". As a case of indirect causal relationship, the stock rise or salary increase might exert positive effects on product sale. Based on our empirical analysis (See Section 3), a considerable proportion, i.e. 50%, of hot trends discussed on the largest Chinese microblog (i.e. Sina Weibo) indeed have corresponding product entries in the largest Chinese *C2C* e-commerce website (i.e. Taobao), which indicates a strong correlation between hot trends and product sale.

Although the task is important and emergent, it has at least two major challenges. First of all, how to infer users' trend-driven purchase intents promptly. A trend usually happens unexpectedly. Without prior knowledge and experiences, it is particularly difficult to make rapid response to relate the trend to candidate products. Our solution is to *leverage trend-related commercial intents from microblogs* by mining users' real-time response to a trending topic. We adopt the solution based on two key considerations: (1) Microblogs are fast. As previous studies showed,

[1]See http://www.nytimes.com/2013/04/04/world/asia/two-major-air-pollutants-increase-in-china.html to find more details about the trending topic "Beijing Air Pollution".

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1337–1347,
Seattle, Washington, USA, 18-21 October 2013.

the first story of a trending topic indeed was usually reported in microblogs rather than traditional news media (Sakaki et al., 2010; Kwak et al., 2010; Leskovec et al., 2009). (2) Microblogs contain users' commercial intents. The microblogging service has become one of the most popular social network platforms, where users may tweet about their needs and desires (Hollerit et al., 2013). E.g., a microblog user may complain about the air quality and evince the desire to buy a mouth mask in a tweet. The example indicates we can make use of tweet-level relatedness to capture the correlation between *trends* and *products*.

Second, how to achieve a comprehensive coverage of related products but not hurting precision. The above solution will miss the related products which have not been discussed in microblogs. Our idea is to take the associativity between products into consideration. Our definition about associativity is very general and can have different instantiations in specific settings. For example, we can define product associativity to be the similarity between product descriptions, or the ratio of historical purchase records in e-commerce companies. However, one-step associativity may not fully discover the underlying relatedness between products due to the fact that the product associativity is indeed transitive. Thus, a transitable associativity model is needed.

To address these two challenges, we propose a unified graph based ranking algorithm which jointly models the above two aspects, i.e., relevance and associativity. Given a trend, the algorithm runs in an iterative way and seeks a trade-off between relevance and associativity by propagating the scores on the product graph. Our contribution can be summarized as follows: (1) we introduce the novel task of identifying trend related products, most of all, we propose to leverage trend-related commercial intents from microblogs; (2) we present insightful empirical analysis to illustrate the correlation between hot trends and product sale (See Section 3); (3) we propose a novel graph based ranking algorithm which jointly considers relevance and associativity; (4) we carefully construct the test collection based on real data of the largest microblog and the largest *C2C* e-commerce website in China. (5) we perform extensive experiments and present some important implications for practice.

To the best of our knowledge, our work was the first to consider identifying trend related products by leveraging commercial intents from microblogs. We believe the current work will have important impact on industry and inspire more follow-up research studies. The rest of this paper is organized as follows. We present the data collection and empirical analysis of the impact of hot trends on product sale in Section 3. We present a novel graph-based method in Section 4. Experimental setup and results are discussed in Section 5 and Section 6. Finally, the related work is discussed in Section 7. And the conclusions and future work are given in Section 8.

2 Problem Definition

A *trend* is a hot topic widely discussed by the public, e.g., the release of a hot movie. Usually, a trend e can be described by a small set of keywords denoted by $\mathcal{K}_e$ and a corresponding time span $\mathcal{T}_e$.

Trend-related Products Identification: Given a trend e, we assume that the following inputs are available: 1) tweets that contain trend keywords $\mathcal{K}_e$ and 2) a product database which provides a set of candidate products $\mathcal{P} = \{p_1, p_2, ..., p_n\}$ with necessary detailed information, e.g., titles and descriptions. The objective of trend-related products identification is to identify products in $\mathcal{P}$ that are related to trend e within the time span $\mathcal{T}_e$, denoted by $\mathcal{P}_R$. For convenience, we will not explicitly mention the time span unless needed.

To better understand the problem, we first present an illustrative example in Table 1, which will be discussed as the running case throughout the paper. In this example, we can see that a few users tweet their product needs related to the trend "Air Pollution". We take Taobao as the product database and present a few related products in it.

Table 1: An illustrative example for the studied task.

Trend keywords: Air Pollution
Tweets:
What bad air! We need to buy masks ASAP!!!
I am planing to buy an air purifier. Hoping it can defend air pollution.
#air_pollution I will recommend to keep some houseplants at home.
Product database: Taobao[2]
Related products: Mouth Mask, Air Purifier, Houseplant

[2]The biggest C2C e-commerce site in China, similar to eBay.

3 Data and Observations

As discussed earlier, hot trends may exert positive effects on the sale of related products. In this section, we will construct a deep analysis on this point by presenting quantitative answers to the following two problems:

- Q_1: What is the proportion of hot trends that potentially lead to business opportunities, and how is their impact on related products?
- Q_2: How is the associativity between related products?

These findings are key and fundamental to develop our models.

3.1 Data Collection

To perform the above analysis, the key is how to construct an experimental data collection which relates hot trends to corresponding related products. We jointly consider microblogs and e-commerce platforms: we obtain hot trends in microblogs and manually identify trend-related products in e-commerce websites. In this paper, we adopt Sina Weibo[3] as the microbloging platform and Taobao[4] as the e-commerce platform, which are the biggest microblogging service and the largest C2C company in China respectively. The analysis method is general and can equally apply to other platforms. For both two data signals, we consider a two-month time span, i.e. from May 2013 to June 2013.

Trend detection. Since trend detection is not our focus, we directly obtained trends from "trending topics" provided by the microblog platform. Our work can be easily extended to incorporate a trend detection component. Similar to "trending topics" in Twitter, Sina Weibo provides a public list of top searched keywords which can be obtained by the Weibo search API[5]. In the list, top 50 keywords are presented and ordered by the number of being searched. Weibo classifies these keywords into five categories: *China*, *movie*, *business*, *person* and *sports*. We consider these keywords to be trend keywords. These keywords are dynamically updated and we monitor the trend lists in the considered time span. We define the start and end time of a trend to be the first day and the last day on the trend list respectively, which spans the active interval of a trend. We only keep the trend which has an active interval with more than one day. For each trend, we use the trend keywords to retrieve all related tweets in the active interval, and use the pattern based method in (Hollerit et al., 2013) to extract all mentioned product keywords. We present a few example patterns used for extracting product keywords in Table 2. After that we can obtain a set of product keywords for each trend.

Table 2: Example patterns for extracting product keywords.

Patterns	Example segments of tweets
买*(buy)*	买了飞利浦剃须刀送父亲 *bought father a Philips PT720 (Electric Razor).*
使用*(use)*	使用N95口罩降低污染 *use N95 (mouth mask) to reduce the impact of bad air*
推荐 *(recommend)*	推荐Galaxy S4 *recommend Galaxy S4 (cell phone)*

Related product identification and annotation. For each trend, we have the product keyword set together with the trend keywords as described above. We use these keywords to retrieve candidate products in the product search engine of Taobao within the active interval of the trend. For each candidate product, we further crawl its product page and obtain corresponding related products suggested by Taobao, which are treated as candidate, too. We invite two senior post-graduate students major in economics as human judges. The judge is required to make a binary decision whether a product is related to a trend by following a detailed guideline compiled by a senior officer of an e-commerce company in Beijing. For each trend, we provide the trend keywords, product keywords in tweets, related tweets, related news articles from China Daily[6]. Web access is available during the annotation process. Due to space limit, we do not present the annotation guideline here. We use Cohen's kappa to measure the agreement of these two judges, which has a high value of 0.75. To speed up the work, we further group all products which have the same lowest categorial label (e.g., leaf label) [7], and we

[3]http://www.weibo.com/

[4]http://www.taobao.com/

[5]http://s.weibo.com/top/summary

[6]http://www.chinadaily.com.cn

[7]Taobao has provided a category tree for products: http://list.taobao.com/browse/cat-0.htm).

will treat a group as a product in later experiments. We only keep the products with the same judgments and the trends with at least one related product. We present the statistics of data set in Table 3 [8]. Since current e-commerce search engines mainly adopt keyword matching based retrieval method, we further examine the performance of simply using trend keywords as queries. We compute the percentage of related/unrelated products with at least one trend keyword in their description. We can see that only 29.7% related products can be found on average. These statistics indicate that more effective methods are needed for the current task.

Table 3: Statitics of the data set.

# business-related trends	113
average candidate products per trend	55.1
average related products per trend	7.3
average perc. of rel. prod. with trend keywords	29.7%
average perc. of unrel. prod. with trend keywords	6.3%

3.2 Observations

Now we analyze the data collection and present our observations.

A_1: First of all, it is important to find out the proportion of hot trends that potentially leads to business opportunities. Recall that each trend has a category label and possibly a set of related products identified by the judges. We refer to a trend with related products as a business-related trend. We present the statistics in Fig. 1. We can see that about 36% of all trends have corresponding related products in Taobao, which indicates that these trends highly relate to business. *Movies* and *Sports* have higher proportions of business-related trends, i.e. 81% and 52% respectively, while the other categories have lower proportions but still with a substantial number of business related trends. It is noteworthy that *Business* has the lowest proportion, the major reason is that trends in *Business* are usually general events, i.e., the release of new economic policy, which do not directly correspond to related products. As we discussed earlier, these trends may have indirect impact on product sales. Currently, we only focus on direct impact, and indirect impacts will be considered in future work.

[8]The data set can be downloaded at `http://sewm.pku.edu.cn/~wjp`.

Next we continue to examine the impact of hot trends on the sale of related products. We obtain product sales from Taobao product pages. As we can see in Fig. 2, the average sale of related products in all categories gradually increased with trends going on. Interestingly, we can see that categories *Movies* and *China* achieved very significant increase. Products related to *Movies* trends are usually related to the movie itself, e.g., movie tickets; while products related to *China* tend to be commodities (e.g., the mouth masks for the trend of "Air Pollution") or trending products (e.g., Shenzhou-10 Spacecraft Model for the trend of "the launch of Shenzhou-10").

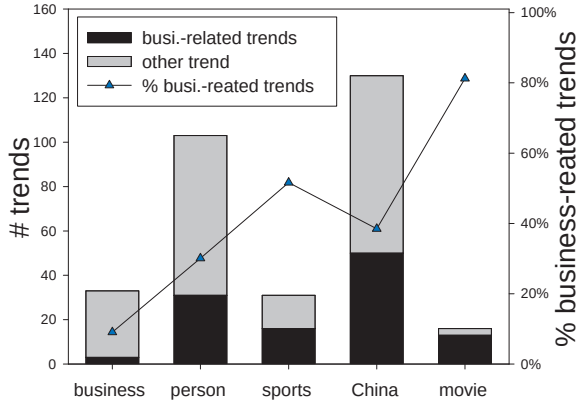

Figure 1: The proportion and volume of business-related trends in five categories.

A_2: Recall we have discussed that product associativity is useful for improving the coverage of related products. Here we would like to quantitatively examine the associativity between related products given a trend. For a trend, we first compute the average pairwise similarity between *related* products in terms of their descriptive texts (e.g. title and description). Since there are more unrelated products, we randomly sample an equal number of unrelated products from the candidate products we previously generated. Then we compute the average similarity between a related product and an unrelated product. We further average these values over all the trends of each category. The average similarity of related-related product pairs is 0.112, while the average similarities of unrelated-unrelated and related-unrelated

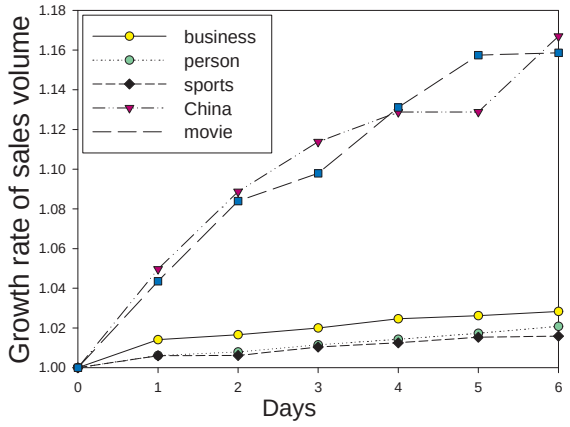

Figure 2: An illustrative analysis of the impact on related products in five categories. We measure the impact by computing the average growth ratio of sale in Taobao.

product pairs are 0.039 and 0.058 respectively.[9]

In summary, A_1 indicates that a large proportion of hot trends are potentially related to products and will exert positive effects on product sale; A_2 indicates that there is a strong associativity between related products, which can be utilized to improve both precision and recall of the algorithm.

4 The Proposed Method

In this section, we present a graph based ranking algorithm jointly models the relevance of a product and the associativity between products. Recall that we have collected a set of product keywords and a set of candidate products for each trend. Our aim is to re-rank these candidate products to obtain a better ranking of related products. We adopt a biased random walk algorithm: 1) relevance is modeled as biased restart probability and 2) associativity is modeled through random walk on the product graph.

4.1 Modeling the Product Relevance

Recall that in Section 2 we use the pattern based method to extract product keywords from tweets related to a trend. However, to stimulate the real scenario that we want to identify the related products at the beginning of a trend, we only keep the keywords which were contained in tweets published in the first three days when a trend began. These extracted product keywords directly reveal users' commercial intents on the trends. Instead of modeling personalized intents, we consider learning a unified trend-driven intent by representing the intent as a weighted vector over these product keywords. And the key is how to set the keyword weight.

Keyword weighting. A good weighting method should be able to leverage commercial interests/intents of users well and emphasize the keywords users really focus on. Thus we consider making use of the *retweeting* (a.k.a. *forwarding*) mechanism in microblogs. Retweet links are shown to be better in revealing relevance and interests (Welch et al., 2011). Formally, we use the following weighting formula for a keyword k:

$$\text{Weight}(k) = \sum_{t \in \mathcal{C}_k} \log_{10}(\#rt_t + 1), \quad (1)$$

where $\mathcal{C}_k$ is the set of all originally-written tweets (i.e., not a retweet) that contain the keyword k in the considered time span, and $\#rt_t$ is the retweet number of a tweet t. We further normalize and build the weight vector over all the considered keywords, called as *intent vector*. We denote the intent vector of a trend e by $\vec{e}$.

Product relevance. Having the intent vector, now we discuss about how to define the product relevance. Given a product p, we extract all the words in the title and description parts of a product. We represent it as a vector using the widely *tf-idf* weighting method. We denote the weight vector of product p by $\vec{p}$. We measure the product relevance between e and p as $\text{rel}(e,p) = \frac{\vec{e}\cdot\vec{p}}{|\vec{e}||\vec{p}|}$.

4.2 Modeling the Associativity between Products

To start this part, we first present an illustrative example in Fig. 3. We can see there are four related products for the trend "Air Pollution". We assume that only "mouth mask" was mentioned in microblogs. Now we expect to mine more related products with "mouth mask" as a known related product. We can compute the similarity between a pair of products. Intuitively, if the similarity between a candidate product and "mouth mask" is higher than a predefined threshold, we can consider it to be related, too. In this example, "air detector" and "air purifier" are similar to "mouth mask" in terms of prod-

[9]The difference was tested to be statistically significant.

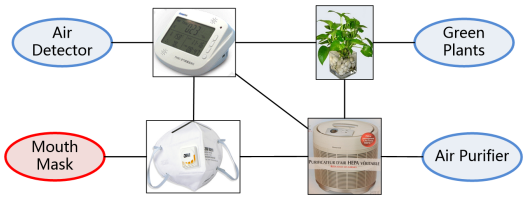

Figure 3: An example to illustrate the importance of associativity. Products which were mentioned in tweets related to "Air Pollution" are marked in red circles while the others are marked in blue circles. The link between products indicate the similarity between two products. Links with weights lower than a predefined threshold are not considered. Although "green plants" is related to this trend, it was not mentioned in tweets and did not have a direct link to "mouth mask".

uct descriptions and considered to be related, while "Green plants" is determined to be unrelated since it has very little overlap words with "mouth mask" in the description. It indicates one-step similarity method is not able to fully capture the real associativity between products.

Thus, we propose to use the random walk method to propagate the relatedness score on the product graph. Let P denote the number of all the candidate products, and $\boldsymbol{r}_{P\times 1}$ denote the relatedness score vector where r_i denote the relatedness score of product p_i.

We first construct the product graph. We represent each candidate product as a vertex in the graph and built the link with the cosine similarity between the descriptive texts of two products as the link weight.[10] We denote the similarity matrix by $\mathbf{M}_{P\times P}$ and $M_{i,j}$ denotes the similarity between products p_i and p_j. Formally, we formulate the problem in a standard PageRank form

$$\boldsymbol{r}^{(n+1)} = \mu \cdot \boldsymbol{r}^{(n)} \cdot \mathbf{M} + (1-\mu)\cdot \boldsymbol{y}, \qquad (2)$$

where $\boldsymbol{y}$ is the restart probability vector usually set to be uniform. With this method, it is easy to see that relatedness score can be propagated on the product graph, which better captures underlying associativity between products.

[10]Other similarity methods can be used, e.g., co-purse history record.

4.3 Jointly Modeling Relevance and Associativity

Having discussed about how to model both relevance and associativity, now we are ready to present a joint model to capture these two factors. By following (Zhao et al., 2013), the main idea is that instead of using a uniform restart distribution $\boldsymbol{y}$, we use an relevance biased restart distribution in Eq. 2. We set the restart probability of a product to its corresponding relevance. Formally, we set $y_i = \text{rel}(e, p_i)$. Let us further explain the idea. At the beginning of each iteration, each product is first assigned to its relevance score: the more relevant it is, the larger score it has. During the iteration, each product begins to collect relevance evidence from its neighbors on the product graph: the more relevant neighbors it has, the larger score it obtains. And the final score is indeed a trade-off between its own relevance score and neighboring relevance scores it receives. In order to obtain an ergodic walk, we add a small value, i.e. $1e-4$, to each entry of $\boldsymbol{y}$ and then normalize this vector. We denote our algorithm as JMRA (Jointly Modeling Relevance and Associativity).

To have an intuitive understanding of our algorithm, let us turn to the example in Fig. 3 again. At the beginning, only "mouth mask" has a large relevance score, with the iteration going on, the relatedness score will be propagated between products on the graph. Although "green plants" has not a direct link with "mouth mask", it can obtain relatedness score from its neighbors, i.e. "air detector" and "air purifier". JMRA is able to discover such latent associativity between products.

5 Experimental Setup

We use the test collection which have been described in Section 3. The statistics of the data set is shown in Table 3.

5.1 Evaluation Metrics

For a real product search engine, top results are particularly important, thus we adopt *precision@5* and *precision@10* as the evaluation metrics. Similar to Information Retrieval, we also consider using Mean Average Precision (MAP) as metrics to measure the overall quality of retrieved products.

5.2 Methods to Compare

We compare the following methods for inferring relating products:

SALES: we rank the candidate products by their historical sales volume descendingly.

TREND: we use trend keywords as queries and rank the products by their relevance.

TREND+fb: based on *TREND*, we further incorporate pseudo-relevance feedback (Salton, 1971; Salton and Buckley, 1997). After some tuning (See Section 6.5), top 3 search results were used to update the query.

JMRA$_r$: it is our method which only considers product relevance in Section 4.1.

JMRA$_r + fb$: we further apply pseudo-relevance feedback to *JMRA*$_r$.

JMRA$_{r+a}$: it is our method which considers both relevance and associativity in Section 4.3.

JMRA$_{r+a} + fb$: we further apply pseudo-relevance feedback to *JMRA*$_{r+a}$.

6 Experimental Results and Analysis

In this section, we first evaluate the performance of the proposed approach and the comparison methods. Next, we analyze a problem in real e-commerce search engines, i.e., the cold start. Then, we give a qualitative case study to further demonstrate the effectiveness of the proposed approach. Finally, we examine the parameter sensitivity to the performance.

6.1 Comparison of Performance

We present the results of various methods in Table 4. We first examine the performance of baselines *SALES*, *TREND* and *TREND+fb*. First, *SALES* has the worst performance due to the fact that a trend usually happen unexpectedly and historical records may not predict it well. The second observation is that the improvement of *TREND+fb* over *TREND* is little. This is mainly because that very few related products can be identified only based on trend keywords so feedback method does not work very well on it.

Then we compare our relevance based methods with the above three baselines. Note that the major difference between *JMRA*$_r$ and *TREND* is that *JMRA*$_r$ makes uses of both trend keywords and product keywords extracted from microblogs. We can see that *JMRA*$_r$ performs better than all three baselines. It proves the effectiveness of leveraging commercial intents from microblogs. Another interesting point is that the relative improvement *JMRA*$_r$*+fb* over *JMRA*$_r$ is larger than that *TREND+fb* over *TREND*. The reason is that pseudo relevance feedback relies highly on top results and a system with better search quality will benefit more from it.

Finally, we consider evaluating our full models which jointly consider relevance and associativity. It is easy to see *JMRA*$_{r+a}$ yields a significant improvement over *JMRA*$_r$ and even outperforms *JMRA*$_r$*+fb*. This observation supports our assumption that product associativity is very important in this task. Again, pseudo relevance feedback has also improved *JMRA*$_{r+a}$.

In summary, our results have shown some important implications for trend-related product retrieval on e-commerce search engines: 1) microblogs are very good signals to learn users' commercial intents; 2) product associativity is particularly important; 3) other advanced retrieval methods are potentially useful, e.g., pseudo relevance feedback.

Table 4: The overall performance of all the methods.

Models	P@5	P@10	MAP
SALES	0.345	0.379	0.225
TREND	0.543	0.325	0.327
TREND+fb	0.550	0.325	0.328
JMRA$_r$	0.611	0.527	0.336
JMRA$_r$*+fb*	0.661	0.552	0.348
JMRA$_{r+a}$	0.733	0.609	0.392
JMRA$_{r+a}$*+fb*	**0.734**	**0.624**	**0.404**

6.2 Cold Start

It is noteworthy that we have considered all the candidate products within the entire active interval of a trend when constructing the test collection. This is mainly to obtain a good coverage of related products since some e-commerce companies might release new products as the response to a trend. During the active interval of a trend, the e-commerce companies may make some heuristic rules to enhance the retrieval of related products, e.g., incorporating trend keywords into product titles and descriptions. In the

real application scenario, an effective method is expected to identify related products at the beginning of a trend when the e-commerce workers may not make any response to the trend. How would it be if we do not have the manually generated trend keywords from workers in product titles and descriptions?

To answer the question, in this part, we continue to examine the impact of cold start on different methods. We select three methods as comparisons, i.e., *TREND+fb*, *JMRA*$_r$ + fb and *JMRA*$_{r+a}$ + fb. We first use keyword matching methods to obtain all the products that related to trend keywords. The descriptive text (i.e., title and description) of these products has been refined to match trend queries by sellers in e-commerce websites. We further removed all the trend keywords in the desriptive text of these products, and gradually add the trend keywords back to original products. In such a process, we would like to examine how cold start affects the performance of different methods.

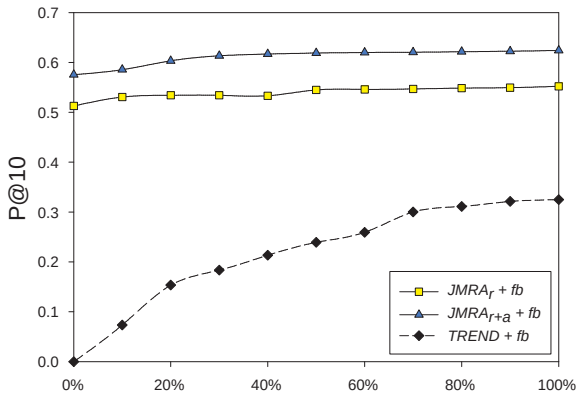

Figure 4: **The impact of cold start for different methods.**

We present the results in Fig. 4. First, performance of all these methods improve with the increase of products with trend keywords. Second, cold start does not affect the relative performance order of different methods, i.e., *TREND+fb* < *JMRA*$_r$ + fb < *JMRA*$_{r+a}$ + fb. Finally, all the methods display similar impact patterns: "significantli increasing" → "stable". An interesting observation is that *JMRA*$_r$ + fb and *JMRA*$_{r+a}$ + fb have much more stable performance compared to *TREND+fb*. It indicates that our methods are very robust to the cold start, and potentially applicable in real e-commerce search engines.

6.3 Case Study

In order to have a intuitive understanding of how different method perform, we present a case study in this part. We select *JMRA*$_r$, *JMRA*$_r$*+fb* and *JMRA*$_{r+a}$*+fb* as comparisons. The results are shown in Table 5. We can see that *JMRA*$_{r+a}$*+fb* have identified the most related products. We further analyze the contribution of different factors. Compared with *JMRA*$_r$, *JMRA*$_r$*+fb* has got one more related product "Houseplant" due to the reason pseudo feedback can make use of top related search results to improve the queries. In this case, "Houseplant" is identified to be related because it is very similar to "Air Detector" (We have presented the corresponding most associative products in brackets in Table 5). Similarly, the comparison between *JMRA*$_r$*+fb* and *JMRA*$_{r+a}$*+fb* shows the effectiveness of product associativity.

6.4 Error Analysis

To further understand the shortcomings of the proposed methods, we use the example in Table 5 for error analysis. Based on our manual inspection, errors may arise from two major sources for our method:

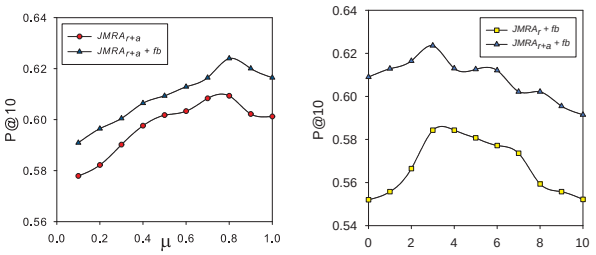
- Product keyword extraction errors: we use a pattern-based product keyword extraction method, and it tends to incorporate some irrelevant words. For example, given the topic "air pollution", users would talk about the impact of "car exhaust" on air quality and advocate to reduce automobile usage and sale. The current keyword extraction method might mistake the word "car" for a product related keyword.

- Search engine retrieval errors: in this paper, we rely on the Taobao product search engine for candidate product generation. It is highly based on surface-form matching to retrieve related products. Therefore, given a query "mouth mask", it might return some irrelevant products, e.g., "party mask". Clearly, pseudo-relevance feedback will also bring additional irrelevant products if top search results contain irrelevant ones.

Table 5: A qualitative comparison of three methods on the topic of "Air Pollution". We mark related products in bold.

Sample keywords learnt from microblogs:
air pollution, mouth mask, air, air purifier, respirator, house, mask, warm, bus, car, purified water

$JMRA_r$	$JMRA_r$+*fb*	$JMRA_{r+a}$+*fb*
Mouth Mask	**Mouth Mask**	**Mouth Mask**
Air Detector	**Air Detector**	**Air Purifier**
Air Purifier	**Air Purifier**	**Air Detector**
Toy House	Humidifier	**Respirator**
Respirator	**Respirator**	**Oxygen Bag (*Mouth Mask*)**
Toy Car	Party Mask	Humidifier
Environment-friendly Bags	Toy Car	**Houseplant (*Air Detector*)**
Humidifier	**Houseplant (*Air Detector*)**	**Anti-pollution Medicine (*Oxygen Bag*)**
Purified Water	Environment-friendly bags	Purified Water
Warmer	Purified Water	Party Mask



(a) (b)

Figure 5: Parameter sensitivity. a) The impact of the damping factor μ and b) the impact of the number of top products used for pseudo feedback.

To solve these problems, one promising way is to leverage more context information about the candidate products and construct deep semantic analysis. We will leave it as future work.

6.5 Parameter Sensitivity

The only parameter for *JMRA* is the damping factor in the random walk model, i.e., μ. Intuitively, a larger value of μ emphasize the associativity more while a smaller value emphasize the relevance more. We tune this parameter at a step of 0.1 and present the results in Fig. 5(a). We can see the performance of $JMRA_{r+a}$+*fb* is consistently better than that of $JMRA_r$+*fb* and peaks at around "0.8". It indicates the robustness of $JMRA_{r+a}$+*fb* and the importance of product associtivity.

We further examine the impact of the number of top products used for pseudo feedback for $JMRA_r$+*fb* and $JMRA_{r+a}$+*fb*. In Fig. 5(b), we can see that both $JMRA_{r+a}$+*fb* and $JMRA_r$+*fb* achieved their best at "3". It indicates that we only need to consider very top results for pseudo feedback.

6.6 Title or Description?

In previous experiments, for each product, we used the descriptive text in both title and description. In this part, we consider examining the individual effect of *title* and *description*. We use $JMRA_{r+a}$+*fb* as the examined method since both relevance and associativity relies on the text information.

Table 6: Evaluating the performance of $JMRA_{r+a}$+*fb* with different text sources.

sources	P@5	P@10	MAP
title	0.690	0.591	0.364
description	0.711	0.602	0.387
title+description	0.734	0.624	0.404

As shown in Table 6, we can see that the performance of only using *description* is better than that of only using *title* and a combination of both parts achieve the best. *title* is usually carefully compiled by e-commerce sellers, thus it reveals the most highlights of the products but very short; while *description* contains more informative text but tends to incorporate noise. In future work, we will consider a more principled way to combine *title* and *description*, e.g., weighted combination.

6.7 Efficiency

Finally, we present a few discussions about the issue of efficiency. All codes were implemented in Python 2.7, and all experiments were performed on a PC with *Intel(R) Core(TM)i5 CPU 760 @ 2.8GHz* and 8GB memory.

Sicne we group products by the categorial label, the number of candidate products is usually very small. Thus, our method *JMRA* runs very efficiently. Even on an extremely large set of candidate products, the iterative random walk algorithm can be easily implemented in a distributed way (Bahmani et al., 2011) and would have very good efficiency.

7 Related Work

Our work is mainly related to the following lines:

Mining the microblogs. Microblogs have been one of the most popular social networking platforms, and they have recently attracted much attention from research communities. The studies on trend (or event) detection (Benson et al., 2011; Weng and Lee, 2011; Sakaki et al., 2010; Zhao et al., 2012) tried to make use of the rapid response of microblogs users as the signal to automatically identify external events. Another important aspect is the content analysis of tweets, including the recommendation of real-time topical news (Phelan et al., 2009), sentiment or opinions analysis (Meng et al., 2012), event summarization using tweets (Chakrabarti and Punera, 2011; Lin et al., 2012; Zhao et al., 2013), etc. Our work do not explicitly incorporate a trend detection component, instead we make use of the trending topics provided by the microblogs platforms. It will be easy to incorporate other trend detection methods as our input.

Identifying online users' commercial intents. The identification of online users' commercial intents has been quite an important research problem in the past. Most researches focus on capturing commercial intention from search queries (Dai et al., 2006; Strohmaier and Kröll, 2012), click-through behaviors (Ashkan and Clarke, 2009), users' mouse movements or scrolling behaviors (Guo and Agichtein, 2010) and search logs (Strohmaier and Kröll, 2012). The most related to our work is the work in (Hollerit et al., 2013), which attempts to detect commercial intent on twitter. But we have very different focus. They aim to identify tweet-level commercial intents while ours aim to identify trend-driven commercial intents. In addition, we also present how to make use of these identified intents and our paper focuses on how to identify trend related products for e-commerce companies to improve service when faced with hot trends.

8 Conclusions

In this paper, we make the first attempt to identify trend related products by leveraging commercial intents from microblogs. We propose a way to construct the evaluation set for this task and present some insightful findings. We propose a graph based method to joint model relevance and associativity. We perform extensive experiments, including quantitative and qualitative analysis.

Currently, our approach is indeed a framework to solve this task, and we may consider improving the individual components in it, e.g. consider non-product keywords in tweets. For future work, we will consider incorporating a trend detection component into our method, which can be more flexible to adapt to various trend signals. We can also refine the method of the product keyword extraction by using more principled solutions.

Abstract

We investigate the value-add of topic modeling in text analysis for depression, and for neuroticism as a strongly associated personality measure. Using Pennebaker's Linguistic Inquiry and Word Count (LIWC) lexicon to provide baseline features, we show that straightforward topic modeling using Latent Dirichlet Allocation (LDA) yields interpretable, psychologically relevant "themes" that add value in prediction of clinical assessments.

1 Introduction

In the United States, where 25 million adults per year suffer a major depressive episode (NAMI, 2013), identifying people with mental health problems is a key challenge. For clinical psychologists, language plays a central role in diagnosis: many clinical instruments fundamentally rely on what is, in effect, manual coding of patient language. Automating language assessment in this domain potentially has enormous impact, for two reasons. First, conventional clinical assessments for affective disorders (e.g. The Minnesota Multiphasic Personality Inventory, MMPI) are based on norm-referenced self-report, and therefore depend on patients' willingness and ability to report symptoms. However, some individuals are motivated to underreport symptoms to avoid negative consequences (e.g. active duty soldiers, parents undergoing child custody evaluations), and others lack the self awareness to report accurately.[1] Second, many people – e.g. those without adequate insurance or in rural areas – cannot access a clinician qualified to perform a psychological evaluation (Sibelius, 2013; APA, 2013). There is enormous value in inexpensive screening measures that could be administered in primary care and by social workers and other providers.

We take as a starting point the well known lexicon-driven methods of Pennebaker and colleagues (LIWC, Pennebaker and King (1999)), which relate language use to psychological variables, and improve on them straightforwardly using topic modeling (LDA, Blei et al. (2003)). First, we show that taking automatically derived topics into account improves prediction of neuroticism (emotional instability, John and Srivastava (1999)), as measured by correlation with widely used clinical instruments, when compared with lexically-based prediction alone. Neuroticism is of particular interest as a personality measure because higher scores on neuroticism scales are consistent with increased distress and more difficulty coping; individuals with high levels of neuroticism may also be at higher risk of psychiatric problems categorized as Axis I in the DSM-IV (Association, 2000), including the internalizing disorders (depression, anxiety).[2] Second, we show a similar correlation improvement result for prediction of depression, adding improvement

[1] As evidenced by the fact that assessments such as the MMPI-2-RF include validity scales to detect, e.g., defensiveness, atypical responses, and overly positive self-portrayals (Tellegen et al., 2003).

[2] The Diagnostic and Statistical Manual of Mental Disorders is a widely used organization of mental health conditions; it served as the standard for diagnosis from 1994 until the release of the (quite controversial) DSM-5 in May, 2013. Axis I in the DSM-IV includes all the major diagnostic categories, excluding mental retardation and personality disorders.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1348–1353,
Seattle, Washington, USA, 18-21 October 2013.

on precision (with no decrease in recall), as well as comparison with human performance by clinical psychologists. Third, we show that LDA has identified meaningful, population-specific themes that go beyond the pre-defined LIWC categories and are psychologically relevant.

2 Predicting neuroticism

2.1 Experimental framework

Data. We utilize a collection of 6,459 stream-of-consciousness essays collected from college students by Pennebaker and King (1999) between 1997 and 2008, averaging approximately 780 words each. Students were asked to think about their thoughts, sensations, and feelings in the moment and "write your thoughts as they come to you".

Each essay is accompanied by metadata for its author, which includes scores for the Big-5 personality traits (John and Srivastava, 1999): agreeableness, conscientiousness, extraversion, neuroticism, and openness. Because Big-5 assessment can be done using a variety of different survey instruments (John et al., 2008), and different instruments were used from year to year, we treat the data from each year as an independent dataset.

Any author missing any Big-5 attribute was excluded. Essays were tokenized using NLTK (Bird et al., 2009) and lowercased, eliminating those that failed tokenization because of encoding issues. This resulted in a dataset containing 4,777 essays with associated Big-5 metadata.

LIWC features. For each document, we calculate the number of observed words in each of Pennebaker and King's 64 LIWC categories. These include, among others, syntactic categories (e.g. pronouns, verbs), affect categories (e.g. negative emotion words, anger words), semantic categories (e.g. causation words, cognitive words), and topical categories (e.g. health, religion). For instance, the anger category contains 190 word patterns specifying, for example, words descriptive of contexts involving anger (e.g. *brutal*, *hostile*, *shoot*) and words that would be used by someone when angry (e.g. *bullshit*, *hate*, *moron*). We also explored including essays' average sentence length and total word-count, as an initial proxy for language complexity, which often figures into psychological assessments. However, results adding these features to LIWC did not differ significantly from LIWC alone, and for brevity we do not report them.[3]

LDA features. We use vanilla LDA as implemented in the Mallet toolkit (McCallum, 2002), developing a k-topic model on just training documents, and using the posterior topic distribution for each training and test document as a set of k features. Mallet's stoplist and default parameters were used for burn-in, lag, number of iterations, priors, etc. Details on train/test splits and number k of topics appear below.

LIWC+LDA features. The union of the LIWC features (one feature per category) and LDA features (one feature per topic).

Prediction. We utilize linear regression in the WEKA toolkit (Hall et al., 2009), estimated on training documents, to predict the neuroticism score associated with the author of each test document.[4]

2.2 Results

Table 1 shows the quality of prediction via linear regression, averaged over the eleven datasets, 1997 through 2008, using Pearson correlation (r) as the evaluation metric. For each year, we used 10-fold cross-validation to ensure proper separation of training and test data. We experimented with LDA using 20, 30, 40, and 50 topics.[5]

A first thing to observe is that the multiple regressions using all LIWC categories produce much stronger correlations with neuroticism than the individual category correlations reported by Pennebaker and King.[6] There the strongest individual correlations with neuroticism for any LIWC categories are .16 (negative emotion words) and -.13 (positive emotion words), though it should be noted that their goal was to validate their categories as a meaningful

[3] Using richer measures of complexity, e.g. Pakhomov et al. (2011), is a topic for future work.

[4] In previous work we have found that multiple linear regression is competitive with more complicated techniques such as SVM regression, though we plan to explore the latter in future work.

[5] Full year-by-year data appears in supplemental materials at `http://umiacs.umd.edu/~resnik/papers/emnlp2013-supplemental/`.

[6] The comparison is not perfect, since they used Big-5 data collected between 1993 and 1998, and we also eliminated some files during preprocessing.

Feature set	LIWC	LDA20	LIWC+LDA20	LDA30	LIWC+LDA30	LDA40	LIWC+LDA40	LDA50	LIWC+LDA50
Average r	0.413	0.384	0.430	0.407	0.442*	0.420	0.459**	0.440	0.443*

Table 1: Prediction quality for neuroticism, for alternative feature sets (Pearson's r). *p$<$ .03, **$p < .02$

way to explore personality differences, not prediction.

As noted in Table 1, paired t-tests (df=10, $\alpha = .05$) establish that, in comparing the cross-year averages, augmenting LIWC with topic features improves average correlation significantly over using LIWC features alone for 30, 40, and 50 topics. LDA features alone do not improve significantly over LIWC.

3 Predicting Depression

3.1 Experimental framework

Data. We use essays collected by Rude et al. (2004) similarly to §2.1; in this case, students were asked to "describe your deepest thoughts and feelings about being in college". Each essay is accompanied by the author's Beck Depression Inventory score (BDI). BDI (Beck et al., 1961) is a widely used 21-question instrument that correlates strongly with ratings of depression by psychiatrists. Following Rude et al., we treat BDI ≥ 14 as the threshold for a positive instance of depression.[7] Text preprocessing was done as in §2.1, with 124 documents in total averaging around 390 words each.

Training/test split. Because only 12 of 124 authors met the BDI ≥ 14 threshold, we did not split randomly, lest the test sample include too few positive instances to be useful. Instead we included a random 6 of the 12 above-threshold cases, plus 24 more items sampled at random, to create a 30-item test set. To form the training set from the complementary items, we added two more copies of each positive instance to help address class imbalance (Batista et al., 2004) and, following Rude et al., we excluded items with with BDI of 0 or 1 as potentially invalid.

Human comparison. We created a set of expert human results for comparison by asking three practicing clinical psychologists to review the test documents and rate whether or not the author is suffering depression.[8] They were asked to "decide how at-risk this person might be for depression", assigning 0 (no significant concerns), 1 (mild concerns, but does not require futher evaluation), or 2 (requires attention, refer for further evaluation). Following recommended practice for cases where different labels are not equally distinct from each other (Artstein and Poesio, 2008), we evaluate inter-coder agreement using Krippendorff's α; our α, computed for ordinal data, is 0.722.

Features. We ran 50-topic LDA on the 4,777 essays from §2.1 plus the BDI training items, using the posterior topic distributions as features as in §2.1. As in §2.1, the LIWC features comprised one count per LIWC category, and LIWC+LDA features were the union of the two.

3.2 Results

Regression on LIWC features alone achieved $r = .288$, and adding topic features improved this substantially to $r = .416$. Treating BDI ≥ 14 as the threshold for positive instances (i.e. that an author is depressed), Table 2 shows that adding topic features improves precision without harming recall. Automatic prediction is more conservative than human ratings, trading recall for precision to achieve comparable F-measure on this test set.[9]

[7] Each question contributes a score value from 0 to 3, so BDI scores range from 0 to 63.

[8] These psychologists all have doctoral degrees, are licensed, and spend significant time primarily in assessment and diagnosis of psychological disorders. None were familiar with the specifics of this study.

[9] A reviewer observes, correctly, that in a scenario where a system is providing preliminary screenings to aid psychologists, the precision/recall tradeoff demonstrated here would potentially be undesirable, since a presumed goal would be to not miss any cases, even at the risk of some false positives. We note, however, that the real world is unfortunately replete with situations where there is significant cost or social/professional stigma associated with interventions or follow-up testing; in such situations it might be high precision that is desirable. These are challenging questions, and the ability to trade off precision versus recall more flexibly is a topic we are interested in investigating in future work.

4 Qualitative themes

In order to explore the relevance of the themes uncovered by LDA, the third author, a practicing clinical psychologist, reviewed the 50 LDA categories created in §3.1. Each category, represented by its 20 highest-probability words, was given a readable description. Then, for each category, she was asked: "If you were conducting a clinical interview, would observing these themes in a patient's responses make you more (less) likely to feel that the patient merited further evaluation for depression?"

Table 3 shows the seven topics selected as particularly indicative of further evaluation.[10] These capture population-specific properties in ways that LIWC cannot — for example, although LIWC does have a *body* category, it does not have a category that corresponds to somatic complaints, which often co-occur with depression. Similarly, some words related to energy level, e.g. *tired*, would be captured in LIWC's *body*, *bio*, and/or *health* category, but the LDA theme corresponding to low energy or lack of sleep, another potential depression cue, contains words that make sense there only in context (e.g. *tomorrow*, *late*). Other themes, such as the one labeled HOMESICKNESS, are clearly relevant (potentially indicative of an adjustment disorder), but even more specific to the population and context.

5 Related Work

The application of NLP to psychological variables has seen a recent uptick in community activity. One recent shared task brings together research on the Big-5 personality traits (Celli et al., 2013; Kosinski et al., 2013), and another involved research on identification of emotion in suicide notes (Pestian et al., 2012). Other examples include NLP research on autistic spectrum disorders (Van Santen et al., 2010; Prudhommeaux et al., 2011; Lehr et al., 2013) and dementia (Pakhomov et al., 2011; Lehr et al., 2012; Roark et al., 2011).

With regard to depression, Neuman et al. (2012) develop a corpus-based "depression lexicon" and produce promising screening results, and De Choudhury et al. (2013) predict social network behavior changes related to post-partum depression. Neither, however, evaluates using formal instruments for clinical assessment.

Related investigations involving LDA include Zhai et al. (2012), who use LIWC to provide priors for corpus-specific emotion categories; Stark et al. (2012), who combine LIWC and LDA-based features in classification of social relationships; and Schwartz et al. (2013), who use lexical and topic-based features in Twitter to predict life satisfaction.

6 Conclusions

In this paper, we have aimed for a small, focused contribution, investigating the value-add of topic modeling in text analysis for depression, and for neuroticism as a strongly associated personality measure. Our contribution here is not technical: corpus-specific topics/themes are anticipated by Zhai et al. (2012), and Stark et al. (2012) employ topic-based features for prediction in a supervised setting. Rather, our contribution here has been to show that topic models can get us beyond the LIWC categories to relevant, population-specific themes related to neuroticism and depression, and to support that claim using evaluation against formal clinical assessments. More data (e.g. Kosinski et al. (2013)) and more sophisticated models (e.g. supervised LDA, Blei and McAuliffe (2008), and extensions such as Nguyen et al. (2013)) will be the key to further progress.

Acknowledgments

We are grateful to Jamie Pennebaker for the LIWC lexicon and for allowing us to use data from Pennebaker and King (1999) and Rude et al. (2004), to the three psychologists who kindly took the time to provide human ratings, and to our reviewers for helpful comments. This work has been supported in part by NSF grant IIS-1211153.

Predicting the resolution of referring expressions from user behavior

Abstract

We present a statistical model for predicting how the user of an interactive, situated NLP system resolved a referring expression. The model makes an initial prediction based on the meaning of the utterance, and revises it continuously based on the user's behavior. The combined model outperforms its components in predicting reference resolution and when to give feedback.

1 Introduction

Speakers and listeners in natural communication are engaged in a highly interactive process. In order to achieve some communicative goal, the speaker will perform an utterance which they believe has a high chance of achieving that goal. They will then monitor the listener's behavior to see whether this goal is actually being achieved. This process is a core part of what is commonly called *grounding* in the dialogue literature (see e.g. (Clark, 1996; Traum, 1994; Paek and Horvitz, 1999; Hirst et al., 1994)). Interactive computer systems that are to carry out an effective and efficient conversation with a user must model this grounding process, and should ideally respond to the user's observed behavior in real time. For instance, if the user of a pedestrian navigation system takes a wrong turn, the system should interpret this as evidence of misunderstanding and bring the user back on track.

We focus here on the problem of predicting how the user has resolved a *referring expression (RE)* that was generated by the system, i.e. a noun phrase that is intended to identify some object uniquely to the listener. A number of authors have recently offered statistical models for parts of this problem. Golland et al. (2010) and Garoufi and Koller (2011) have presented log-linear models for predicting how the listener will resolve a given RE in a given scene; however, these models do not update the probability model based on observing the user's reactions. Nakano et al. (2007), Buschmeier and Kopp (2012), and Koller et al. (2012) all predict what the listener understood based on their behavior, but do not consider the RE itself in the model. The models of Frank and Goodman (2012) and Vogel et al. (2013) aim at explaining the effect of implicatures on the listener's RE resolution process in terms of hypothesized interactions, but do not actually support a real-time interaction between a system and a user.

In this paper, we show how to predict how the listener has resolved an RE by combining a statistical model of RE resolution based on the RE itself with a statistical model of RE resolution based on the listener's behavior. To our knowledge, this is the first approach to combine two such models explicitly. We consider the RE grounding problem in the context of interactive, situated natural language generation (NLG) for the GIVE Challenge (Koller et al., 2010a), where NLG systems must generate real-time instructions in virtual 3D environments. Our evaluation is based on interaction corpora from the GIVE-2 and GIVE-2.5 Challenges, which contain the systems' utterances along with the behavior of human hearers in response to these utterances. We find that the combined model predicts RE resolution more accurately than each of the two component models alone. We see this as a first step towards implementing an actual interactive system that performs human-like grounding based on our RE resolution model.

Seattle, Washington, USA, 18-21 October 2013.

Figure 1: An example scene in the GIVE environment.

2 Problem definition

In the GIVE Challenge, an interactive NLG system faces the task of guiding a human instruction follower (IF) through a treasure-hunt game in a virtual 3D environment (see Fig. 1). To complete the task, the IF must press a number of buttons in the correct order; these buttons are the colored boxes in Fig. 1, and are scattered all over the virtual environment. The IF can move around freely in the virtual environment, but has no prior knowledge about the world. The NLG system's task is to guide the IF towards the successful completion of the treasure-hunt task. To this end, it is continuously being informed about the IF's movements and visual field, and can generate written utterances at any time. As a comparative evaluation effort, the GIVE Challenges connected NLG systems to thousands of users over the Internet (see e.g. Koller et al. (2010a) for details).

Many system utterances are *manipulation instructions*, such as "press the blue button", containing an RE in the form of a definite NP. We call a given part of an interaction between the system and the IF an *episode* of that interaction if it starts with a manipulation instruction, ends with the IF performing an *action* (i.e., pressing a button), and contains only IF movements and no further utterances in between. Not all manipulation instructions initiate an episode, because the system may decide to perform further utterances (not containing REs) before the IF performs their action. An NLG system will choose the RE for an instruction at runtime out of potentially many semantically valid alternatives ("the blue button", "the button next to the chair", "the button to the right of the red button", etc.). Ideally, it will predict which of these REs has the highest chance to be understood by the IF, given the current scene, and utter an instruction that uses this RE.

After uttering the manipulation instruction, the system needs to ascertain whether the IF understood the RE correctly, i.e. it must engage in grounding. A naive grounding mechanism might wait until the IF actually presses a button and check whether it was the right one. This is what many NLG systems in the GIVE Challenges actually did. However, this can make the communication ineffective (IF performs many useless actions) and risky (IF may press the wrong button and lose). Thus, it is important that the system updates its prediction of how the IF resolved the RE continuously by observing the IF's behavior, *before* the actual button press. For instance, if the IF walks towards the target, this might reinforce the system's belief in a correct understanding; turning away or exiting the room could be strong evidence of the opposite. The system can then exploit the updated prediction to give the IF feedback ("no, the *blue* button") to prevent costly mistakes.

We address these challenges by estimating the probability distribution over the possible objects to which the IF may resolve the RE. We then update this distribution in real time by observing the IF's movements. More specifically, assume that a system tries to refer to some object a^* among some set A of available objects. Given an RE r generated for a^* at time t_0, the state of the world s at t_0, and the observed behavior $\sigma(t)$ of the user at $t \geq t_0$, we estimate the probability $p(a|r, s, \sigma(t))$ that the user resolved r to an object $a \in A$. When generating the instruction, an optimal NLG system will use the RE r that maximizes $p(a^*|r, s, \sigma(t_0))$. It can then track $p(a|r, s, \sigma(t))$ for time points $t > t_0$ throughout the episode, and generate feedback when $p(a'|r, s, \sigma(t))$ exceeds $p(a^*|r, s, \sigma(t))$ for some $a' \neq a^*$; that is, when the updated probability distribution predicts that the IF resolved r to an incorrect button.

3 A model of RE resolution

In order to model the distribution over possible objects, we assume the following generative story: when receiving an instruction containing an RE r at a given world state s, the IF resolves it to an object a; depending on the object a, the IF then moves towards it, exhibiting behavior σ. These assumptions correspond to the following factorization:

$$p(a, \sigma|r, s) = p(\sigma|a)p(a|r, s)$$

The posterior probability distribution over objects a can be obtained by applying the Bayes rule and using the above assumptions:

$$p(a|r, s, \sigma) \propto p(a|r, s)p(a|\sigma)/p(a)$$

For simplicity, we assume a uniform $p(a)$ over all objects in a world. We can thus represent $p(a|r, s, \sigma)$ as the normalized product of a *semantic* model $p_{sem}(a|r, s)$ and an *observational* model $p_{obs}(a|\sigma)$. We use log-linear models for both, and train them separately. The feature functions we use only consider general properties of objects (such as color and distance), and not the identity of the objects themselves. This means that we can train a model on one virtual environment (containing a certain set of objects), and then apply the model to another virtual environment, containing a different set of objects.

Semantic model The semantic model estimates for each object a in the environment the initial probability $p_{sem}(a|r, s)$ that the IF will understand a given RE r uttered in a scene s as referring to a. It represents the meaning of r, contextualized to s, and is only ever evaluated at the time t_0 of the utterance. The features used by this model are:

- **Semantic features** aim to encode whether r is a good description of a. *IsColorModifying* evaluates to 1 if a's color appears as an adjective modifying the head noun of r, e.g. "the blue button". *IsRelPosModifying* evaluates to 1 if a's relative position to the IF is mentioned as an adjective in r, e.g. "the left button".
- **Confusion features** capture the hypothesis that the IF may be confused by the description of a landmark when resolving the RE; e.g. an RE like "the button next to the red button" might confuse the IF into pressing a red button, rather than the one meant by the system. These are the same features as in the Semantic case, but looking for modifier keywords in the entire RE, including the head.
- **Salience features** account for the fact that an IF is more likely to resolve r to a if a was visually salient in s. *IsVisible* evaluates to 1 if a is visible to the IF in s. *IsInRoom* evaluates to 1 if the IF and a are in the same room. *IsTargetInFront* evaluates to 1 if the *angular distance* towards a, i.e. the absolute angle between the camera direction and the straight line from the IF to a, is less than $\frac{\pi}{4}$. *VisualSalience* approximates the visual salience of Kelleher and van Genabith (2004), a weighted count of the number of pixels on which a is rendered (pixels near the center of the screen have higher weights).

Observational model The observational model estimates for each object a the probability $p_{obs}(a|\sigma)$ that the IF will interact with a, given the IF's recent behavior $\sigma(t) = (\sigma_1, \ldots, \sigma_n)$, where σ_i is the state of the world at time $t - (i - 1) \cdot 500\text{ms}$, and $n \geq 1$ is the length of the observed behavior. p_{obs} is constantly re-evaluated for times $t > t_0$ as the IF moves around. p_{obs} uses the following features:

- **Linear distance features** assume that the closest button is also the one the IF understood. *InRoom* returns the number of frames σ_i in σ in which the IF and a are in the same room. *ButtonDistance* returns the distance between the IF and a at σ_1 divided by a constant such that the result never exceeds 1. If a is neither in the same room nor visible, the feature returns 1.
- **Angular distance features** analyze the direction in which the IF looks. *TargetInFront* returns the angular distance towards a at σ_1. *AngleToTarget* returns *TargetInFront* divided by π, or 1 if a is neither in the same room nor visible. *LinearRegAngleTo* applies linear regression to a list of observed angular distances towards a over all frames σ_i, and returns the slope of the regression as a measure of variation. Negative values indicate that the IF turned towards a, while positive values mean the opposite. If a is neither visible nor in the same room as the IF at σ_i, the angle is set to π.
- **Combined distance feature**: a weighted sum of linear and angular distance towards a, called *overall distance* in Koller et al. (2012).
- **Salience features** capture visual salience and its change over time. Defining VS_i as the result of applying the p_{sem} feature *VisualSalience* to σ_i and a, *LastVisualSalience* returns VS_n. *LinearRegVisualSalience* applies linear regression to all values VS_i and returns the slope as a measure of change in salience. *VisualSalienceSum* returns $(\Sigma_{i=1}^{n}\text{VS}_i) * \text{VS}_1$. This emphasizes the contribution of VS_1, which we assume is the

most reliable predictor of the IF's intentions.

- **Binary features** aim to detect concrete behavior patterns: *LastIsVisible* applies the p_{sem} feature *IsVisible* to σ_1, and *IsClose* evaluates to 1 if the IF is close enough and correctly oriented to manipulate a in the GIVE environment at σ_1.

4 Evaluation

Data We evaluated our model using data from the GIVE-2 (Koller et al., 2010b) and the GIVE-2.5 Challenges (Striegnitz et al., 2011), obtained from GIVE Organizers (2012). These datasets constitute *interaction corpora*, in which the IF's activities in the virtual environment were recorded along with the utterances automatically generated by the participating NLG systems. The data consists of 1833 games for GIVE-2 and 687 games for GIVE-2.5.

To extract training data for our model from the GIVE-2.5 data, we first identified moments in the recorded data where the IF pressed a button. From these, we discarded all instances from the tutorial phase of the GIVE game and those that happened within 200 ms after the previous utterance, as these clearly didn't happen in response to it. This yielded 6478 training instances for p_{obs}, each consisting of σ at 1 second before the action, and the button a which the IF pressed. We chose $n = 4$ for representing σ, except to ensure that the features only considered IF behavior that happened in response to an utterance. We achieved this by reducing n for the first few frames after each utterance, such that the time of σ_n was always after the time of the utterance. Finally, we selected those instances which are episodes in the sense of Section 2, i.e. those in which the last utterance before the action contained an RE r. This gave us 3414 training instances for p_{sem}, each consisting of a, r, the time t_0 of the utterance, and the world state s at time t_0.

We obtained test instances from the GIVE-2 data in the same way. This yielded 5028 instances, each representing an episode. We chose GIVE-2 for testing because the mean episode length is higher (3.3s, vs. 2.0s in GIVE-2.5), thus making the evaluation more challenging. Feature selection was done using the training data and a similar dataset from Koller et al. (2012). Note that the test data and training data are based on distinct sets of three virtual environments each, and were obtained with different NLG systems and users. This demonstrates the ability of our model to generalize to unseen environments.

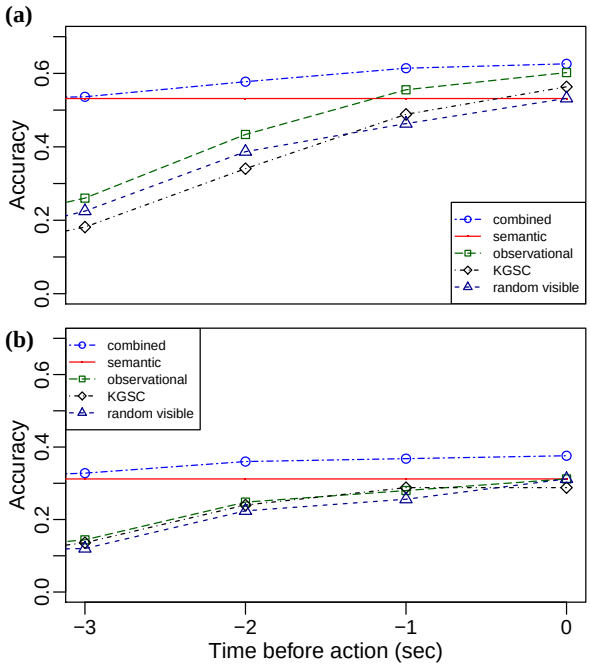

Figure 2: Prediction accuracy for (a) all episodes, (b) unsuccessful episodes as a function of time.

An example video showing our models' predictions on some training episodes can be found at `http://tinyurl.com/re-demo-v`.

Prediction accuracy We first evaluated the ability of our model to predict the button to which the IF resolved each RE. For each test instance $\langle r, s, \sigma, a \rangle$, we compare the object returned by $\arg\max_a p(a|r, s, \sigma(t))$ to the one manipulated by the IF. We call the proportion of correctly classified instances the *prediction accuracy*.

Fig. 2a compares our model's prediction accuracy to that of several baselines. We plot prediction accuracy as a function of the time at which the model is queried for a prediction, by evaluating at 3s, 2s, 1s, and 0s before the button press. The graph is based on the 2094 test instances with an episode length of at least three seconds, to ensure that results for different prediction times are comparable. As expected, prediction accuracy increases as we approach the time of the action. Furthermore, the combined model outperforms both p_{sem} and p_{obs} reliably. This indicates that the component models pro-

vide complementary useful information. Our model also outperforms two more baselines: *KGSC* predicts that the IF will press the button with the minimal *overall distance*, which is the distance metric used by the "movement-based system" of Koller et al. (2012); *random visible* selects a random button from the ones that are currently visible to the IF.

The fact that this last baseline does not approach 1 at action time suggests that multiple buttons tend to be visible when the IF presses one, confirming that the prediction task is not trivial.

Correctly predicting the button that the IF will press is especially useful, and challenging, in those cases where the IF pressed a different button than the one the NLG system intended. Fig. 2b shows a closer look at the 125 unsuccessful episodes of at least three seconds in the test data. These tend to be hard instances, and thus as expected, prediction accuracy drops for all systems. However, by integrating semantic and observational information, the combined model compensates better for this than all other systems, with an accuracy of 37.6% against 31.2% for each individual component.

Feedback appropriateness Second, we evaluated the ability of our model to predict whether the user misunderstood the RE and requires feedback. For all the above models, we assumed a simple feedback mechanism which predicts that the user misunderstood the RE if $p(a') - p(a^*) > \theta$ for some object $a' \neq a^*$, where θ is a confidence threshold; we used $\theta = 0.1$ here. We can thus test on recorded data in which no actual feedback can be given anymore.

We evaluated the models on the 848 test episodes of at least 3s in which the NLG systems logged the button they tried to refer to. The results are shown in Fig. 3 in terms of F1 measure. Here precision is the proportion of instances in which the IF pressed the wrong button (i.e., where feedback should have been given) among the instances where the model actually suggested feedback. Recall is the proportion of instances in which the model suggested feedback among the instances where the IF pressed the wrong button. Again, the combined model outperforms its components and the baselines, primarily due to increased recall. The difference is particularly pronounced early on, which would be useful in giving timely feedback in an actual real-time system.

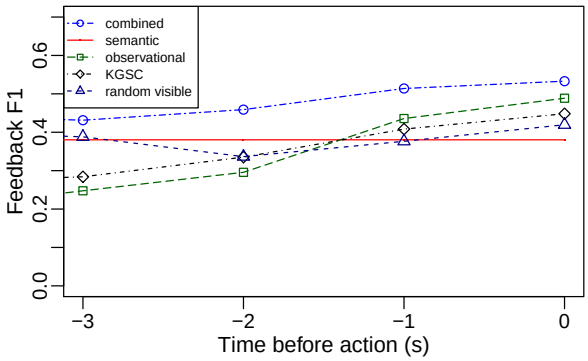

Figure 3: Feedback F1-measure as a function of time.

5 Conclusion and future work

We presented a statistical model for predicting how a user will resolve the REs generated by an interactive, situated NLG system. The model continuously updates an initial estimate based on the meaning of the RE with a model of the user's behavior. It outperforms its components and two baselines on prediction and feedback accuracy.

Our model captures a real-time grounding process on the part of the interactive system. We thus believe that it provides a solid foundation for detecting misunderstandings and generating suitable feedback in an end-to-end dialogue system. We have presented our model in terms of a situated dialogue setting, where clues about what the hearer understood can be observed directly. However, we believe that the fundamental mechanism should apply to other domains as well. This would amount to finding observable linguistic and non-linguistic clues of hearer understanding that can be used as features of p_{obs}.

The immediate next step for future research is to extend our model to an implemented end-to-end situated NLG system for the GIVE Challenge, and evaluate whether this actually improves task performance. This requires, in particular, to compute the RE that is optimal with respect to p_{sem}. We will furthermore improve p_{obs} by switching to a more temporally dynamic probability model.

Chinese Zero Pronoun Resolution: Some Recent Advances

Chen Chen and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{yzcchen,vince}@hlt.utdallas.edu

Abstract

We extend Zhao and Ng's (2007) Chinese anaphoric zero pronoun resolver by (1) using a richer set of features and (2) exploiting the coreference links between zero pronouns during resolution. Results on OntoNotes show that our approach significantly outperforms two state-of-the-art anaphoric zero pronoun resolvers. To our knowledge, this is the first work to report results obtained by an *end-to-end* Chinese zero pronoun resolver.

1 Introduction

A zero pronoun (ZP) is a gap in a sentence that is found when a phonetically null form is used to refer to a real-world entity. An anaphoric zero pronoun (AZP) is a ZP that corefers with one or more preceding noun phrases (NPs) in the associated text. Unlike overt pronouns, ZPs lack grammatical attributes that are useful for overt pronoun resolution such as number and gender. This makes ZP resolution more challenging than overt pronoun resolution.

We aim to improve the state of the art in Chinese AZP resolution by proposing two extensions. First, while previous approaches to this task have primarily focused on employing positional and syntactic features (e.g., Zhao and Ng (2007) [Z&N], Kong and Zhou (2010) [K&Z]), we exploit a richer set of features for capturing the context of an AZP and its candidate antecedents. Second, to alleviate the difficulty of resolving an AZP to an antecedent far away from it, we break down the process into smaller, intermediate steps, where we allow coreference links between AZPs to be established.

We apply our two extensions to a state-of-the-art Chinese AZP resolver proposed by Z&N and evaluate the resulting resolver on the OntoNotes corpus. Experimental results show that this resolver significantly outperforms both Z&N's resolver and another state-of-the-art resolver proposed by K&Z. It is worth noting that while previous work on Chinese ZP resolution has reported results obtained via gold information (e.g., using gold AZPs and extracting candidate antecedents and other features from gold syntactic parse trees), this is the first work to report the results of an *end-to-end* Chinese ZP resolver.

The rest of this paper is organized as follows. Section 2 describes the two baseline AZP resolvers. Sections 3 and 4 discuss our two extensions. We present our evaluation results in Section 5 and our conclusions in Section 6.

2 Baseline AZP Resolution Systems

An AZP resolution algorithm takes as input a set of AZPs produced by an AZP identification system. Below we first describe the AZP identifier we employ, followed by our two baseline AZP resolvers.

2.1 Anaphoric Zero Pronoun Identification

We employ two steps to *identify* AZPs. In the *extraction* step, we heuristically extract candidate ZPs. In the *classification* step, we train a classifier to distinguish AZPs from non-AZPs.

To implement the extraction step, we use Z&N's and K&Z's observation: ZPs can only occur before a VP node in a syntactic parse tree. However, according to K&Z, ZPs do not need to be extracted from every VP: if a VP node occurs in a coordinate structure or is modified by an adverbial node, then only its parent VP node needs to be considered. We extract ZPs from all VPs that satisfy the above constraints.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1360–1365,
Seattle, Washington, USA, 18-21 October 2013.

Syntactic features (13)	whether z is the first gap in an IP clause; whether z is the first gap in a subject-less IP clause, and if so, POS(w_1); whether POS(w_1) is NT; whether t_1 is a verb that appears in a NP or VP; whether P_l is a NP node; whether P_r is a VP node; the phrasal label of the parent of the node containing POS(t_1); whether V has a NP, VP or CP ancestor; whether C is a VP node; whether there is a VP node whose parent is an IP node in the path from t_1 to C.
Lexical features (13)	the words surrounding z and/or their POS tags, including w_1, w_{-1}, POS(w_1), POS(w_{-1})+POS(w_1), POS(w_1)+POS(w_2), POS(w_{-2})+POS(w_{-1}), POS(w_1)+POS(w_2)+POS(w_3), POS(w_{-1})+w_1, and w_{-1}+POS(w_1); whether w_1 is a transitive verb, an intransitive verb or a preposition; whether w_{-1} is a transitive verb without an object.
Other features (6)	whether z is the first gap in a sentence; whether z is in the headline of the text; the type of the clause in which z appears; the grammatical role of z; whether w_{-1} is a punctuation; whether w_{-1} is a comma.

Table 1: Features for AZP identification. z is a zero pronoun. V is the VP node following z. w_i is the ith word to the right of z (if i is positive) or the ith word to the left of z (if i is negative). C is lowest common ancestor of w_{-1} and w_1. P_l and P_r are the child nodes of C that are the ancestors of w_{-1} and w_1 respectively.

Features between a and z (4)	the sentence distance between a and z; the segment distance between a and z, where segments are separated by punctuations; whether a is the closest NP to z; whether a and z are siblings in the associated parse tree.
Features on a (12)	whether a has an ancestor NP, and if so, whether this NP is a descendent of a's lowest ancestor IP; whether a has an ancestor VP, and if so, whether this VP is a descendent of a's lowest ancestor IP; whether a has an ancestor CP; the grammatical role of a; the clause type in which a appears; whether a is an adverbial NP, a temporal NP, a pronoun or a named entity; whether a is in the headline of the text.
Features on z (10)	whether V has an ancestor NP, and if so, whether this NP node is a descendent of V's lowest ancestor IP; whether V has an ancestor VP, and if so, whether this VP is a descendent of V's lowest ancestor IP; whether V has an ancestor CP; the grammatical role of z; the type of the clause in which V appears; whether z is the first or last ZP of the sentence; whether z is in the headline of the text.

Table 2: Features for AZP resolution in the Zhao and Ng (2007) baseline system. z is a zero pronoun. a is a candidate antecedent of z. V is the VP node following z in the parse tree.

To implement the classification step, we train a classifier using SVM^{light} (Joachims, 1999) to distinguish AZPs from non-AZPs. We employ 32 features, 13 of which were proposed by Z&N and 19 of which were proposed by Yang and Xue (2010). A brief description of these features can be found in Table 1.

2.2 Two Baseline AZP Resolvers

The Zhao and Ng (2007) [Z&N] baseline. In our implementation of the Z&N baseline, we use SVM^{light} to train a mention-pair model for determining whether an AZP z and a candidate antecedent of z are coreferent. We consider all NPs preceding z that do not have the same head as its parent NP in the parse tree to be z's candidate antecedents. We use Soon et al.'s (2001) method to create training instances: we create a positive instance between an AZP, z, and its closest overt antecedent, and we create a negative instance between z and each of the intervening candidates. Each instance is represented by the 26 features employed by Z&N. A brief description of these features can be found in Table 2. During testing, we adopt the *closest-first* resolution strategy, resolving an AZP to the closest candidate antecedent that is classified as coreferent with it.[1]

The Kong and Zhou (2010) [K&Z] baseline. K&Z employ a tree kernel-based approach to AZP resolution. Like Z&N, K&Z (1) train a mention-pair model for determining whether an AZP z and a candidate antecedent of z are coreferent, (2) use Soon et al.'s method to create training instances, and (3) resolve an AZP to its closest coreferent candidate antecedent. Unlike Z&N, however, K&Z use the SVM$^{light-TK}$ learning algorithm (Moschitti,

[1] When resolving a *gold* AZP z, if none of the preceding candidate antecedents is classified as coreferent with it, we resolve it to the candidate that has the highest coreference likelihood with it. Here, we employ the signed distance from the SVM hyperplane to measure the coreference likelihood.

2006) to train their model, employing a parse subtree known as a dynamic expansion tree (Zhou et al., 2008) as a structured feature to represent an instance.

3 Extension 1: Novel Features

We propose three kinds of features to better capture the context of an AZP, as described below.

Antecedent compatibility. AZPs are omitted subjects that precede VP nodes in a sentence's parse tree. From the VP node, we can extract its head verb ($Pred_z$) and the head of its object NP (Obj), if any. Note that $Pred_z$ and Obj contain important contextual information for an AZP.

Next, observe that if a NP is coreferent with an AZP, it should be able to fill the AZP's gap and be compatible with the gap's context. Consider the following example:

E1: **他们**在试**那个服务**。那么啊就是 $*pro*$ 希望到九月我们的旅客来的时候。
(**They** are trying **that service**. That means $*pro*$ hope that our visitors can try it when they come in September.)

The head of the VP following $*pro*$ is 希望 (hope). There are two candidate antecedents, 他们 (They) and 那个服务 (that service). If we try using them to fill this AZP's gap, we know based on selectional preferences that 他们希望 (They hope) makes more sense than 那个服务希望 (that service hope). We supply the AZP resolver with the following information to help it make these decisions. First, we find the head word of each candidate antecedent, $Head_c$. Then we form two strings, $Head_c + Pred_z$ and $Head_c + Pred_z + Obj$ (if the object of the VP is present). Finally, we employ them as binary lexical features, setting their feature values to 1 if and only if they can be extracted from the instance under consideration. The training data can be used to determine which of these features are useful.[2]

Narrative event chains. A narrative event chain is a partially ordered set of events related by a common protagonist (Chambers and Jurafsky, 2008). For example, we can infer from the chain "borrow-s invest-s spend-s lend-s" that a person who borrows (presumably money) can invest it, spend it, or lend it to other people.[3] Consider the following example:

E2: **国家**给钱了，$*pro*$ 提供这部分的钱都是自己所里挣的。
(**The country** gives our department money, but all $*pro*$ provides is exactly what we worked for.)

In E2, $*pro*$ is coreferent with 国家 (The country), and the presence of the narrative event chain 给 − 提供 (gives−provides) suggests that the subjects of the two events are likely to be coreferent.

However, given the unavailability of induced or hand-crafted narrative chains in Chinese[4], we make the simplifying assumption that two verbs form a lexical chain if they are lexically identical.[5] We create two features to exploit narrative event chains for a candidate NP, c, if it serves as a subject or object. Specifically, let the verb governing c be $Pred_c$. The first feature, which encodes whether narrative chains are present, has three possible values: 0 if $Pred_c$ and $Pred_z$ are not the same; 1 if $Pred_c$ and $Pred_z$ are the same and c is a subject; and 2 if $Pred_c$ and $Pred_z$ are the same and c is an object. The second feature is a binary lexical feature, $Pred_c$+$Pred_z$+$Subject/Object$; its value is 1 if and only if $Pred_c$, $Pred_z$, and $Subject/Object$ can be found in the associated instance, where $Subject/Object$ denotes the grammatical role of c.

Final punctuation hint. We observe that the punctuation ($Punc$) at the end of a sentence where an AZP occurs also provides contextual information, especially in conversation documents. In conversations, if a sentence containing an AZP ends with a

[2] We tried to apply Kehler et al.'s (2004) and Yang et al.'s (2005) methods to learn Chinese selectional preferences from unlabeled data, but without success.

[3] "-s" denotes the fact that the protagonist serves as the grammatical subject in these events.

[4] We tried to construct narrative chains for Chinese using both learning-based and dictionary-based methods. Specifically, we induced narrative chains using Chambers and Jurafsky's (2008) method, but were not successful owing to the lack of an accurate Chinese coreference resolver. In addition, we constructed narrative chains using both lexically identical verbs and the synonyms obtained from a WordNet-like Chinese resource called Tongyicicilin, but they did not help improve resolution performance.

[5] Experiments on the training data show that if an AZP and a candidate antecedent are subjects of (different occurrences of) the same verb, then the probability that the candidate antecedent is coreferent with the AZP is 0.703. This result suggests that our assumption, though somewhat simplistic, is useful as far as AZP resolution is concerned.

A: **她**现在生活怎么样？
(A: How is **her** life now?)
B: $*pro_1*$ 对生活，就是很朴素，很简单。
(B: $*pro_1*$ attitude toward life is plain and simple.)
A: 嗯。
(A: Yes.)
A: $*pro_2*$ 是在北京还是在美国？
(A: $*pro_2*$ is living in Beijing or the USA?)
B: $*pro_3*$ 在美国。
(B: $*pro_3*$ is living in the USA.)

Figure 1: An illustrative example.

question mark, the mention this AZP refers to is less likely to be the speaker himself[6], as illustrated in the following example:

E3: 冬天 $*pro*$ 冷吗？
(Are $*pro*$ cold in the winter?)

Here, $*pro*$ refers to the person the speaker talks with. To capture this information, we create a binary lexical feature, $Head_c$+$Punc$, whose value is 1 if and only if $Head_c$ and $Punc$ appear in the instance under consideration.

4 Extension 2: Zero Pronoun Links

4.1 Motivation

Like an overt pronoun, a ZP whose closest overt antecedent is far away from it is harder to resolve than one that has a nearby overt antecedent. However, a corpus study of our training data reveals that only 55.2% of the AZPs appear in the same sentence as their closest overt antecedent, and 22.7% of the AZPs appear two or more sentences away from their closest overt antecedent.

Fortunately, we found that some of the difficult-to-resolve AZPs (i.e., AZPs whose closest overt antecedents are far away from them) are coreferential with nearby ZPs. Figure 1, which consists of a set of sentences from a conversation, illustrates this phenomenon. There are three AZPs (denoted by $*pro_i*$, where $1 \leq i \leq 3$), all of which refer to the overt pronoun 她 (She) in the first sentence. In this example, it is fairly easy to resolve $*pro_1*$ correctly,

[6]One may wonder whether we can similarly identify constraints on the antecedents of a ZP from clause conjunctions. Our preliminary analysis suggests that the answer is no.

	Training	Test
Documents	1,391	172
Sentences	36,487	6,083
Words	756,063	110,034
ZPs	23,065	3,658
AZPs	12,111	1,713

Table 3: Statistics on the training and test sets.

since its antecedent is the subject of previous sentence. However, $*pro_3*$ and its closest overt antecedent 她 (She) are four sentences apart. Together with the fact that there are many intervening candidate antecedents, it is not easy for a resolver to correctly resolve $*pro_3*$.

To facilitate the resolution of $*pro_3*$ and difficult-to-resolve AZPs in general, we propose the following idea. We allow an AZP resolver to (1) establish coreferent links between two consecutive ZPs (i.e., $*pro_1*-*pro_2*$ and $*pro_2*-*pro_3*$ in our example), which are presumably easy to establish because the two AZPs involved are close to each other; and then (2) treat them as bridges and infer that $*pro_3*$'s overt antecedent is 她 (She).

4.2 Modified Resolution Algorithm

We implement the aforementioned idea by modifying the AZP resolver as follows. When we resolve an AZP z during testing, we augment the set of candidate antecedents for z with the set of AZPs preceding z. Since we have only specified how to compute features for instances composed of an AZP and an overt candidate antecedent thus far (see Section 2.2), the question, then, is: how can we compute features for instances composed of two AZPs?

To answer this question, we first note that the AZPs in a test text are resolved in a left-to-right manner. Hence, by the time we resolve an AZP z, all the AZPs preceding z have been resolved. Hence, when we create a test instance i between z and one of the preceding AZPs (say y), we create i as if the gap y was filled with the smallest tree embedding the NP to which y was resolved.

By allowing coreference links between (presumably nearby) ZPs to be established, we can reason over the resulting coreference links, treating them as bridges that can help us find an overt antecedent that is far away from an AZP.

System Variation	Gold AZP Gold Parse Tree			System AZP Gold Parse Tree			System AZP System Parse Tree		
	R	P	F	R	P	F	R	P	F

Full System	**47.7**	**47.7**	**47.7**	**25.3**	**27.6**	**26.4**	**14.9**	**16.7**	**15.7**

Table 4: Resolution results on the test set.

5 Evaluation

5.1 Experimental Setup

Dataset. For evaluation, we employ the portion of the OntoNotes 4.0 corpus that was used in the official CoNLL-2012 shared task. The shared task dataset is composed of a training set, a development set, and a test set. Since only the training set and the development set are annotated with ZPs, we use the training set for classifier training and reserve the development set for testing purposes. Statistics on the datasets are shown in Table 3. In these datasets, a ZP is marked as $*pro*$. We consider a ZP anaphoric if it is coreferential with a preceding ZP or overt NP.

Evaluation measures. We express the results of both AZP identification and AZP resolution in terms of recall (R), precision (P) and F-score (F).

5.2 Results and Discussion

The three major columns of Table 4 show the results obtained in three settings, which differ in terms of whether gold/system AZPs and manually/automatically constructed parse trees are used to extract candidate antecedents and features.

In the first setting, the resolvers are provided with gold AZPs and gold parse trees. Results are shown in column 1. As we can see, the Z&N baseline significantly outperforms the K&Z baseline by 3.5% in F-score.[7] Adding the contextual features, the ZP links, and both extensions to Z&N increase its F-score significantly by 4.7%, 1.2% and 6.2%, respectively.

In the next two settings, the resolvers operate on the *system* AZPs provided by the AZP identification component. When gold parse trees are employed, the recall, precision and F-score of AZP identification are 50.6%, 55.1% and 52.8% respectively. Column 2 shows the results of the resolvers obtained when these automatically identified AZPs are used. As we can see, Z&N again significantly outperforms K&Z by 3.5% in F-score. Adding the contextual features, the ZP links, and both extensions to Z&N increase its F-score by 3.0%, 0.2% and 3.1%, respectively. The system with contextual features and the full system both yield results that are significantly better than those of the Z&N baseline. A closer examination of the results reveals why the ZP links are not effective in improving performance: when employing system AZPs, many erroneous ZP links were introduced to the system.

Column 3 shows the results of the resolvers when we employ system AZPs and the automatically generated parse trees provided by the CoNLL-2012 shared task organizers to compute candidate antecedents and features. Hence, these are *end-to-end* ZP resolution results. To our knowledge, these are the first reported results on end-to-end Chinese ZP resolution. Using automatic parse trees, the performance on AZP identification drops to 30.8% (R), 34.4% (P) and 32.5% (F). In this setting, Z&N still outperforms K&Z significantly, though by a smaller margin when compared to the previous settings. Incorporating the contextual features, the ZP links, and both extensions increase the F-score by 1.8%, 0.5% and 2.3%, respectively. The system with contextual features and the full system both yield results that are significantly better than those of the Z&N baseline.

6 Conclusions

We proposed two extensions to a state-of-the-art Chinese AZP resolver proposed by Zhao and Ng (2007). Experimental results on the OntoNotes dataset showed that the resulting resolver significantly improved both Zhao and Ng's and Kong and Zhou's (2010) resolvers, regardless of whether gold or system AZPs and syntactic parse trees are used.

[7] All significance tests are paired t-tests, with $p < 0.05$.

Abstract

This paper proposes a novel approach for relation extraction from free text which is trained to jointly use information from the text and from existing knowledge. Our model is based on scoring functions that operate by learning low-dimensional embeddings of words, entities and relationships from a knowledge base. We empirically show on New York Times articles aligned with Freebase relations that our approach is able to efficiently use the extra information provided by a large subset of Freebase data (4M entities, 23k relationships) to improve over methods that rely on text features alone.

1 Introduction

Information extraction (IE) aims at generating structured data from free text in order to populate Knowledge Bases (KBs). Hence, one is given an incomplete KB composed of a set of triples of the form (h, r, t); h is the left-hand side entity (or *head*), t the right-hand side entity (or *tail*) and r the relationship linking them. An example from the Freebase KB[1] is (/m/2d3rf ,<director-of>, /m/3/324), where /m/2d3rf refers to the director "Alfred Hitchcock" and /m/3/324 to the movie "The Birds".

This paper focuses on the problem of learning to perform relation extraction (RE) under weak supervision from a KB. RE is sub-task of IE that considers that entities have already been detected by a different process, such as a named-entity recognizer. RE then aims at assigning to a relation mention m (i.e. a sequence of text which states that some relation is true) the corresponding relationship from the KB, given a pair of extracted entities (h, t) as context. For example, given the triple (/m/2d3rf ,"wrote and directed", /m/3/324), a system should predict <director-of>. The task is said to be weakly supervised because for each pair of entities (h, t) detected in the text, all relation mentions m associated with them are labeled with all the relationships connecting h and t in the KB, whether they are actually expressed by m or not.

Our key contribution is a novel model that employs not only weakly labeled text mention data, as most approaches do, but also leverages triples from the known KB. The model thus learns the plausibility of new (h, r, t) triples by generalizing from the KB, even though this triple is not present. A ranking-based embedding framework is used to train our model. Thereby, relation mentions, entities and relationships are all embedded into a common low-dimensional vector space, where scores are computed. We show that our method can successfully take into account information from a large-scale KB (Freebase: 4M entities, 23k relationships) to improve over systems that are only using text features.

This paper is organized as follows: Section 2 presents related work, Section 3 introduces our model and its main influences, and experimental results are displayed in Section 4.

2 Previous Work

Learning under weak supervision is common in natural language processing, especially for tasks where the annotation costs are significant such as in se-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1366–1371,
Seattle, Washington, USA, 18-21 October 2013.

mantic parsing (Kate and Mooney, 2007; Liang et al., 2009; Bordes et al., 2010; Matuszek et al., 2012). This is also naturally used in IE, since it allows to train large-scale systems without requiring to label numerous texts. The idea was introduced by (Craven et al., 1999), which matched the Yeast Protein Database with PubMed abstracts. It was also used to train open extractors based on Wikipedia infoboxes and corresponding sentences (Wu and Weld, 2007; Wu and Weld, 2010). Large-scale open IE projects (e.g. (Banko et al., 2007)) also rely on weak supervision, since they learn models from a seed KB in order to extend it.

Weak supervision is also a popular option for RE: Mintz et al. (2009) used Freebase to train weakly supervised relational extractors on Wikipedia, an approach generalized by the multi-instance learning frameworks (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). All these works only use textual information to perform extraction.

Lao et al. (2012) proposed the first work aiming to perform RE employing both KB data and text, using a rule-based random walk method. Recently, Riedel et al. (2013) proposed another joint approach based on collaborative filtering for learning entity embeddings. This approach connects text with Freebase by learning shared embeddings of entities through weak supervision, in contrast to our method where no joint learning is performed. We do not compare to these two approaches since they use two different evaluation protocols that greatly differ from those used in all aforementioned previous works. Nevertheless, our method is easier to integrate into existing systems than those, since KB data is used via the addition of a scoring term, which is trained separately beforehand (with no shared embeddings). Besides, we demonstrate in our experimental section that our system can handle a large number of relationships, significantly larger than that presented in (Lao et al., 2012; Riedel et al., 2013).

3 Embedding-based Framework

Our work concerns energy-based methods, which learn low-dimensional vector representations (*embeddings*) of atomic symbols (words, entities, relationships, etc.). In this framework, we learn two models: one for predicting relationships given relation mentions and another one to encode the interactions among entities and relationships from the KB. The joint action of both models in prediction allows us to use the connection between the KB and text to perform relation extraction. One could also share parameters between models (via shared embeddings), but this is not implemented in this work. This approach is inspired by previous work designed to connect words and Wordnet (Bordes et al., 2012).

Both submodels end up learning vector embeddings of symbols, either for entities or relationships in the KB, or for each word/feature of the vocabulary (denoted $\mathcal{V}$). The set of entities and relationships in the KB are denoted by $\mathcal{E}$ and $\mathcal{R}$, and n_v, n_e and n_r denote the size of $\mathcal{V}$, $\mathcal{E}$ and $\mathcal{R}$ respectively. Given a triple (h, r, t) the embeddings of the entities and the relationship (vectors in $\mathbb{R}^k$) are denoted with the same letter, in boldface characters (i.e. $\mathbf{h}$, $\mathbf{r}$, $\mathbf{t}$).

3.1 Connecting Text and Relationships

The first part of the framework concerns the learning of a function $S_{m2r}(m, r)$, based on embeddings, that is designed to score the similarity of a relation mention m and a relationship r.

Our scoring approach is inspired by previous work for connecting word labels and images (Weston et al., 2010), which we adapted, replacing images by mentions and word labels by relationships. Intuitively, it consists of first projecting words and features into the embedding space and then computing a similarity measure (the dot product in this paper) between this projection and a relationship embedding. The scoring function is then:

$$S_{m2r}(m, r) = \mathbf{f}(m)^\top \mathbf{r}$$

with $\mathbf{f}$ a function mapping words and features into $\mathbb{R}^k$, $\mathbf{f}(m) = \mathbf{W}^\top \Phi(m)$. $\mathbf{W}$ is the matrix of $\mathbb{R}^{n_v \times k}$ containing all word embeddings $\mathbf{w}$, $\Phi(m)$ is the (sparse) binary representation of m ($\in \mathbb{R}^{n_v}$) indicating absence or presence of words/features, and $\mathbf{r} \in \mathbb{R}^k$ is the embedding of the relationship r.

This approach can be easily applied at test time to score (mention, relationship) pairs. Since this type of learning problem is weakly supervised, Bordes et al. (2010) showed that a convenient way to train it is by using a ranking loss. Hence, given a data set $\mathcal{D} = \{(m_i, r_i), i = 1, \ldots, |\mathcal{D}|\}$ consisting of (mention, relationship) training pairs, one could learn the

embeddings using constraints of the form:

$$\forall i,\ \forall r' \neq r_i,\ \ \mathbf{f}(m_i)^\top \mathbf{r}_i > 1 + \mathbf{f}(m_i)^\top \mathbf{r}' \ , \quad (1)$$

where 1 is the margin. That is, we want the relation that (weakly) labels a given mention to be scored higher than other relation by a margin of 1. Then, given any mention m one can predict the corresponding relationship $\hat{r}(m)$ with:

$$\hat{r}(m) = \arg\max_{r' \in \mathcal{R}} S_{m2r}(m, r') = \arg\max_{r' \in \mathcal{R}} \left(\mathbf{f}(m)^\top \mathbf{r}'\right).$$

Learning $S_{m2r}(\cdot)$ under constraints (1) is well suited when one is interested in building a per-mention prediction system. However, performance metrics of relation extraction are sometimes measured using precision recall curves aggregated for all mentions concerning the same pair of entities, as in (Riedel et al., 2010). In that case the scores across predictions for different mentions need to be calibrated so that the most confident ones have the higher scores. This can be better encoded with constraints of the following form:

$$\forall i, j,\ \ \forall r' \neq r_i, r_j,\ \ \mathbf{f}(m_i)^\top \mathbf{r}_i > 1 + \mathbf{f}(m_j)^\top \mathbf{r}' \ .$$

In this setup, scores of pairs observed in the training set should be larger than that of any other prediction across all mentions. In practice, we use "soft" ranking constraints (optimizing the hinge loss), i.e. we minimize:

$$\forall i, j,\ \forall r' \neq r_i, r_j,\ \ \max(0, 1 - \mathbf{f}(m_i)^\top \mathbf{r}_i + \mathbf{f}(m_j)^\top \mathbf{r}').$$

Finally, we also enforce a (hard) constraint on the norms of the columns of $\mathbf{W}$ and $\mathbf{r}$, i.e. $\forall_i, ||\mathbf{W}_i||_2 \leq 1$ and $\forall_j, ||\mathbf{r}_j||_2 \leq 1$. Training is carried out by Stochastic Gradient Descent (SGD), updating $\mathbf{W}$ and $\mathbf{r}$ at each step, following (Weston et al., 2010; Bordes et al., 2013). That is, at the start of training the parameters to be learnt (the $n_v \times k$ word/feature embeddings in W and the $n_r \times k$ relation embeddings r) are initialized to random weights. We initialize each k-dimensional embedding vector randomly with mean 0, standard deviation $\frac{1}{k}$. Then, we iterate the following steps to train them:

1. Select at random a positive training pair (m_i, r_i).
2. Select at random a secondary training pair (m_j, r_j), used to calibrate the scores.
3. Select at random a negative relation r' such that $r' \neq r_i$ and $r' \neq r_j$.
4. Make a stochastic gradient step to minimize $\max(0, 1 - \mathbf{f}(m_i)^\top \mathbf{r}_i + \mathbf{f}(m_j)^\top \mathbf{r}')$.
5. Enforce the constraint that each embedding vector is normalized, i.e. if $||\mathbf{W}_i||_2 > 1$ then $\mathbf{W}_i \leftarrow \mathbf{W}_i / ||\mathbf{W}_i||_2$.

3.2 Encoding Structured Data of KBs

Using only weakly labeled text mentions for training ignores much of the prior knowledge we can leverage from a large KB such as Freebase. In order to connect this relational data with our model, we propose to encode its information into entity and relationship embeddings. This allows us to build a model which can score the plausibility of new entity relationship triples which are missing from Freebase. Several models have been recently developed for that purpose (e.g. in (Nickel et al., 2011; Bordes et al., 2011; Bordes et al., 2012)): we chose in this work to follow the approach of (Bordes et al., 2013), which is simple, flexible and has shown very promising results on Freebase data.

Given a training set $\mathcal{S} = \{(h_i, r_i, t_i), i = 1, \ldots, |\mathcal{S}|\}$ of relations extracted from the KB, this model learns vector embeddings of the entities and of the relationships using the idea that the functional relation induced by the r-labeled arcs of the KB should correspond to a translation of the embeddings. That is, given a k-dimensional embedding of the left-hand side (head) entity, adding the k-dimensional embedding of a given relation should yield the point (or close to the point) of the k-dimensional embedding of the right-hand side (tail) entity. Hence, this method enforces that $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ when (h, r, t) holds, while $\mathbf{h} + \mathbf{r}$ should be far away from $\mathbf{t}$ otherwise. The model thus gives the following score for the plausibility of a relation:

$$S_{kb}(h, r, t) = -||\mathbf{h} + \mathbf{r} - \mathbf{t}||_2^2 .$$

A ranking loss is also used for training S_{kb}. The ranking objective is designed to assign higher scores

to existing relations versus any other possibility:

$$\forall i, \forall h' \neq h_i, \quad S_{kb}(h_i, r_i, t_i) \geq 1 + S_{kb}(h', r_i, t_i),$$
$$\forall i, \forall r' \neq r_i, \quad S_{kb}(h_i, r_i, t_i) \geq 1 + S_{kb}(h_i, r', t_i),$$
$$\forall i, \forall t' \neq t_i, \quad S_{kb}(h_i, r_i, t_i) \geq 1 + S_{kb}(h_i, r_i, t').$$

That is, for each known triple (h, r, t), if we replaced the (i) head, (ii) relation or (iii) tail with some other possibility, the modified triple should have a lower score (i.e. be less plausible) than the original triple. The three sets of constraints defined above encode the three types of modification. As in Section 3.1 we use soft constraints via the hinge loss, enforce constraints on the norm of embeddings, i.e. $\forall_{h,r,t}, ||h||_2 \leq 1, ||r||_2 \leq 1, ||t||_2 \leq 1$, and training is performed using SGD, as in (Bordes et al., 2013).

At test time, one may again need to calibrate the scores S_{kb} across entity pairs. We propose a simple approach: we convert the scores by ranking all relationships $\mathcal{R}$ by S_{kb} and instead output:

$$\tilde{S}_{kb}(h, r, t) = \Phi\Big(\sum_{r' \neq r} \delta(S_{kb}(h, r, t) > S_{kb}(h, r', t))\Big),$$

i.e. a function of the rank of r. We chose the simplified model $\Phi(x) = 1$ if $x < \tau$ and 0 otherwise; $\delta(\cdot)$ is the Kronecker function.

3.3 Implementation for Relation Extraction

Our framework can be used for relation extraction in the following way. First, for each pair of entities (h, t) that appear in the test set, all the corresponding mentions $\mathcal{M}_{h,t}$ in the test set are collected and a prediction is performed with:

$$\hat{r}_{h,t} = \operatorname*{argmax}_{r \in \mathcal{R}} \sum_{m \in \mathcal{M}_{h,t}} S_{m2r}(m, r)\,.$$

The predicted relationship can either be a valid relationship or NA – a marker that means that there is no relation between h and t (NA is added to $\mathcal{R}$ during training and is treated like other relationships). If $\hat{r}_{h,t}$ is a relationship, a composite score is defined:

$$S_{m2r+kb}(h, \hat{r}_{h,t}, t) = \sum_{m \in \mathcal{M}_{h,t}} S_{m2r}(m, \hat{r}_{h,t}) + \tilde{S}_{kb}(h, \hat{r}_{h,t}, t)$$

That is, only the top scoring non-NA predictions are re-scored. Hence, our final composite model favors predictions that agree with both the mentions and the KB. If $\hat{r}_{h,t}$ is NA, the score is unchanged.

4 Experiments

We use the training and test data, evaluation framework and baselines from (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012).

NYT+FB This dataset, developed by (Riedel et al., 2010), aligns Freebase relations with the New York Times corpus. Entities were found using the Stanford named entity tagger (Finkel et al., 2005), and were matched to their name in Freebase. For each mention, sentence level features are extracted which include part of speech, named entity and dependency tree path properties. Unlike some of the previous methods, we do not use features that aggregate properties across multiple mentions. We kept the 100,000 most frequent features.There are 52 possible relationships and 121,034 training mentions of which most are labeled as no relation (labeled "NA") – there are 4700 Freebase relations mentioned in the training set, and 1950 in the test set.

Freebase Freebase is a large-scale KB that has around 80M entities, 23k relationships and 1.2B relations. We used a subset restricted to the top 4M entities for scalability reasons – where top is defined as the ones with the largest number of relations to other entities. We used all the 23k possible relationships in Freebase. To make a realistic setting, we did not choose the entity set using the NYT+FB data set, so it may not overlap completely. For that reason, we needed to keep the set rather large. Keeping the top 4M entities gives an overlap of 80% with the entities in the NYT+FB test set. Most importantly, we then removed all the entity pairs present in the NYT+FB test set from Freebase, i.e. all relations they are involved in independent of the relationship. This ensures that we cannot just memorize the true relations for an entity pair – we have to learn to generalize from other entities and relations.

As the NYT+FB dataset was built on an earlier version of Freebase we also had to translate the deprecated relationships into their new variants (e.g. "/p/business/company/place_founded " → "/organization/organization/place_founded") to make the two datasets link (then, the 52 relationships in NYT+FB are now a subset of the 23k from Freebase). We then trained the S_{kb} model on the remaining triples.

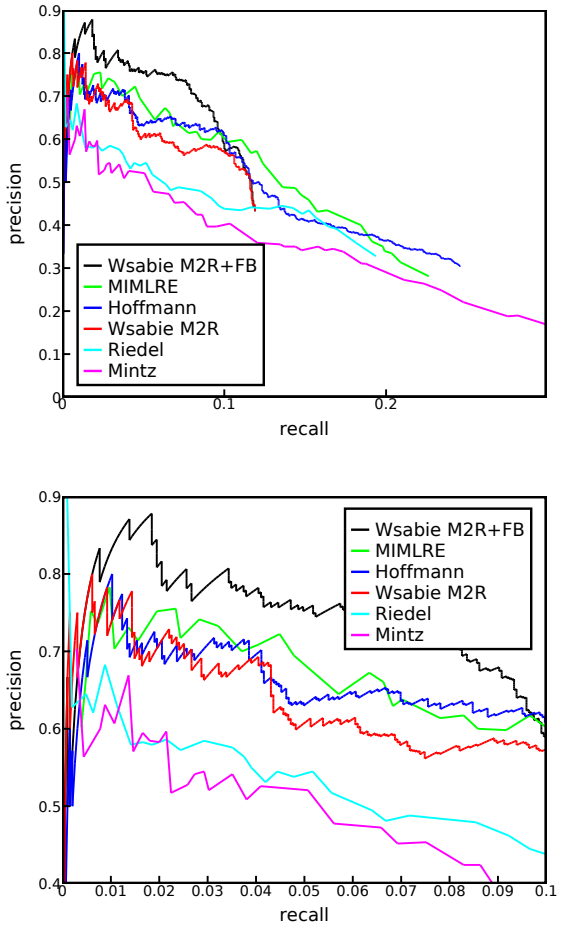

Figure 1: Top: Aggregate extraction precision/recall curves for a variety of methods. Bottom: the same plot zoomed to the recall [0-0.1] region. Wsabie$_{M2R}$ is our method trained only on mentions, Wsabie$_{M2R+FB}$ uses Freebase annotations as well.

Modeling Following (Bordes et al., 2013) we set the embedding dimension k to 50. The learning rate for SGD was selected using a validation set: we obtained 0.001 for S_{m2r}, and 0.1 for S_{kb}. For the calibration of $\hat{S}_{kb}$, $\tau = 10$ (note, here we are ranking all 23k Freebase relationships). Training S_{m2r} took 5 minutes, whilst training S_{kb} took 2 days due to the large scale of the data set.

Results Figure 1 displays the aggregate precision / recall curves of our approach WSABIE$_{M2R+FB}$ which uses the combination of $S_{m2r} + S_{kb}$, as well as WSABIE$_{M2R}$, which only uses S_{m2r}, and existing state-of-the-art approaches: HOFFMANN (Hoffmann et al., 2011)[2], MIMLRE (Surdeanu et al., 2012). RIEDEL (Riedel et al., 2010) and MINTZ (Mintz et al., 2009).

WSABIE$_{M2R}$ is comparable to, but slightly worse than, the MIMLRE and HOFFMANN methods, possibly due to its simplified assumptions (e.g. predicting a single relationship per entity pair). However, the addition of extra knowledge from other Freebase entities in WSABIE$_{M2R+FB}$ provides superior performance to all other methods, by a wide margin, at least between 0 and 0.1 recall (see bottom plot).

Performance of WSABIE$_{M2R}$ and WSABIE$_{M2R+FB}$ for recall > 0.1 degrades rapidly, faster than that of other methods. This is also caused by the simplifications of WSABIE$_{M2R}$ that prevent it from reaching high precision when the recall is greater than 0.1. We recall that Freebase data is not used to detect relationships i.e. to discriminate between NA and the rest, but only to select the best relationship in case of detection. That is WSABIE$_{M2R+FB}$ only improves precision, not recall, so both versions of Wsabie are similar w.r.t. recall. This could be improved by borrowing ideas from HOFFMANN (Hoffmann et al., 2011) or MIMLRE (Surdeanu et al., 2012) for dealing with the multi-label case. Our approach, which uses Freebase to increase precision, is general and could improve any other method.

5 Conclusion

In this paper we described a framework for leveraging large scale knowledge bases to improve relation extraction by training not only on (mention, relationship) pairs but using all other KB triples as well. We empirically showed that it allows to significantly improve precision on extracted relations. Our modeling approach is general and should apply to other settings, e.g. for the task of entity linking.

Abstract

In this paper, we present a recursive neural network (RNN) model that works on a syntactic tree. Our model differs from previous RNN models in that the model allows for an explicit weighting of important phrases for the target task. We also propose to average parameters in training. Our experimental results on semantic relation classification show that both phrase categories and task-specific weighting significantly improve the prediction accuracy of the model. We also show that averaging the model parameters is effective in stabilizing the learning and improves generalization capacity. The proposed model marks scores competitive with state-of-the-art RNN-based models.

1 Introduction

Recursive Neural Network (RNN) models are promising deep learning models which have been applied to a variety of natural language processing (NLP) tasks, such as sentiment classification, compound similarity, relation classification and syntactic parsing (Hermann and Blunsom, 2013; Socher et al., 2012; Socher et al., 2013). RNN models can represent phrases of arbitrary length in a vector space of a fixed dimension. Most of them use minimal syntactic information (Socher et al., 2012).

Recently, Hermann and Blunsom (2013) proposed a method for leveraging syntactic information, namely CCG combinatory operators, to guide composition of phrases in RNN models. While their models were successfully applied to binary sentiment classification and compound similarity tasks, there are questions yet to be answered, e.g., whether such enhancement is beneficial in other NLP tasks as well, and whether a similar improvement can be achieved by using syntactic information of more commonly available types such as phrase categories and syntactic heads.

In this paper, we present a supervised RNN model for a semantic relation classification task. Our model is different from existing RNN models in that important phrases can be explicitly weighted for the task. Syntactic information used in our model includes part-of-speech (POS) tags, phrase categories and syntactic heads. POS tags are used to assign vector representations to word-POS pairs. Phrase categories are used to determine which weight matrices are chosen to combine phrases. Syntactic heads are used to determine which phrase is weighted during combining phrases. To incorporate task-specific information, phrases on the path between entity pairs are further weighted.

The second contribution of our work is the introduction of parameter averaging into RNN models. In our preliminary experiments, we observed that the prediction performance of the model often fluctuates significantly between training iterations. This fluctuation not only leads to unstable performance of the resulting models, but also makes it difficult to fine-tune the hyperparameters of the model. Inspired by Swersky et al. (2010), we propose to average the model parameters in the course of training. A recent technique for deep learning models of similar vein is *dropout* (Hinton et al., 2012), but averaging is simpler to implement.

Our experimental results show that our model per-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1372–1376,
Seattle, Washington, USA, 18-21 October 2013.

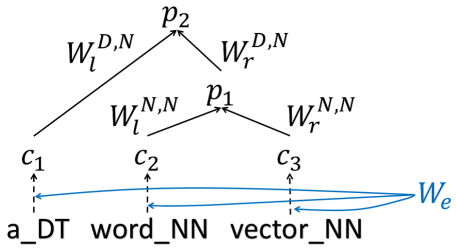

Figure 1: A recursive representations of a phrase "a word vector" with POS tags of the words (DT, NN and NN respectively). For example, the two word-POS pairs "word_NN" and "vector_NN" with a syntactic category N are combined to represent the phrase "word vector".

forms better than standard RNN models. By averaging the model parameters, our model achieves performance competitive with the MV-RNN model in Socher et al. (2012), without using computationally expensive word-dependent matrices.

2 An Averaged RNN Model with Syntax

Our model is a supervised RNN that works on a binary syntactic tree. As our first step to leverage information available in the tree, we distinguish words with the same spelling but POS tags in the vector space. Our model also uses different weight matrices dependent on the phrase categories of child nodes (phrases or words) in combining phrases. Our model further weights those nodes that appear to be important.

Compositional functions of our model follow those of the SU-RNN model in Socher et al. (2013).

2.1 Word-POS Vector Representations

Our model simply assigns vector representations to word-POS pairs. For example, a word "caused" can be represented in two ways: "caused_VBD" and "caused_VBN". The vectors are represented as column vectors in a matrix $\boldsymbol{W}_e \in \mathbb{R}^{d\times|\mathbb{V}|}$, where d is the dimension of a vector and $\mathbb{V}$ is a set of all word-POS pairs we consider.

2.2 Compositional Functions with Syntax

In construction of parse trees, we associate each of the tree node with its d-dimensional vector representation computed from vector representations of its subtrees. For leaf nodes, we look up word-POS vector representations in $\mathbb{V}$. Figure 1 shows an example of such recursive representations. A parent vector $\boldsymbol{p} \in \mathbb{R}^{d\times 1}$ is computed from its direct child vectors $\boldsymbol{c}_l$ and $\boldsymbol{c}_r \in \mathbb{R}^{d\times 1}$:

$$\boldsymbol{p} = \tanh(\alpha_l \boldsymbol{W}_l^{T_{c_l},T_{c_r}} \boldsymbol{c}_l + \alpha_r \boldsymbol{W}_r^{T_{c_l},T_{c_r}} \boldsymbol{c}_r + \boldsymbol{b}^{T_{c_l},T_{c_r}}),$$

where $\boldsymbol{W}_l^{T_{c_l},T_{c_r}}$ and $\boldsymbol{W}_r^{T_{c_l},T_{c_r}} \in \mathbb{R}^{d\times d}$ are weight matrices that depend on the phrase categories of $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$. Here, $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ have phrase categories T_{c_l} and T_{c_r} respectively (such as *N*, *V*, etc.). $\boldsymbol{b}^{T_{c_l},T_{c_r}} \in \mathbb{R}^{d\times 1}$ is a bias vector. To incorporate the importance of phrases into the model, two subtrees of a node may have different weights $\alpha_l \in [0,1]$ and $\alpha_r (= 1-\alpha_l)$, taking phrase importance into account. The value of α_l is manually specified and automatically applied to all nodes based on prior knowledge about the task. In this way, we can compute vector representations for phrases of arbitrary length. We denote a set of such matrices as $\boldsymbol{W}_{lr}$ and bias vectors as $\boldsymbol{b}$.

2.3 Objective Function and Learning

As with other RNN models, we add on the top of a node $\boldsymbol{x}$ a $\mathrm{softmax}$ classifier. The classifier is used to predict a K-class distribution $\boldsymbol{d}(\boldsymbol{x}) \in \mathbb{R}^{K\times 1}$ over a specific task to train our model:

$$\boldsymbol{d}(\boldsymbol{x}) = \mathrm{softmax}(\boldsymbol{W}^{label}\boldsymbol{x} + \boldsymbol{b}^{label}), \qquad (1)$$

where $\boldsymbol{W}^{label} \in \mathbb{R}^{K\times d}$ is a weight matrix and $\boldsymbol{b}^{label} \in \mathbb{R}^{K\times 1}$ is a bias vector. We denote $\boldsymbol{t}(\boldsymbol{x}) \in \mathbb{R}^{K\times 1}$ as the target distribution vector at node $\boldsymbol{x}$. $\boldsymbol{t}(\boldsymbol{x})$ has a 0-1 encoding: the entry at the correct label of $\boldsymbol{t}(\boldsymbol{x})$ is 1, and the remaining entries are 0. We then compute the cross entropy error between $\boldsymbol{d}(\boldsymbol{x})$ and $\boldsymbol{t}(\boldsymbol{x})$:

$$E(\boldsymbol{x}) = -\sum_{k=1}^{K} \boldsymbol{t}_k(\boldsymbol{x}) \log \boldsymbol{d}_k(\boldsymbol{x}),$$

and define an objective function as the sum of $E(\boldsymbol{x})$ over all training data:

$$J(\theta) = \sum_{\boldsymbol{x}} E(\boldsymbol{x}) + \frac{\lambda}{2}\|\theta\|^2,$$

where $\theta = (\boldsymbol{W}_e, \boldsymbol{W}_{lr}, \boldsymbol{b}, \boldsymbol{W}^{label}, \boldsymbol{b}^{label})$ is the set of our model parameters that should be learned. λ is a vector of regularization parameters.

To compute $\boldsymbol{d}(\boldsymbol{x})$, we can directly leverage any other nodes' feature vectors in the same tree. We denote such additional feature vectors as $\boldsymbol{x}'_i \in \mathbb{R}^{d \times 1}$, and extend Eq. (1):

$$\boldsymbol{d}(\boldsymbol{x}) = \mathrm{softmax}(\boldsymbol{W}^{label}\boldsymbol{x} + \sum_i \boldsymbol{W}_i^{add}\boldsymbol{x}'_i + \boldsymbol{b}^{label}),$$

where $\boldsymbol{W}_i^{add} \in \mathbb{R}^{K \times d}$ are weight matrices for additional features. We denote these matrices $\boldsymbol{W}_i^{add}$ as $\boldsymbol{W}^{add}$. We also add $\boldsymbol{W}^{add}$ to θ:

$$\theta = (\boldsymbol{W}_e, \boldsymbol{W}_{lr}, \boldsymbol{b}, \boldsymbol{W}^{label}, \boldsymbol{W}^{add}, \boldsymbol{b}^{label}).$$

The gradient of $J(\theta)$

$$\frac{\partial J(\theta)}{\partial \theta} = \sum_{\boldsymbol{x}} \frac{\partial E(\boldsymbol{x})}{\partial \theta} + \lambda\theta$$

is efficiently computed via backpropagation through structure (Goller and Küchler, 1996). To minimize $J(\theta)$, we use batch L-BFGS[1] (Hermann and Blunsom, 2013; Socher et al., 2012).

2.4 Averaging

We use averaged model parameters

$$\overline{\theta} = \frac{1}{T+1}\sum_{t=0}^{T}\theta_t$$

at test time, where θ_t is the vector of model parameters after t iterations of the L-BFGS optimization. Our preliminary experimental results suggest that averaging θ except $\boldsymbol{W}_e$ works well.

3 Experimental Settings

We used the Enju parser (Miyao and Tsujii, 2008) for syntactic parsing. We used 13 phrase categories given by Enju.

3.1 Task: Semantic Relation Classification

We evaluated our model on a semantic relation classification task: SemEval 2010 Task 8 (Hendrickx et al., 2010). Following Socher et al. (2012), we regarded the task as a 19-class classification problem. There are 8,000 samples for training, and 2,717 for test. For the validation set, we randomly sampled 2,182 samples from the training data.

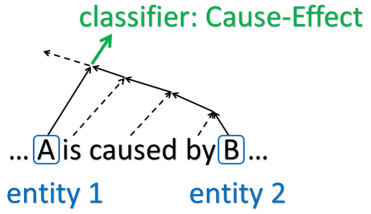

Figure 2: Classifying the relation between two entities.

To predict a class label, we first find the minimal phrase that covers the target entities and then use the vector representation of the phrase (Figure 2).

As explained in Section 2.3, we can directly connect features on any other nodes to the softmax classifier. In this work, we used three such internal features: two vector representations of target entities and one averaged vector representation of words between the entities[2].

3.2 Weights on Phrases

We tuned the weight α_l (or α_r) introduced in Section 2.2 for this particular task. There are two factors: syntactic heads and syntactic path between target entities. Our model puts a weight $\beta \in [0.5, 1]$ on head phrases, and $1-\beta$ on the others. For relation classification tasks, syntactic paths between target entities are important (Zhang et al., 2006), so our model also puts another weight $\gamma \in [0.5, 1]$ on phrases on the path, and $1-\gamma$ on the others. When both child nodes are on the path or neither of them on the path, we set $\gamma = 0.5$. The two weight factors are summed up and divided by 2 to be the final weights α_l and α_r to combine the phrases. For example, we set $\alpha_l = \frac{(1-\beta)+\gamma}{2}$ and $\alpha_r = \frac{\beta+(1-\gamma)}{2}$ when the right child node is the head and the left child node is on the path.

3.3 Initialization of Model Parameters and Tuning of Hyperparameters

We initialized $\boldsymbol{W}_e$ with 50-dimensional word vectors[3] trained with the model of Collobert et

[1] We used libLBFGS provided at `http://www.chokkan.org/software/liblbfgs/`.

[2] Socher et al. (2012) used richer features including words around entity pairs in their implementation.

[3] The word vectors are provided at `http://ronan.collobert.com/senna/`. We used the vectors without any modifications such as normalization.

Method	F1 (%)

al. (2011), and $\boldsymbol{W}_{lr}$ with $\frac{I}{2} + \varepsilon$, where $I \in \mathbb{R}^{d \times d}$ is an identity matrix. Here, ε is zero-mean gaussian random variable with a variance of 0.01. The initialization of $\boldsymbol{W}_{lr}$ is the same as that of Socher et al. (2013). The remaining model parameters were initialized with 0.

We tuned hyperparameters in our model using the validation set for each experimental setting. The hyperparameters include the regularization parameters for $\boldsymbol{W}_e$, $\boldsymbol{W}_{lr}$, $\boldsymbol{W}^{label}$ and $\boldsymbol{W}^{add}$, and the weights β and γ. For example, the best performance for our model with all the proposed methods was obtained with the values: 10^{-6}, 10^{-4}, 10^{-3}, 10^{-3}, 0.7 and 0.9 respectively.

4 Results and Discussion

Table 1 shows the performance of our model and that of previously reported systems on the test set. The performance of an SVM system with bag-of-words features was reported in Rink and Harabagiu (2010), and the performance of the RNN and MV-RNN models was reported in Socher et al. (2012). Our model achieves an F1 score of 79.4% and outperforms the RNN model (74.8% F1) as well as the simple SVM-based system (73.1% F1). More notably, the score of our model is competitive with that of the MV-RNN model (79.1% F1), which is computationally much more expensive. Readers are referred to Hermann and Blunsom (2013) for the discussion about the computational complexity of the MV-RNN model. We improved the performance of RNN models on the task without much increasing the complexity. This is a significant practical advantage of our model, although its expressive power is not the same as that of the MV-RNN model.

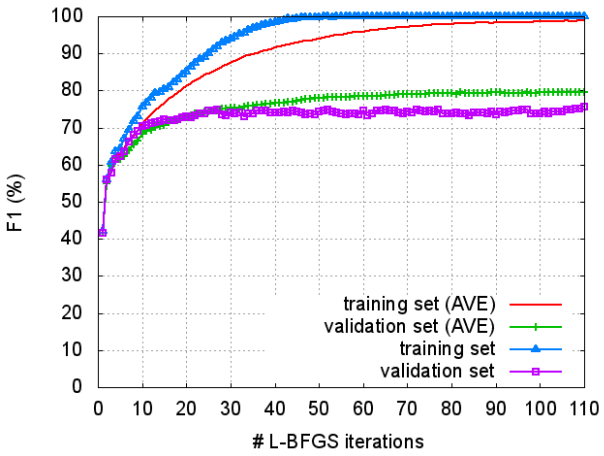

Figure 3: F1 vs Training iterations.

Our model outperforms the RNN model with one lexical and two semantic external features: POS tags, WordNet hypernyms and named entity tags (NER) of target word pairs (external features). The MV-RNN model with external features shows better performance than our model. An SVM with rich lexical and semantic features (Rink and Harabagiu, 2010) also outperforms ours. Note, however, that this is not a fair comparison because those models use rich external resources such as WordNet and named entity tags.

4.1 Contributions of Proposed Methods

We conducted additional experiments to quantify the contributions of phrase categories, heads, paths and averaging to our classification score. As shown in Table 2, our model without phrase categories, heads or paths still outperforms the RNN model with external features. On the other hand, our model without averaging yields a lower score than the RNN model with external features, though it is still bet-

ter than the RNN model alone. Without utilizing these four properties, our model obtained only 74.1% F1. These results indicate that syntactic and task-specific information and averaging contribute to the performance improvement. The improvement is achieved by a simple modification of compositional functions in RNN models.

4.2 Effects of Averaging in Training

Figure 3 shows the training curves in terms of F1 scores. These curves clearly demonstrate that parameter averaging helps to stabilize the learning and improve generalization capacity.

5 Conclusion

We have presented an averaged RNN model for semantic relation classification. Our experimental results show that syntactic information such as phrase categories and heads improves the performance, and the task-specific weighting is also beneficial. The results also demonstrate that averaging the model parameters not only stabilizes the learning but also improves the generalization capacity of the model. As future work, we plan to combine deep learning models with richer information such as predicate-argument structures.

Abstract

Automatically clustering words from a monolingual or bilingual training corpus into classes is a widely used technique in statistical natural language processing. We present a very simple and easy to implement method for using these word classes to improve translation quality. It can be applied across different machine translation paradigms and with arbitrary types of models. We show its efficacy on a small German→English and a larger French→German translation task with both standard phrase-based and hierarchical phrase-based translation systems for a common set of models. Our results show that with word class models, the baseline can be improved by up to 1.4% BLEU and 1.0% TER on the French→German task and 0.3% BLEU and 1.1% TER on the German→English task.

1 Introduction

Data sparsity is one of the major problems for statistical learning methods in natural language processing (NLP) today. Even with the huge training data sets available in some tasks, for many phenomena that need to be modeled only few training instances can be observed. This is partly due to the large vocabularies of natural languages. One possiblity to reduce the sparsity for model estimation is to reduce the vocabulary size. By clustering the vocabulary into a fixed number of word classes, it is possible to train models that are less prone to sparsity issues. This work investigates the performance of standard models used in statistical machine translation when they are trained on automatically learned word classes rather than the actual word identities.

In the popular tooklit GIZA++ (Och and Ney, 2003), word classes are an essential ingredient to model alignment probabilities with the HMM or IBM translation models. It contains the `mkcls` tool (Och, 1999), which can automatically cluster the vocabulary into classes.

Using this tool, we propose to re-parameterize the standard models used in statistical machine translation (SMT), which are usually conditioned on word identities rather than word classes. The idea is that this should lead to a smoother distribution, which is more reliable due to less sparsity. Here, we focus on the phrase-based and lexical channel models in both directions, simple count models identifying frequency thresholds, lexicalized reordering models and an n-gram language model. Although our results show that it is not a good idea to replace the original models, we argue that adding them to the log-linear feature combination can improve translation quality. They can easily be computed for different translation paradigms and arbitrary models. Training and decoding is possible without or with only little change to the code base.

Our experiments are conducted on a medium-sized French→German task and a small German→English task and with both phrase-based and hierarchical phrase-based translation decoders. By using word class models, we can improve our respective baselines by 1.4% BLEU and 1.0% TER on the French→German task and 0.3% BLEU and 1.1% TER on the German→English task.

Training an additional language model for trans-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1377–1381,
Seattle, Washington, USA, 18-21 October 2013.

lation based on word classes has been proposed in (Wuebker et al., 2012; Mediani et al., 2012; Koehn and Hoang, 2007). In addition to the reduced sparsity, an advantage of the smaller vocabulary is that longer n-gram context can be modeled efficiently.

Mathematically, our idea is equivalent to a special case of the Factored Translation Models proposed by Koehn and Hoang (2007). We will go into more detail in Section 4. Also related to our work, Cherry (2013) proposes to parameterize a hierarchical reordering model with sparse features that are conditioned on word classes trained with `mkcls`. However, the features are trained with MIRA rather than estimated by relative frequencies.

2 Word Class Models

2.1 Standard Models

The translation model of most phrase-based and hierarchical phrase-based SMT systems is parameterized by two phrasal and two lexical channel models (Koehn et al., 2003) which are estimated as relative frequencies. Their counts are extracted heuristically from a word aligned bilingual training corpus.

In addition to the four channel models, our baseline contains binary count features that fire, if the extraction count of the corresponding phrase pair is greater or equal to a given threshold τ. We use the thresholds $\tau = \{2, 3, 4\}$.

Our phrase-based baseline contains the hierarchical reordering model (HRM) described by Galley and Manning (2008). Similar to (Cherry et al., 2012), we apply it in both translation directions with separate scaling factors for the three orientation classes, leading to a total of six feature weights.

An n-gram language model (LM) is another important feature of our translation systems. The baselines apply 4-gram LMs trained by the SRILM toolkit (Stolcke, 2002) with interpolated modified Kneser-Ney smoothing (Chen and Goodman, 1998). The smaller vocabulary size allows us to efficiently model larger context, so in addition to the 4-gram LM, we also train a 7-gram LM based on word classes. In contrast to an LM of the same size trained on word identities, the increase in computational resources needed for translation is negligible for the 7-gram word class LM (wcLM).

2.2 Training

By replacing the words on both source and target side of the training data with their respective word classes and keeping the word alignment unchanged, all of the above models can easily be trained conditioned on word classes by using the same training procedure as usual. We end up with two separate model files, usually in the form of large tables, one with word identities and one with classes. Next, we sort both tables by their word classes. By walking through both sorted tables simultaneously, we can then efficiently augment the standard model file with an additonal feature (or additional features) based on word classes. The word class LM is directly passed on to the decoder.

2.3 Decoding

The decoder searches for the best translation given a set of models $h_m(e_1^I, s_1^K, f_1^J)$ by maximizing the log-linear feature score (Och and Ney, 2004):

$$\hat{e}_1^{\hat{I}} = \arg\max_{I, e_1^I} \left\{ \sum_{m=1}^{M} \lambda_m h_m(e_1^I, s_1^K, f_1^J) \right\}, \quad (1)$$

where $f_1^J = f_1 \dots f_J$ is the source sentence, $e_1^I = e_1 \dots e_I$ the target sentence and $s_1^K = s_1 \dots s_K$ the hidden alignment or derivation.

All the above mentioned models can easily be integrated into this framework as additional features h_m. The feature weights λ_m are tuned with minimum error rate training (MERT) (Och, 2003).

3 Experiments

3.1 Data

Our experiments are performed on a French→German task. In addition to some project-internal data, we train the system on the data provided for the WMT 2012 shared task[1]. Both the `dev` and the `test` set are composed of a mixture of broadcast news and broadcast conversations crawled from the web and have two references. Table 1 shows the data statistics.

To confirm our results we also run experiments on the German→English task of the IWSLT 2012 evaluation campaign[2].

test	Sentences	2037	
	Running Words	60K	54K

Table 1: Corpus statistics for the French→German task. The running word counts for the German side of dev and test are averaged over both references.

3.2 Setup

In the French→German task, our baseline is a standard phrase-based system augmented with the hierarchical reordering model (HRM) described in Section 2.1. The language model is a 4-gram LM trained on all German monolingual sources provided for WMT 2012. For the class-based models, we run mkcls on the source and target side of the bilingual training data to cluster the vocabulary into 100 classes each. This clustering is used to train the models described above for word classes on the same training data as their counterparts based on word identity. This also holds for the wcLM, which is a 4-gram LM trained on the same data as the baseline LM. Further, the smaller vocabulary allows us to build an additional wcLM with a 7-gram context length. On this task we also run additional experiments with 200 and 500 classes.

On the German→English task, we evaluate our method for both a standard phrase-based and the hierarchical phrase-based baseline. Again, the phrase-based baseline contains the HRM model. As bilingual training data we use the *TED* talks, which we cluster into 100 classes on both source and target side. The 4-gram LM is trained on the *TED*, *Europarl* and *news-commentary* corpora. On this data set, we directly use a 7-gram wcLM.

In all setups, the feature weights are optimized with MERT. Results are reported in BLEU (Papineni et al., 2002) and TER (Snover et al., 2006), confidence level computation is based on (Koehn, 2004). Our experiments are conducted with the open source toolkit *Jane* (Wuebker et al., 2012; Vilar et al., 2010).

	dev		test	
	BLEU [%]	TER [%]	BLEU [%]	TER [%]
-TM +wcTM	21.2	64.2	24.7	59.5
-LM +wcLM	22.2	62.9	25.9	58.9
-HRM +wcHRM	24.6	61.9	27.5	58.1
phrase-based	24.6	61.8	27.8	57.6
+ wcTM	24.7	61.4	28.1	57.1

+ wcHRM	25.4‡	60.9‡	28.9‡	56.9‡
+ wcLM^7	25.5‡	60.7‡	29.2‡	56.6‡
+ wcModels$_{200}$	25.5‡	60.8‡	29.3‡	56.4‡
+ wcModels$_{500}$	25.2†	60.8‡	29.0‡	56.6‡

Table 2: BLEU and TER results on the French→German task. Results marked with ‡ are statistically significant with 95% confidence, results marked with † with 90% confidence. *-X +wcX* denote the systems, where the model *X* in the baseline is replaced by its word class counterpart. The 7-gram word class LM is denoted as *wcLM*^{7}. *wcModels*$_X$ denotes all word class models trained on *X* classes.

3.3 Results

Results for the French→German task are given in Table 2. In a first set of experiments we replaced one of the standard TM, LM and HRM models by the same model based on word classes. Unsurprisingly, this degrades performance with different levels of severity. The strongest degradation can be seen when replacing the TM, while replacing the HRM only leads to a small drop in performance. However, when the word class models are added as additional features to the baseline, we observe improvements. The wcTM yields 0.3% BLEU and 0.5% TER on test. By adding the 4-gram wcLM, we get another 0.3% BLEU and the wcHRM shows further improvements of 0.5% BLEU and 0.2% TER. Extending the context length of the wcLM to 7-grams gives an additional boost, reaching a total gain over the baseline of 1.4% BLEU and 1.0% TER. Using 200 classes instead of 100 seems to perform slightly better on test, but with 500 classes, translation quality degrades again.

On the German→English task, the results shown in Table 3 are similar in TER, but less pronounced in BLEU. Here we are able to improve over the phrase-based baseline by 0.3% BLEU and 1.1% TER

	dev		test	
	BLEU [%]	TER [%]	BLEU [%]	TER [%]
phrase-based	30.2	49.6	28.6	51.6
+ wcTM	30.2	49.2	28.9	51.3

+ wcLM^7	30.0	49.8	28.2	51.7

Table 3: BLEU and TER results on the German→English task. Results marked with ‡ are statistically significant with 95% confidence, results marked with † with 90% confidence.

by adding the wcTM, the 7-gram wcLM and the wcHRM. With the hierarchical decoder we gain 0.3% BLEU and 0.8% TER by adding the wcTM and the 7-gram wcLM.

4 Equivalence to Factored Translation

Koehn and Hoang (2007) propose to integrate different levels of annotation (e.g. morphologial analysis) as *factors* into the translation process. Here, the surface form of the source word is analyzed to produce the factors, which are then translated and finally the surface form of the target word is generated from the target factors. Although the translations of the factors operate on the same phrase segmentation, they are assumed to be independent. In practice this is done by *phrase expansion*, which generates a joint phrase table as the cross product from the phrase tables of the individual factors.

In contrast, in this work each word is mapped to a single class, which means that when we have selected a translation option for the surface form, the target side on the word class level is predetermined. Thus, no phrase expansion or generation steps are necessary to incorporate the word class information. The phrase table can simply be extended with additional scores, keeping the set of phrases constant.

Although the implementation is simpler, our approach is mathematically equivalent to a special case of the factored translation framework, which is shown in Figure 1. The generation step from target word e to its target class $c(e)$ assigns all probability

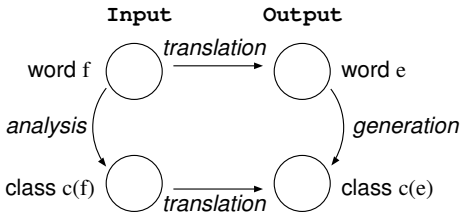

Figure 1: The factored translation model equivalent to our approach. The generation step assigns all probability mass to a single event: $p_{gen}(c(e)|e) = 1$.

mass to a single event:

$$p_{gen}(c|e) = \begin{cases} 1, \text{ if } c = c(e) \\ 0, \text{ else} \end{cases} \quad (2)$$

5 Conclusion

We have presented a simple and very easy to implement method to make use of word clusters for improving machine translation quality. It is applicable across different paradigms and for arbitrary types of models. Depending on the model type, it requires little or no change to the training and decoding software. We have shown the efficacy of this method on two translation tasks and with both the standard phrase-based and the hierarchical phrase-based translation paradigm. It was applied to relative frequency translation probabilities, the n-gram language model and a hierarchical reordering model. In our experiments, the baseline is improved by 1.4% BLEU and 1.0% TER on the French→German task and by 0.3% BLEU and 1.1% TER on the German→English task.

In future work we plan to apply our method to a wider range of languages. Intuitively, it should be most effective for morphologically rich languages, which naturally have stronger sparsity problems.

Acknowledgments

This work was partially realized as part of the Quaero Programme, funded by OSEO, French State agency for innovation. The research leading to these results has also received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 287658.

Abstract

This paper presents a novel word reordering model that employs a shift-reduce parser for inversion transduction grammars. Our model uses rich syntax parsing features for word reordering and runs in linear time. We apply it to postordering of phrase-based machine translation (PBMT) for Japanese-to-English patent tasks. Our experimental results show that our method achieves a significant improvement of $+3.1$ BLEU scores against 30.15 BLEU scores of the baseline PBMT system.

1 Introduction

Even though phrase-based machine translation (PBMT) (Koehn et al., 2007) and tree-based MT (Graehl and Knight, 2004; Chiang, 2005; Galley et al., 2006) systems have achieved great success, many problems remain for distinct language pairs, including long-distant word reordering.

To improve such word reordering, one promising way is to separate it from the translation process as preordering (Collins et al., 2005; DeNero and Uszkoreit, 2011) or postordering (Sudoh et al., 2011; Goto et al., 2012). Many studies utilize a rule-based or a probabilistic model to perform a reordering decision at each node of a syntactic parse tree.

This paper presents a parser-based word reordering model that employs a shift-reduce parser for inversion transduction grammars (ITG) (Wu, 1997). To the best of our knowledge, this is the first study on a shift-reduce parser for word reordering.

The parser-based reordering approach uses rich syntax parsing features for reordering decisions. Our propoesd method can also easily define such non-local features as the N-gram words of reordered strings. Even when using these non-local features, the complexity of the shift-reduce parser does not increase at all due to give up achieving an optimal solution. Therefore, it works much more efficient.

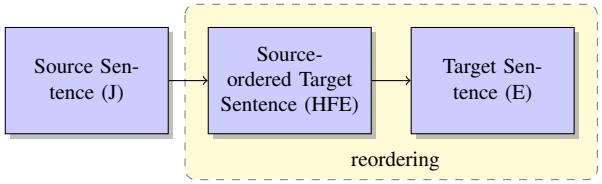

Figure 1: A description of the postordering MT system.

In our experiments, we apply our proposed method to postordering for J-to-E patent tasks because their training data for reordering have little noise and they are ideal for evaluating reordering methods. Although our used J-to-E setups need a language-dependent scheme and we describe our proposed method as a J-to-E postordering method, the key algorithm is language-independent and it can be applicable to preordering as well as postordering if the training data for reordering are available.

2 Postordering by Parsing

As shown in Fig.1, postordering (Sudoh et al., 2011) has two steps; the first is a translation step that translates an input sentence into source-ordered translations. The second is a reordering step in which the translations are reordered in the target language order. The key to postordering is the second step.

Goto et al. (2012) modeled the second step by parsing and created training data for a postordering parser using a language-dependent rule called **head-finalization**. The rule moves syntactic heads of a lexicalized parse tree of an English sentence to the

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1382–1386,
Seattle, Washington, USA, 18-21 October 2013.

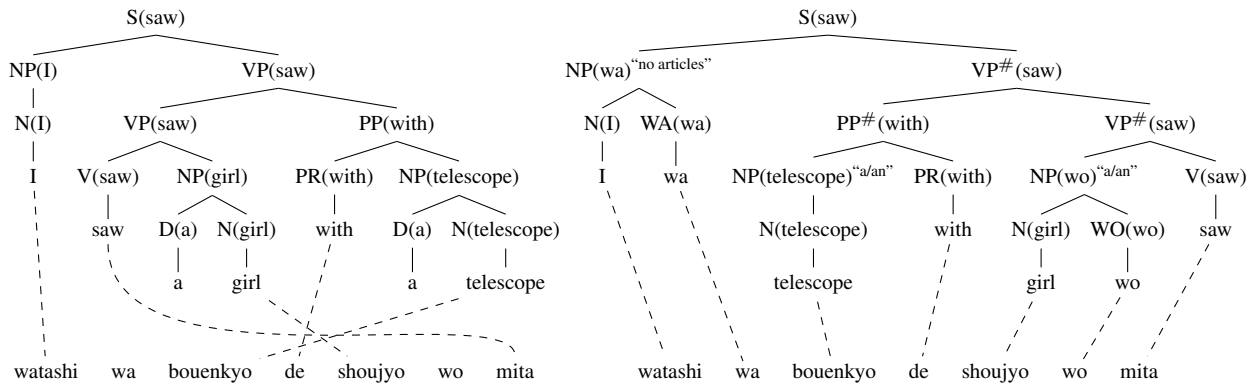

Figure 2: An example of the head-finzalizaton process for an English-Japanese sentence pair: the left-hand side tree is the original English tree, and the right-hand side tree is its head-final English tree.

end of the corresponding syntactic constituents. As a result, the terminal symbols of the English tree are sorted in a Japanese-like order. In Fig.2, we show an example of head-finalization and a tree on the right-hand side is a head-finalized English (HFE) tree of an English tree on the left-hand side. We annotate each parent node of the swapped edge with # symbol. For example, a nonterminal symbol PP$^{\#}$(with) shows that a noun phrase "a/an telescope" and a word "with" are inverted.

For better word alignments, Isozaki et al. (2012) also deleted articles "the" "a" "an" from English because Japanese has no articles, and inserted Japanese particles "ga" "wo" "wa" into English sentences. We privilege the nonterminals of a phrase modified by a deleted article to determine which "the" "a/an" or "no articles" should be inserted at the front of the phrase. Note that an original English sentence can be recovered from its HFE tree by using # symbols and annotated articles and deleting Japanese particles.

As well as Goto et al. (2012), we solve postordering by a parser whose model is trained with a set of HFE trees. The main difference between Goto et al. (2012)'s model and ours is that while the former simply used the Berkeley parser (Petrov and Klein, 2007), our shift-reduce parsing model can use such non-local task specific features as the N-gram words of reordered strings without sacrificing efficiency.

Our method integrates postediting (Knight and Chander, 1994) with reordering and inserts articles into English translations by learning an additional "insert" action of the parser. Goto et al. (2012) solved the article generation problem by using an N-gram language model, but this somewhat complicates their approach. Compared with other parsers, one advantage of the shift-reduce parser is to easily define such additional operations as "insert".

HFE trees can be defined as monolingual ITG trees (DeNero and Uszkoreit, 2011). Our monolingual ITG G is a tuple $G = (V, T, P, I, S)$ where V is a set of nonterminals, T is a set of terminals, P is a set of production rules, I is a set of nonterminals on which "the" "a/an" or "no articles" must be determined, and S is the start symbol.

Set P consists of terminal production rules that are responsible for generating word $w(\in T)$:

$$\mathrm{X} \rightarrow w$$

and binary production rules in two forms:

$$\begin{aligned} \mathrm{X} &\rightarrow \mathrm{Y}\,\mathrm{Z} \\ \mathrm{X}^{\#} &\rightarrow \mathrm{Y}\,\mathrm{Z} \end{aligned}$$

where X, X$^{\#}$, Y and Z are nonterminals. On the right-hand side, the second rule generates two phrases Y and Z in the reverse order. In our experiments, we removed all unary production rules.

3 Shift-Reduce Parsing

Given an input sentence $w_1 \ldots w_n$, the shift-reduce parser uses a stack of partial derivations, a buffer of input words, and a set of actions to build a parse tree.

The following is the parser's configuration:

$$\ell : \langle i, j, S \rangle : \pi$$

where ℓ is the step size, S is a stack of elements $s_0, s_1, \ldots$, i is the leftmost span index of the stack

top element s_0, j is an index of the next input word of the buffer, and π is a set of **predictor states**[1].

Each stack element has at least the following components of its partial derivation tree:

$$s = \{\mathrm{H}, h, w_{left}, w_{right}, a\}$$

where H is a root nonterminal or a part-of-speech tag of the subtree, h is a head index of H, a is a variable to which "the" "a/an" "no articles" or null are assigned, and w_{left}, w_{right} are the leftmost and rightmost words of phrase H. When referring to component $*$, we use a $s.*$ notation.

Our proposed system has 4 actions shift-X, insert-x, reduce-MR-X and reduce-SR-X.

The shift-X action pushes the next input word onto the stack and assigns a part-of-speech tag X to the word. The deduction step is as follows:

$$\frac{\mathrm{X} \rightarrow w_j \in P \qquad \overbrace{\ell : \langle i, j, S | s_0' \rangle : \pi}^{p}}{\ell + 1 : \langle j, j+1, S | s_0' | s_0 \rangle \rangle : \{p\}}$$

where s_0 is $\{\mathrm{X}, j, w_j, w_j, \mathrm{null}\}$.

The insert-x action determines whether to generate "the" "a/an" or "no articles" ($= x$):

$$\frac{s_0'.\mathrm{X} \in I \wedge (s_0'.a \neq \text{“the”} \wedge s_0'.a \neq \text{“a/an”}) \quad \ell : \langle i, j, S | s_0' \rangle \rangle : \pi}{\ell + 1 : \langle i, j, S | s_0 \rangle : \pi}$$

where s_0' is $\{\mathrm{X}, h, w_{left}, w_{right}, a\}$ and s_0 is $\{\mathrm{X}, h, w_{left}, w_{right}, x\}$ ($i \leq h, left, right < j$). The side condition prevents the parser from inserting articles into phrase X more than twice. During parsing, articles are not explicitly inserted into the input string: they are inserted into it when backtracking to generate a reordered string after parsing.

The reduce-MR-X action has a deduction rule:

$$\frac{\mathrm{X} \rightarrow \mathrm{Y\ Z} \in P \wedge q \in \pi \qquad \overbrace{\_ : \langle k, i, S | s_2' | s_1' \rangle : \pi'}^{q} \quad \ell : \langle i, j, S | s_1' | s_0' \rangle : \pi}{\ell + 1 : \langle k, j, S | s_2' | s_0 \rangle : \pi'}$$

[1]Since our notion of predictor states is identical to that in (Huang and Sagae, 2010), we omit the details here.

$s_0.w_h \circ s_0.t_h$ $s_0.\mathrm{H}$ $s_0.\mathrm{H} \circ s_0.t_h$ $s_0.w_h \circ s_0.\mathrm{H}$ $s_1.w_h \circ s_1.t_h$ $s_1.\mathrm{H}$ $s_1.\mathrm{H} \circ s_1.t_h$ $s_1.w_h \circ s_1.\mathrm{H}$ $s_2.t_h \circ s_2.\mathrm{H}$ $s_2.w_h \circ s_2.\mathrm{H}$ $q_0.w$ $q_1.w$ $q_2.w$
$s_0.t_l \circ s_0.\mathrm{L}$ $s_0.w_l \circ s_0.\mathrm{L}$ $s_1.t_l \circ s_1.\mathrm{L}$ $s_1.w_l \circ s_1.\mathrm{L}$
$s_0.w_h \circ s_0.\mathrm{H} \circ s_1.w_h \circ s_1.\mathrm{H}$ $s_0.\mathrm{H} \circ s_1.w_h$ $s_0.w_h \circ s_1.\mathrm{H}$ $s_0.\mathrm{H} \circ s_1.\mathrm{H}$ $s_0.w_h \circ s_0.\mathrm{H} \circ q_0.w$ $s_0.\mathrm{H} \circ q_0.w$ $s_1.w_h \circ s_1.\mathrm{H} \circ q_0.w$ $s_1.\mathrm{H} \circ q_0.w$ $s_1.t_h \circ q_0.w \circ q_1.w$

$s_0.\mathrm{H} \circ s_0.\mathrm{R} \circ s_0.\mathrm{L}$ $s_1.\mathrm{H} \circ s_1.\mathrm{R} \circ s_1.\mathrm{L}$ $s_0.\mathrm{H} \circ s_0.\mathrm{R} \circ q_0.w$ $s_0.\mathrm{H} \circ s_0.\mathrm{L} \circ s_1.\mathrm{H}$ $s_0.\mathrm{H} \circ s_0.\mathrm{L} \circ s_1.w_h$ $s_0.\mathrm{H} \circ s_1.\mathrm{H} \circ s_1.\mathrm{L}$ $s_0.w_h \circ s_1.\mathrm{H} \circ s_1.\mathrm{R}$
$s_0.w_{left} \circ s_1.w_{right}$ $s_0.t_{left} \circ s_1.t_{right}$ $s_0.w_{right} \circ s_1.w_{left}$ $s_0.t_{right} \circ s_1.t_{left}$
$s_0.a \circ s_0.w_{left}$ $s_0.a \circ s_0.t_{left}$ $s_0.a \circ s_0.w_{left} \circ s_1.w_{right}$ $s_0.a \circ s_0.t_{left} \circ s_1.t_{right}$ $s_0.a \circ s_0.w_h$ $s_0.a \circ s_0.t_h$

Table 1: Feature templates: $s.\mathrm{L}$ and $s.\mathrm{R}$ denote the left and right subnodes of s. l and r are head indices of L and R. q denotes a buffer element. t is a part-of-speech tag.

where s_0' is $\{\mathrm{Z}, h_0, w_{left0}, w_{right0}, a_0\}$ and s_1' is $\{\mathrm{Y}, h_1, w_{left1}, w_{right1}, a_1\}$. The action generates s_0 by combining s_0' and s_1' with binary rule X→Y Z:

$$s_0 = \{\mathrm{X}, h_0, w_{left1}, w_{right0}, a_1\}.$$

New nonterminal X is lexicalized with head word w_{h_0} of right nonterminal Z. This action expands Y and Z in a straight order. The leftmost word of phrase X is set to leftmost word w_{left1} of Y, and the rightmost word of phrase X is set to rightmost word w_{right0} of Z. Variable a is set to a_1 of Y.

The difference between reduce-MR-X and reduce-SR-X actions is new stack element s_0. The reduce-SR-X action generates s_0 by combining s_0' and s_1' with binary rule $\mathrm{X}^{\#}$ →Y Z:

$$s_0 = \{\mathrm{X}^{\#}, h_0, w_{left0}, w_{right1}, a_0\}.$$

This action expands Y and Z in a reverse order, and the leftmost word of $\mathrm{X}^{\#}$ is set to w_{left0} of Z, and the rightmost word of $\mathrm{X}^{\#}$ is set to w_{right1} of Y. Variable a is set to a_0 of Z.

We use a linear model that is discriminatively trained with the averaged perceptron (Collins and Roark, 2004). Table 1 shows the feature templates used in our experiments and we call the features in the bottom two rows "non-local" features.

	train	dev	test9	test10
# of sent.	3,191,228	2,000	2,000	2,300
ave. leng. (J)	36.4	36.6	37.0	43.1
ave. leng. (E)	33.3	33.3	33.7	39.6

Table 2: NTCIR-9 and 10 data statistics.

4 Experiments

4.1 Experimental Setups

We conducted experiments for NTCIR-9 and 10 patent data using a Japanese-English language pair. Mecab[2] was used for the Japanese morphological analysis. The data are summarized in Table 2.

We used Enju (Miyao and Tsujii, 2008) for parsing the English training data and converted parse trees into HFE trees by a head-finalization scheme. We extracted grammar rules from all the HFE trees and randomly selected 500,000 HFE trees to train the shift-reduce parser.

We used Moses (Koehn et al., 2007) with lexicalized reordering and a 6-gram language model (LM) trained using SRILM (Stolcke et al., 2011) to translate the Japanese sentences into HFE sentences.

To recover the English sentences, our shift-reduce parser reordered only the 1-best HFE sentence. Our strategy is much simpler than Goto et al. (2012)'s because they used a linear inteporation of MT cost, parser cost and N-gram LM cost to generate the best English sentence from the n-best HFE sentences.

4.2 Main Results

The main results in Table 3 indicate our method was significantly better and faster than the conventional PBMT system. Our method also ourperformed Goto et al. (2012)'s reported systems as well as a tree-based (moses-chart) system[3]. Our proposed model with "non-local" features (w/ nf.) achieved gains against that without the features (w/o nf.). Further feature engineering may improve the accuracy more.

4.3 Analysis

We show N-gram precisions of PBMT (dist=6, dist=20) and proposed systems in Table 5. The results clearly show that improvements of 1-gram precisions are the main factors that contribute to better performance of our proposed system than PBMT systems. It seems that the gains of 1-gram presicions come from postediting (article generation).

In table 4, we show the effectiveness of our joint reordering and postediting approach ("proposed"). The "w/o art." results clearly show that generating articles has great effects on MT evaluations especially for BLEU metric. Comparing "proposed" and "HFE w/ art." systems, these results show that postediting is much more effective than generating articles by MT. Our joint approach also outperformed "N-gram" postediting system.

	test9		test10	
	BLEU	RIBES	BLEU	RIBES
HFE w/ art.	28.86	73.45	29.9	73.52
proposed	**32.93**	**76.68**	**33.25**	**76.74**
w/o art.	19.86	75.62	20.17	75.63
N-gram	32.15	76.52	32.28	76.46

Table 4: The effects of article generation: "w/o art." denotes evaluation scores for translations of the best system ("proposed") in Table 3 from which articles are removed. "HFE w/ art." system used HFE data with articles and generated them by MT system and the shift-reduce parser performed only reordering. "N-gram" system inserted articles into the translations of "w/o art." by Goto et al. (2012)'s article generation method.

	(1–4)-gram precision
moses (dist=6)	67.1 / 36.9 / 20.7 / 11.5
moses (dist=20)	67.7 / 38.9 / 23.0 / 13.7
proposed	68.9 / 40.6 / 25.7 / 16.7

Table 5: N-gram precisions of moses (dist=6, dist=20) and proposed systems for test9 data.

5 Conclusion

We proposed a shift-reduce word ordering model and applied it to J-to-E postordering. Our experimental results indicate our method can significantly improve the performance of a PBMT system.

Future work will investigate our method's usefulness on various language datasets. We plan to study more general methods that use word alignments to embed swap information in trees (Galley et al., 2006).

Abstract

We explore the application of neural language models to machine translation. We develop a new model that combines the neural probabilistic language model of Bengio et al., rectified linear units, and noise-contrastive estimation, and we incorporate it into a machine translation system both by reranking k-best lists and by direct integration into the decoder. Our large-scale, large-vocabulary experiments across four language pairs show that our neural language model improves translation quality by up to 1.1 B .

1 Introduction

Machine translation (MT) systems rely upon language models (LMs) during decoding to ensure fluent output in the target language. Typically, these LMs are n-gram models over discrete representations of words. Such models are susceptible to data sparsity–that is, the probability of an n-gram observed only few times is difficult to estimate reliably, because these models do not use any information about similarities between words.

To address this issue, Bengio et al. (2003) propose distributed word representations, in which each word is represented as a real-valued vector in a high-dimensional feature space. Bengio et al. (2003) introduce a feed-forward neural probabilistic LM (NPLM) that operates over these distributed representations. During training, the NPLM learns both a distributed representation for each word in the vocabulary and an n-gram probability distribution over words in terms of these distributed representations.

Although neural LMs have begun to rival or even surpass traditional n-gram LMs (Mnih and Hinton, 2009; Mikolov et al., 2011), they have not yet been widely adopted in large-vocabulary applications such as MT, because standard maximum likelihood estimation (MLE) requires repeated summations over all words in the vocabulary. A variety of strategies have been proposed to combat this issue, many of which require severe restrictions on the size of the network or the size of the data.

In this work, we extend the NPLM of Bengio et al. (2003) in two ways. First, we use rectified linear units (Nair and Hinton, 2010), whose activations are cheaper to compute than sigmoid or tanh units. There is also evidence that deep neural networks with rectified linear units can be trained successfully without pre-training (Zeiler et al., 2013). Second, we train using noise-contrastive estimation or NCE (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012), which does not require repeated summations over the whole vocabulary. This enables us to efficiently build NPLMs on a larger scale than would be possible otherwise.

We then apply this LM to MT in two ways. First, we use it to rerank the k-best output of a hierarchical phrase-based decoder (Chiang, 2007). Second, we integrate it directly into the decoder, allowing the neural LM to more strongly influence the model. We achieve gains of up to 0.6 B translating French, German, and Spanish to English, and up to 1.1 B on Chinese-English translation.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1387–1392,
Seattle, Washington, USA, 18-21 October 2013.

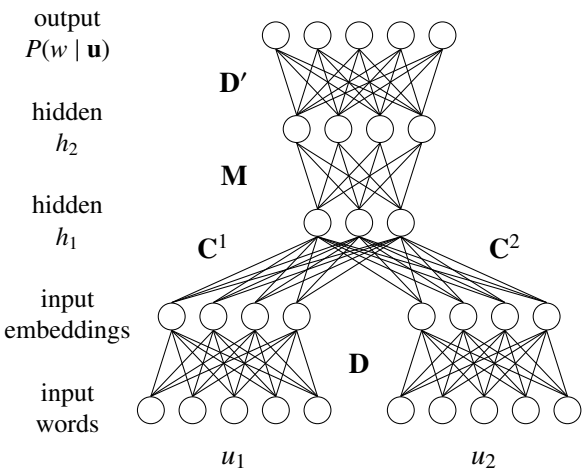

Figure 1: Neural probabilistic language model (Bengio et al., 2003).

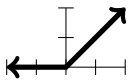
2 Neural Language Models

Let V be the vocabulary, and n be the order of the language model; let $\mathbf{u}$ range over contexts, i.e., strings of length $(n-1)$, and w range over words. For simplicity, we assume that the training data is a single very long string, $w_1 \cdots w_N$, where w_N is a special stop symbol, </s>. We write $\mathbf{u}_i$ for $w_{i-n+1} \cdots w_{i-1}$, where, for $i \leq 0$, w_i is a special start symbol, <s>.

2.1 Model

We use a feedforward neural network as shown in Figure 1, following Bengio et al. (2003). The input to the network is a sequence of one-hot representations of the words in context $\mathbf{u}$, which we write u_j $(1 \leq j \leq n-1)$. The output is the probability $P(w \mid \mathbf{u})$ for each word w, which the network computes as follows.

The hidden layers consist of rectified linear units (Nair and Hinton, 2010), which use the activation function $\phi(x) = \max(0, x)$ (see graph at right).



The output of the first hidden layer h_1 is

$$h_1 = \phi\left(\sum_{j=1}^{n-1} \mathbf{C}^j \mathbf{D} u_j\right) \tag{1}$$

where $\mathbf{D}$ is a matrix of input word embeddings which is shared across all positions, the $\mathbf{C}^j$ are the context matrices for each word in $\mathbf{u}$, and ϕ is applied elementwise. The output of the second layer h_2 is

$$h_2 = \phi\left(\mathbf{M} h_1\right),$$

where $\mathbf{M}$ is the matrix of connection weights between h_1 and h_2. Finally, the output layer is a softmax layer,

$$P(w \mid \mathbf{u}) \propto \exp\left(\mathbf{D}' h_2 + \mathbf{b}\right) \tag{2}$$

where $\mathbf{D}'$ is the output word embedding matrix and $\mathbf{b}$ is a vector of biases for every word in the vocabulary.

2.2 Training

The typical way to train neural LMs is to maximize the likelihood of the training data by gradient ascent. But the softmax layer requires, at each iteration, a summation over all the units in the output layer, that is, all words in the whole vocabulary. If the vocabulary is large, this can be prohibitively expensive.

Noise-contrastive estimation or NCE (Gutmann and Hyvärinen, 2010) is an alternative estimation principle that allows one to avoid these repeated summations. It has been applied previously to log-bilinear LMs (Mnih and Teh, 2012), and we apply it here to the NPLM described above.

We can write the probability of a word w given a context $\mathbf{u}$ under the NPLM as

$$\begin{aligned} P(w \mid \mathbf{u}) &= \frac{1}{Z(\mathbf{u})} p(w \mid \mathbf{u}) \\ p(w \mid \mathbf{u}) &= \exp\left(\mathbf{D}' h_2 + \mathbf{b}\right) \\ Z(\mathbf{u}) &= \sum_{w'} p(w' \mid \mathbf{u}) \end{aligned} \tag{3}$$

where $p(w \mid \mathbf{u})$ is the *unnormalized* output of the unit corresponding to w, and $Z(\mathbf{u})$ is the normalization factor. Let θ stand for the parameters of the model.

One possibility would be to treat $Z(\mathbf{u})$, instead of being defined by (3), as an additional set of model parameters which are learned along with θ. But it is easy to see that we can make the likelihood arbitrarily large by making the $Z(\mathbf{u})$ arbitrarily small.

In NCE, we create a noise distribution $q(w)$. For each example $\mathbf{u}_i w_i$, we add k noise samples $\bar{w}_{i1}, \ldots, \bar{w}_{ik}$ into the data, and extend the model to account for noise samples by introducing a random

variable C which is 1 for training examples and 0 for noise samples:

$$P(C = 1, w \mid \mathbf{u}) = \frac{1}{1+k} \cdot \frac{1}{Z(\mathbf{u})} p(w \mid \mathbf{u})$$
$$P(C = 0, w \mid \mathbf{u}) = \frac{k}{1+k} \cdot q(w).$$

We then train the model to classify examples as training data or noise, that is, to maximize the *conditional* likelihood,

$$L = \sum_{i=1}^{N} \Bigg(\log P(C = 1 \mid \mathbf{u}_i w_i) + \sum_{j=1}^{k} \log P(C = 0 \mid \mathbf{u}_i \bar{w}_{ij}) \Bigg)$$

with respect to both θ and $Z(\mathbf{u})$.

We do this by stochastic gradient ascent. The gradient with respect to θ turns out to be

$$\frac{\partial L}{\partial \theta} = \sum_{i=1}^{N} \Bigg(P(C = 0 \mid \mathbf{u}_i w_i) \frac{\partial}{\partial \theta} \log p(w_i \mid \mathbf{u}_i) - \sum_{j=1}^{k} P(C = 1 \mid \mathbf{u}_i \bar{w}_{ij}) \frac{\partial}{\partial \theta} \log p(\bar{w}_{ij} \mid \mathbf{u}_i) \Bigg)$$

and similarly for the gradient with respect to $Z(\mathbf{u})$. These can be computed by backpropagation. Unlike before, the $Z(\mathbf{u})$ will converge to a value that normalizes the model, satisfying (3), and, under appropriate conditions, the parameters will converge to a value that maximizes the likelihood of the data.

3 Implementation

Both training and scoring of neural LMs are computationally expensive at the scale needed for machine translation. In this section, we describe some of the techniques used to make them practical for translation.

3.1 Training

During training, we compute gradients on an entire minibatch at a time, allowing the use of matrix-matrix multiplications instead of matrix-vector multiplications (Bengio, 2012). We represent the inputs as a sparse matrix, allowing the computation of the input layer (1) to use sparse matrix-matrix multiplications. The output activations (2) are computed only for the word types that occur as the positive example or one of the noise samples, yielding a sparse matrix of outputs. Similarly, during backpropagation, sparse matrix multiplications are used at both the output and input layer.

In most of these operations, the examples in a minibatch can be processed in parallel. However, in the sparse-dense products used when updating the parameters $\mathbf{D}$ and $\mathbf{D}'$, we found it was best to divide the vocabulary into blocks (16 per thread) and to process the blocks in parallel.

3.2 Translation

To incorporate this neural LM into a MT system, we can use the LM to rerank k-best lists, as has been done in previous work. But since the NPLM scores n-grams, it can also be integrated into a phrase-based or hierarchical phrase-based decoder just as a conventional n-gram model can, unlike a RNN.

The most time-consuming step in computing n-gram probabilities is the computation of the normalization constants $Z(\mathbf{u})$. Following Mnih and Teh (2012), we set all the normalization constants to one during training, so that the model learns to produce approximately normalized probabilities. Then, when applying the LM, we can simply ignore normalization. A similar strategy was taken by Niehues and Waibel (2012). We find that a single n-gram lookup takes about 40 μs.

The technique, described above, of grouping examples into minibatches works for scoring of k-best lists, but not while decoding. But caching n-gram probabilities helps to reduce the cost of the many lookups required during decoding.

A final issue when decoding with a neural LM is that, in order to estimate future costs, we need to be able to estimate probabilities of n'-grams for $n' < n$. In conventional LMs, this information is readily available,[1] but not in NPLMs. Therefore, we defined a special word <null> whose embedding is the weighted average of the (input) embeddings of all the other words in the vocabulary. Then, to estimate the probability of an n'-gram $\mathbf{u}'w$, we used the probability of $P(w \mid \texttt{<null>}^{n-n'}\mathbf{u}')$.

[1] However, in Kneser-Ney smoothed LMs, this information is also incorrect (Heafield et al., 2012).

setting	dev	2004	2005	2006
baseline	38.2	38.4	37.7	34.3
reranking	38.5	38.6	37.8	34.7
decoding	39.1	39.5	38.8	34.9

Table 1: Results for Chinese-English experiments, without neural LM (baseline) and with neural LM for reranking and integrated decoding. Reranking with the neural LM improves translation quality, while integrating it into the decoder improves even more.

	Fr-En		De-En		Es-En	
setting	dev	test	dev	test	dev	test
baseline	33.5	25.5	28.8	21.5	33.5	32.0
reranking	33.9	26.0	29.1	21.5	34.1	32.2
decoding	34.1[2]	26.1[2]	29.3	21.9	34.2[2]	32.1[2]

Table 2: Results for Europarl MT experiments, without neural LM (baseline) and with neural LM for reranking and integrated decoding. The neural LM gives improvements across three different language pairs. Superscript 2 indicates a score averaged between two runs; all other scores were averaged over three runs.

4 Experiments

We ran experiments on four language pairs – Chinese to English and French, German, and Spanish to English – using a hierarchical phrase-based MT system (Chiang, 2007) and GIZA++ (Och and Ney, 2003) for word alignments.

For all experiments, we used four LMs. The baselines used conventional 5-gram LMs, estimated with modified Kneser-Ney smoothing (Chen and Goodman, 1998) on the English side of the bitext and the 329M-word Xinhua portion of English Gigaword (LDC2011T07). Against these baselines, we tested systems that included the two conventional LMs as well as two 5-gram NPLMs trained on the same datasets. The Europarl bitext NPLMs had a vocabulary size of 50k, while the other NPLMs had a vocabulary size of 100k. We used 150 dimensions for word embeddings, 750 units in hidden layer h_1, and 150 units in hidden layer h_2. We initialized the network parameters uniformly from $(-0.01, 0.01)$ and the output biases to $-\log|V|$, and optimized them by 10 epochs of stochastic gradient ascent, using minibatches of size 1000 and a learning rate of 1. We drew 100 noise samples per training example from the unigram distribution, using the alias method for efficiency (Kronmal and Peterson, 1979).

We trained the discriminative models with MERT (Och, 2003) and the discriminative rerankers on 1000-best lists with MERT. Except where noted, we ran MERT three times and report the average score. We evaluated using case-insensitive NIST B .

4.1 NIST Chinese-English

For the Chinese-English task (Table 1), the training data came from the NIST 2012 constrained track, excluding sentences longer than 60 words. Rules without nonterminals were extracted from all training data, while rules with nonterminals were extracted from the FBIS corpus (LDC2003E14). We ran MERT on the development data, which was the NIST 2003 test data, and tested on the NIST 2004–2006 test data.

Reranking using the neural LM yielded improvements of 0.2–0.4 B , while integrating the neural LM yielded larger improvements, between 0.6 and 1.1 B .

4.2 Europarl

For French, German, and Spanish translation, we used a parallel text of about 50M words from Europarl v7. Rules without nonterminals were extracted from all the data, while rules with nonterminals were extracted from the first 200k words. We ran MERT on the development data, which was the WMT 2005 test data, and tested on the WMT 2006 news commentary test data (nc-test2006).

The improvements, shown in Table 2, were more modest than on Chinese-English. Reranking with the neural LM yielded improvements of up to 0.5 B , and integrating the neural LM into the decoder yielded improvements of up to 0.6 B . In one case (Spanish-English), integrated decoding scored higher than reranking on the development data but lower on the test data – perhaps due to the difference in domain between the two. On the other tasks, integrated decoding outperformed reranking.

4.3 Speed comparison

We measured the speed of training a NPLM by NCE, compared with MLE as implemented by the CSLM toolkit (Schwenk, 2013). We used the first 200k

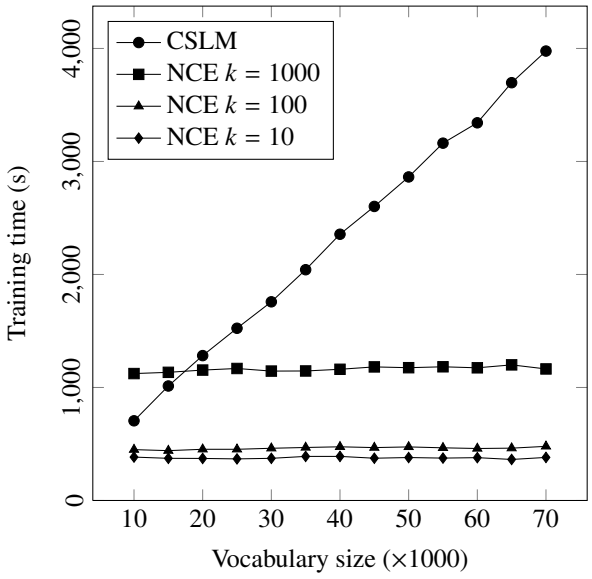


Figure 2: Noise contrastive estimation (NCE) is much faster, and much less dependent on vocabulary size, than MLE as implemented by the CSLM toolkit (Schwenk, 2013).

lines (5.2M words) of the Xinhua portion of Gigaword and timed one epoch of training, for various values of k and $|V|$, on a dual hex-core 2.67 GHz Xeon X5650 machine. For these experiments, we used minibatches of 128 examples. The timings are plotted in Figure 2. We see that NCE is considerably faster than MLE; moreover, as expected, the MLE training time is roughly linear in $|V|$, whereas the NCE training time is basically constant.

5 Related Work

The problem of training with large vocabularies in NPLMs has received much attention. One strategy has been to restructure the network to be more hierarchical (Morin and Bengio, 2005; Mnih and Hinton, 2009) or to group words into classes (Le et al., 2011). Other strategies include restricting the vocabulary of the NPLM to a *shortlist* and reverting to a traditional n-gram LM for other words (Schwenk, 2004), and limiting the number of training examples using resampling (Schwenk and Gauvain, 2005) or selecting a subset of the training data (Schwenk et al., 2012). Our approach can be efficiently applied to large-scale tasks without limiting either the model or the data.

NPLMs have previously been applied to MT, most notably feed-forward NPLMs (Schwenk, 2007; Schwenk, 2010) and RNN-LMs (Mikolov, 2012). However, their use in MT has largely been limited to reranking k-best lists for MT tasks with restricted vocabularies. Niehues and Waibel (2012) integrate a RBM-based language model directly into a decoder, but they only train the RBM LM on a small amount of data. To our knowledge, our approach is the first to integrate a large-vocabulary NPLM directly into a decoder for a large-scale MT task.

6 Conclusion

We introduced a new variant of NPLMs that combines the network architecture of Bengio et al. (2003), rectified linear units (Nair and Hinton, 2010), and noise-contrastive estimation (Gutmann and Hyvärinen, 2010). This model is dramatically faster to train than previous neural LMs, and can be trained on a large corpus with a large vocabulary and directly integrated into the decoder of a MT system. Our experiments across four language pairs demonstrated improvements of up to 1.1 B . Code for training and using our NPLMs is available for download.[2]

Bilingual Word Embeddings for Phrase-Based Machine Translation

Will Y. Zou[†], **Richard Socher, Daniel Cer, Christopher D. Manning**

Abstract

We introduce bilingual word embeddings: semantic embeddings associated across two languages in the context of neural language models. We propose a method to learn bilingual embeddings from a large unlabeled corpus, while utilizing MT word alignments to constrain translational equivalence. The new embeddings significantly out-perform baselines in word semantic similarity. A single semantic similarity feature induced with bilingual embeddings adds near half a BLEU point to the results of NIST08 Chinese-English machine translation task.

1 Introduction

It is difficult to recognize and quantify semantic similarities across languages. The Fr-En phrase-pair {'*un cas de force majeure*', '*case of absolute necessity*'}, Zh-En phrase pair {'依然故我','*persist in a stubborn manner*'} are similar in semantics. If co-occurrences of exact word combinations are rare in the training parallel text, it can be difficult for classical statistical MT methods to identify this similarity, or produce a reasonable translation given the source phrase.

We introduce an unsupervised neural model to learn bilingual semantic embedding for words across two languages. As an extension to their monolingual counter-part (Turian et al., 2010; Huang et al., 2012; Bengio et al., 2003), bilingual embeddings capture not only semantic information of monolingual words, but also semantic relationships across different languages. This property allows them to define semantic similarity metrics across phrase-pairs, making them perfect features for machine translation.

To learn bilingual embeddings, we use a new objective function which embodies both monolingual semantics and bilingual translation equivalence. The latter utilizes word alignments, a natural sub-task in the machine translation pipeline. Through large-scale curriculum training (Bengio et al., 2009), we obtain bilingual distributed representations which lie in the same feature space. Embeddings of direct translations overlap, and semantic relationships across bilingual embeddings were further improved through unsupervised learning on a large unlabeled corpus.

Consequently, we produce for the research community a first set of Mandarin Chinese word embeddings with 100,000 words trained on the Chinese Gigaword corpus. We evaluate these embedding on Chinese word semantic similarity from *SemEval-2012* (Jin and Wu, 2012). The embeddings significantly out-perform prior work and pruned *tf-idf* base-lines. In addition, the learned embeddings give rise to 0.11 F1 improvement in Named Entity Recognition on the OntoNotes dataset (Hovy et al., 2006) with a neural network model.

We apply the bilingual embeddings in an end-to-end phrase-based MT system by computing semantic similarities between phrase pairs. On NIST08 Chinese-English translation task, we obtain an improvement of 0.48 BLEU from a competitive baseline (30.01 BLEU to 30.49 BLEU) with the Stanford Phrasal MT system.

2 Review of prior work

Distributed word representations are useful in NLP applications such as information retrieval (Paşca et al., 2006; Manning et al., 2008), search query expansions (Jones et al., 2006), or representing semantics of words (Reisinger et al., 2010). A number of methods have been explored to train and apply word embeddings using continuous models for language. Collobert et al. (2008) learn embeddings in an unsupervised manner through a contrastive estimation technique. Mnih and Hinton (2008), Morin and Bengio (2005) proposed efficient hierarchical continuous-space models. To systematically compare embeddings, Turian et al. (2010) evaluated improvements they bring to state-of-the-art NLP benchmarks. Huang et al. (2012) introduced global document context and multiple word prototypes. Recently, morphology is explored to learn better word representations through Recursive Neural Networks (Luong et al., 2013).

Bilingual word representations have been explored with hand-designed vector space models (Peirsman and Padó , 2010; Sumita, 2000), and with unsupervised algorithms such as LDA and LSA (Boyd-Graber and Resnik, 2010; Tam et al., 2007; Zhao and Xing, 2006). Only recently have continuous space models been applied to machine translation (Le et al., 2012). Despite growing interest in these models, little work has been done along the same lines to train bilingual distributioned word represenations to improve machine translation. In this paper, we learn bilingual word embeddings which achieve competitive performance on semantic word similarity, and apply them in a practical phrase-based MT system.

3 Algorithm and methods

3.1 Unsupervised training with global context

Our method starts with embedding learning formulations in Collobert et al. (2008). Given a context window c in a document d, the optimization minimizes the following Context Objective for a word w in the vocabulary:

$$J_{CO}^{(c,d)} = \sum_{w^r \in V_R} \max(0, 1 - f(c^w, d) + f(c^{w^r}, d)) \quad (1)$$

Here f is a function defined by a neural network. w^r is a word chosen in a random subset V_R of the vocabulary, and c^{w^r} is the context window containing word w^r. This unsupervised objective function contrasts the score between when the correct word is placed in context with when a random word is placed in the same context. We incorporate the global context information as in Huang et al. (2012), shown to improve performance of word embeddings.

3.2 Bilingual initialization and training

In the joint semantic space of words across two languages, the Chinese word '政府' is expected to be close to its English translation 'government'. At the same time, when two words are not direct translations, e.g. 'lake' and the Chinese word '潭' (deep pond), their semantic proximity could be correctly quantified.

We describe in the next sub-sections the methods to intialize and train bilingual embeddings. These methods ensure that bilingual embeddings retain their translational equivalence while their distributional semantics are improved during online training with a monolingual corpus.

3.2.1 Initialization by MT alignments

First, we use MT Alignment counts as weighting to initialize Chinese word embeddings. In our experiments, we use MT word alignments extracted with the Berkeley Aligner (Liang et al., 2006) [1]. Specifically, we use the following equation to compute starting word embeddings:

$$W_{t\text{-}init} = \sum_{s=1}^{S} \frac{C_{ts} + 1}{C_t + S} W_s \quad (2)$$

In this equation, S is the number of possible target language words that are aligned with the source word. C_{ts} denotes the number of times when word t in the target and word s in the source are aligned in the training parallel text; C_t denotes the total number of counts of word t that appeared in the target language. Finally, Laplace smoothing is applied to this weighting function.

[1] On NIST08 Zh-En training data and data from GALE MT evaluation in the past 5 years

Single-prototype English embeddings by Huang et al. (2012) are used to initialize Chinese embeddings. The initialization readily provides a set (*Align-Init*) of benchmark embeddings in experiments (Section 4), and ensures translation equivalence in the embeddings at start of training.

3.2.2 Bilingual training

Using the alignment counts, we form alignment matrices $A_{en \to zh}$ and $A_{zh \to en}$. For $A_{en \to zh}$, each row corresponds to a Chinese word, and each column an English word. An element a_{ij} is first assigned the counts of when the ith Chinese word is aligned with the jth English word in parallel text. After assignments, each row is normalized such that it sums to one. The matrix $A_{zh \to en}$ is defined similarly. Denote the set of Chinese word embeddings as V_{zh}, with each row a word embedding, and the set of English word embeddings as V_{en}. With the two alignment matrices, we define the Translation Equivalence Objective:

$$J_{TEO\text{-}en \to zh} = \|V_{zh} - A_{en \to zh} V_{en}\|^2 \quad (3)$$

$$J_{TEO\text{-}zh \to en} = \|V_{en} - A_{zh \to en} V_{zh}\|^2 \quad (4)$$

We optimize for a combined objective during training. For the Chinese embeddings we optimize for:

$$J_{CO\text{-}zh} + \lambda J_{TEO\text{-}en \to zh} \quad (5)$$

For the English embeddings we optimize for:

$$J_{CO\text{-}en} + \lambda J_{TEO\text{-}zh \to en} \quad (6)$$

During bilingual training, we chose the value of λ such that convergence is achieved for both J_{CO} and J_{TEO}. A small validation set of word similarities from (Jin and Wu, 2012) is used to ensure the embeddings have reasonable semantics. [2]

In the next sections, 'bilingual trained' embeddings refer to those initialized with MT alignments and trained with the objective defined by Equation 5. 'Monolingual trained' embeddings refer to those intialized by alignment but trained without $J_{TEO\text{-}en \to zh}$.

[2] In our experiments, $\lambda = 50$.

3.3 Curriculum training

We train 100k-vocabulary word embeddings using curriculum training (Turian et al., 2010) with Equation 5. For each curriculum, we sort the vocabulary by frequency and segment the vocabulary by a band-size taken from {5k, 10k, 25k, 50k}. Separate bands of the vocabulary are trained in parallel using minibatch L-BFGS on the Chinese Gigaword corpus [3]. We train 100,000 iterations for each curriculum, and the entire 100k vocabulary is trained for 500,000 iterations. The process takes approximately 19 days on a eight-core machine. We show visualization of learned embeddings overlaid with English in Figure 1. The two-dimensional vectors for this visualization is obtained with t-SNE (van der Maaten and Hinton, 2008). To make the figure comprehensible, subsets of Chinese words are provided with reference translations in boxes with green borders. Words across the two languages are positioned by the semantic relationships implied by their embeddings.

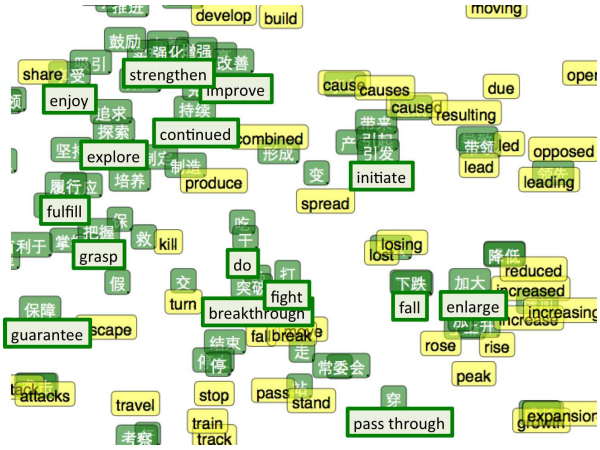

Figure 1: Overlaid bilingual embeddings: English words are plotted in yellow boxes, and Chinese words in green; reference translations to English are provided in boxes with green borders directly below the original word.

4 Experiments

4.1 Semantic Similarity

We evaluate the Mandarin Chinese embeddings with the semantic similarity test-set provided by the or-

[3] Fifth Edition. LDC catelog number *LDC2011T13*. We only exclude *cna_cmn*, the Traditional Chinese segment of the corpus.

Mono-trained	0.54	0.62	**0.58**	**0.17**
Biling-trained	0.48	0.55	0.52	0.11

Table 3: Vector Matching Alignment *AER* (lower is better)

Embeddings	*Prec.*	*Rec.*	*AER*
Mono-trained	0.27	0.32	0.71
Biling-trained	0.37	0.45	**0.59**

ganizers of *SemEval-2012* Task 4. This test-set contains 297 Chinese word pairs with similarity scores estimated by humans.

The results for semantic similarity are shown in Table 1. We show two evaluation metrics: Spearman Correlation and Kendall's Tau. For both, bilingual embeddings trained with the combined objective defined by Equation 5 perform best. For pruned tf-idf, we follow Reisinger et al. (2010; Huang et al. (2012) and count word co-occurrences in a 10-word window. We use the best results from a range of pruning and feature thresholds to compare against our method. The bilingual and monolingual trained embeddings[4] out-perform pruned *tf-idf* by 14.1 and 12.6 Spearman Correlation ($\times$100), respectively. Further, they out-perform embeddings initialized from alignment by 7.9 and 6.4. Both our *tf-idf* implementation and the word embeddings have significantly higher Kendall's Tau value compared to Prior work (Jin and Wu, 2012). We verified Tau calculations with original submissions provided by the authors.

4.2 Named Entity Recognition

We perform NER experiments on OntoNotes (v4.0) (Hovy et al., 2006) to validate the quality of the Chinese word embeddings. Our experimental setup is the same as Wang et al. (2013). With embeddings, we build a naive feed-forward neural network (Collobert et al., 2008) with 2000 hidden neurons and a sliding window of five words. This naive setting, without sequence modeling or sophisticated join optimization, is not competitive with state-of-the-art (Wang et al., 2013). Table 2 shows that the bilingual embeddings obtains 0.11 F1 improvement, lagging monolingual, but significantly better than *Align-Init* (as in Section3.2.1) on the NER task.

4.3 Vector matching alignment

Translation equivalence of the bilingual embeddings is evaluated by naive word alignment to match word embeddings by cosine distance.[5] The Alignment Error Rates (AER) reported in Table 3 suggest that bilingual training using Equation 5 produces embeddings with better translation equivalence compared to those produced by monolingual training.

4.4 Phrase-based machine translation

Our experiments are performed using the Stanford Phrasal phrase-based machine translation system (Cer et al., 2010). In addition to NIST08 training data, we perform phrase extraction, filtering and phrase table learning with additional data from GALE MT evaluations in the past 5 years. In turn, our baseline is established at 30.01 BLEU and reasonably competitive relative to NIST08 results. We use Minimum Error Rate Training (MERT) (Och, 2003) to tune the decoder.

In the phrase-based MT system, we add one feature to bilingual phrase-pairs. For each phrase, the word embeddings are averaged to obtain a feature vector. If a word is not found in the vocabulary, we disregard and assume it is not in the phrase; if no word is found in a phrase, a zero vector is assigned

[4]Due to variations caused by online minibatch L-BFGS, we take embeddings from five random points out of last 10^5 minibatch iterations, and average their semantic similarity results.

[5]This is evaluated on 10,000 randomly selected sentence pairs from the MT training set.

Table 4: NIST08 Chinese-English translation *BLEU*

Method	*BLEU*
Our baseline	30.01
Embeddings	
Random-Init Mono-trained	30.09
Align-Init	30.31
Mono-trained	30.40
Biling-trained	**30.49**

to it. We then compute the cosine distance between the feature vectors of a phrase pair to form a semantic similarity feature for the decoder.

Results on NIST08 Chinese-English translation task are reported in Table 4[6]. An increase of 0.48 BLEU is obtained with semantic similarity with bilingual embeddings. The increase is modest, just surpassing a reference standard deviation 0.29 BLEU Cer et al. (2010)[7] evaluated on a similar system. We intend to publish further analysis on statistical significance of this result as an appendix. From these suggestive evidence in the MT results, random initialized monolingual trained embeddings add little gains to the baseline. Bilingual initialization and training seem to be offering relatively more consistent gains by introducing translational equivalence.

5 Conclusion

In this paper, we introduce bilingual word embeddings through initialization and optimization constraint using MT alignments The embeddings are learned through curriculum training on the Chinese Gigaword corpus. We show good performance on Chinese semantic similarity with bilingual trained embeddings. When used to compute semantic similarity of phrase pairs, bilingual embeddings improve NIST08 end-to-end machine translation results by just below half a BLEU point. This implies that semantic embeddings are useful features for improving MT systems. Further, our results offer suggestive evidence that bilingual word embeddings act as high-quality semantic features and embody bilingual translation equivalence across languages.

[6]We report case-insensitive BLEU

[7]With 4-gram BLEU metric from Table 4

Abstract

In this paper we present a novel approach to automatic creation of anchor texts for hyperlinks in a document pointing to similar documents. Methods used in this approach rank parts of a document based on the similarity to a presumably related document. Ranks are then used to automatically construct the best anchor text for a link inside original document to the compared document. A number of different methods from information retrieval and natural language processing are adapted for this task. Automatically constructed anchor texts are manually evaluated in terms of relatedness to linked documents and compared to baseline consisting of originally inserted anchor texts. Additionally we use crowdsourcing for evaluation of original anchors and automatically constructed anchors. Results show that our best adapted methods rival the precision of the baseline method.

1 Introduction

One of the features of hypertext documents are hyperlinks that point to other resources – pictures, videos, tweets, or other hypertext documents. A fairly familiar category of the latter is *related articles*; these usually appear at the end of a news article or a blog post with the title of the target document as anchor text. The target document is similar in content to original document; it may tell the story from another point of view, it may be a more detailed version of a part of the events in the original document, etc. Another category are the in-text links; these appear inside the main body of text and use some of the existing text as anchor. Ideally the anchor text is selected in such a way that it conveys some information about the target document; in reality sometimes just an adverb (e.g. here, there) is used, or even the destination URL may serve as anchor.

Our goal is to develop a system that automatically constructs in-text links, i.e. for a query document finds a target document and an appropriate part of the text of the query document that serves as the anchor text for the hyperlink. We want the target document to be similar in content to the query document and the anchor text to indicate that content.

There are many potential uses for such a system, especially for simplifying and streamlining document creation. This includes authors of blogs that may use the system for adding related content from other sources without exhausting manual search for such material. It may also be used when writing a scientific paper, automatically adding citations to other relevant papers inside the main body. This accelerates the writing, again reducing the time spent searching for possible existing research in the field. A citation can be considered an in-text link without a defined starting point.

We have addressed the problem in two steps, separately finding a similar document, and finding the anchor text for it. Since the retrieval of similar documents was a research focus for many years and is thus better researched, we have decided in this paper to focus on the placement of the anchor text for a link to a preselected document.

This paper is organized as follows: related work is discussed in Section 2, the methods, corpus, and evaluation are described in Section 3, followed by

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1399–1404,
Seattle, Washington, USA, 18-21 October 2013.

results and discussion in Section 4 and ending with conclusions in Section 5.

2 Related Work

Semantic similarity of textual documents offers a way to organize the increasing number of available documents. It can be used in many applications such as summarization, educational systems, finding duplicated bug reports in software testing (Lintean et al., 2010), plagiarism detection (Kasprzak and Brandejs, 2010), and research of a scientific field (Koberstein and Ng, 2006). Documents can vary in length from microblogs (Twitter) and sentences (Li et al., 2006; Koberstein and Ng, 2006) to paragraphs (Lintean et al., 2010) and larger documents (Budanitsky and Hirst, 2006).

There is also commercial software such as nRelate[1], Zemanta[2] and OpenCalais[3] with functionality that ranges from named entity recognition (NER) and event detection to related content. Publishers use in-house tools that offer automatic retrieval of in-house similar documents.

Most of the methods for comparing documents focus on the query document as a whole. The calculated score therefore belongs to the whole document and nothing can be said about more or less similar parts of the document. Our goal is to localize the similarity to a part of the query document, a paragraph, sentence, or even a part of the sentence that is most similar to another document. This part of the query document can then serve as anchor text for a hyperlink connection to the similar document.

Plagiarism detection methods (Alzahrani et al., 2012; Monostori et al., 2002) have a task of verifying the originality of the document. Extrinsic plagiarism detection methods compare two documents to determine if some of the material in one is plagiarised from the other. Methods range from simple exact substring matching to more advanced ones like semantic based methods that are able to recognize paraphrasing and refactoring (Alzahrani et al., 2012). These methods have localization of similarity already built-in as they are searching for parts of the text that seem to be plagiarised. We have focused on one such method, the winner of the PAN 2010 challenge (Kasprzak and Brandejs, 2010). This method uses shared n-grams from the two documents in order to determine if one of them is plagiarised.

Another similar research is automatic citation placement for scientific papers. Most of the work (Strohman et al., 2007; McNee et al., 2002) is concerned with putting citations at the end of the paper (non-localized), which is a task similar to inserting related articles for a news article at the of the text. There have been some attempts to place the citations in the main body of text (Tang and Zhang, 2009; He et al., 2011), typically used when referring to an idea or method.

Tang and Zang (2009) used a placeholder constraint: the query document must contain placeholders for citations, i.e. the places in text where citation might be inserted. Their method then just ranks all possible documents for a particular placeholder and chooses the best ranked document as a result. Documents are ranked on the basis of a learned topic model, obtained by a two-layer Restricted Boltzmann Machine.

He et al.(2011) made a step further towards generality of a citation location; they divide the text into overlapping windows and then decide which windows are viable citation context. The best method for deciding which citation context to use was a dependency feature model, an ensemble method using 17 different features and decision trees.

Named entity recognition (NER) also offers a useful insight into document similarity. If two documents share a named entity (NE), it is more likely they are similar. Detected NEs may also serve as anchor text for the link. NER is a fairly researched field (Finkel et al., 2005; Ratinov et al., 2011; Bunescu and Pasca, 2006; Kulkarni et al., 2009; Milne and Witten, 2008) and is also used in several commercial applications such as Zemanta, OpenCalais and AlchemyAPI[4], which are able to automatically insert links for a NE pointing to a knowledge base such as Wikipedia or IMDB. However, at this point they are unable to link to arbitrary documents, but may be useful in conjunction with other methods.

3 Methodology

3.1 Corpus

We have chosen 100 web articles (posts) at random from the end of January 2012. We extracted the body and title of each document. All the present in-text links were also extracted and filtered. First, automatic filtering was applied to remove unwanted categories of links (videos, definition pages on wikipedia and imdb, etc.), and articles that were deemed too short for similarity comparison. The threshold was set at 200 words of automatically scraped body text of a linked document.

All the remaining links were manually checked to ensure the integrity of link targets. This way we collected 265 articles (hereinafter *related articles* - RA). A number of different methods were then used to calculate similarity rank and select the best part of the post text to be used as anchor text for a hyperlink pointing to the originally linked RA.

We have used CrowdFlower[5], a crowdsourcing platform, to evaluate how many of the 265 post–RA pairs were really related; the final corpus thus consisted of 236 pairs.

3.2 Evaluation

We have used each of the methods described in Subsection 3.3 to automatically construct anchor text for each of the 236 pairs of documents in the final corpus. If a method could not find a suitable anchor, no result was returned; on average there were 147 anchors per method. All the automatically created links were then manually scored by the authors with an in-house evaluation tool using scores and guidelines summarized in Table 1. To calculate precision and recall, we have counted scores 2 and 3 as positive result.

Additionally we crowdsourced the evaluation of results for some of the methods. For this task we prepared a special description of evaluation tasks and defined a set of questions for collecting results. We provided simplified guidelines for assigning scores to automatically created anchors and set a confidence threshold of 0.55 for an assignment to be considered valid. It is important to mention that the use of crowdsourcing for such tasks has to be carefully planned, because many issues related to monetary incentives, which are out of the scope of this paper, may arise.

[5]CrowdFlower: `http://crowdflower.com/`

Score	Description
0	Anchor does not signify anything about RA or gets it wrong
1	Some connection can be established (anchor is a shared Named Entity, Noun Phrase, Verb Phrase, etc.)
2	Anchor is a good estimation of RA topics, but not wholly (anchor is a non-main topic in RA)
3	RA topics can be directly inferred from the anchor

Table 1: Scores used for internal evaluation of automatically created anchors

3.3 Methods for constructing anchor texts

We have adapted a number of methods from a variety of sources to test how they perform for our exact purpose. Below is a short overview of the different methods used in this work.

3.3.1 Longest chunk

This method is based on natural language processing and extensively uses NLTK package (Bird et al., 2009); the text is first tokenized with the default NLTK tokenizer, and then POS tagged with one of the included POS taggers. After much testing, we have decided on a combination of Brill – Trigram – Bigram – Unigram – Affix – Regex backoff tagger with *noun* as default tag. The trainable parts of the tagger were trained on the included CoNLL 2000 tagged corpus.

Before chunking was applied, we also simplified some tags and removed some others to get a simpler structure of POS tags. We then used a regex chunker to find a sequence of a proper noun and a verb separated by zero or more other tokens. We have also tested a proper noun - verb - proper noun combination, but there were even fewer results, so this direction was abandoned.

3.3.2 Latent Semantic Indexing (LSI) based

A corpus is represented in LSI (Deerwester et al., 1990) as a large matrix of term occurrences

in individual documents. The rank of the matrix is then reduced using singular value decomposition that groups together terms that occur in similar context which should therefore account for synonyms.

We have used a tool called gensim (Řehůřek and Sojka, 2010) that enabled us to quickly train a LSI model using the whole corpus and index just the related articles. In order to localize the similarity and place an anchor, we split the source document into paragraphs and compute similarity scores between target document and each paragraph of the source document. We then split the paragraph with the highest score into sentences and again obtain scores for each. The sentence with the best score is then chosen as the result.

3.3.3 Sorted n-grams

Drawing on plagiarism detection, the winning method from the PAN 2010 (Kasprzak and Brandejs, 2010) seemed a viable choice. The basis of the method is comparing n-grams of the source and the destination documents. First, the text was again tokenized with NLTK, removed stopwords and tokens with two or less characters. Then overlapping n-grams were constructed. We have deviated from Kasprzak's merging policy and decided to merge two results if they are less than 20 tokens apart. We also required only one shared n-gram to consider the documents similar. Results were ranked based on the number of shared tokens within each.

3.3.4 Unigrams tf*idf

This method uses unigram tf*idf weighted scores. Since we had a closed system, we used corpus-wide frequencies; stopwords were also removed. We have scored tokens in the source document with tf*idf summary of the destination document; tokens not in summary are given a zero weight. We have experimentally determined that a summary of just top 150 tokens improves results. Sentences were ranked based on the sum of its tokens weights. We also included NEs from Zemanta API response for both source and destination document. Sentences containing shared NEs get their score multiplied by the sum of shared NE tf*idf weights. The result was then the sentence with the highest score.

	Manual		CrowdFlower	
	P	R	P	R
Original links	0.691	0.691	0.981	0.432
Sorted 5-grams	0.822	0.254		
Sorted 4-grams	0.741	0.352		
Sorted 3-grams	0.680	0.424	0.956	0.275
Longest Chunk	0.080	0.075	0.907	0.165
Unigrams tf*idf	0.626	0.242	0.882	0.127
LSI based	0.648	0.640		

Table 2: Precision and recall for manual and CrowdFlower evaluation

3.3.5 Baseline

Our baseline was a method that inserted links that were originally present in the source documents. This method was used to compare our automatic methods to what people are actually linking in the real world.

4 Evaluation Results and Discussion

Results are presented as precision and recall for different methods and both evaluations in Table 2. Empty cells in the table indicate that these methods were not evaluated using CrowdFlower. Recall is the fraction of relevant results out of all the possible results (236) and precision is the fraction of relevant results out of all the retrieved results.

The first thing we notice is the general disagreement between results from the authors and CrowdFlower workers; the latter tend to give higher scores, which leads to higher precision and recall. The reason for this might be in the authors' background knowledge and thus higher expectations.

As a contrast almost half of CrowdFlower workers stated they don't blog and of the rest, more than a third of them don't link out, i.e. do not use related articles. We also have only 74% median inter-annotator agreement leading us to believe that some of the annotators answered without being familiar with the question (monetary incentive issue).

Furthermore, CrowdFlower results for original links (our baseline) indicate that almost all of them were recognized as relevant, while our evaluators discarded 30% of them. Clearly seen in the results of different sorted n-grams methods is also the precision-recall trade-off.

5 Conclusion

Based on evaluation results and despite differences between the evaluators with background knowledge and the crowds, we can conclude that that our approach for automatic construction of in-text links rivals manual creation by professional writers and bloggers and is thus a promising direction for further research.

Abstract

Sentence completion is a challenging semantic modeling task in which models must choose the most appropriate word from a given set to complete a sentence. Although a variety of language models have been applied to this task in previous work, none of the existing approaches incorporate syntactic information. In this paper we propose to tackle this task using a pair of simple language models in which the probability of a sentence is estimated as the probability of the lexicalisation of a given syntactic dependency tree. We apply our approach to the Microsoft Research Sentence Completion Challenge and show that it improves on n-gram language models by 8.7 percentage points, achieving the highest accuracy reported to date apart from neural language models that are more complex and expensive to train.

1 Introduction

The verbal reasoning sections of standardised tests such as the Scholastic Aptitude Test (SAT) feature problems where a partially complete sentence is given and the candidate must choose the word or phrase from a list of options which completes the sentence in a logically consistent way. Sentence completion is a challenging semantic modelling problem. Systematic approaches for solving such problems require models that can judge the global coherence of sentences. Such measures of global coherence may prove to be useful in various applications, including machine translation and natural language generation (Zweig and Burges, 2012).

Most approaches to sentence completion employ language models which use a window of immediate context around the missing word and choose the word that results in the completed sentence with the highest probability (Zweig and Burges, 2012; Mnih and Teh, 2012). However, such language models may fail to identify sentences that are locally coherent but are improbable due to long-range syntactic/semantic dependencies. Consider, for example, completing the sentence

I saw a tiger which was really very ...

with either *fierce* or *talkative*. A language model relying on up to five words of immediate context would ignore the crucial dependency between the missing word and the noun *tiger*.

In this paper we tackle sentence completion using language models based on dependency grammar. These models are similar to standard n-gram language models, but instead of using the linear ordering of the words in the sentence, they generate words along paths in the dependency tree of the sentence. Unlike other approaches incorporating syntax into language models (e.g., Chelba et al., 1997), our models are relatively easy to train and estimate, and can exploit standard smoothing methods. We apply them to the Microsoft Research Sentence Completion Challenge (Zweig and Burges, 2012) and show an improvement of 8.7 points in accuracy over n-gram models, giving the best results to date for any method apart from the more computationally demanding neural language models.

Seattle, Washington, USA, 18-21 October 2013.

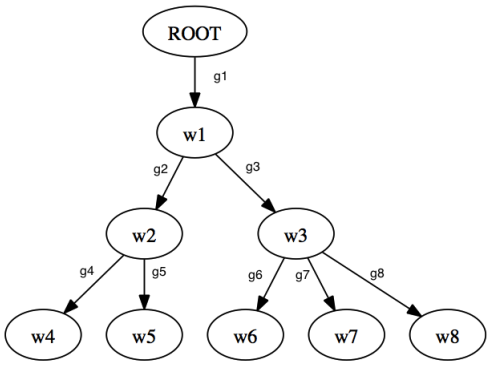

Figure 1: Dependency tree example

2 Unlabelled Dependency Language Models

In dependency grammar, each word in a sentence is associated with a node in a dependency tree (Figure 1). We define a dependency tree as a rooted, connected, acyclic directed graph together with a mapping from the nodes of the tree to a set of grammatical relation labels $\mathcal{R}$. We define a lexicalised dependency tree as a dependency tree along with a mapping from the vertices of the tree to a vocabulary $\mathcal{V}$.

We seek to model the probability distribution of the lexicalisation of a given dependency tree. We will use this as a language model; we neglect the fact that a given lexicalised dependency tree can correspond to more than one sentence due to variations in word order. Let S^T be a lexicalised dependency tree, where T is the unlexicalised tree and let $w_1 w_2 \dots w_m$ be an ordering of the words corresponding to a breadth-first enumeration of the tree. In order for this representation to be unique, when we parse a sentence, we will use the unique breadth-first ordering where the children of any node appear in the same order as they did in the sentence. We define w_0 to be a special symbol denoting the root of the tree. We denote the grammatical relation between w_k and its parent by $g_k \in \mathcal{R}$.
We apply the chain rule to the words in the tree in the order of this breadth-first enumeration:

$$\mathbb{P}[S^T|T] = \prod_{i=1}^{m} \mathbb{P}[w_i|(w_k)_{k=0}^{i-1}, T] \tag{1}$$

Given a word w_i, we define the ancestor sequence $A(w)$ to be the subsequence of $(w_k)_{k=0}^{i-1}$ describing the path from the root node to the parent of w, where each element of the sequence is the parent of the next element. For example in Figure 1, $A(w_8) = (w_0, w_1, w_3)$. We make the following two assumptions:

- that each word w_i is conditionally independent of the words outside of its ancestor sequence $(w_k)_{k=0}^{i-1} \cap A(w_i)^c$, given the ancestor sequence $A(w_i)$;
- that the words are independent of the labels $(g_k)_{k=1}^{m}$.

Using these assumptions, we can write the probability as:

$$\mathbb{P}[S^T|T] = \prod_{i=1}^{m} \mathbb{P}[w_i|A(w_i)] \tag{2}$$

Given a training data corpus consisting of sentences parsed into dependency trees, the maximum likelihood estimator for the probability $\mathbb{P}[w_i|A(w_i)]$ is given by the proportion of cases where the ancestor sequence $A(w_i)$ was followed by w_i. Let $C(\cdot)$ be the count of the number of observations of a pattern in the corpus. We have

$$\hat{\mathbb{P}}[w_i|A(w_i)] = \frac{C((A(w_i), w_i))}{\sum_{w \in \mathcal{V}} C((A(w_i), w))} \tag{3}$$

As is the case for n-gram language models, we can't hope to observe all possible sequences of words no matter how big the corpus. To deal with this data sparsity issue, we take inspiration from n-gram models and assume a Markov property of order $(N-1)$:

$$\mathbb{P}[w|A(w)] = \mathbb{P}[w|A^{(N-1)}(w)] \tag{4}$$

where $A^{(N-1)}(w)$ denotes the sequence of up to $(N-1)$ closest ancestors of w.

The maximum likelihood estimator for this probability is:

$$\hat{\mathbb{P}}[w_i|A^{(N-1)}(w_i)] = \frac{C((A^{(N-1)}(w_i), w_i))}{\sum_{w \in \mathcal{V}} C((A^{(N-1)}(w_i), w))}$$

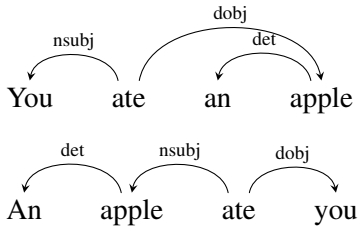
We have arrived at a model which is quite similar to n-gram language models. The main difference

is that each word in the tree can have several children, while in the n-gram models it can only be followed by one word. Thus the sum in the denominator above does not simplify to the count of the ancestor sequence in the way that it does for n-gram language models. However, we can calculate and store the denominators easily during training, so that we do not need to sum over the vocabulary each time we evaluate the estimator. We refer to this model as the **order N unlabelled dependency language model**.

As is the case for n-gram language models, even for low values of N, we will often encounter sequences $(A^{(N-1)}(w), w)$ which were not observed in training. In order to avoid assigning zero probability to the entire sentence, we need to use a smoothing method. We can use any of the smoothing methods used for n-gram language models. For simplicity, we use stupid backoff smoothing (Brants et al., 2007).

3 Labelled Dependency Language Models

We assumed above that the words are generated independently from the grammatical relations. However, we are likely to ignore valuable information in doing so. To illustrate this point, consider the following pair of sentences:



The dependency trees of the two sentences are very similar, with only the grammatical relations between *ate* and its arguments differing. The unlabelled dependency language model will assign the same probability to both of the sentences as it ignores the labels of grammatical relations. In order to be able to distinguish between them, the nature of the grammatical relations between the words in the dependency tree needs to be incorporated in the language model. We relax the assumption that the words are independent of the labels of the parse tree, assuming instead the each word is conditionally independent of the words and labels outside its ancestor path given the words and labels in its ancestor path. We define $G(w_i)$ to be the sequence of grammatical relations between the successive elements of $(A(w_i), w_i)$. $G(w_i)$ is the sequence of grammatical relations found on the path from the root node to w_i. For example, in Figure 1, $G(w_8) = (g_1, g_3, g_8)$. With our modified assumption we have:

$$\mathbb{P}[S^T|T] = \prod_{i=1}^{m} \mathbb{P}[w_i|A(w_i), G(w_i)] \qquad (5)$$

Once again we apply a Markov assumption. Let $G^{(N-1)}(w)$ be the sequence of grammatical relations between successive elements of $(A^{(N-1)}(w), w)$. With an $(N-1)^{th}$ order Markov assumption, we have:

$$\mathbb{P}[S^T|T] = \prod_{i=1}^{m} \mathbb{P}[w_i|A^{(N-1)}(w_i), G^{(N-1)}(w_i)]$$

The maximum likelihood estimator for the probability is once again given by the ratio of the counts of labelled paths. We refer to this model as the **order N labelled dependency language model**.

4 Dataset and Implementation Details

We carried out experiments using the Microsoft Research Sentence (MSR) Completion Challenge (Zweig and Burges, 2012). This consists of a set of 1,040 sentence completion problems taken from five of the Sherlock Holmes novels by Arthur Conan Doyle. Each problem consists of a sentence in which one word has been removed and replaced with a blank and a set of 5 candidate words to complete the sentence. The task is to choose the candidate word which, when inserted into the blank, gives the most probable complete sentence. The set of candidates consists of the original word and 4 imposter words with similar distributional statistics. Human judges were tasked with choosing imposter words which would lead to grammatically correct sentences and such that, with some thought, the correct answer should be unambiguous. The training data set consists of 522 19th century novels from Project Gutenberg. We parsed the training data using the Nivre arc-eager deterministic dependency parsing algorithm (Nivre and Scholz, 2004) as implemented in MaltParser (Nivre et al., 2006). We trained order N labelled and unabelled dependency

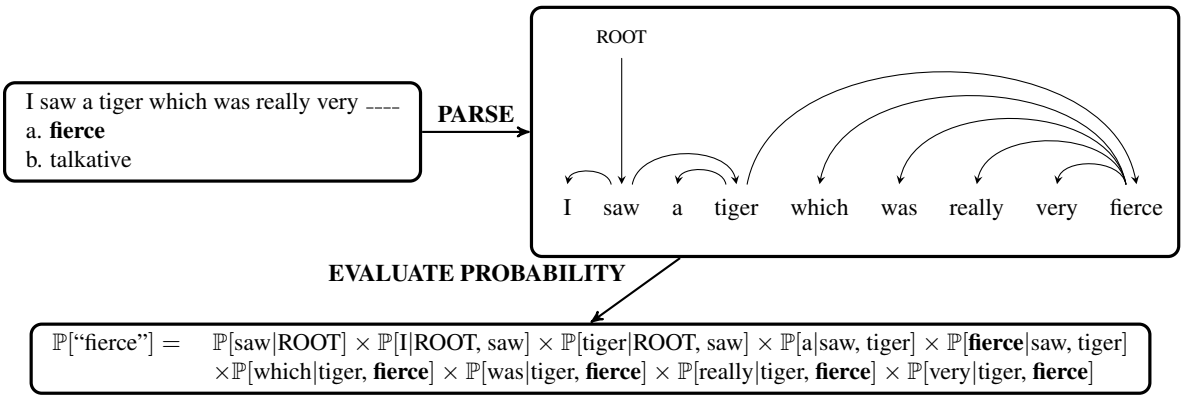


Figure 2: Procedure for evaluating sentence completion problems

N	Unlab-SB	Lab-SB	Ngm-SB	Ngm-KN
2	43.2%	43.0%	28.1%	27.8%
3	48.3%	49.8%	38.5%	38.4%
4	48.3%	**50.0%**	40.8%	41.1%
5	47.4%	49.9%	41.3%	40.8%

Table 1: Summary of results for Sentence Completion

Method	Accuracy
n-grams (Various)	39% - 41%
Skip-grams (Mikolov)	48%
Unlabelled Dependency Model	**48.3%**
Average LSA (Zweig)	49%
Labelled Dependency Model	**50.0%**
Log-bilinear Neural LM (Mnih)	54.7%
Recurrent Neural LM (Mikolov)	55.4%

Table 2: Comparison against previous results

language models for $2 \leq N \leq 5$. Words which occured fewer than 5 times were excluded from the vocabulary. In order to have a baseline to compare against, we also trained n-gram language models with Kneser-Ney smoothing and stupid backoff using the Berkeley Language Modeling Toolkit (Pauls and Klein, 2011).

To test a given language model, we calculated the scores it assigned to each candidate sentence and chose the completion with the highest score. For the dependency language models we parsed the sentence with each of the 5 possible completions and calculated the probability in each case. Figure 2 illustrates an example of this process for the order 3 unlabelled model.

5 Results

Table 1 summarises the results. **Unlab-SB** is the order N unlabelled dependency language model with Stupid Backoff, **Lab-SB** is the order N labelled dependency language model with Stupid Backoff, **Ngm-SB** is the n-gram language model with Stupid Backoff and **Ngm-KN** is the interpolated Kneser-Ney smoothed n-gram language model.

Both of the dependency language models outperfomed the n-gram language models by a substantial margin for all orders considered. The best result was achieved by the order 4 labelled dependency model which is 8.7 points in accuracy better than the best n-gram model. Furthermore, the labelled dependency models outperformed their unlabelled counterparts for every order except 2.

Comparing against previous work (Table 2), the performance of our n-gram baseline is slightly better than the accuracy reported by other authors (Mnih and Teh, 2012; Zweig et al., 2012) for models of this type. The performance of the labelled dependency language model is superior to the results reported for any single model method, apart from those relying on neural language models (Mnih and Teh, 2012; Mikolov et al., 2013) . However the superior performance of neural networks comes at the cost of long training times. The best result achieved in Zweig et al. (2012) using a single method was 49% accuracy with a method based on LSA. Mikolov et al. (2013) also reported accuracy of 48% for a method called skip-grams, which uses a log-linear classifier to predict which words will appear close to each other in sentences.

6 Related Work and Discussion

The best-known language model based on dependency parsing is that of Chelba et al. (1997). This model writes the probability in the familiar left-to-right chain rule decomposition in the linear order of the sentence, conditioning the probability of the next word on the linear trigram context, as well as some part of the dependency graph information relating to the words on its left. The language models we propose are far simpler to train and compute. A somewhat similar model to our unlabelled dependency language model was proposed in Graham and van Genabith (2010). However they seem to have used different probability estimators which ignore the fact that each node in the dependency tree can have multiple children. Other research on syntactic language modelling has focused on using phrase structure grammars (Pauls and Klein, 2012; Charniak, 2001; Roark, 2001; Hall and Johnson, 2003). The linear complexity of deterministic dependency parsing makes dependency language models such as ours more scalable than these approaches.

The most similar task to sentence completion is lexical substitution (McCarthy and Navigli, 2007). The main difference between them is that in the latter the word to be substituted provides a very important clue in choosing the right candidate, while in sentence completion this is not available. Another related task is selectional preference modeling (Séaghdha, 2010; Ritter et al., 2010), where the aim is to assess the plausibility of possible syntactic arguments for a given word.

The dependency language models described in this paper assign probabilities to full sentences. Language models which require full sentences can be used in automatic speech recognition (ASR) and machine translation (MT). The approach is to use a conventional ASR or MT decoder to produce an N-best list of the most likely candidate sentences and then re-score these with the language model. This was done by Chelba et al. (1997) for ASR using a dependency language model and by Pauls and Klein (2011) for MT using a PSG-based syntactic language model.

7 Conclusion

We have proposed a pair of language models which are probabilistic models for the lexicalisation of a given dependency tree. These models are simple to train and evaluate and are scalable to large data sets. We applied them to the Microsoft Research Sentence Completion Challenge. They performed substantially better than n-gram language models, achieving the best result reported for any single method except for the more expensive and complex to train neural language models.

A Walk-based Semantically Enriched Tree Kernel Over Distributed Word Representations

Shashank Srivastava[1] **Dirk Hovy**[2] **Eduard Hovy**[1]

Abstract

In this paper, we propose a walk-based graph kernel that generalizes the notion of tree-kernels to continuous spaces. Our proposed approach subsumes a general framework for word-similarity, and in particular, provides a flexible way to incorporate distributed representations. Using vector representations, such an approach captures both distributional semantic similarities among words as well as the structural relations between them (encoded as the structure of the parse tree). We show an efficient formulation to compute this kernel using simple matrix operations. We present our results on three diverse NLP tasks, showing state-of-the-art results.

1 Introduction

Capturing semantic similarity between sentences is a fundamental issue in NLP, with applications in a wide range of tasks. Previously, tree kernels based on common substructures have been used to model similarity between parse trees (Collins and Duffy, 2002; Moschitti, 2004; Moschitti, 2006b). These kernels encode a high number of latent syntactic features within a concise representation, and compute the similarity between two parse trees based on the matching of node-labels (words, POS tags, etc.), as well as the overlap of tree structures. While this is sufficient to capture *syntactic similarity*, it does not capture *semantic similarity* very well, even when using discrete semantic types as node labels. This constrains the utility of many traditional tree kernels in two ways: i) two sentences that are syntactically identical, but have no semantic similarity can receive a high matching score (see Table 1, top) while ii) two sentences with only local syntactic overlap, but high semantic similarity can receive low scores (see Table 1, bottom).

tree pairs	semantic	syntactic	score
love(we, toys(green)) — crush(they, puppies(little))	×	✓	high
kissed(she, cat(her)) — gave(she, friend, kiss(her, feline, a))	✓	×	low

Table 1: Traditional tree kernels do not capture semantic similarity

In contrast, distributional vector representations of words have been successful in capturing fine-grained semantics, but lack syntactic knowledge. Resources such as Wordnet, dictionaries and ontologies that encode different semantic perspectives can also provide additional knowledge infusion.

In this paper, we describe a generic walk-based graph kernel for dependency parse trees that subsumes general notions of word-similarity, while focusing on vector representations of words to capture lexical semantics. Through a convolutional framework, our approach takes into account the distributional semantic similarities between words in a sentence as well as the structure of the parse tree. Our main contributions are:

1. We present a new graph kernel for NLP that extends to distributed word representations, and diverse word similarity measures.

2. Our proposed approach provides a flexible framework for incorporating both syntax and semantics of sentence level constructions.

3. Our generic kernel shows state-of-the-art performance on three eclectic NLP tasks.

Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Tree kernels in NLP Tree kernels have been extensively used to capture syntactic information about parse trees in tasks such as parsing (Collins and Duffy, 2002), NER (Wang et al., 2010; Cumby and Roth, 2003), SRL (Moschitti et al., 2008) and relation extraction (Qian et al., 2008). These kernels are based on the paradigm that parse trees are similar if they contain many common substructures, consisting of nodes with identical labels (Vishwanathan and Smola, 2003; Collins and Duffy, 2002). Moschitti (2006a) proposed a partial tree kernel that adds flexibility in matching tree substructures. Croce et al. (2011) introduce a lexical semantic tree kernel that incorporates continuous similarity values between node labels, albeit with a different focus than ours and would not match words with different POS. This would miss the similarity of "feline friend" and "cat" in our examples, as it requires matching the adjective "feline" with "cat", and verb "kissed" with "kiss".

Walk based kernels Kernels for structured data derive from the seminal Convolution Kernel formalism by Haussler (1999) for designing kernels for structured objects through local decompositions. Our proposed kernel for parse trees is most closely associated with the random walk-based kernels defined by Gartner et al. (2003) and Kashima et al. (2003). The walk-based graph kernels proposed by Gartner et al. (2003) count the common walks between two input graphs, using the adjacency matrix of the product graph. This work extends to graphs with a finite set of edge and node labels by appropriately modifying the adjacency matrix. Our kernel differs from these kernels in two significant ways: (i) Our method extends beyond label matching to continuous similarity metrics (this conforms with the very general formalism for graph kernels in Vishwanathan et al. (2010)). (ii) Rather than using the adjacency matrix to model edge-strengths, we modify the product graph and the corresponding adjacency matrix to model node similarities.

3 Vector Tree Kernels

In this section, we describe our kernel and an algorithm to compute it as a simple matrix multiplication formulation.

3.1 Kernel description

The similarity kernel K between two dependency trees can be defined as:

$$K(T_1, T_2) = \sum_{\substack{h_1 \subseteq T_1, h_2 \subseteq T_2 \\ len(h_1)=len(h_2)}} k(h_1, h_2)$$

where the summation is over pairs of equal length walks h_1 and h_2 on the trees T_1 and T_2 respectively. The similarity between two n length walks, $k(h_1, h_2)$, is in turn given by the pairwise similarities of the corresponding nodes ${v_i}^h$ in the respective walks, measured via the node similarity kernel κ:

$$k(h_1, h_2) = \prod_{i:1}^{n} \kappa(v_i^{h_1}, v_i^{h_2})$$

In the context of parse trees, nodes $v_i^{h_1}$ and $v_i^{h_2}$ correspond to words in the two parse trees, and thus can often be conveniently represented as vectors over distributional/dependency contexts. The vector representation allows us several choices for the node kernel function κ. In particular, we consider:

1. Gaussian : $\kappa(v_1, v_2) = \exp\big(-\frac{\|v_1 - v_2\|^2}{2\sigma^2}\big)$
2. Positive-Linear: $\kappa(v_1, v_2) = \max(v_1^T v_2, 0)$
3. Sigmoid: $\kappa(v_1, v_2) = \big(1 + \tanh(\alpha v_1^T v_2)\big)/2$

We note that the kernels above take strictly non-negative values in $[0, 1]$ (assuming word vector representations are normalized). Non-negativity is necessary, since we define the walk kernel to be the product of the individual kernels. As walk kernels are products of individual node-kernels, boundedness by 1 ensures that the kernel contribution does not grow arbitrarily for longer length walks.

The kernel function K puts a high similarity weight between parse trees if they contain common walks with semantically similar words in corresponding positions. Apart from the Gaussian kernel, the other two kernels are based on the dot-product of the word vector representations. We observe that the positive-linear kernel defined above is *not* a Mercer kernel, since the max operation makes it non-positive semidefinite (PSD). However, this formulation has desirable properties, most significant being that all walks with one or more node-pair mismatches are strictly penalized and add no score to

the tree-kernel. This is a more selective condition than the other two kernels, where mediocre walk combinations could also add small contributions to the score. The sigmoid kernel is also non-PSD, but is known to work well empirically (Boughorbel et al., 2005). We also observe while the summation in the kernel is over equal length walks, the formalism can allow comparisons over different length paths by including self-loops at nodes in the tree.

With a notion of similarity between words that defines the local node kernels, we need computational machinery to enumerate all pairs of walks between two trees, and compute the summation over products in the kernel $K(T_1, T_2)$ efficiently. We now show a convenient way to compute this as a matrix geometric series.

3.2 Matrix Formulation for Kernel Computation

Walk-based kernels compute the number of common walks using the adjacency matrix of the product graph (Gartner et al., 2003). In our case, this computation is complicated by the fact that instead of *counting* common walks, we need to compute a product of node-similarities for each walk. Since we compute similarity scores over nodes, rather than edges, the product for a walk of length n involves $n+1$ factors.

However, we can still compute the tree kernel K as a simple sum of matrix products. Given two trees $T(V, E)$ and $T'(V', E')$, we define a modified product graph $G(V_p, E_p)$ with an additional ghost node u added to the vertex set. The vertex and edge sets for the modified product graph are given as:

$$V_p := \{(v_{i1}, {v_{j1}}') : v_{i1} \in V, {v_{j1}}' \in V'\} \cup u$$

$$E_p := \{((v_{i1}, {v_{j1}}'), (v_{i2}, {v_{j2}}')) : (v_{i1}, v_{i2}) \in E, ({v_{j1}}', {v_{j2}}') \in E'\} \bigcup \{(u, (v_{i1}, {v_{j1}}')) : v_{i1} \in V, {v_{j1}}' \in V'\}$$

The modified product graph thus has additional edges connecting u to all other nodes. In our formulation, u now serves as a starting location for all random walks on G, and a $k+1$ length walk of G corresponds to a pair of k length walks on T and T'. We now define the weighted adjacency matrix W for G, which incorporates the local node kernels.

$$W_{(v_{i1}, {v_{j1}}'), (v_{i2}, {v_{j2}}')} = \begin{cases} 0 : ((v_{i1}, {v_{j1}}'), (v_{i2}, {v_{j2}}')) \notin E_p \\ \kappa(v_{i2}, {v_{j2}}') : otherwise \end{cases}$$

$$W_{u, (v_{i1}, {v_{j1}}')} = \kappa(v_{i1}, {v_{j1}}')$$
$$W_{(v,u)} = 0 \ \ \forall\, v \in V_p$$

There is a straightforward bijective mapping from walks on G starting from u to pairs of walks on T and T'. Restricting ourselves to the case when the first node of a $k+1$ length walk is u, the next k steps allow us to efficiently compute the products of the node similarities along the k nodes in the corresponding k length walks in T and T'. Given this adjacency matrix for G, the sum of values of k length walk kernels is given by the u^{th} row of the $(k+1)^{th}$ exponent of the weighted adjacency matrix (denoted as W^{k+1}). This corresponds to $k+1$ length walks on G starting from u and ending at any node. Specifically, $W_{u,(v_i, v_j')}$ corresponds to the sum of similarities of all common walks of length n in T and T' that end in v_i in T and v_j' in T'. The kernel K for walks upto length N can now be calculated as :

$$K(T, T') = \sum_{i}^{|V_p|} S_{u,i}$$

where

$$S = W + W^2 + ...W^{N+1}$$

We note that in out formulation, longer walks are naturally discounted, since they involve products of more factors (generally all less than unity).

The above kernel provides a similarity measure between any two pairs of dependency parse-trees. Depending on whether we consider directional relations in the parse tree, the edge set E_p changes, while the procedure for the kernel computation remains the same. Finally, to avoid larger trees yielding larger values for the kernel, we normalize the kernel by the number of edges in the product graph.

4 Experiments

We evaluate the Vector Tree Kernel (VTK) on three NLP tasks. We create dependency trees using the FANSE parser (Tratz and Hovy, 2011), and use distribution-based SENNA word embeddings by Collobert et al. (2011) as word representations. These embeddings provide low-dimensional vector

representations of words, while encoding distributional semantic characteristics. We use LibSVM for classification. For sake of brevity, we only report results for the best performing kernel.

We first consider the Cornell Sentence Polarity dataset by Pang and Lee (2005). The task is to identify the polarity of a given sentence. The data consists of 5331 sentences from positive and negative movie reviews. Many phrases denoting sentiments are lexically ambiguous (cf. "*terribly* entertaining" vs "*terribly* written"), so simple lexical approaches are not expected to work well here, while syntactic context could help disambiguation.

Next, we try our approach on the MSR paraphrase corpus. The data contains a training set of 4077 pairs of sentences, annotated as paraphrases and non-paraphrases, and a test-set of 1726 sentence pairs. Each instance consists of a pair of sentences, so the VTK cannot be directly used by a kernel machine for classification. Instead, we generate 16 kernel values based for each pair on different parameter settings of the kernel, and feed these as features to a linear SVM.

We finally look at the annotated Metaphor corpus by (Hovy et al., 2013). The dataset consists of sentences with specified target phrases. The task here is to classify the target use as literal or metaphorical. We focus on target phrases by upweighting walks that pass through target nodes. This is done by simply multiplying the corresponding entries in the adjacency matrix by a constant factor.

5 Results

5.1 Sentence Polarity Dataset

	Prec	Rec	F1	Acc
Albornoz et al	0.63	–	–	0.63
WNA+synsets	0.61	–	–	0.61
WNA	0.53	–	–	0.51
DSM	0.54	0.55	0.55	0.54
SSTK	0.49	0.48	0.48	0.49
VTK	**0.65**	**0.58**	**0.62**	**0.67**

Table 2: Results on Sentence Polarity dataset

On the polarity data set, Vector Tree Kernel (VTK) significantly outperforms the state-of-the-art method by Carrillo de Albornoz et al. (2010), who use a hybrid model incorporating databases of affective lexicons, and also explicitly model the effect of negation and quantifiers (see Table 2). Lexical approaches using pairwise semantic similarity of SENNA embeddings (DSM), as well as Wordnet Affective Database-based (WNA) labels perform poorly (Carrillo de Albornoz et al., 2010), showing the importance of syntax for this particular problem. On the other hand, a syntactic tree kernel (SSTK) that ignores distributional semantic similarity between words, fails as expected.

5.2 MSR Paraphrase Dataset

	Prec	Rec	F1	Acc
BASE	0.72	0.86	0.79	0.69
Zhang et al	0.74	0.88	0.81	0.72
Qiu et al	0.73	0.93	0.82	0.72
Malakasiotis	0.74	0.94	0.83	0.74
Finch	**0.77**	0.90	**0.83**	**0.75**
VTK	0.72	**0.95**	0.82	0.72

Table 3: Results on MSR Paraphrase corpus

On the MSR paraphrase corpus, VTK performs competitively against state-of-the-art-methods. We expected paraphrasing to be challenging to our method, since it can involve little syntactic overlap. However, data analysis reveals that the corpus generally contains sentence pairs with high syntactic similarity. Results for this task are encouraging since ours is a general approach, while other systems use multiple task-specific features like semantic role labels, active-passive voice conversion, and synonymy resolution. In the future, incorporating such features to VTK should further improve results for this task .

5.3 Metaphor Identification

	Acc	P	R	F1
CRF	0.69	**0.74**	0.50	0.59
SVM+DSM	0.70	0.63	0.80	0.71
SSTK	0.75	0.70	0.80	0.75
VTK	**0.76**	0.67	**0.87**	**0.76**

Table 4: Results on Metaphor dataset

On the Metaphor corpus, VTK improves the previous score by Hovy et al. (2013), whose approach uses an conjunction of lexical and syntactic tree kernels (Moschitti, 2006b), and distributional vectors. VTK identified several templates of metaphor usage such as "warm heart" and "cold shoulder". We look towards approaches for automatedly mining such metaphor patterns from a corpus.

6 Conclusion

We present a general formalism for walk-based kernels to evaluate similarity of dependency trees.

Our method generalizes tree kernels to take distributed representations of nodes as input, and capture both lexical semantics and syntactic structures of parse trees. Our approach has tunable parameters to look for larger or smaller syntactic constructs. Our experiments shows state-of-the-art performance on three diverse NLP tasks. The approach can generalize to any task involving structural and local similarity, and arbitrary node similarity measures.

Automatic Idiom Identification in Wiktionary

Grace Muzny and **Luke Zettlemoyer**
Computer Science & Engineering

{muznyg,lsz}@cs.washington.edu

Abstract

Online resources, such as Wiktionary, provide an accurate but incomplete source of idiomatic phrases. In this paper, we study the problem of automatically identifying idiomatic dictionary entries with such resources. We train an idiom classifier on a newly gathered corpus of over 60,000 Wiktionary multi-word definitions, incorporating features that model whether phrase meanings are constructed compositionally. Experiments demonstrate that the learned classifier can provide high quality idiom labels, more than doubling the number of idiomatic entries from 7,764 to 18,155 at precision levels of over 65%. These gains also translate to idiom detection in sentences, by simply using known word sense disambiguation algorithms to match phrases to their definitions. In a set of Wiktionary definition example sentences, the more complete set of idioms boosts detection recall by over 28 percentage points.

1 Introduction

Idiomatic language is common and provides unique challenges for language understanding systems. For example, a *diamond in the rough* can be the literal unpolished object or a crude but lovable person. Understanding such distinctions is important for many applications, including parsing (Sag et al., 2002) and machine translation (Shutova et al., 2012).

We use Wiktionary as a large, but incomplete, reference for idiomatic entries; individual entries can be marked as idiomatic but, in practice, most are not. Using these incomplete annotations as supervision, we train a binary Perceptron classifier for identifying idiomatic dictionary entries. We introduce new lexical and graph-based features that use WordNet and Wiktionary to compute semantic relatedness. This allows us to learn, for example, that the words in the phrase *diamond in the rough* are more closely related to the words in its literal definition than the idiomatic one. Experiments demonstrate that the classifier achieves precision of over 65% at recall over 52% and that, when used to fill in missing Wiktionary idiom labels, it more than doubles the number of idioms from 7,764 to 18,155.

These gains also translate to idiom detection in sentences, by simply using the Lesk word sense disambiguation (WSD) algorithm (1986) to match phrases to their definitions. This approach allows for scalable detection with no restrictions on the syntactic structure or context of the target phrase. In a set of Wiktionary definition example sentences, the more complete set of idioms boosts detection recall by over 28 percentage points.

2 Related Work

To the best of our knowledge, this work represents the first attempt to identify dictionary entries as idiomatic and the first to reduce idiom detection to identification via a dictionary.

Previous idiom detection systems fall in one of two paradigms: *phrase classification*, where a phrase p is always idiomatic or literal, e.g. (Gedigian et al., 2006; Shutova et al., 2010), or *token classification*, where each occurrence of a phrase p can be idiomatic or literal, e.g. (Katz and Giesbrecht, 2006;

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1417–1421,
Seattle, Washington, USA, 18-21 October 2013.

Birke and Sarkar, 2006; Li and Sporleder, 2009). Most previous idiom detection systems have focused on specific syntactic constructions. For instance, Shutova et al. (2010) consider subject/verb (*campaign surged*) and verb/direct-object idioms (*stir excitement*) while Fazly and Stevenson (2006), Cook et al. (2007), and Diab and Bhutada (2009) detect verb/noun idioms (*blow smoke*). Fothergill and Baldwin (2012) are syntactically unconstrained, but only study Japanese idioms. Although we focus on identifying idiomatic dictionary entries, one advantage of our approach is that it enables syntactically unconstrained token-level detection for any phrase in the dictionary.

3 Formal Problem Definitions

Identification For identification, we assume data of the form $\{(\langle p_i, d_i \rangle, y_i) : i = 1 \ldots n\}$ where p_i is the phrase associated with definition d_i and $y_i \in \{\text{literal, idiomatic}\}$. For example, this would include both the literal pair ⟨ "leave for dead", "To abandon a person or other living creature that is injured or otherwise incapacitated, assuming that the death of the one abandoned will soon follow."⟩ and the idiomatic pair ⟨ "leave for dead", "To disregard or bypass as unimportant." ⟩. Given $\langle p_i, d_i \rangle$, we aim to predict y_i.

Detection To evaluate identification in the context of detection, we assume data $\{(\langle p_i, e_i \rangle, y_i) : i = 1 \ldots n\}$. Here, p_i is the phrase in example sentence e_i whose idiomatic status is labeled $y_i \in \{\text{idiomatic, literal}\}$. One such idiomatic pair is ⟨"heart to heart", "They sat down and had a long overdue heart to heart about the future of their relationship."⟩. Given $\langle p_i, e_i \rangle$, we again aim to predict y_i.

4 Data

We gathered phrases, definitions, and example sentences from the English-language Wiktionary dump from November 13th, 2012.[1]

Identification Phrase, definition pairs $\langle p, d \rangle$ were gathered with the following restrictions: the title of the Wiktionary entry must be English, p must composed of two or more words w, and $\langle p, d \rangle$ must be in its base form—senses that are not defined as a different tense of a phrase—e.g. the pair ⟨ "weapons of mass destruction", "Plural form of weapon of mass destruction" ⟩ was removed while the pair ⟨ "weapon of mass destruction", "A chemical, biological, radiological, nuclear or other weapon that ... "⟩ was kept.

Data Set	Literal	Idiomatic	Total
All	56,037	7,764	63,801
Train	47,633	6,600	54,233
Unannotated Dev	2,801	388	3,189
Annotated Dev	2,212	958	3,170
Unannotated Test	5,603	776	6,379
Annotated Test	4,510	1,834	6,344

Figure 1: Number of dictionary entries with each class for the Wiktionary identification data.

Data Set	Literal	Idiomatic	Total
Dev	171	330	501
Test	360	695	1055

Figure 2: Number of sentences of each class for the Wiktionary detection data.

Each pair $\langle p, d \rangle$ was assigned label y according to the idiom labels in Wiktionary, producing the Train, Unannotated Dev, and Unannotated Test data sets. In practice, this produces a noisy assignment because a majority of the idiomatic senses are not marked. The development and test sets were annotated to correct these potential omissions. Annotators used the definition of an idiom as a "phrase with a non-compositional meaning" to produce the Annotated Dev and Annotated Test data sets. Figure 1 presents the data statistics.

We measured inter-annotator agreement on 1,000 examples. Two annotators marked each dictionary entry as literal, idiomatic, or indeterminable. Less than one half of one percent could not be determined[2]—the computed kappa was 81.85. Given this high level of agreement, the rest of the data were only labeled by a single annotator, following the methodology used with the VNC-Tokens Dataset (Cook et al., 2008).

Detection For detection, we gathered the example sentences provided, when available, for each definition used in our annotated identification data sets. These sentences provide a clean source of develop-

[1] We used the Java Wiktionary Library (Zesch et al., 2008).

[2] The indeterminable pairs were omitted from the data.

ment and test data containing idiomatic and literal phrase usages. In all, there were over 1,300 unique phrases, half of which had more than one possible dictionary definition in Wiktionary. Figure 2 provides the complete statistics.

5 Identification Model

For identification, we use a linear model that predicts class $y^* \in \{\text{literal, idiomatic}\}$ for an input pair $\langle p, d \rangle$ with phrase p and definition d. We assign the class:

$$y^* = \arg\max_y \theta \cdot \phi(p, d, y)$$

given features $\phi(p, d, y) \in \mathbb{R}^n$ with associated parameters $\theta \in \mathbb{R}^n$.

Learning In this work, we use the averaged Perceptron algorithm (Freund and Schapire, 1999) to perform learning, which was optimized in terms of iterations T, bounded by range [1, 100], by maximizing F-measure on the development set.

The models described correspond to the features they use. All models are trained on the same, unannotated training data.

Features The features that were developed fall into two categories: lexical and graph-based features. The lexical features were motivated by the intuition that literal phrases are more likely to have closely related words in d to those in p because literal phrases do not break the principle of compositionality. All words compared are stemmed versions. Let $count(w, t)$ = number of times word w appears in text t.

- synonym overlap: Let S be the set of synonyms as defined in Wiktionary for all words in p. Then, we define the synonym overlap = $\frac{1}{|S|} \sum_{s \in S} count(s, d)$.
- antonym overlap: Let A be the set of antonyms as defined in Wiktionary for all words in p. Then, we define the antonym overlap = $\frac{1}{|A|} \sum_{a \in A} count(a, d)$.
- average number of capitals:[3] The value of $\frac{\text{number of capital letters in } p}{\text{number of words in } p}$.

[3] In practice, this feature identifies most proper nouns.

Graph-based features use the graph structure of WordNet 3.0 to calculate path distances. Let $distance(w, v, rel, n)$ be the minimum distance via links of type rel in WordNet from a word w to a word v, up to a threshold max integer value n, and 0 otherwise. The features compute:

- closest synonym:

$$\min_{w \in p, v \in d} distance(w, v, synonym, 5)$$

- closest antonym:[4]

$$\min_{w \in p, v \in d} distance(w, v, antonym, 5)$$

- average synonym distance:

$$\frac{1}{|p|} \sum_{w \in p, v \in d} distance(w, v, synonym, 5)$$

- average hyponym:

$$\frac{1}{|p|} \sum_{w \in p, v \in d} distance(w, v, hyponym, 5)$$

- synsets connected by an antonym: This feature indicates whether the following is true. The set of synsets Syn_p, all synsets from all words in p, and the set of synsets Syn_d, all synsets from all words in d, are connected by a shared antonym. This feature follows an approach described by Budanitsky et al. (2006).

6 Experiments

We report identification and detection results, varying the data labeling and choice of feature sets.

6.1 Identification

Random Baseline We use a proportionally random baseline for the identification task that classifies according to the proportion of literal definitions seen in the training data.

Results Figure 3 provides the results for the baseline, the full approach, and variations with subsets of the features. Results are reported for the original, unannotated test set, and the same test examples with corrected idiom labels. All models increased

[4] The first relation expanded was the antonym relation. All subsequent expansions were via synonym relations.

Data Set	Model	Rec.	Prec.	F1
Unannotated	Lexical	85.8	21.9	34.9
	Graph	62.4	26.6	37.3
	Lexical+Graph	70.5	28.1	**40.1**
	Baseline	12.2	11.9	12.0
Annotated	Lexical	81.2	49.3	61.4
	Graph	64.3	51.3	57.1
	Lexical+Graph	75.0	52.9	**62.0**
	Baseline	29.5	12.5	17.6

Figure 3: Results for idiomatic definition identification.

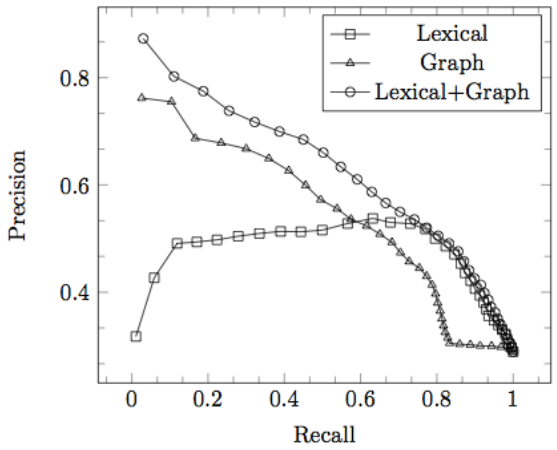

Figure 4: Precision and recall with varied features on the annotated test set.

over their corresponding baselines by more than 22 points and both feature families contributed.[5]

Figure 4 shows the complete precision, recall curve. We selected our operating point to optimize F-measure, but we see that the graph features perform well across all recall levels and that adding the lexical features provides consistent improvement in precision. However, other points are possible, especially when aiming for high precision to extend the labels in Wiktionary. For example, the original 7,764 entries can be extended to 18,155 at 65% precision, 9,594 at 80%, or 27,779 at 52.9%.

Finally, Figures 5 and 6 present qualitative results, including newly discovered idioms and high scoring false identifications. Analysis reveals where our system has room to improve—errors most often occur with phrases that are specific to a certain field, such as sports or mathematics, and with phrases whose words also appear in their definitions.

[5]We also ran ablations demonstrating that removing each feature from the Lexical+Graph model hurt performance, but omit the detailed results for space.

Phrase	Definition
feel free	You have my permission.
live down	To get used to something shameful.
nail down	To make something (e.g. a decision or plan) firm or certain.
make after	To chase.
get out	To say something with difficulty.
good riddance to bad rubbish	A welcome departure.
as all hell	To a great extent or degree; very.
roll around	To happen, occur, take place.

Figure 5: Newly discovered idioms.

Phrase	Definition
put asunder	To sunder; disjoin; separate; disunite; divorce; annul; dissolve.
add up	To take a sum.
peel off	To remove (an outer layer or covering, such as clothing).
straighten up	To become straight, or straighter.
wild potato	The edible root of this plant.
shallow embedding	The act of representing one logic or language with another by providing a syntactic translation.

Figure 6: High scoring false identifications.

6.2 Detection

Approach We use the Lesk (1986) algorithm to perform WSD, matching an input phrase p from sentence e to the definition d in Wiktionary that defines the sense p is being used in. The final classification y is then assigned to $\langle p, d \rangle$ by the identification model.

Results Figure 7 shows detection results. The baseline for this experiment is a model that assigns the default labels within Wiktionary to the disambiguated definition. The Annotated model is the Lexical+Graph model shown in Figure 3 evaluated on the annotated data. The +Default setting augments the identification model by labeling the $\langle p, e \rangle$ as idiomatic if either the model or the original label within Wiktionary identifies it as such.

7 Conclusions

We presented a supervised approach to classifying definitions as idiomatic or literal that more than dou-

Model	Rec.	Prec.	F1
Default	60.5	1	75.4
Annotated	78.3	76.7	77.5
Annotated+Default	89.2	79.0	**83.8**

Figure 7: Detection results.

bles the number of marked idioms in Wiktionary, even when training on incomplete data. When combined with the Lesk word sense algorithm, this approach provides a complete idiom detector for any phrase in the dictionary.

We expect that semi-supervised learning techniques could better recover the missing labels and boost overall performance. We also think it should be possible to scale the detection approach, perhaps with automatic dictionary definition discovery, and evaluate it on more varied sentence types.

Acknowledgments

Abstract

Tokenization is widely regarded as a solved problem due to the high accuracy that rule-based tokenizers achieve. But rule-based tokenizers are hard to maintain and their rules language specific. We show that high-accuracy word and sentence segmentation can be achieved by using supervised sequence labeling on the character level combined with unsupervised feature learning. We evaluated our method on three languages and obtained error rates of 0.27 ‰ (English), 0.35 ‰ (Dutch) and 0.76 ‰ (Italian) for our best models.

1 An Elephant in the Room

Tokenization, the task of segmenting a text into words and sentences, is often regarded as a solved problem in natural language processing (Dridan and Oepen, 2012), probably because many corpora are already in tokenized format. But like an elephant in the living room, it is a problem that is impossible to overlook whenever new raw datasets need to be processed or when tokenization conventions are reconsidered. It is moreover an important problem, because any errors occurring early in the NLP pipeline affect further analysis negatively. And even though current tokenizers reach high performance, there are three issues that we feel haven't been addressed satisfactorily so far:

- Most tokenizers are rule-based and therefore hard to maintain and hard to adapt to new domains and new languages (Silla Jr. and Kaestner, 2004);
- Word and sentence segmentation are often seen as separate tasks, but they obviously inform each other and it could be advantageous to view them as a combined task;
- Most tokenization methods provide no alignment between raw and tokenized text, which makes mapping the tokenized version back onto the actual source hard or impossible.

In short, we believe that regarding tokenization, there is still room for improvement, in particular on the methodological side of the task. We are particularly interested in the following questions: Can we use supervised learning to avoid hand-crafting rules? Can we use unsupervised feature learning to reduce feature engineering effort and boost performance? Can we use the same method across languages? Can we combine word and sentence boundary detection into one task?

2 Related Work

Usually the text segmentation task is split into word tokenization and sentence boundary detection. Rule-based systems for finding word and sentence boundaries often are variations on matching hand-coded regular expressions (Grefenstette, 1999; Silla Jr. and Kaestner, 2004; Jurafsky and Martin, 2008; Dridan and Oepen, 2012).

Several unsupervised systems have been proposed for sentence boundary detection. Kiss and Strunk (2006) present a language-independent, unsupervised approach and note that abbreviations form a major source of ambiguity in sentence boundary detection and use collocation detection to build a high-accuracy abbreviation detector. The resulting system reaches high accuracy, rivalling handcrafted rule-based and supervised systems. A similar system was proposed earlier by Mikheev (2002).

Existing supervised learning approaches for sentence boundary detection use as features tokens preceding and following potential sentence boundary, part of speech, capitalization information and lists of abbreviations. Learning methods employed in

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1422–1426,
Seattle, Washington, USA, 18-21 October 2013.

these approaches include maximum entropy models (Reynar and Ratnaparkhi, 1997) decision trees (Riley, 1989), and neural networks (Palmer and Hearst, 1997).

Closest to our work are approaches that present token and sentence splitters using conditional random fields (Tomanek et al., 2007; Fares et al., 2013). However, these previous approaches consider tokens (i.e. character sequences) as basic units for labeling, whereas we consider single characters. As a consequence, labeling is more resource-intensive, but it also gives us more expressive power. In fact, our approach kills two birds with one stone, as it allows us to integrate token and sentence boundaries detection into one task.

3 Method

3.1 IOB Tokenization

IOB tagging is widely used in tasks identifying chunks of tokens. We use it to identify chunks of characters. Characters outside of tokens are labeled O, inside of tokens I. For characters at the beginning of tokens, we use S at sentence boundaries, otherwise T (for token). This scheme offers some nice features, like allowing for discontinuous tokens (e.g. hyphenated words at line breaks) and starting a new token in the middle of a typographic word if the tokenization scheme requires it, as e.g. in *did|n't*. An example is given in Figure 1.

```
It didn't matter if the faces were male,
SIOTIITIIOTIIIIIOTIOTIIOTIIIIOTIIIOTIIITO
female or those of children. Eighty-
TIIIIIOTIOTIIIIOTIOTIIIIIIITOSIIIIIIO
three percent of people in the 30-to-34
IIIIIOTIIIIIIOTIOTIIIIIOTIOTIIOTIIIIIIIO
year old age range gave correct responses.
TIIIOTIIOTIIOTIIIIOTIIIOTIIIIIIOTIIIIIIIIT
```

Figure 1: Example of IOB-labeled characters

3.2 Datasets

In our experiments we use three datasets to compare our method for different languages and for different domains: manually checked English newswire texts taken from the Groningen Meaning Bank, GMB (Basile et al., 2012), Dutch newswire texts, comprising two days from January 2000 extracted from the Twente News Corpus, TwNC (Ordelman et al., 2007), and a random sample of Italian texts from the PAISÀ corpus (Borghetti et al., 2011).

Table 1: Datasets characteristics.

Name	Language	Domain	Sentences	Tokens
GMB	English	Newswire	2,886	64,443
TNC	Dutch	Newswire	49,537	860,637
PAI	Italian	Web/various	42,674	869,095

The data was converted into IOB format by inferring an alignment between the raw text and the segmented text.

3.3 Sequence labeling

We apply the Wapiti implementation (Lavergne et al., 2010) of Conditional Random Fields (Lafferty et al., 2001), using as features the output label of each character, combined with 1) the character itself, 2) the output label on the previous character, 3) characters and/or their Unicode categories from context windows of varying sizes. For example, with a context size of 3, in Figure 1, features for the E in *Eighty-three* with the output label S would be E/S, O/S, ␣/S, i/S, Space/S, Lowercase/S. The intuition is that the 31 existing Unicode categories can generalize across similar characters whereas character features can identify specific contexts such as abbreviations or contractions (e.g. *didn't*). The context window sizes we use are 0, 1, 3, 5, 7, 9, 11 and 13, centered around the focus character.

3.4 Deep learning of features

Automatically learned word embeddings have been successfully used in NLP to reduce reliance on manual feature engineering and boost performance. We adapt this approach to the character level, and thus, in addition to hand-crafted features we use text representations induced in an unsupervised fashion from character strings. A complete discussion of our approach to learning text embeddings can be found in (Chrupała, 2013). Here we provide a brief overview.

Our representations correspond to the activation of the hidden layer in a simple recurrent neural (SRN) network (Elman, 1990; Elman, 1991), implemented in a customized version of Mikolov (2010)'s RNNLM toolkit. The network is sequentially presented with a large amount of raw text and learns to

predict the next character in the sequence. It uses the units in the hidden layer to store a generalized representation of the recent history. After training the network on large amounts on unlabeled text, we run it on the training and test data, and record the activation of the hidden layer at each position in the string as it tries to predict the next character. The vector of activations of the hidden layer provides additional features used to train and run the CRF. For each of the $K = 10$ most active units out of total $J = 400$ hidden units, we create features $(f(1) \dots f(K))$ defined as $f(k) = 1$ if $s_{j(k)} > 0.5$ and $f(k) = 0$ otherwise, where $s_j(k)$ returns the activation of the k^{th} most active unit. For training the SRN only raw text is necessary. We trained on the entire GMB 2.0.0 (2.5M characters), the portion of TwNC corresponding to January 2000 (43M characters) and a sample of the PAISÀ corpus (39M characters).

4 Results and Evaluation

In order to evaluate the quality of the tokenization produced by our models we conducted several experiments with different combinations of features and context sizes. For these tests, the models are trained on an 80% portion of the data sets and tested on a 10% development set. Final results are obtained on a 10% test set. We report both absolute number of errors and error rates per thousand (‰).

4.1 Feature sets

We experiment with two kinds of features at the character level, namely Unicode categories (31 different ones), Unicode character codes, and a combination of them. Unicode categories are less sparse than the character codes (there are 88, 134, and 502 unique characters for English, Dutch and Italian, respectively), so the combination provide some generalization over just character codes.

Table 2: Error rates obtained with different feature sets. Cat stands for Unicode category, Code for Unicode character code, and Cat-Code for a union of these features.

Feature set	Error rates per thousand (‰) English	Dutch	Italian
Cat-9	45 (1.40)	1,403 (2.87)	1,548 (2.67)
Code-9	**6 (0.19)**	782 (1.60)	692 (1.20)
Cat-Code-9	8 (0.25)	**774 (1.58)**	**657 (1.14)**

From these results we see that categories alone perform worse than only codes. For English there is no gain from the combination over using only character codes. For Dutch and Italian there is an improvement, although it is only significant for Italian ($p = 0.480$ and $p = 0.005$ respectively, binomial exact test). We use this feature combination in the experiments that follow. Note that these models are trained using a symmetrical context of 9 characters (four left and four right of the current character). In the next section we show performance of models with different window sizes.

4.2 Context window

We run an experiment to evaluate how the size of the context in the training phase impacts the classification. In Table 4.2 we show the results for symmetrical windows ranging in size from 1 to 13.

Table 3: Using different context window sizes.

Feature set	Error rates per thousand (‰) English	Dutch	Italian
Cat-Code-1	273 (8.51)	4,924 (10.06)	9,108 (15.86)
Cat-Code-3	118 (3.68)	3,525 (7.20)	2,013 (3.51)
Cat-Code-5	20 (0.62)	930 (1.90)	788 (1.37)
Cat-Code-7	10 (0.31)	778 (1.60)	667 (1.16)
Cat-Code-9	**8 (0.25)**	774 (1.58)	**657 (1.14)**
Cat-Code-11	9 (0.28)	761 (1.56)	692 (1.21)
Cat-Code-13	**8 (0.25)**	**751 (1.54)**	670 (1.17)

4.3 SRN features

We also tested the automatically learned features derived from the activation of the hidden layer of an SRN language model, as explained in Section 3. We combined these features with character code and Unicode category features in windows of different sizes. The results of this test are shown in Table 4. The first row shows the performance of SRN features on their own. The following rows show the combination of SRN features with the basic feature sets of varying window size. It can be seen that augmenting the feature sets with SRN features results in large reductions of error rates. The Cat-Code-1-SRN setting has error rates comparable to Cat-Code-9.

The addition of SRN features to the two best previous models, Cat-Code-9 and Cat-Code-13, reduces the error rate by 83% resp. 81% for Dutch,

and by 24% resp. 26% for Italian. All these differences are statistically significant according to the binomial test ($p < 0.001$). For English, there are too few errors to detect a statistically significant effect for Cat-Code-9 ($p = 0.07$), but for Cat-Code-13 we find $p = 0.016$.

Table 4: Results obtained using different context window sizes and addition of SRN features.

Feature set	Error rates per thousand (‰) English	Dutch	Italian
SRN	24 (0.75)	276 (0.56)	738 (1.28)
Cat-Code-1-SRN	7 (0.21)	212 (0.43)	549 (0.96)
Cat-Code-3-SRN	4 (0.13)	165 (0.34)	507 (0.88)
Cat-Code-5-SRN	3 (0.10)	136 (0.28)	476 (0.83)
Cat-Code-7-SRN	**1 (0.03)**	**111 (0.23)**	497 (0.86)
Cat-Code-9-SRN	2 (0.06)	135 (0.28)	497 (0.86)
Cat-Code-11-SRN	2 (0.06)	132 (0.27)	**468 (0.81)**
Cat-Code-13-SRN	**1 (0.03)**	142 (0.29)	496 (0.86)

In a final step, we selected the best models based on the development sets (Cat-Code-7-SRN for English and Dutch, Cat-Code-11-SRN for Italian), and checked their performance on the final test set. This resulted in 10 errors (0.27 ‰) for English (GMB corpus), 199 errors (0.35 ‰) for Dutch (TwNC corpus), and 454 errors (0.76 ‰) for Italian (PAISÀ corpus).

5 Discussion

It is interesting to examine what kind of errors the SRN features help avoid. In the English and Dutch datasets many errors are caused by failure to recognize personal titles and initials or misparsing of numbers. In the Italian data, a large fraction of errors is due to verbs with clitics, which are written as a single word, but treated as separate tokens. Table 5 shows examples of errors made by a simpler model that are fixed by adding SRN features. Table 6 shows the confusion matrices for the Cat-Code-7 and Cat-Code-7-SRN sets on the Dutch data. The mistake most improved by SRN features is T/I with 89% error reduction (see also Table 5). The is also the most common remaining mistake.

A comparison with other approaches is hard because of the difference in datasets and task definition (combined word/sentence segmentation). Here we just compare our results for sentence segmentation (sentence F_1 score) with Punkt, a state-of-the-art sentence boundary detection system (Kiss and Strunk, 2006). With its standard distributed models, Punkt achieves 98.51% on our English test set, 98.87% on Dutch and 98.34% on Italian, compared with 100%, 99.54% and 99.51% for our system. Our system benefits here from its ability to adapt to a new domain with relatively little (but annotated) training data.

6 What Elephant?

Word and sentence segmentation can be recast as a combined tagging task. This way, tokenization is cast as a supervised learning task, causing a shift of labor from writing rules to manually correcting labels. Learning this task with CRF achieves high accuracy.[1] Furthermore, our tagging method does not lose the connection between original text and tokens.

In future work, we plan to broaden the scope of this work to other steps in document preparation,

[1] All software needed to replicate our experiments is available at `http://gmb.let.rug.nl/elephant/experiments.php`

such as normalization of punctuation, and their interaction with segmentation. We further plan to test our method on a wider range of datasets, allowing a more direct comparison with other approaches. Finally, we plan to explore the possibility of a statistical universal segmentation model for mutliple languages and domains.

In a famous scene with a live elephant on stage, the comedian Jimmy Durante was asked about it by a policeman and surprisedly answered: "What elephant?" We feel we can say the same now as far as tokenization is concerned.

Abstract

We present a novel unsupervised approach to detecting the compositionality of multi-word expressions. We compute the compositionality of a phrase through substituting the constituent words with their "neighbours" in a semantic vector space and averaging over the distance between the original phrase and the substituted neighbour phrases. Several methods of obtaining neighbours are presented. The results are compared to existing supervised results and achieve state-of-the-art performance on a verb-object dataset of human compositionality ratings.

1 Introduction

Multi-word expressions (MWEs) are defined as "idiosyncratic interpretations that cross word boundaries" (Sag et al., 2002). They tend to have a standard syntactic structure but are often semantically non-compositional; i.e. their meaning is not fully determined by their syntactic structure and the meanings of their constituents. A classic example is *kick the bucket*, which means *to die* rather than *to hit a bucket with the foot*. These types of expressions account for a large proportion of day-to-day language interactions (Schuler and Joshi, 2011) and present a significant problem for natural language processing systems (Sag et al., 2002).

This paper presents a novel unsupervised approach to detecting the compositionality of MWEs, specifically of verb-noun collocations. The idea is that we can recognize compositional phrases by substituting related words for constituent words in the phrase: if the result of a substitution yields a meaningful phrase, its individual constituents are likely to contribute toward the overall meaning of the phrase. Conversely, if a substitution yields a non-sensical phrase, its constituents are likely to contribute less or not at all to the overall meaning of the phrase. For the phrase *eat her hat*, for example, we might consider the following substituted phrases:

1. *consume* her hat
2. eat her *trousers*

Both phrases are semantically anomalous, implying that *eat hat* is a highly non-compositional verb-noun collocation. Following a similar procedure for *eat apple*, however, would not lead to an anomaly: *consume apple* and *eat pear* are perfectly meaningful, leading us to believe that *eat apple* is compositional.

In the context of distributional models, this idea can be formalised in terms of vector spaces:

> the average distance between a phrase vector and its substituted phrase vectors is related to its compositionality.

Since we are relying on the relative distances of *phrases* in semantic space, we require a method for computing vectors for phrases. We experimented with a number of composition operators from Mitchell and Lapata (2010), in order to compose constituent word vectors into phrase vectors. The relation between phrase vectors and substituted phrase vectors is most pronounced in the case of

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1427–1432,
Seattle, Washington, USA, 18-21 October 2013.

pointwise multiplication, which has the effect of placing semantically anomalous phrases relatively close together in space (since the vectors for the constituent words have little in common), whereas the semantically meaningful phrases are further apart. This implies that compositional phrases are less similar to their neighbours, which is to say that the greater the average distance between a phrase vector and its substituted phrase vectors, the greater its compositionality.

The contribution of this short focused research paper is a novel approach to detecting the compositionality of multi-word expressions that makes full use of the ability of semantic vector space models to calculate distances between words and phrases. Using this unsupervised approach, we achieve state-of-the-art performance in a direct comparison with existing supervised methods.

2 Dataset and Vectors

The verb-noun collocation dataset from Venkatapathy and Joshi (2005), which consists of 765 verb-object pairs with human compositionality ratings, was used for evaluation. Venkatapathy & Joshi used a support vector machine (SVM) to obtain a Spearman ρ_s correlation of 0.448. They employed a variety of features ranging from frequency to LSA-derived similarity measures and used 10% of the dataset as training data with tenfold cross-validation. McCarthy et al. (2007) used the same dataset and expanded on the original approach by adding WordNet and distributional prototypes to the SVM, achieving a ρ_s correlation of 0.454.

The distributional vectors for our experiments were constructed from the ukWaC corpus (Baroni et al., 2009). Vectors were obtained using a standard window method (with a window size of 5) and the 50,000 most frequent context words as features, with stopwords removed. We also experimented with syntax-based co-occurrence features extracted from a dependency-parsed version of ukWaC, but in agreement with results obtained by Schulte im Walde et al. (2013) for predicting compositionality in German, the window-based co-occurrence method produced better results.

We tried several weighting schemes from the literature, such as t-test (Curran, 2004), positive mutual information (Bullinaria and Levy, 2012) and the ratio of the probability of the context word given the target word[1] to the context word's overall probability (Mitchell and Lapata, 2010). We found that a tf-idf variant called LTU yielded the best results, defined as follows (Reed et al., 2006):

$$w_{ij} = \frac{(\log(f_{ij}) + 1.0)\ \log(\frac{N}{n_j})}{0.8 + 0.2 \times \frac{|\textit{context word}|}{|\textit{avg context word}|}}$$

where f_{ij} is the number of times that the target word and context word co-occur in the same window, n_j is the context word frequency, N is the total frequency and $|\textit{context word}|$ is the total number of occurrences of a context word. Distance is calculated using the standard cosine measure:

$$dist(v_1, v_2) = 1 - \frac{v_1 \cdot v_2}{|v_1||v_2|}$$

where v_1 and v_2 are vectors in the semantic vector space model.

3 Finding Neighbours and Computing Compositionality

We experimented with two different ways of obtaining neighbours for the constituent words in a phrase. Since vector space models lend themselves naturally to similarity computations, one way to get neighbours is to take the k-most similar vectors from a similarity matrix. This approach is straightforward, but has some potential drawbacks: it assumes that we have a large number of vectors to select neighbours from, and becomes computationally expensive when the number of neighbours is increased.

An alternative source for obtaining neighbours is the lexical database WordNet (Fellbaum, 1998). We define neighbours as siblings in the hypernym hierarchy, so that the neighbours of a word can be found by taking the hyponyms of its hypernyms. WordNet also allows us to extract only neighbours of the same grammatical type (yielding noun neighbours for nouns and verb neighbours for verbs, for example). Since not every word has the same number of neighbours in WordNet, we use only the first k

[1] We use *target word* to refer to the word for which a vector is being constructed.

neighbours, which means that the neighbours have to be ranked. An obvious ranking method is to use the frequency with which each neighbour co-occurs with the other constituent(s) of the same phrase. For example, for all the WordNet neighbours of *eat* (for all senses of *eat*), we count the co-occurrences with *hat* in a given window size and rank them accordingly. This ranking method also has the desirable side-effect of performing some word sense disambiguation, at least in some cases. For example, the highly ranked neighbours of *apple* for *eat apple* are likely to be items of food, and not (inedible) trees (apple is also a tree in WordNet).

In order to obtain frequency-ranked neighbours, we used the ukWaC corpus with a window size of 5. One reason for having multiple neighbours is that it allows us to correct for word sense disambiguation errors (as mentioned above), since averaging over results for several neighbours reduces the impact of including incorrect senses. For example, the first 20 neighbours of *eat*, ranked by co-occurrence frequency with all the objects of *eat* in the dataset, are:

> *eat use consume drink sample smoke swallow spend break hit save afford burn partake dine breakfast worry damage deplete drug*

One problem with the evaluation dataset is that it does not solely consist of verb-noun pairs: 84 phrases contain pronouns, while there are also several examples containing words that WordNet considers to be adjectives rather than nouns. This problem was mitigated by part-of-speech tagging the dataset. As neighbours for pronouns (which are not included in WordNet), we used the other pronouns present in the dataset. For the remaining words, we included the part-of-speech when looking up the word in WordNet.

3.1 Average distance compositionality score

We considered several different ways of constructing phrasal vectors. We chose not to use the compositional models of Baroni and Zamparelli (2010) and Socher et al. (2011) because we believe that it is important that our methods are completely unsupervised and do not require any initial learning phase. Hence, we experimented with different ways of constructing phrasal vectors according to Mitchell and Lapata (2010) and found that pointwise multiplication $\odot$ worked best in our experiments. Thus, we define the composed vector $\overrightarrow{eat\ hat}$ as:

$$\overrightarrow{eat} \odot \overrightarrow{hat}$$

We can now compute a compositionality score s_c by averaging the distance between the original phrase vector and its substituted neighbour phrase vectors via the following formula:

$$s_c(\overrightarrow{eat\ hat}) = \frac{1}{2k}(\sum_{i=1}^{k} dist(\overrightarrow{eat} \odot \overrightarrow{hat}, \overrightarrow{eat} \odot \overrightarrow{neighbour_i}) + \sum_{j=1}^{k} dist(\overrightarrow{eat} \odot \overrightarrow{hat}, \overrightarrow{neighbour_j} \odot \overrightarrow{hat}))$$

We also experimented with substituting only for the noun or the verb, and in fact found that only taking neighbours for the verb yields better results:

$$s_c(\overrightarrow{eat\ hat}) = \frac{1}{k} \sum_{j=1}^{k} dist(\overrightarrow{eat} \odot \overrightarrow{hat}, \overrightarrow{neighbour_j} \odot \overrightarrow{hat})$$

To illustrate the method, consider the collocations *take breath* and *lend money*. The annotators assigned these phrases a compositionality score of 1 out of 6 and 6 out of 6, respectively, meaning that the former is non-compositional and the latter is compositional. The distances between the first ten verb-substituted phrases and the original phrase, together with the average distance, are shown in Table 1 and Table 2.

Substituting the verb in the non-compositional phrase yields semantically anomalous vectors, which leads to very small changes in the distance between it and the original phrase vector. This is a result of using pointwise multiplication, where overlapping components are stressed: since the vectors for *take* and *breath* have little overlap outside of

Neighbour	Dist
get breath	0.049
find breath	0.051
use breath	0.050
work breath	0.060
hold breath	0.094
run breath	0.079
carry breath	0.076
look breath	0.065
play breath	0.071
buy breath	0.100
AvgDist	0.069

Table 1: Example *take breath*

Neighbour	Dist
pay money	0.446
put money	0.432
bring money	0.405
provide money	0.442
owe money	0.559
sell money	0.404
cost money	0.482
look money	0.425
distribute money	0.544
offer money	0.428
AvgDist	0.457

Table 2: Example *lend money*

the idiomatic sense in *take breath*, its neighbour-substituted phrases also have little overlap, resulting in a smaller change in distance upon substitution. Conversely, substituting the verb in the compositional phrase yields meaningful vectors, putting them in locations in semantic vector space which are sufficiently far apart to distinguish them from the non-compositional cases.

4 Results

Results are given for the two methods of obtaining neighbours: via frequency-ranked WordNet neighbours and via vector space neighbours. The compositionality score was computed by using only the verb, only the noun, or both constituent neighbours in the substituted phrase vectors.

System	ρ_s
Venkatapathy and Joshi (2005)	0.447
McCarthy et al. (2007)	0.454
AvgDist VSM neighbours-both	0.131
AvgDist VSM neighbours-verb	0.420
AvgDist VSM neighbours-noun	0.245
AvgDist WN-ranked neighbours-both	0.165
AvgDist WN-ranked neighbours-verb	**0.461**
AvgDist WN-ranked neighbours-noun	0.169

Table 3: Spearman ρ_s results

The results are compared with the scores reported in Venkatapathy and Joshi (2005) and McCarthy et al. (2007), which were achieved using SVMs with a wide variety of features. Values of $1 \leq k \leq 20$ were tried. If a phrase has fewer than k neighbours because not enough neighbours have been found to co-occur with the other constituent, we use all of them. The results for $k = 20$ are reported here because that gave the best overall score. The dataset has an inter-annotator agreement of Kendall's τ of 0.61 and a Spearman ρ_s of 0.71 and all reported differences in values are highly significant. Table 3 gives the results.

Note that, even though the current approach is unsupervised (in terms of not having access to compositionality ratings during training, although it does rely on WordNet), it outperforms SVMs that require an ensemble of complex feature sets (some of which are also based on WordNet).

It is interesting to observe that the state-of-the-art performance is reached when only using the verb's neighbours to compute substituted phrase vectors. One might initially expect this not to be the case, since e.g. *eat trousers*, where the noun has been substituted, does not make a lot of sense either — which we would expect to be informative for determining compositionality. There are two possible explanations for this, which might be at play simultaneously: since our dataset consists of verb-object pairs, the verb constituent is always the head word of the phrase, and the dataset contains several so-called "light verbs", which have little semantic content of their own. Head words have been found to have a higher impact on compositionality scores for compound nouns: Reddy et al. (2011) weighted

the contribution of individual constituents in such a way that the modifier's contribution is included but is weighted less highly than the head's contribution, which led to an improvement in performance. Our results might be improved by weighting the contribution of constituent words in a similar fashion, and by more closely examining the impact of light verbs for the compositionality of a phrase.

5 Related Work

The past decade has seen extensive work on computational and statistical methods in detecting the compositionality of MWEs (Lin, 1999; Schone and Jurafsky, 2001; Katz and Giesbrecht, 2006; Sporleder and Li, 2009; Biemann and Giesbrecht, 2011). Many of these methods rely on distributional models and vector space models (Schütze, 1993; Turney and Pantel, 2010; Erk, 2012). Work has been done on different types of phrases, including work on particle verbs (McCarthy et al., 2003; Bannard et al., 2003), verb-noun collocations (Venkatapathy and Joshi, 2005; McCarthy et al., 2007), adjective-noun combinations (Vecchi et al., 2011) and noun-noun compounds (Reddy et al., 2011), as well as on languages other than English (Schulte im Walde et al., 2013). Recent developments in distributional compositional models (Widdows, 2008; Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Coecke et al., 2010; Socher et al., 2011) have opened up a number of possibilities for constructing vectors for phrases, which have also been applied to compositionality tests (Giesbrecht, 2009; Kochmar and Briscoe, 2013).

This paper takes that work a step further: by constructing phrase vectors and evaluating these vectors on a dataset of human compositionality ratings, we show that existing compositional models allow us to detect compositionality of multi-word expressions in a straightforward and intuitive manner.

6 Conclusion

We have presented a novel unsupervised approach that can be used to detect the compositionality of multi-word expressions. Our results show that the underlying intuition appears to be sound: substituting neighbours may lead to meaningful or meaningless phrases depending on whether or not the phrase is compositional. This can be formalized in vector space models to obtain compositionality scores by computing the average distance to the original phrase's substituted neighbour phrases. In this short focused research paper, we show that, depending on how we obtain neighbours, we are able to achieve a higher performance than that achieved by supervised methods which rely on a complex feature set and support vector machines.

Naive Bayes Word Sense Induction

Abstract

We introduce an extended naive Bayes model for word sense induction (WSI) and apply it to a WSI task. The extended model incorporates the idea the words closer to the target word are more relevant in predicting its sense. The proposed model is very simple yet effective when evaluated on SemEval-2010 WSI data.

1 Introduction

The task of word sense induction (WSI) is to find clusters of tokens of an ambiguous word in an unlabeled corpus that have the same sense. For instance, given a target word "crane," a good WSI system should find a cluster of tokens referring to avian cranes and another referring to mechanical cranes. We believe that neighboring words contain enough information that these clusters can be found from plain texts.

WSI is related to word sense disambiguation (WSD). In a WSD task, a system learns a sense classifier in a supervised manner from a sense-labeled corpus. The performance of the learned classifier is measured on some unseen data. WSD systems perform better than WSI systems, but building labeled data can be prohibitively expensive. In addition, WSD systems are not suitable for newly created words, new senses of existing words, or domain-specific words. On the other hand, WSI systems can learn new senses of words directly from texts because these programs do not rely on a predefined set of senses.

In Section 2 we describe relevant previous work. In Section 3 and 4 we introduce the naive Bayes model for WSI and inference schemes for the model. In Section 5 we evaluate the model on SemEval-2010 data. In Section 6 we conclude.

2 Related Work

Yarowsky (1995) introduces a semi-supervised bootstrapping algorithm with two assumptions that rivals supervised algorithms: one-sense-per-collocation and one-sense-per-discourse. But this algorithm cannot easily be scaled up because for any new ambiguous word humans need to pick a few seed words, which initialize the algorithm. In order to automate the semi-supervised system, Eisner and Karakos (2005) propose an unsupervised bootstrapping algorithm. Their system tries many different seeds for bootstrapping and chooses the "best" classifier at the end. Eisner and Karakos's algorithm is limited in that their system is designed for disambiguating words that have only 2 senses.

Bayesian WSI systems have been developed by several authors. Brody and Lapata (2009) apply Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to WSI. They run a topic modeling algorithm on texts with some fixed number of topics that correspond to senses and induce a cluster by finding target words assigned to the same topic. Their system is evaluated on SemEval-2007 noun data (Agirre and Soroa, 2007). Lau et al. (2012) apply a nonparametric model, Hierarchical Dirichlet Processes (HDP), to SemEval-2010 data (Manandhar et al., 2010).

3 Model

Following Yarowsky (1995), we assume that a word in a document has one sense. Multiple occurrences of a word in a document refer to the same object or concept. The naive Bayes model is well suited for this one-sense-per-document assumption. Each document has one topic corresponding to the sense of the target word that needs disambiguation. Context words in a document are drawn from the conditional distribution of words given the sense. Context words are assumed to be independent from each other given

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1433–1437,
Seattle, Washington, USA, 18-21 October 2013.

the sense, which is far from being true yet effective.

3.1 Naive Bayes

The naive Bayes model assumes that every word in a document is generated independently from the conditional distribution of words given a sense, $p(w|s)$. The mathematical definition of the naive Bayes model is as follows:

$$p(\boldsymbol{w}) = \sum_s p(s, \boldsymbol{w}) = \sum_s p(s)p(\boldsymbol{w}|s) = \sum_s p(s) \prod_w p(w|s), \quad (1)$$

where $\boldsymbol{w}$ is a vector of words in the document. With the model, a new document can be easily labeled using the following classifier:

$$s' = \operatorname*{argmax}_s p(s) \prod_w p(w|s), \quad (2)$$

where s' is the label of the new document. In contrast to LDA-like models, it is easy to construct the closed form classifier from the model. The parameters of the model, $p(s)$ and $p(w|s)$, can be learned by maximizing the probability of the corpus, $p(\boldsymbol{d}) = \prod_d p(d) = \prod_{\boldsymbol{w}} p(\boldsymbol{w})$ where $\boldsymbol{d}$ is a vector of documents and $d = \boldsymbol{w}$.

3.2 Distance Incorporated Naive Bayes

Intuitively, context words near a target word are more indicative of its sense than ones that are farther away. To account for this intuition, we propose a more sophisticated model that uses the distance between a context word and a target word. Before introducing the new model, we define a probability distribution, $f(w|s)$, that incorporates distances as follows:

$$f(w|s) = \frac{p(w|s)^{l(w)}}{\sum_{w' \in \mathcal{W}} p(w'|s)^{l(w)}}, \quad (3)$$

where $l(w) = \frac{1}{dist(w)^x}$. $\mathcal{W}$ is a set of types in the corpus. x is a tunable parameter that takes nonnegative real values. With the new probability distribution, the model and the classifier become:

$$p(\boldsymbol{w}) = \sum_s p(s) \prod_w f(w|s) \quad (4)$$

$$s' = \operatorname*{argmax}_s p(s) \prod_w f(w|s), \quad (5)$$

where $f(w|s)$ replaces $p(w|s)$. The naive Bayes model is a special case; set $x = 0$. The new model puts more weight on context words that are close to the target word. The distribution of words that are farther away approaches the uniform distribution. $l(w)$ smoothes the distribution more as x becomes larger.

4 Inference

Given the generative model, we employ two inference algorithms to learn the sense distribution and word distributions given a sense. Expectation Maximization (EM) is a natural choice for the naive Bayes (Dempster et al., 1977). When initialized with random parameters, EM gets stuck at local maxima. To avoid local maxima, we use a Gibbs sampler for the plain naive Bayes to learn parameters that initialize EM.

5 Experiments

5.1 Data

We evaluate the model on SemEval-2010 WSI task data (Manandhar et al., 2010). The task has 100 target words, 50 nouns and 50 verbs. For each target word, there are training and test documents. Table 1 have details. The training and test data are plain texts without sense tags. For evaluation, the inferred sense labels are compared with human annotations. To tune some parameters we use the trial data of SemEval-2010. The trial data consists of training and test portions of 4 verbs. On average there are 137 documents for each target word in the training part of the trial data.

	Training	Testing	Senses (#)
All	879807	8915	3.79
Nouns	716945	5285	4.46
Verbs	162862	3630	3.12

Table 1: Details of SemEval-2010 data

5.2 Task

Participants induce clusters from the training data and use them to label the test data. Resources other than NLP tools for morphology and syntax such as lemmatizer, POS-tagger, and parser are not allowed. Tuning parameters and inducing clusters are only allowed during the training phase. After training, participants submit their sense-labeled test data to organizers.

LDA models are not compatible with the scoring rules for the SemEval-2010 competition, and that is the work against which we most want to compare. These rules require that training be done strictly before the testing is done. Note however that LDA requires learning the mixture weights of topics for each

individual document p(topic | document). These are, of course, learned during training. But the documents in the testing corpus have never been seen before, so clearly their topic mixture weights are not learned during training, and thus not learned at all. The way to overcome this is by training on both train and test documents, but this is exactly what SemEval-2010 forbids.

5.3 Implementation Details

The documents are tokenized and stemmed by Stanford tokenizer and stemmer. Stop words and punctuation in the training and test data are discarded. Words that occur at most 10 times are discarded from the training data. Context words within a window of 50 about a target word are used to construct a bag-of-words.

When a target word appears more than once in a document, the distance between that target word and a context word is ambiguous. We define this distance to be minimum distance between a context word and an instance of the target word. For example, the word "chip" appears 3 times. For

$\cdots$ of memory **chip**s . Currently , **chip**s are produced by shining light through a mask to produce an image on the **chip** , much as $\cdots$

Example 1: an excerpt from "chip" test data

a context word, e.g., "shining" there are three possible distances: 8 away from the first "chip," 4 away from the second "chip" and 11 away from the last "chip." We set the distance of "shining" from the target to 4.

We model each target word individually. We set α, a Dirichlet prior for senses, to 0.02 and β, a Dirichlet prior for contextual words, to 0.1 for the Gibbs sampler as in Brody and Lapata (2009). We initialize EM with parameters learned from the sampler. We run EM until the likehood changes less than 1%. We run the sampler 2000 iterations including 1000 iterations of burn-in: 10 samples at an interval of 100 are averaged. For comparison, we also evaluate EM with random initialization. All reported scores (described in Section 5.4) are averaged over ten different runs of the program.[1]

5.3.1 Tuning Parameters

Two parameters, the number of senses and x of the function $l(w)$, need to be determined before running the program. To find a good setting we do grid search on the trial data with the number of senses ranging from 2 to 5 and x ranging from 0 to 1.1 with an interval 0.1. Due to the small size of the training portion of the trial data, words that occur once are thrown out in the training portion. All the other parameters are as described in Section 5.3. We choose (4, 0.4), which achieves the highest supervised recall. See Table 2 for the performance of the model with various parameter settings. With a fixed value of x, a column is nearly unimodal in the number of senses and vice versa. $x = 0$ is not optimal and there is some noticeable difference between scores with optimal x and scores with $x = 0$.

5.4 Evaluation

We compare our system to other WSI systems and discuss two metrics for unsupervised evaluation (V-Measure, paired F-Score) and one metric for supervised evaluation (supervised recall). We refer to the true group of tokens as a gold class and to an induced group of tokens as a cluster. We refer to the model learned with the sampler and EM as NB, and to the model learned with EM only as NB0.

5.4.1 Short Descriptions of Other WSI Systems Evaluated on SemEval-2010

The baseline assigns every instance of a target word with the most frequent sense (MFS). UoY runs a clustering algorithm on a graph with words as nodes and co-occurrences between words as edges (Korkontzelos and Manandhar, 2010). Hermit approximates co-occurrence space with Random Indexing and applies a hybrid of k-means and Hierarchical Agglomerate Clustering to co-occurrence space (Jurgens and Stevens, 2010). NMF$_{lib}$ factors a matrix using nonnegative matrix factorization and runs a clustering algorithm on test instances represented by factors (Van de Cruys et al., 2011).

5.4.2 V-Measure

V-Measure computes the quality of induced clusters as the harmonic mean of two values, homogeneity and completeness. Homogeneity measures whether instances of a cluster belong to a single gold class. Completeness measures whether instances of a gold class belong to a cluster. V-Measure is between 0 and 1; higher is better. See Table 3 for details of V-Measure evaluation (#cl is the number of induced clusters).

With respect to V-Measure, NB performs much better than NB0. This holds for paired F-Score and supervised recall evaluations. The sampler improves the log-likelihood of NB by 3.8% on average (4.8% on nouns and 2.9% on verbs).

Pedersen (2010) points out that it is possible to increase the V-Measure of bad models by increasing

NB	**18.0**	**23.7**	9.9	3.42
NB0	14.9	19.0	9.0	3.77
Hermit	16.2	16.7	**15.6**	10.78
UoY	15.7	20.6	8.5	11.54
NMF_{lib}	11.8	13.5	9.4	4.80
MFS	0.0	0.0	0.0	1.00

Table 3: Unsupervised evaluation: V-Measure

the number of clusters. But increasing the number of clusters harms paired F-Score, which results in bad supervised recalls. NB attains a very high V-Measure with few induced clusters, which indicates that those clusters are high quality. Other systems use more induced clusters but fail to attain the V-Measure of NB.

5.4.3 Paired F-Score

Paired F-Score is the harmonic mean of paired recall and paired precision. Paired recall is fraction of pairs belonging to the same gold class that belong to the same cluster. Paired precision is fraction of pairs belonging to the same cluster that belong to the same class. See Table 4 for details of paired F-Score evaluation.

As with V-Measure, it is possible to attain a high paired F-Score by producing only one cluster. The baseline, MFS, attains 100% paired recall, which together with the poor performance of WSI systems makes its paired F-Score difficult to beat. V-Measure and paired F-Score are meaningful when systems produce about the same numbers of clusters as the numbers of classes and attain high scores on these metrics.

FS(%)	all	nouns	verbs	#cl
MFS	**63.5**	**57.0**	**72.7**	1.00
NB	52.9	52.5	53.5	3.42
NB0	46.8	47.4	46.0	3.77
UoY	49.8	38.2	66.6	11.54
NMF_{lib}	45.3	42.2	49.8	4.80
Hermit	26.7	24.4	30.1	10.78

Table 4: Unsupervised evaluation: paired F-Score

5.4.4 Supervised Recall

For the supervised task, the test data is split into two groups: one for mapping clusters to classes and the other for standard WSD evaluation. 2 different split schemes (80% mapping, 20% evaluation and 60% mapping, 40% evaluation) are evaluated. 5 random splits are averaged for each split scheme. Mapping is induced automatically by the program provided by organizers. See Table 5 for details of supervised recall evaluation (#s is the average number of classes mapped from clusters).[2]

SR(%)	all	nouns	verbs	#s
NB	**65.4**	**62.6**	69.5	1.72
NB0	63.5	59.8	69.0	1.76
NMF_{lib}	62.6	57.3	**70.2**	1.82
UoY	62.4	59.4	66.8	1.51
MFS	58.7	53.2	66.6	1.00
Hermit	58.3	53.6	65.3	2.06

Table 5: Supervised evaluation: supervised recall, 80% mapping and 20% evaluation

Overall our system performs better than other systems with respect to supervised recall. When a system has higher V-Measure and paired F-Score on nouns than another system, it achieves a higher supervised recall on nouns too. However, this behavior is not observed on verbs. For example, NB has higher V-Measure and paired F-Score on verbs than NMF_{lib} but NB attains a lower supervised recall on verbs than NMF_{lib}. It is difficult to see which verbs clusters are better than some other clusters.

6 Conclusion

Of the four SemEval-2010 evaluation metrics, and restricting ourselves to systems obeying the evaluation conditions for that competition, our new model achieves new best results on three. The exception is paired F-Score. As we note earlier, this metric tends to assign very high scores when every word receives only one sense, and our model is bested by the baseline system that does exactly that.

[2] 60-40 split is omitted here due to almost identical result.

If we loosen possible comparison systems, the LDA/HDP model of Lau et al. (2012) achieves superior numbers to ours for the two supervised metrics, but at the expense of requiring LDA type processing on the test data, something that the SemEval organizers ruled out, presumably with the reasonable idea that such processing would not be feasible in the real world. More generally, their system assigns many senses (about 10) to each word, and thus no-doubt does poorly on the paired F-Score (they do not report results on V-Measure and paired F-Score).

Abstract

This research describes efforts to use crowdsourcing to improve the validity of the semantic predicates in VerbNet, a lexicon of about 6300 English verbs. The current semantic predicates can be thought of semantic primitives, into which the concepts denoted by a verb can be decomposed. For example, the verb *spray* (of the Spray class), involves the predicates MOTION, NOT, and LOCATION, where the event can be decomposed into an AGENT causing a THEME that was originally not in a particular location to now be in that location. Although VerbNet's predicates are theoretically well-motivated, systematic empirical data is scarce. This paper describes a recently-launched attempt to address this issue with a series of human judgment tasks, posed to subjects in the form of games.

1 Introduction

One key application of Natural Language Processing (NLP) is meaning extraction. Of particular importance is propositional meaning: To understand "Jessica sprayed paint on the wall," it is not enough to know who Jessica is, what paint is, and where the wall is, but that, by the end of the event, some quantity of paint that was not previously on the wall now is. One must extract not only meanings for individual words but also the relations between them.

One option is to learn these relations in a largely bottom-up, data-driven fashion (Chklovski and Pantel, 2004; Poon and Domingos, 2009). For instance, Poon and Domingos (2009) first extracts dependency trees, converts those into quasi-logical form, recursively induces lambda expressions from them, and uses clustering to derive progressively abstract knowledge.

An alternative is to take a human-inspired approach, mapping the linguistic input onto the kinds of representations that linguistic and psychological research suggests are the representations employed by humans. While the exact characterization of meaning (and by extension, thought) remains an area of active research in the cognitive sciences (Margolis and Laurence, 1999), decades of research in linguistics and psychology suggests that much of the meaning of a sentence – as well as its syntactic structure – can be accounted for by invoking a small number of highly abstract semantic features (usually represented as predicates), such as causation, agency, basic topological relations, and directed motion (Ambridge et al., 2013; Croft, 2012; Jackendoff, 1990; Levin and Rappaport Hovav, 2005; Pesetsky, 1995; Pinker, 1989). For instance, a given verb can appear in some syntactic frames (*Sally broke the vase. Sally broke the vase with the hammer. The vase broke.*) and not others (**Sally broke the vase to the floor. *Sally broke John the vase.*). When verbs are classified according to the syntactic frames they can appear in, most if not all the verbs in a class involve the same set of abstract semantic features.[1]

Interestingly, roughly these same features (causation, etc.) have been singled out by developmental psychologists as part of "core knowledge" – a set of early-learned or perhaps innate concepts upon which

[1] Whether all verbs in a class share the same abstract predicates or merely most is an area of active research (Levin and Rappaport Hovav, 2005).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1438–1442,
Seattle, Washington, USA, 18-21 October 2013.

the rest of cognition is built (Spelke and Kinzler, 2007). Thus these semantic features/predicates may be not only crucial to describing linguistic meaning but may be central organizing principles for a human's (reasonably successful) thinking about and conceptualization of the world. As such, they provide a potentially rewarding target for NLP.

2 VerbNet

2.1 Overview and Structure

Perhaps the most comprehensive implementation of this approach appears in VerbNet (Kipper et al., 2008; based on Levin, 1993). VerbNet classifies verbs based on the syntactic frames they can appear in, providing a semantic description of each frame for each class. An example entry is shown below:

Syntactic Frame NP V NP PP.DESTINATION
Example Jessica sprayed the wall.
Syntax AGENT V THEME {+LOC|+DEST_CONF} DESTINATION
Semantics MOTION(DURING(E), THEME)
NOT(PREP(START(E), THEME, DESTINATION))
PREP(END(E), THEME, DESTINATION)
CAUSE(AGENT, E)

The "Syntactic Frame" provides a flat syntactic parse. "Syntax" provides semantic role labels for each of the NPs and PPs, which are invoked in "Semantics". VerbNet decomposes the semantics of this sentence into four separate predicates: 1) the THEME (the paint) moves doing the event E; 2) at the start of the event E, the THEME (the paint) is not at the DESTINATION (on the wall), whereas 3) at the end of the event E, the THEME (the paint) is at the DESTINATION (on the wall), and; 4) the event is caused by the AGENT (Sally). Note that this captures only the core aspects of semantics shared by all verbs in the class; differences between verbs in the same class (e.g., *spray* vs. *splash*) are omitted.

Importantly, the semantics of the sentence is dependent on both the matrix verb (paint) and the syntactic frame. Famously, when inserted in the slightly different frame NP V NP.DESTINATION PP.THEME – "Sally sprayed the wall with paint" – "spray" entails that destination (the wall) is now fully painted, an entailment that does not follow in the example above (Pinker, 1989).

2.2 Uses and Limitations

VerbNet has been used in a variety of NLP applications, such as semantic role labeling (Swier and Stevenson, 2004), inferencing (Zaenen et al., 2008), verb classification (Joanis et al., 2008), and information extraction (Maynard, Funk, and Peters, 2009).

While such applications have been successful thus far, an important constraint on how well VerbNet-based NLP applications can be expected to perform is the accuracy of the semantics encoded in VerbNet. Here, several issues arise. Leaving aside miscategorized verbs and other inaccuracies, as noted above VerbNet assumes that all verbs in the same class share the same core predicates, which may or may not be empirically justified. Given the number of semantic predicates (146),[2] verb entries (6580), and unique verb lemmas (6284) it is not feasible for a single research team to check, particularly since after a certain number of verbs, intuitions become less clear. In any case, it may not be ideal to rely solely on the intuitions of invested researchers, whose intuitions about subtle judgments may be clouded by theoretical commitments (Gibson and Federenko, 2013); the only way to ensure this is not the case is through independent validation. Unfortunately, of the 280 verb classes in VerbNet, this has been done for only a few (cf Ambridge et al., 2013).

3 VerbCorner

The VerbCorner project was designed to address these issues by crowd-sourcing the semantic judgments online (gameswithwords.org/VerbCorner/). Several previous projects have successfully crowd-sourced linguistic annotations, such as Phrase Detectives, where volunteers have contributed 2.5 million judgments on anaphoric relations (Poesio et al., 2012). Below, we outline the VerbCorner project and describe one specific annotation task in detail.

3.1 Developing Semantic Annotation Tasks

Collecting accurate judgments on subtle questions from naive participants with limited metalinguistic

[2]Note that these vary in applicability from those specific to a small number of verbs (CHARACTERIZE, CONSPIRE) to those frequently invoked (BEGIN, EXIST).

skills is difficult. Rare is the non-linguist who can immediately answer the question, "Does the verb 'throw,' when used transitively, entail a change of location on the part of its THEME?" Thus, we began by developing tasks that isolate semantic features in a way accessible to untrained annotators.

We converted the metalinguistic judgments ("Does this verb entail this abstract predicate?") into real-world problems, which previous research suggests should be easier (Cosmides and Tooby, 1992). Each judgment tasks involved a fanciful backstory. For instance, in "Simon Says Freeze", a task designed to elicit judgments about movement, the Galactic Overlord (Simon) decrees "Galactic Stay Where You Are Day," during which nobody is allowed to move from their current location. Participants read descriptions of events and decide whether anyone violated the rule. In "Explode on Contact", designed to elicit judgments about physical contact, objects and people explode when they touch one another. The participant reads descriptions of events and decides whether anything has exploded.[3]

Each task was piloted until inter-coder reliability was acceptably high and the modal response nearly always corresponded with researcher intuitions. As such, these tasks cannot be used to establish whether researcher intuitions for the pilot stimuli are correct (this would be circular); however, there is no guarantee that agreement with the researcher will generalize to new items (the pilot stimuli cover a trivial proportion of all verbs in VerbNet).

3.2 Crowd-sourcing Semantic Judgments

The pilot experiments showed that it is possible to elicit reliable semantic judgments corresponding to VerbNet predicates from naive participants (see section 3.3). At the project website, volunteers choose one of the tasks from a list and begin tagging sentences. The sentences are sampled smartly, avoiding sentences already tagged by that volunteer and biased in favor of of the sentences with the fewest judgments so far. Rather than assessing annotator quality through gold standard trials with known answers (which wastes data – the answers to these trials are known), approximately 150 sentences were chosen to be "over-sampled." As the volunteer tags sentences, approximately one out of every five are from this over-sampled set until that volunteer has tagged all of them. This guarantees that any given volunteer will have tried some sentences targeted by many other volunteers, allowing inter-annotator agreement to be used to assess annotator quality.

Following the example of Zooniverse (zooniverse.org), a popular "Citizen Science" platform, volunteers are encouraged but required to register (requiring registration prior to seeing the tasks was found to be a significant barrier to entry). Registration allows collecting linguistic and educational background from the volunteer, and also makes it possible to track the same volunteer across sessions.

Multiple gamification elements were incorporated into VerbCorner in order to recruit and motivate volunteers. Each task has a leaderboard, where the volunteer can see his/her rank out of all volunteers in terms of number of contributions made. In addition, there is a general leaderboard, which sums across tasks. Volunteers can earn badges, displayed on their homepage, for answering certain numbers of questions in each task. Finally, at random intervals bonus points are awarded, with the explanation for the bonus points tailored to the task's backstory.

VerbCorner was launched on May 21, 2013. After six weeks, 555 volunteers had provided at least one annotation, for a total of 39,274 annotations, demonstrating the feasibility of collecting large numbers of annotations through this method.

3.3 Case Study: Equilibrium

"Equilibrium" was designed to elicit judgments about application of force, frequently argued to be a core semantic feature in the sense discussed above (Pinker, 1989). The backstory involves the "Zen Dimension," in which nobody is allowed to exert force on anything else. The participant reads descriptions of events (*Sally sprayed paint onto the wall*) and decides whether they would be allowable in the Zen Dimension – and, in particular, which participants in the event are illegally applying force.

In order to minimize unwanted effects of world

[3]Note that each task is designed to elicit judgments about entailments – things that must be true rather than are merely likely to be true. If John greeted Bill, they might have come into contact (e.g., by shaking hands), but perhaps they did not. Previous work suggests that it is entailments that matter, particularly for explaining the syntactic behavior of verbs (Levin and Rappaport Hovav, 2005)

knowledge, the verb's arguments are replaced with nonsense words or randomly chosen proper names (*Sally sprayed the dax onto the blicket*). In the context of the story, this is explained as necessary anonymization: You are a government official determining whether certain activities are allowable, and ensuring anonymity is an important safeguard against favoritism and corruption. An alternative wouod be to use multiple different content words, randomly chosen for each annotator. However, this greatly increases the number of annotators needed and quickly becomes infeasible.

3.3.1 Pilot Results

The task was piloted on 138 sentences, which comprised all possible syntactic frames for three verbs from each of five verb classes in VerbNet. After two rounds of piloting (between the first and second, wording in the backstory was adjusted for clarity based on pilot subject feedback and results), Kripp's alpha reached .76 for 8 annotators, which represents a reasonably high level of inter-annotator agreement. Importantly, the modal response matched the intuitions of the researchers in 137 of 138 cases.[4]

3.3.2 Preliminary VerbCorner Results

"Equillibrium" was one of the first tasks posted on VerbCorner, with data currently being collected on 12 of the 280 VerbNet classes, for a total of 5,171 sentences. As of writing, 414 users have submitted 14,294 judgments. Individual annotators annotated anywhere from 1 to 195 sentences (mean=8, median=4). While most sentences have relatively few judgments, each of the 194 over-sampled sentences has between 15 and 20 judgments.[5]

Comparing the modal response with the researchers' intuitions resulted in a match for 184 of 194 sentences. In general, where the modal response did not match researcher intuitions, the modal response was itself not popular, comprising an average of 53% of responses, compared with an average of 77% where the modal response matched researcher intuitions. Thus, these appear to be cases of disagreement, either because the correct intuition requires more work to obtain or because of differences across idiolects (at the moment, there is no obvious pattern as to which sentences caused difficulty, but the sample size is small). Thus, follow-up investigation of sentences with little inter-coder agreement may be warranted.

4 Conclusion and Future Work

Data-collection is ongoing. VerbNet identifies approximately 150 different semantic predicates. Annotating every verb in each of its syntactic frames for each semantic predicate would take many millions of judgments. However, most of the semantic predicates employed in VerbNet are very narrow in scope and only apply to a few classes. Thus, we have begun with broad predicates that are thought to apply to many verbs and are adding progressively narrower predicates as work progresses. At the current rate, we should complete annotation for the half-dozen most frequent semantic predicates in the space of a year.

Future work will explore using an individual annotator's history across trials to weight that user's contributions, something that VerbCorner was specifically designed to allow (see above). How to assess annotator quality without gold standard data is an active area of research (Passonneau and Carpenter, 2013; Rzhetsky, Shatkay and Wilbur, 2009; Whitehill et al., 2009). For instance, Whitehill and colleagues (2009) provide an algorithm for jointly estimating both annotator quality and annotation difficulty (including the latter is important because some annotators will have low agreement with others due to their poor luck in being assigned difficult-to-annotate sentences). This algorithm is shown to outperform using the modal response.

Note that this necessarily biases against annotators with few responses. In our case study above, excluding annotators who contributed small numbers of annotations led to progressively worse match to researcher intuition, suggesting that the loss in data

[4]The remaining case was "The crose smashed sondily." for which four pilot subjects thought involved the crose applying force – matching researcher intuition – and four thought did not involve any application of force, perhaps interpreting the sentence was a passive.

[5]These are the same 15 verbs used in the piloting. The number of sentences is larger in order to test a wider range of possible arguments. In particular, wherever appropriate, separate sentences were constructed using animate and inanimate arguments. Compare *Sally sprayed the dax onto Mary* and *Sally sprayed the dax onto the blicket*.

caused by excluding these annotations may not be worth the increased confidence in annotation quality. Future research will be needed to assess this trade-off.

The above work shows the feasibility of crowd-sourcing VerbNet semantic entailments, as has been shown for a handful of other linguistic judgments (Artignan, Hascoet and Lafourcade, 2009; Poesio et al., 2012; Venhuizen et al., 2013). There are many domains in which gold standard human judgments are scarce; crowd-sourcing has considerable potential at addressing this need.

Abstract

This paper offers an approach for governments to harness the information contained in social media in order to make public inspections and disclosure more efficient. As a case study, we turn to restaurant hygiene inspections – which are done for restaurants throughout the United States and in most of the world and are a frequently cited example of public inspections and disclosure. We present the first empirical study that shows the viability of statistical models that learn the mapping between textual signals in restaurant reviews and the hygiene inspection records from the Department of Public Health. The learned model achieves over 82% accuracy in discriminating severe offenders from places with no violation, and provides insights into salient cues in reviews that are indicative of the restaurant's sanitary conditions. Our study suggests that public disclosure policy can be improved by mining public opinions from social media to target inspections and to provide alternative forms of disclosure to customers.

1 Introduction

Public health inspection records help customers to be wary of restaurants that have violated health codes. In some counties and cities, e.g., LA, NYC, it is required for restaurants to post their inspection grades at their premises, which have shown to affect the revenue of the business substantially (e.g., Jin and Leslie (2005), Henson et al. (2006)), thereby motivating restaurants to improve their sanitary practice. Other studies have reported correlation between the frequency of unannounced inspections per year, and the average violation scores, confirming the regulatory role of inspections in improving the hygiene quality of the restaurants and decreasing food-borne illness risks (e.g., Jin and Leslie (2003), Jin and Leslie (2009), Filion and Powell (2009), NYC-DoHMH (2012)).

However, one practical challenge in the current inspection system is that the department of health has only limited resources to dispatch inspectors, leaving out a large number of restaurants with unknown hygiene grades. We postulate that online reviews written by the very citizens who have visited those restaurants can serve as a proxy for predicting the likely outcome of the health inspection of any given restaurant. Such a prediction model can complement the current inspection system by enlightening the department of health to make a more informed decision when allocating inspectors, and by guiding customers when choosing restaurants.

Our work shares the spirit of recently emerging studies that explores social media analysis for public health surveillance, in particular, monitoring influenza or food-poisoning outbreaks from microblogs (e.g., Aramaki et al. (2011), Sadilek et al. (2012b), Sadilek et al. (2012a), Sadilek et al. (2013), Lamb et al. (2013), Dredze et al. (2013), von Etter et al. (2010)). However, no prior work has examined the utility of review analysis as a predictive tool for accessing hygiene of restaurants, perhaps because the connection is not entirely conspicuous: after all, customers are neither familiar with inspection codes, nor have the full access to the kitchen, nor have been asked to report on the hygiene aspects of their expe-

rience.

In this work, we report the first empirical study demonstrating the utility of review analysis for predicting health inspections, achieving over 82% accuracy in discriminating severe offenders from places with no violation, and find predictive cues in reviews that correlate with the inspection results.

2 Data

We scraped entire reviews written for restaurants in Seattle from Yelp over the period of 2006 to 2013.[1] The inspection records of Seattle is publicly available at `www.datakc.org`. More than 50% of the restaurants listed under Yelp did not have inspection records, implying the limited coverage of inspections. We converted street addresses into canonical forms when matching restaurants between Yelp and inspection database. After integrating reviews with inspection records, we obtained about 13k inspections over 1,756 restaurants with 152k reviews. For each restaurant, there are typically several inspection records. We defined an "inspection period" of each inspection record as the period of time starting from the day after the previous inspection to the day of the current inspection. If there is no previous inspection, then the period stretches to the past 6 months in time. Each inspection period corresponds to an instance in the training or test set. We merge all reviews within an inspection period into one document when creating the feature vector.

Note that non-zero penalty scores may not necessarily indicate alarming hygiene issues. For example, violating codes such as *"proper labeling"* or *"proper consumer advisory posted for raw or undercooked foods"* seem relatively minor, and unlikely to be noted and mentioned by reviewers. Therefore, we focus on restaurants with severe violations, as they are exactly the set of restaurants that inspectors and customers need to pay the most attention to. To define restaurants with "severe violations" we experiment with a varying threshold t, such that restaurants with score $\geq t$ are labeled as *"unhygienic"*.[2]

3 Correlates of Inspection Penalty Scores

We examine correlation between penalty scores and several statistics of reviews:

I. Volume of Reviews:

[1] Available at `http://www.cs.stonybrook.edu/~junkang/hygiene/`

[2] For restaurants with *"hygienic"* labels, we only consider those without violation, as there are enough number of such restaurants to keep balanced distribution between two classes.

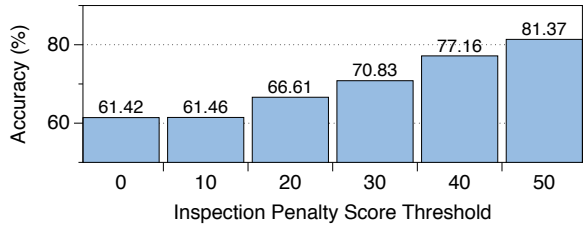

Figure 3: Trend of penalty score thresholds & accuracies.

- *count of all reviews*
- *average length of all reviews*

II. Sentiment of Reviews: We examine whether the overall sentiment of the customers correlates with the hygiene of the restaurants based on following measures:

- *average review rating*
- *count of negative (≤ 3) reviews*

III. Deceptiveness of Reviews: Restaurants with bad hygiene status are more likely to attract negative reviews, which would then motivate the restaurants to solicit fake reviews. But it is also possible that some of the most assiduous restaurants that abide by health codes strictly are also diligent in soliciting fake positive reviews. We therefore examine the correlation between hygiene violations and the degree of deception as follows.

- *bimodal distribution of review ratings*

  The work of Feng et al. (2012) has shown that the shape of the distribution of opinions, overtly skewed bimodal distributions in particular, can be a telltale sign of deceptive reviewing activities. We approximately measure this by computing the variance of review ratings.

- *volume of deceptive reviews based on linguistic patterns*

  We also explore the use of deception classifiers based on linguistic patterns (Ott et al., 2011) to measure the degree of deception. Since no deception corpus is available in the restaurant domain, we collected a set of fake reviews and truthful reviews (250 reviews for each class), following Ott et al. (2011).[3]

[3] 10 fold cross validation on this dataset yields 79.2% accuracy based on unigram and bigram features.

Features	Acc.	MSE	SCC
-	*50.00	0.500	-
review count	*50.00	0.489	0.0005
np review count	*52.94	0.522	0.0017
cuisine	*66.18	0.227	0.1530
zip code	*67.32	0.209	0.1669
avrg. rating	*57.52	0.248	0.0091
inspection history	*72.22	0.202	0.1961
unigram	78.43	0.461	0.1027
bigram	*76.63	0.476	0.0523
unigram + bigram	82.68	0.442	0.0979
all	81.37	0.190	0.2642

Table 1: Feature Compositions & Respective Accuracies, Respective Mean Squared Errors(MSE) & Squared Correlation Coefficients (SCC), np=non-positive

Filtering Reviews: When computing above statistics over the set of reviews corresponding to each restaurant, we also consider removing a subset of reviews that might be dubious or just noise. In particular, we remove reviews that are too far away (delta ≥ 2) from the average review rating. Another filtering rule can be removing all reviews that are classified as deceptive by the deception classifier explained above. For brevity, we only show results based on the first filtering rule, as we did not find notable differences in different filtering strategies.

Results: Fig 1 and 2 show Spearman's rank correlation coefficient with respect to the statistics listed above, with and without filtering, computed at different threshold cutoffs $\in \{0, 10, 20, 30, 40, 50\}$ of inspection scores. Although coefficients are not strong,[4] they are mostly statistically significant with $p \leq 0.05$ (marked with '*'), and show interesting contrastive trends as highlighted below.

In Fig 1, as expected, average review rating is negatively correlated with the inspection penalty scores. Interestingly, all three statistics corresponding to the volume of customer reviews are positively correlated with inspection penalty. What is more interesting is that if potentially deceptive reviews are filtered, then the correlation gets stronger, which suggests the existence of deceptive reviews covering up unhappy customers. Also notice that correlation is

[4] Spearman's coefficient assumes monotonic correlation. We suspect that the actual correlation of these factors and inspection scores are not entirely monotonic.

Hygienic gross, mess, sticky, smell, restroom, dirty
Basic Ingredients: beef, pork, noodle, egg, soy, ramen, pho,
Cuisines Vietnamese, Dim Sum, Thai, Mexican, Japanese, Chinese, American, Pizza, Sushi, Indian, Italian, Asian
Sentiment: cheap, never,
Service & Atmosphere cash, worth, district, delivery, think, really, thing, parking, always, usually, definitely - door: "The wait is always out the *door* when I actually want to go there", - sticker: "I had *sticker* shock when I saw the prices.", - student: "heap, large portions and tasty = the perfect *student* food!", - the size: "i was pretty astonished at *the size* of all the plates for the money.", - was dry: "The beef *was dry*, the sweet soy and anise-like sauce was TOO salty (almost inedible).", - pool: "There are *pool* tables, TV airing soccer games from around the globe and of course - great drinks!"

Table 2: Lexical Cues & Examples - Unhygienic (dirty)

Hygienic:
Cooking Method & Garnish: brew, frosting, grill, crush, crust, taco, burrito, toast **Healthy or Fancier Ingredients**: celery, calamity, wine, broccoli, salad, flatbread, olive, pesto
Cuisines : Breakfast, Fish & Chips, Fast Food, German, Diner, Belgian, European, Sandwiches, Vegetarian
Whom & When: date, weekend, our, husband, evening, night
Sentiment: lovely, yummy, generous, friendly, great, nice
Service & Atmosphere: selection, attitude, atmosphere, ambiance, pretentious

Table 3: Lexical Cues & Examples - Hygienic (clean)

generally stronger when higher cutoffs are used (x-axis), as expected. Fig 2 looks at the relation between the deception level and the inspection scores more directly. As suspected, restaurants with high penalty scores show increased level of deceptive reviews.

Although various correlates of hygiene scores examined so far are insightful, these alone are not informative enough to be used as a predictive tool, hence we explore content-based classification next.

4 Content-based Prediction

We examine the utility of the following features:

Features based on customers' opinion:

1. Aggregated opinion: average review rating
2. Content of the reviews: unigram, bigram

Features based on restaurant's metadata:

3. Cuisine: e.g., Thai, Italian, as listed under Yelp
4. Location: first 5 digits of zip code
5. Inspection History: a boolean feature ("hygienic" or "unhygienic"), a numerical feature (previous penalty score rescaled $\in [0, 1]$), a numeric feature (average penalty score over all previous inspections)
6. Review Count
7. Non-positive Review Count

Classification Results We use liblinear's SVM (Fan et al., 2008) with L1 regularization and 10 fold cross validation. We filter reviews that are farther than 2 from the average rating. We also run Support Vector Regression (SVR) using liblinear. Fig 3 shows the results. As we increase the threshold, the accuracy also goes up in most cases. Table 1 shows feature ablation at threshold $t = 50$, and '*' denotes statistically significant ($p \leq 0.05$) difference over the performance with all features based on student t-test.

We find that metadata information of restaurants such as location and cuisine alone show good predictive power, both above 66%, which are significantly higher than the expected accuracy of random guessing (50%).

Somewhat unexpected outcome is aggregated opinion, which is the average review rating during the corresponding inspection period, as it performs not much better than chance (57.52%). This result suggest that the task of hygiene prediction from reviews differs from the task of sentiment classification of reviews.

Interestingly, the inspection history feature alone is highly informative, reaching accuracy upto 72%, suggesting that the past performance is a good predictor of the future performance.

Textual content of the reviews (unigram+bigram) turns out to be the most effective features, reaching upto 82.68% accuracy. Lastly, when all the features

are combined together, the performance decreases slightly to 81.37%, perhaps because n-gram features perform drastically better than all others.

4.1 Insightful Cues

Table 2 and 3 shows representative lexical cues for each class with example sentences excerpted from actual reviews when context can be helpful.

Hygiene: Interestingly, hygiene related words are overwhelmingly negative, e.g., *"gross", "mess", "sticky"*. What this suggests is that reviewers do complain when the restaurants are noticeably dirty, but do not seem to feel the need to complement on cleanliness as often. Instead, they seem to focus on other positive aspects of their experience, e.g., details of food, atmosphere, and their social occasions.

Service and Atmosphere: Discriminative features reveal that it is not just the hygiene related words that are predictive of the inspection results of restaurants. It turns out that there are other qualities of restaurants, such as service and atmosphere, that also correlate with the likely outcome of inspections. For example, when reviewers feel the need to talk about *"door", "student", "sticker"*, or *"the size"* (see Table 2 and 3), one can extrapolate that the overall experience probably was not glorious. In contrast, words such as *"selection", "atmosphere", "ambiance"* are predictive of hygienic restaurants, even including those with slightly negative connotation such as *"attitude"* or *"pretentious"*.

Whom and When: If reviewers talk about details of their social occasions such as *"date", "husband"*, it seems to be a good sign.

The way food items are described: Another interesting aspect of discriminative words are the way food items are described by reviewers. In general, mentions of basic ingredients of dishes, e.g., *"noodle", "egg", "soy"* do not seem like a good sign. In contrast, words that help describing the way dish is prepared or decorated, e.g., *"grill", "toast", "frosting", "bento box" "sugar"* (as in "sugar coated") are good signs of satisfied customers.

Cuisines: Finally, cuisines have clear correlations with inspection outcome, as shown in Table 2 and 3.

5 Related Work

There have been several recent studies that probe the viability of public health surveillance by measuring relevant textual signals in social media, in particular, micro-blogs (e.g., Aramaki et al. (2011), Sadilek et al. (2012b), Sadilek et al. (2012a), Sadilek et al. (2013), Lamb et al. (2013), Dredze et al. (2013), von Etter et al. (2010)). Our work joins this line of research but differs in two distinct ways. First, most prior work aims to monitor a specific illness, e.g., influenza or food-poisoning by paying attention to a relatively small set of keywords that are directly relevant to the corresponding sickness. In contrast, we examine all words people use in online reviews, and draw insights on correlating terms and concepts that may not seem immediately relevant to the hygiene status of restaurants, but nonetheless are predictive of the outcome of the inspections. Second, our work is the first to examine online reviews in the context of improving public policy, suggesting additional source of information for public policy makers to pay attention to.

Our work draws from the rich body of research that studies online reviews for sentiment analysis (e.g., Pang and Lee (2008)) and deception detection (e.g., Mihalcea and Strapparava (2009), Ott et al. (2011), Feng et al. (2012)), while introducing the new task of public hygiene prediction. We expect that previous studies for aspect-based sentiment analysis (e.g., Titov and McDonald (2008), Brody and Elhadad (2010), Wang et al. (2010)) would be a fruitful venue for further investigation.

6 Conclusion

We have reported the first empirical study demonstrating the promise of review analysis for predicting health inspections, introducing a task that has potentially significant societal benefits, while being relevant to much research in NLP for opinion analysis based on customer reviews.

Abstract

The identification of pseudepigraphic texts – texts not written by the authors to which they are attributed – has important historical, forensic and commercial applications. We introduce an unsupervised technique for identifying pseudepigrapha. The idea is to identify textual outliers in a corpus based on the pairwise similarities of all documents in the corpus. The crucial point is that document similarity not be measured in any of the standard ways but rather be based on the output of a recently introduced algorithm for authorship verification. The proposed method strongly outperforms existing techniques in systematic experiments on a blog corpus.

1 Introduction

The Shakespeare attribution problem is centuries old and shows no signs of abating. Some scholars argue that some, or even all, of Shakespeare's works were not actually written by him. The most mainstream theory – and the one that interests us here – is that most of the works were written by Shakespeare, but that several of them were not. Could modern methods of computational authorship attribution be used to detect which, if any, of the works attributed to Shakespeare were not written by him?

More generally, this paper deals with the unsupervised problem of detecting pseudepigrapha: documents in a supposedly single-author corpus that were not actually written by the corpus's presumed author. Studies as early as Mendenhall (1887), have observed that texts by a single author tend to be somewhat homogeneous in style. If this is indeed the case, we would expect that pseudepigrapha would be detectable as outliers.

Identifying such outlier texts is, of course, a special case of general outlier identification, one of the central tasks of statistics. We will thus consider the pseudepigrapha problem in the context of the more general outlier detection problem.

Typically, research on textual outliers assumes that we have a corpus of known authentic documents and are asked to decide if a specified other document is authentic or not (Juola and Stamatatos, 2013). One crucial aspect of our problem is that we do not assume that any specific text in a corpus is known a priori to be authentic or pseudepigraphic; we can assume only that most of the documents in the corpus are authentic.

The method we introduce in this paper builds on the approach of Koppel and Winter (2013) for determining if two documents are by the same author. We apply that method to every pair of documents in a corpus and use properties of the resulting adjacency graph to identify outliers. In the following section, we briefly outline previous work. In Section 3 we provide a framework for outlier detection and in Section 4 we describe our method. In Section 5 we describe the experimental setting and give results and in Section 6 we present results for the plays of Shakespeare.

2 Related Work

Identifying outlier texts consists of two main stages: first, representing each text as a numerical vector representing relevant linguistic features of the text and second, using generic methods to identify outlier vectors.

There is a vast literature on generic methods for outlier detection, summarized in Hodge & Austin (2004) and Chandola et al. (2009). Since our prob-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1449–1454,
Seattle, Washington, USA, 18-21 October 2013.

lem setup does not entail obtaining any labeled examples of authentic or outlier documents, supervised and semi-supervised methods are inapplicable. The available methods are unsupervised, principally probabilistic or proximity-based methods. A classical variant of such methods for univariate normally distributed data uses the the z-score (Grubbs, 1969). Such simple univariate outlier detectors are, however, inappropriate for identifying outliers in a high-dimensional textual corpus. Subsequent work, such as the *Stahel-Donoho Estimator* (Stahel, 1981; Donoho, 1982), *PCout* (Filzmoser et al., 2008), *LOF* (Breunig and Kriegel, 2000) and *ABOD* (Kriegel et al., 2008) have generalized univariate methods to high-dimensional data points.

In his comprehensive review of outlier detection methods in textual data, Guthrie (2008) compares a variety of vectorization methods along with a variety of generic outlier methods. The vectorization methods employ a variety of lexical and syntactic stylistic features, while the outlier detection methods use a variety of similarity/distance measures such as cosine and Euclidean distance. Similar methods have also been used in the field of intrinsic plagiarism detection, which involves segmenting a text and then identifying outlier segments (Stamatatos, 2009; Stein et al., 2010).

3 Proximity Methods

Formally, the problem we wish to solve is defined as follows: Given a set of documents $\mathbf{D} = \{\mathbf{d_1},\ldots,\mathbf{d_n}\}$, all or most of which were written by author A, which, if any, documents in D were not written by A?

We begin by considering the kinds of proximity methods for textual outlier detection considered by Guthrie (2008) and in the work on intrinsic plagiarism detection; these will serve as baseline methods for our approach. The idea is simple: mark as an outlier any document that is too far from the rest of the documents in the corpus.

We briefly sketch the key steps:

1. *Represent a document as a numerical vector.*
   The kinds of measurable features that can be used to represent a document include frequencies of word unigrams, function words, parts-of-speech and character n-grams, as well as complexity measures such as type/token ratio, sentence and word length and so on.
2. *Measure the similarity of two document vectors.*
   We can use either inverses of distance measures such as Euclidean distance or Manhattan distance, or else direct similarity measures such as cosine or min-max.
3. *Use an aggregation method to measure the similarity of a document to a set of documents.*
   One approach is to simply measure the distance from a document to the centroid of all the other documents (*centroid* method). Another approach is to first measure the similarity of a document to each other document and then to aggregate the results by averaging all the obtained values (*mean* method):
   $$mean_{\boldsymbol{d_t}\in\boldsymbol{D}}\big(sim(\boldsymbol{d_i},\boldsymbol{d_t})\big)$$
   Alternatively, we can average the values only for the k nearest neighbors (*k-NN* method):
   $$mean_{\boldsymbol{d_t}\in\boldsymbol{D_k}}\big(sim(\boldsymbol{d_i},\boldsymbol{d_t})\big)$$
   (where $\mathbf{D_k}$ = k nearest neighbors of $\mathbf{d_i}$).
   Yet another method is to use median distance (*median* method).
   $$median_{\boldsymbol{d_t}\in\boldsymbol{D}}\big(sim(\boldsymbol{d_i},\boldsymbol{d_t})\big)$$
   We note that the centroid method and mean method suffer from the *masking effect* (Bendre and Kale, 1987; Rousseeuw and Leroy, 2003): the presence of some outliers in the data can greatly distort the estimator's results regarding the presence of other outliers. The k-NN method and the median method are both much more robust.
4. *Choose some threshold beyond which a document is marked as an outlier.*
   Choosing the threshold is one of the central issues in statistical approaches. For our purposes, however, the choice of threshold is simply a parameter trading off recall and precision.

4 Second-Order Similarity

Our approach is to use an entirely different kind of similarity measure in Step 2. Rather than use a first-order similarity measure, as is customary, we employ a second-order similarity measure that is the output of an algorithm used for the *authorship verification problem* (Koppel et al. 2011), in which we need to determine if two, possibly short, documents were written by the same author.

That algorithm, known as the "impostors method" (*IM*), works as follows. Given two docu-

ments, $\mathbf{d_1}$ and $\mathbf{d_2}$, generate an appropriate set of impostor documents, $\mathbf{p_1},\ldots,\mathbf{p_m}$ and represent each of the documents in terms of some large feature set (for example, the frequencies of various words or character n-grams in the document). For some random subset of the feature set, measure the similarity of $\mathbf{d_1}$ to $\mathbf{d_2}$ as well as to each of the documents $\mathbf{p_1},\ldots,\mathbf{p_m}$ and note if $\mathbf{d_1}$ is closer to $\mathbf{d_2}$ than to any of the impostors. Repeat this k times, choosing a different random subset of the features in each iteration. If $\mathbf{d_1}$ is closer to $\mathbf{d_2}$ than to any of the impostors (and likewise switching the roles of $\mathbf{d_1}$ and $\mathbf{d_2}$) for at least θ% of iterations, then output that $\mathbf{d_2}$ and $\mathbf{d_1}$ are the same author. (The parameter θ is used to trade-off recall and precision.)

Adapting that method for our purposes, we use the proportion of iterations for which $\mathbf{d_1}$ is closer to $\mathbf{d_2}$ than to any of the impostors as our similarity measure (adding a small twist to make the measure symmetric over $\mathbf{d_1}$ and $\mathbf{d_2}$, as can be seen in line 2.2.2 of the algorithm). More precisely, we do the following:

Given: Corpus $\mathbf{D=\{d_1,\ldots,d_n\}}$

1. Choose a feature set **FS** for representing documents, a first-order similarity measure *sim*, and an impostor set $\{\mathbf{p_1},\ldots,\mathbf{p_m}\}$.
2. For each pair of documents $<\mathbf{d_i}, \mathbf{d_j}>$ in set **D**:
   - 2.1. Let $sim2(\mathbf{d_i}, \mathbf{d_j}) := 0$
   - 2.2. Iterate *K* times:
     - 2.2.1. Randomly choose 40% of features in **FS**
     - 2.2.2. If $sim(\mathbf{d_i}, \mathbf{d_j})^2 > max_{u\in\{1,..,m\}} sim(\mathbf{d_i}, \mathbf{p_u}) * max_{u\in\{1,..,m\}} sim(\mathbf{d_j}, \mathbf{p_u})$, then $sim2(\mathbf{d_i}, \mathbf{d_j}) := sim2(\mathbf{d_i}, \mathbf{d_j}) + 1/K$
3. For each document $\mathbf{d_i}$ in set **D**:
   - 3.1. Compute $sim2(\mathbf{d_i}, \mathbf{D}) = agg_{w\in\{1,..,n\}}[sim2(\mathbf{d_i}, \mathbf{d_w})]$ where *agg* is some aggregation function
   - 3.2. If $sim2(\mathbf{d_i}, \mathbf{D}) < \theta$ (where θ is a parameter), then mark $\mathbf{d_i}$ as *outlier*.

The method for choosing the impostor set is corpus-dependent, but quite straightforward: we simply choose random impostors from the same genre and language as the documents in question. The choice of feature set **FS,** first-order similarity measure *sim*, and aggregation function *agg* can be varied. For **FS**, we simply use bag-of-words (BOW). As for *sim* and *agg*, we show below results of experiments comparing the effectiveness of various choices for these parameters.

Using second-order similarity has several surface advantages over standard first-order measures. First, it is decisive: for most pairs, second-order similarity will be close to 0 or close to 1. Second, it is self-normalizing: scaling doesn't depend on the size of the underlying feature sets or the lengths of the documents. As we will see, it is also simply much more effective for identifying outliers.

5 Experiments

We begin by assembling a corpus consisting of 3540 blog posts written by 156 different bloggers. The blogs are taken from the blog corpus assembled by Schler et al. (2006) for use in authorship attribution tasks. Each of the blogs was written in English by a single author in 2004 and each post consists of 1000 words (excess is truncated).

For our initial experiments, each trial consists of 10 blog posts, all but *p* of which are by a single blogger. The number of pseudepigraphic documents, *p*, is chosen from a uniform distribution over the set {0,1,2,3}. Our task is to identify which, if any, documents in the set are not by the main author of the set. The pseudepigraphic documents might be written by a single author or by multiple authors.

To measure the performance of a given similarity measure *sim*, we do the following in each trial:

1. Represent each document in the trial set **D** in terms of BOW.
2. Measure the similarity of each pair of documents in the trial set using the similarity measure *sim*.
3. Using some aggregation function *agg*, compute for each document $\mathbf{d_i}$: $sim(\mathbf{d_i}, \mathbf{D}) = agg_{w\in\{1,..,n\}}[sim(\mathbf{d_i}, \mathbf{d_w})]$.
4. If $sim(\mathbf{d_i}, \mathbf{D}) < \theta$, mark $\mathbf{d_i}$ as an outlier (where θ is a parameter).

Our objective is to show that results using second-order similarity are stronger than those using first-order similarity. Before we do this, we need to determine the best aggregation function to use in our experiments. In Figure 1, we show recall-precision breakeven values (for the *outlier* class) over 250 independent trials, for each of our four first-order similarity measures (inverse Euclidean, inverse Manhattan, cosine, min-max) used in conjunction with each of four aggregation functions (centroid, mean, k-NN mean, median). As is evident, k-NN is the best aggregation function in each case. We will give these baseline methods an advantage by using k-NN as our aggregation function in all our subsequent experiments.

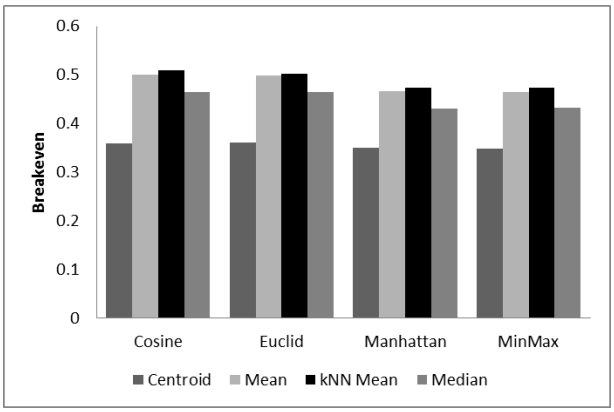

Figure 1. Breakeven values on first-order similarity measures with various aggregation functions.

We are now ready to perform our main experiment. We use BOW as our feature set and k-NN as our aggregation function. We use 500 random blog posts as our impostor set. In Figure 2, we show recall-precision curves for outlier documents over 250 independent trials, as just described, using four first-order similarity measures as well our second-order similarity measure using each of the four as a base measure. As can be seen, even the worst second-order similarity measure significantly outperforms all the standard first-order measures. In Figure 3, we show the breakeven values for each measure, pairing each first-order measure with the second-order measure that uses it as a base. Clearly, the mere use of a second-order method improves results, regardless of the base measure.

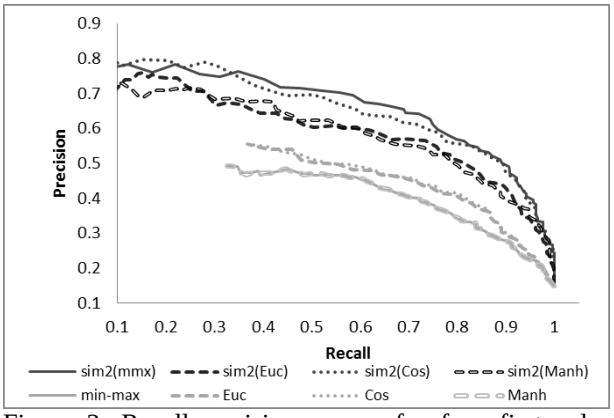

Figure 2. Recall-precision curves for four first-order similarity measures and four second-order similarity measures, based on 250 trials of 10 documents each.

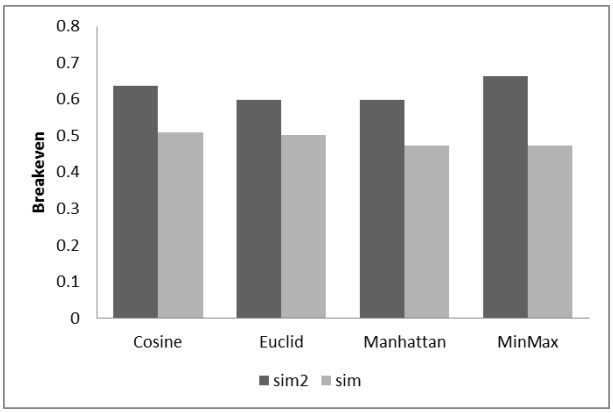

Figure 3. Breakeven values for first-order measures and corresponding second-order measures.

Thus far we have considered authorial corpora consisting of only ten documents. In Figures 4 and 5, we repeat the experiment described in Figures 2 and 3 above, but with each trial consisting of 50 documents including any number of pseudepigraphic documents in the range 0 to 15. The same phenomenon is apparent: second-order similarity strongly improves results over the corresponding first-order base similarity measure.

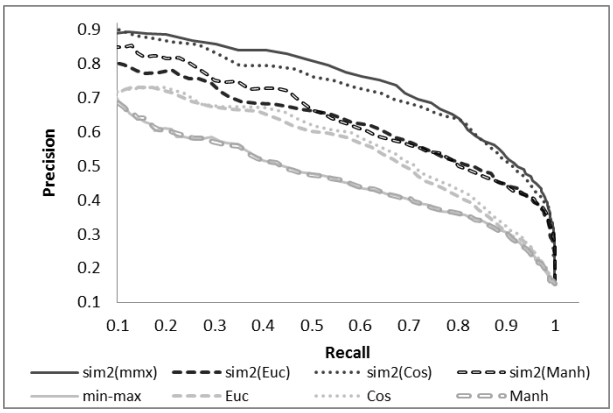

Figure 4. Recall-precision curves for four first-order similarity measures and four second-order similarity measures, based on 250 trials of 50 documents each.

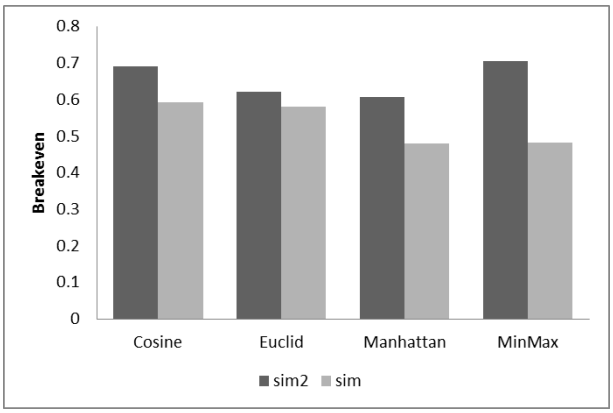

Figure 5. Breakeven values for first-order measures and corresponding second-order measures

6 Results on Shakespeare

We applied our methods to the texts of 42 plays by Shakespeare (taken from Project Gutenberg). We included two plays by Thomas Kyd as sanity checks. In addition, we included three plays occasionally attributed to Shakespeare, but generally regarded by authorities as pseudepigrapha (*A Yorkshire Tragedy*, *The Life of Sir John Oldcastle* and *Pericles Prince of Tyre*). We also included *King Edward III* and *King Henry VI* (Part 1), both of which are subjects of dispute among Shakespeare scholars. As impostors we used 39 works by contemporaries of Shakespeare, including Christopher Marlowe, Ben Jonson and John Fletcher.

We found that the two plays by Thomas Kyd and the three pseudepigraphic plays were all among the seven furthest outliers, as one would expect. In addition, *King Edward III* was 9th furthest. *King Henry VI* (Part 1) was not found to be an outlier at all. Curiously, however, three undisputed plays by Shakespeare were found to be greater outliers than *King Edward III*. These are *The Merry Wives of Windsor*, *The Comedy of Errors* and *The Tragedy of Julius Caesar*. *The Merry Wives of Windsor* is a particularly distant outlier, even further out than *Oldcastle* and *Pericles*. We leave it to Shakespeare scholars to explain the reasons for these anomalies.

7 Conclusion

In this paper we defined the problem of unsupervised outlier detection in the authorship verification domain. Our method combines standard outlier detection methods with a novel inter-document similarity measure. This similarity measure is the output of the impostors method recently developed for solving the authorship verification problem. We have found that use of the kNN method for outlier detection in conjunction with this second-order similarity measure strongly outperforms methods based on any outlier detection method used in conjunction with any standard first-order similarity measures. This improvement proves to be robust, holding for various corpus sizes and various underlying base similarity measures used in the second-order similarity measure.

The method can be used to resolve historical conundrums regarding the authenticity of works in questioned corpora, such as the Shakespeare corpus briefly considered here. This is currently the subject of our ongoing research.

Abstract

Feature computation and exhaustive search have significantly restricted the speed of graph-based dependency parsing. We propose a faster framework of *dynamic feature selection*, where features are added sequentially as needed, edges are pruned early, and decisions are made online for each sentence. We model this as a sequential decision-making problem and solve it by imitation learning techniques. We test our method on 7 languages. Our dynamic parser can achieve accuracies comparable or even superior to parsers using a full set of features, while computing fewer than 30% of the feature templates.

1 Introduction

Graph-based dependency parsing usually consists of two stages. In the scoring stage, we score all possible edges (or other small substructures) using a learned function; in the decoding stage, we use combinatorial optimization to find the dependency tree with the highest *total* score.

Generally linear edge-scoring functions are used for speed. But they use a large set of features, derived from feature templates that consider different conjunctions of the edge's attributes. As a result, parsing time is dominated by the scoring stage—computing edge attributes, using them to instantiate feature templates, and looking up the weights of the resulting features in a hash table. For example, McDonald et al. (2005a) used on average about 120 first-order feature templates on each edge, built from attributes such as the edge direction and length, the two words connected by the edge, and the parts of speech of these and nearby words.

We therefore ask the question: can we use fewer features to score the edges, while maintaining the effect that the true dependency tree still gets a higher score? Motivated by recent progress on dynamic feature selection (Benbouzid et al., 2012; He et al., 2012), we propose to add features one group at a time to the dependency graph, and to use these features together with interactions among edges (as determined by intermediate parsing results) to make hard decisions on some edges before all their features have been seen. Our approach has a similar flavor to cascaded classifiers (Viola and Jones, 2004; Weiss and Taskar, 2010) in that we make decisions for each edge at every stage. However, in place of relatively simple heuristics such as a global relative pruning threshold, we learn a featurized decision-making policy of a more complex form. Since each decision can affect later stages, or later decisions in the same stage, we model this problem as a sequential decision-making process and solve it by Dataset Aggregation (DAgger) (Ross et al., 2011), a recent iterative imitation learning technique for structured prediction.

Previous work has made much progress on the complementary problem: speeding up the decoding stage by pruning the search space of tree structures. In Roark and Hollingshead (2008) and Bergsma and Cherry (2010), pruning decisions are made locally as a preprocessing step. In the recent vine pruning approach (Rush and Petrov, 2012), significant speedup is gained by leveraging structured information via a coarse-to-fine projective parsing cas-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1455–1464,
Seattle, Washington, USA, 18-21 October 2013.

cade (Charniak et al., 2006). These approaches do not directly tackle the feature selection problem. Although pruned edges do not require further feature computation, the pruning step must itself compute similar high-dimensional features just to decide which edges to prune. For this reason, Rush and Petrov (2012) restrict the pruning models to a smaller feature set for time efficiency. We aim to do feature selection and edge pruning dynamically, balancing speed and accuracy by using only as many features as needed.

In this paper, we first explore standard static feature selection methods for dependency parsing, and show that even a few feature templates can give decent accuracy (Section 3.2). We then propose a novel way to dynamically select features for each edge while keeping the overhead of decision making low (Section 4). Our present experiments use the Maximum Spanning Tree (MST) parsing algorithm (McDonald et al., 2005a; McDonald and Pereira, 2006). However, our approach applies to other graph-based dependency parsers as well—including non-projective parsing, higher-order parsing, or approximations to higher-order parsing that use stacking (Martins et al., 2008), belief propagation (Smith and Eisner, 2008), or structured boosting (Wang et al., 2007).

2 Graph-based Dependency Parsing

In graph-based dependency parsing of an n-word input sentence, we must construct a tree $\boldsymbol{y}$ whose vertices $0, 1, \ldots n$ correspond to the root node (namely 0) and the ordered words of the sentence. Each directed edge of this tree points from a head (parent) to one of its modifiers (child).

Following a common approach to structured prediction problems, the score of a tree $\boldsymbol{y}$ is defined as a sum of local scores. That is, $s_{\boldsymbol{\theta}}(\boldsymbol{y}) = \boldsymbol{\theta} \cdot \sum_{E \in \boldsymbol{y}} \phi(E) = \sum_{E \in \boldsymbol{y}} \boldsymbol{\theta} \cdot \phi(E)$, where E ranges over small connected subgraphs of $\boldsymbol{y}$ that can be scored individually. Here $\phi(E)$ extracts a high-dimensional feature vector from E together with the input sentence, and $\boldsymbol{\theta}$ denotes a weight vector that has typically been learned from data.

The first-order model decomposes the tree into edges E of the form $\langle h, m \rangle$, where $h \in [0, n]$ and $m \in [1, n]$ (with $h \neq m$) are a head token and one of its modifiers. Finding the best tree requires first computing $\boldsymbol{\theta} \cdot \phi(E)$ for each of the n^2 possible edges.

Since scoring the edges independently in this way restricts the parser to a local view of the dependency structure, higher-order models can achieve better accuracy. For example, in the second-order model of McDonald and Pereira (2006), each local subgraph E is a triple that includes the head and two modifiers of the head, which are adjacent to each other. Other methods that use triples include grandparent-parent-child triples (Koo and Collins, 2010), or non-adjacent siblings (Carreras, 2007). Third-order models (Koo and Collins, 2010) use quadruples, employing grand-sibling and tri-sibling information.

The usual inference problem is to find the highest scoring tree for the input sentence. Note that in a valid tree, each token $1, \ldots, n$ must be attached to exactly one parent (either another token or the root 0). We can further require the tree to be projective, meaning that edges are not allowed to cross each other. It is well known that dynamic programming can be used to find the best projective dependency tree in $O(n^3)$ time, much as in CKY, for first-order models and some higher-order models (Eisner, 1996; McDonald and Pereira, 2006).[1] When the projectivity restriction is lifted, McDonald et al. (2005b) pointed out that the best tree can be found in $O(n^2)$ time using a minimum directed spanning tree algorithm (Chu and Liu, 1965; Edmonds, 1967; Tarjan, 1977), though only for first-order models.[2] We will make use of this fast non-projective algorithm as a subroutine in early stages of our system.

3 Dynamic Feature Selection

Unlike typical feature selection methods that fix a subset of selected features and use it throughout testing, in dynamic feature selection we choose features adaptively for each instance. We briefly introduce this framework below and motivate our algorithm from empirical results on MST dependency parsing.

[1] Although the third-order model of Koo and Collins (2010), for example, takes $O(n^4)$ time.

[2] The non-projective parsing problem becomes NP-hard for higher-order models. One approximate solution (McDonald and Pereira, 2006) works by doing projective parsing and then rearranging edges.

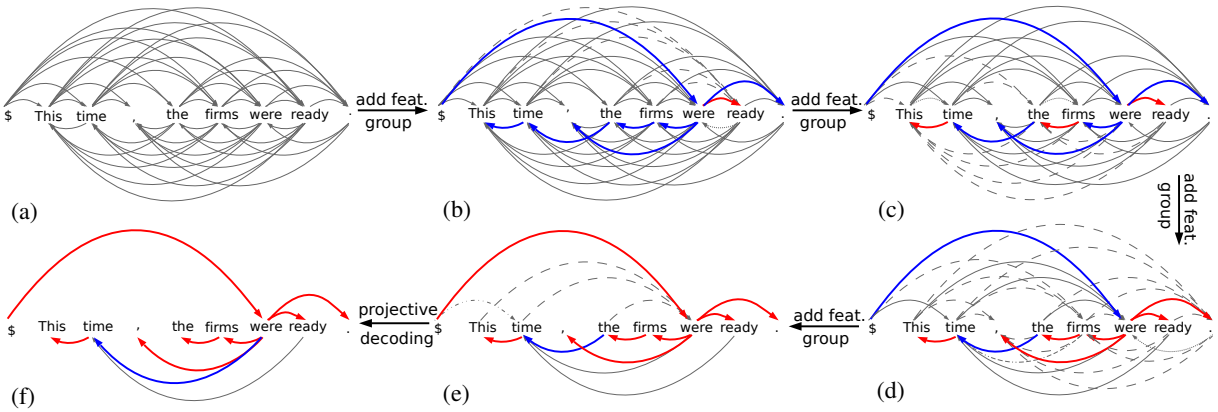

Figure 1: Dynamic feature selection for dependency parsing. (a) Start with all possible edges except those filtered by the length dictionary. (b) – (e) Add the next group of feature templates and parse using the non-projective parser. Predicted trees are shown as blue and red edges, where red indicates the edges that we then decide to lock. Dashed edges are pruned because of having the same child as a locked edge; 2-dot-3-dash edges are pruned because of crossing with a locked edge; fine-dashed edges are pruned because of forming a cycle with a locked edge; and 2-dot-1-dash edges are pruned since the root has already been locked with one child. (f) Final projective parsing.

3.1 Sequential Decision Making

Our work is motivated by recent progress on dynamic feature selection (Benbouzid et al., 2012; He et al., 2012; Grubb and Bagnell, 2012), where features are added sequentially to a test instance based on previously acquired features and intermediate prediction results. This requires sequential decision making. Abstractly, when the system is in some state $s \in S$, it chooses an action $a = \pi(s)$ from the action set A using its policy π, and transitions to a new state s', inducing some cost. In the specific case of dynamic feature selection, when the system is in a given state, it decides whether to add some more features or to stop and make a prediction based on the features added so far. Usually the sequential decision making problem is solved by reinforcement learning (Sutton and Barto, 1998) or imitation learning (Abbeel and Ng, 2004; Ratliff et al., 2004).

The dynamic feature selection framework has been successfully applied to supervised classification and ranking problems (Benbouzid et al., 2012; He et al., 2012; Gao and Koller, 2010). Below, we design a version that avoids overhead in our *structured prediction* setting. As there are n^2 possible edges on a sentence of length n, we wish to avoid the overhead of making many individual decisions about specific features on specific edges, with each decision considering the current scores of all other edges. Instead we will batch the work of dynamic feature selection into a smaller number of coarse-grained steps.

3.2 Strategy

To speed up graph-based dependency parsing, we first investigate time usage in the parsing process on our development set, section 22 of the Penn Treebank (PTB) (Marcus et al., 1993). In Figure 2, we observe that (a) feature computation took more than 80% of the total time; (b) even though non-projective decoding time grows quadratically in terms of the sentence length, in practice it is almost negligible compared to the projective decoding time, with an average of 0.23 ms; (c) the second-order projective model is significantly slower due to higher asymptotic complexity in both the scoring and decoding stages.

At each stage of our algorithm, we need to decide whether to use additional features to refine the edge scores. As making this decision separately for each of the n^2 possible edges is expensive, we instead propose a version that reduces the number of decisions needed. We show the process for one short sentence in Figure 1. The first step is to parse using the current features. We use the fast first-order non-projective parser for this purpose, since given observations (b) and (c), we cannot afford to run projective parsing multiple times. The single resulting tree (blue and red edges in Figure 1) has only

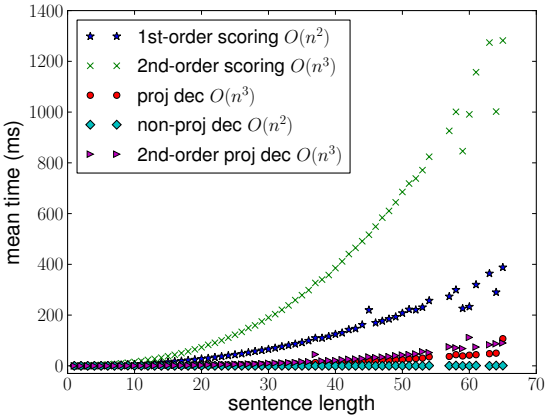

Figure 2: Time comparison of scoring time and decoding time on English PTB section 22.

n edges, and we use a classifier to decide which of these edges are reliable enough that we should "lock" them—i.e., commit to including them in the final tree. This is the only decision that our policy π must make. Locked (red) edges are definitely in the final tree. We also do constraint propagation: we rule out all edges that conflict with the locked edges, barring them from appearing in the final tree.[3] Conflicts are defined as violation of the projective parsing constraints:

- Each word has exactly one parent
- Edges cannot cross each other[4]
- The directed graph is non-cyclic
- Only one word is attached to the root

For example, in Figure 1(d), the dashed edges are removed because they have the same child as one of the locked (red) edges. The 2-dot-3-dash edge *time* ← *firms* is removed because it crosses the locked edge *(comma)* ← *were* (whereas we ultimately seek a projective parse). The fine dashed edge *were* ← *(period)* is removed because it forms a cycle with *were* → *(period)*. In Figure 1(e), the 2-dot-1-dash edge *(root)* → *time* is removed since we allow the root to have only one modifier.

[3]Constraint propagation also automatically locks an edge when all other edges with the same child have been ruled out.

[4]A reviewer asks about the cost of finding edges that cross a locked edge. Naively this is $O(n^2)$. But at most n edges will be locked during the entire algorithm, for a total $O(n^3)$ runtime—the same as *one* call to projective parsing, and far faster in practice. With cleverness this can even be reduced to $O(n^2 \log n)$.

Once constraint propagation has finished, we visit all edges (gray) whose fate is still unknown, and update their scores in parallel by adding the next group of features.

As a result, most edges will be locked in or ruled out without needing to look up all of their features. Some edges may still remain uncertain even after including all features. If so, a final iteration (Figure 1 (f)) uses the slower projective parser to resolve the status of these maximally uncertain edges. In our example, the parser does not figure out the correct parent of *time* until this final step. This final, accurate parser can use its own set of weighted features, including higher-order features, as well as the projectivity constraint. But since it only needs to resolve the few uncertain edges, both scoring and decoding are fast.

If we wanted our parser to be able to produce non-projective trees, then we would skip this final step or have it use a higher-order non-projective parser. Also, at earlier steps we would not prune edges crossing the locked edges.

4 Methods

Our goal is to produce a faster dependency parser by reducing the feature computation time. We assume that we are given three increasingly accurate but increasingly slow parsers that can be called as subroutines: a first-order non-projective parser, a first-order projective parser, and a second-order projective parser. In all cases, their feature weights have already been trained using the *full* set of features, and we will not change these weights. In general we will return the output of one of the projective parsers. But at early iterations, the non-projective parser helps us rapidly consider interactions among edges that may be relevant to our dynamic decisions.

4.1 Feature Template Ranking

We first rank the 268 first-order feature templates by forward selection. We start with an empty list of feature templates, and at each step we greedily add the one whose addition most improves the parsing accuracy on a development set. Since some features may be slower than others (for example, the "between" feature templates require checking all tokens in-between the head and the modifier), we could in-

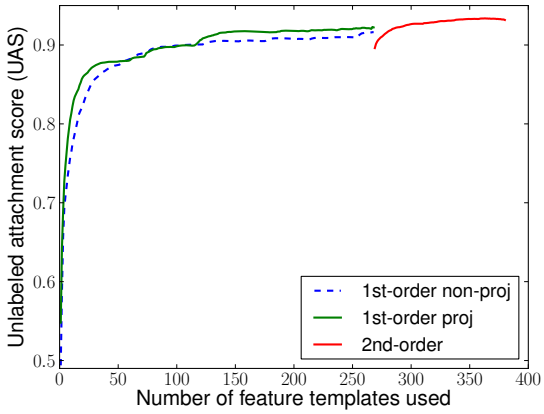

Figure 3: Forward feature selection result using the non-projective model on English PTB section 22.

stead select the feature template with the highest ratio of accuracy improvement to runtime. However, for simplicity we do not consider this: after grouping (see below), minor changes of the ranks within a group have no effect. The accuracy is evaluated by running the first-order non-projective parser, since we will use it to make most of the decisions. The 112 second-order feature templates are then ranked by adding them in a similar greedy fashion (given that all first-order features have already been added), evaluating with the second-order projective parser.

We then divide this ordered list of feature templates into K groups: $\{T_1, T_2, \ldots, T_K\}$. Our parser adds an entire group of feature templates at each step, since adding one template at a time would require too many decisions and obviate speedups. The simplest grouping method would be to put an equal number of feature templates in each group. From Figure 3 we can see that the accuracy increases significantly with the first few templates and gradually levels off as we add less valuable templates. Thus, a more cost-efficient method is to split the ranked list into several groups so that the accuracy increases by roughly the same amount after each group is added. In this case, earlier stages are fast because they tend to have many fewer feature templates than later stages. For example, for English, we use 7 groups of first-order feature templates and 4 groups of second-order feature templates. The sequence of group sizes is 1, 4, 10, 12, 47, 33, 161 and 35, 29, 31, 17 for first- and second-order parsing respectively.

4.2 Sequential Feature Selection

Similar to the length dictionary filter of Rush and Petrov (2012), for each test sentence, we first deterministically remove edges longer than the maximum length of edges in the training set that have the same head POS tag, modifier POS tag, and direction. This simple step prunes around 40% of the non-gold edges in our Penn Treebank development set (Section 6.1) at a cost of less than 0.1% in accuracy.

Given a test sentence of length n, we start with a complete directed graph $\mathcal{G}(\mathcal{V}, \mathcal{E})$, where $\mathcal{E} = \{\langle h, m\rangle : h \in [0, n], m \in [1, n]\}$. After the length dictionary pruning step, we compute T_1 for all remaining edges to obtain a pruned weighted directed graph. We predict a parse tree using the features so far (other features are treated as absent, with value 0). Then for each edge in this intermediate tree, we use a binary linear classifier to choose between two actions: $A = \{lock, add\}$. The *lock* action ensures that $\langle h, m\rangle$ appears in the final parse tree by pruning edges that conflict with $\langle h, m\rangle$.[5] If the classifier is not confident enough about the parent of m, it decides to *add* to gather more information. The *add* action computes the next group of features for $\langle h, m\rangle$ and all other competing edges with child m.

(Since we classify the edges one at a time, decisions on one edge may affect later edges. To improve efficiency and reduce cascaded error, we sort the edges in the predicted tree and process them as above in descending order of their scores.)

Now we can continue with the second iteration of parsing. Overall, our method runs up to $K = K_1 + K_2$ iterations on a given sentence, where we have K_1 groups of first-order features and K_2 groups of second-order features. We run $K_1 - 1$ iterations of non-projective first-order parsing (adding groups $T_1, \ldots, T_{K_1-1}$), then 1 iteration of *projective* first-order parsing (adding group T_{K_1}), and finally K_2 iterations of projective second-order parsing (adding groups $T_{K_1+1}, \ldots T_K$).

Before each iteration, we use the result of the previous iteration (as explained above) to prune some edges and add a new group of features to the rest. We

[5] If the conflicting edge is in the current predicted parse tree (which can happen because of non-projectivity), we forbid the model to prune it. Otherwise in rare cases the non-projective parser at the next stage may fail to find a tree.

then run the relevant parser. Each of the three parsers has a different set of feature weights, so when we switch parsers on rounds K_1 and $K_1 + 1$, we must also *change* the weights of the previously added features to those specified by the new parsing model.

In practice, we can stop as soon as the fate of all edges is known. Also, if no projective parse tree can be constructed at round K_1 using the available unpruned edges, then we immediately fall back to returning the non-projective parse tree from round $K_1 - 1$. This FAIL case rarely occurs in our experiments (fewer than 1% of sentences).

We report results both for a first-order system where $K_2 = 0$ (shown in Figure 1 and Algorithm 1) and for a second-order system where $K_2 > 0$.

Algorithm 1 DynFS($\mathcal{G}(\mathcal{V}, \mathcal{E}), \pi$)

$\mathcal{E} \leftarrow \{\langle h, m\rangle : |h - m| \leq \text{lenDict}(h, m)\}$

  end if
end for
return $\hat{\boldsymbol{y}}$

5 Policy Training

We cast this problem as an imitation learning task and use Dataset Aggregation (DAgger) Ross et al. (2011) to train the policy iteratively.

5.1 Imitation Learning

In imitation learning (also called apprenticeship learning) (Abbeel and Ng, 2004; Ratliff et al., 2004), instead of exploring the environment directed by its feedback (reward) as in typical reinforcement learning problems, the learner observes expert demonstrations and aims to mimic the expert's behavior. The expert demonstration can be represented as trajectories of state-action pairs, $\{(s_t, a_t)\}$ where t is the time step. A typical approach to imitation learning is to collect supervised data from the expert's trajectories to learn a policy (multiclass classifier), where the input is $\psi(s)$, a feature representation of the current state (we call these *policy features* to avoid confusion with the *parsing features*), and the output is the predicted action (label) for that state.

In the sequential feature selection framework, it is hard to directly apply standard reinforcement learning algorithms, as we cannot assign credit to certain features until the policy decides to stop and let us evaluate the prediction result. On the other hand, knowing the gold parse tree makes it easy to obtain expert demonstrations, which enables imitation learning.

5.2 DAgger

Since the above approach collects training data only from the expert's trajectories, it ignores the fact that the distribution of states at training time and that at test time are different. If the learned policy cannot mimic the expert perfectly, one wrong step may lead to states never visited by the expert due to cumulative errors. This problem of insufficient exploration can be alleviated by iteratively learning a policy trained under states visited by both the expert and the learner (Ross et al., 2011; Daumé III et al., 2009; Kääriäinen, 2006).

Ross et al. (2011) proposed to train the policy iteratively and aggregate data collected from the previous learned policy. Let π^* denote the expert's policy and s_{π_i} denote states visited by executing π_i. In its simplest parameter-free form, in each iteration, we first run the most recently learned policy π_i; then for each state s_{π_i} on the trajectory, we collect a training example $(\psi(s_{\pi_i}), \pi^*(s_{\pi_i}))$ by labeling the state with the expert's action. Intuitively, this step intends to correct the learner's mistakes and pull it back to the

expert's trajectory. Thus we can obtain a policy that performs well under its own induced state distribution.

5.3 DAgger for Feature Selection

In our case, the expert's decision is rather straightforward. Replace the policy π in Algorithm 1 by an expert. If the edge under consideration is a gold edge, it executes *lock*; otherwise, it executes *add*. Basically the expert "cheats" by knowing the true tree and always making the right decision. On our PTB dev set, it can get 96.47% accuracy[6] with only 2.9% of the first-order features. This is an upper bound on our performance.

We present the training procedure in Algorithm 2. We begin by partitioning the training set into N folds. To simulate parsing results at test time, when collecting examples on $\mathcal{T}^i$, similar to cross-validation, we use parsers trained on $\bar{\mathcal{T}}^i = \mathcal{T} \setminus \mathcal{T}^i$. Also note that we show only one pass over training sentences in Algorithm 2; however, multiple passes are possible in practice, especially when the training data is limited.

Algorithm 2 DAgger($\mathcal{T}$, π^*)

```
Split the training sentences T into N folds T^1, T^2, ..., T^N
Initialize D ← ∅, π_1 ← π*
for i = 1 to N do
  for G(V, E) ∈ T^i do
    Sample trajectories {(s_{π_i}, π_i(s_{π_i}))} by DynFS(G(V, E), π_i)
    D ← D ⋃ {(ψ(s), π*(s))}
  end for
end for
Train policy π_{i+1} on D
return Best π_i evaluated on development set
```

5.4 Policy Features

Our linear edge classifier uses a feature vector ψ that concatenates all previously acquired parsing features together with "meta-features" that reflect confidence in the edge. The classifier's weights are fixed across iterations, but ψ(edge) changes per iteration.

We standardize the edge scores by a sigmoid function. Let $\dot{s}$ denote the normalized score, defined by $\dot{s}_{\boldsymbol{\theta}}(\langle h, m\rangle) = 1/(1 + \exp\{-s_{\boldsymbol{\theta}}(\langle h, m\rangle)\})$. Our meta-features for $\langle h, m\rangle$ include

- current normalized score, and normalized score before adding the current feature group
- margin to the highest scoring competing edges, i.e., $\dot{s}(\boldsymbol{w}, \langle h, m\rangle) - \max_{h'} \dot{s}(\boldsymbol{w}, \langle h', m\rangle)$ where $h' \in [0, n]$ and $h' \neq h$
- index of the next feature group to be added

We also tried more complex meta-features, for example, mean and variance of the scores of competing edges, and structured features such as whether the head of e is locked and how many locked children it currently has. It turns out that *given all the parsing features*, the margin is the most discriminative meta-feature. When it is present, other meta-features we added do not help much, Thus we do not include them in our experiments due to overhead.

6 Experiment

6.1 Setup

We generate dependency structures from the PTB constituency trees using the head rules of Yamada and Matsumoto (2003). Following convention, we use sections 02–21 for training, section 22 for development and section 23 for testing. We also report results on six languages from the CoNLL-X shared task (Buchholz and Marsi, 2006) as suggested in (Rush and Petrov, 2012), which cover a variety of language families. We follow the standard training/test split specified in the CoNLL-X data and tune parameters by cross validation when training the classifiers (policies). The PTB test data is tagged by a Stanford part-of-speech (POS) tagger (Toutanova et al., 2003) trained on sections 02–21. We use the provided gold POS tags for the CoNLL test data. All results are evaluated by the unlabeled attachment score (UAS). For fair comparison with previous work, punctuation is included when computing parsing accuracy of all CoNLL-X languages but not English (PTB).

For policy training, we train a linear SVM classifier using Liblinear (Fan et al., 2008). For all languages, we run DAgger for 20 iterations and se-

[6]The imperfect performance is because the accuracy is measured with respect to the gold parse trees. The expert only makes optimal pruning decisions but the performance depends on the pre-trained parser as well.

Language	Method	First-order				Second-order			
		Speedup	Cost(%)	UAS(D)	UAS(F)	Speedup	Cost(%)	UAS(D)	UAS(F)

Table 1: Comparison of speedup and accuracy with the vine pruning cascade approach for six languages. In the setup, DynFS means our dynamic feature selection model, VineP means the vine pruning cascade model, UAS(D) and UAS(F) refer to the unlabeled attachment score of the dynamic model (D) and the full-feature model (F) respectively. For each language, the speedup is relative to its corresponding first- or second-order model using the full set of features. Results for the vine pruning cascade model are taken from Rush and Petrov (2012). The cost is the percentage of feature templates used per sentence on edges that are *not pruned by the dictionary filter*.

lect the best policy evaluated on the development set among the 20 policies obtained from each iteration.

6.2 Baseline Models

We use the publicly available implementation of MSTParser[7] (with modifications to the feature computation) and its default settings, so the feature weights of the projective and non-projective parsers are trained by the MIRA algorithm (Crammer and Singer, 2003; Crammer et al., 2006).

Our feature set contains most features proposed in the literature (McDonald et al., 2005a; Koo and Collins, 2010). The basic feature components include lexical features (token, prefix, suffix), POS features (coarse and fine), edge length and direction. The feature templates consists of different conjunctions of these components. Other than features on the head word and the child word, we include features on in-between words and surrounding words as well. For PTB, our first-order model has 268 feature templates and 76,287,848 features; the second-order model has 380 feature templates and 95,796,140 features. The accuracy of our full-feature models is comparable or superior to previous results.

6.3 Results

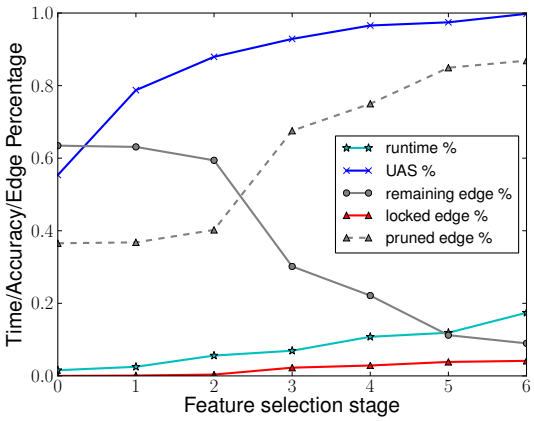

Figure 4: System dynamics on English PTB section 23. Time and accuracy are relative to those of the baseline model using full features. Red (locked), gray (undecided), dashed gray (pruned) lines correspond to edges shown in Figure 1.

In Table 1, we compare the dynamic parsing models with the full-feature models and the vine pruning cascade models for first-order and second-order

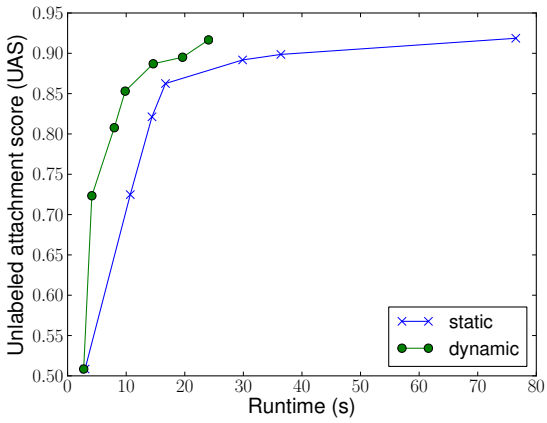

Figure 5: Pareto curves for the dynamic and static approaches on English PTB section 23.

parsing. The *speedup* for each language is defined as the speed relative to its full-feature baseline model. We take results reported by Rush and Petrov (2012) for the vine pruning model. As speed comparison for parsing largely relies on implementation, we also report the percentage of feature templates chosen for each sentence. The *cost* column shows the average number of feature templates computed for each sentence, expressed as a percentage of the number of feature templates if we had only pruned using the length dictionary filter.

From the table we notice that our first-order model's performance is comparable or superior to the vine pruning model, both in terms of speedup and accuracy. In some cases, the model with fewer features even achieves higher accuracy than the model with full features. The second-order model, however, does not work as well. In our experiments, the second-order model is more sensitive to false negatives, i.e. pruning of gold edges, due to larger error propagation than the first-order model. Therefore, to maintain parsing accuracy, the policy must make high-precision pruning decisions and becomes conservative. We could mitigate this by training the original parsing feature weights in conjunction with our policy feature weights. In addition, there is larger overhead during when checking non-projective edges and cycles.

We demonstrate the dynamics of our system in Figure 4 on PTB section 23. We show how the runtime, accuracy, number of locked edges and undecided edges change over the iterations in our first-order dynamic projective parsing. From iterations 1 to 6, we obtain parsing results from the non-projective parser; in iteration 7, we run the projective parser. The plot shows relative numbers (percentage) to the baseline model with full features. The number of remaining edges drops quickly after the second iteration. From Figure 3, however, we notice that even with the first feature group which only contains one feature template, the non-projective parser can almost achieve 50% accuracy. Thus, ideally, our policy should have locked that many edges after the first iteration. The learned policy does not imitate the expert perfectly, either because our policy features are not discriminative enough, or because a linear classifier is not powerful enough for this task.

Finally, to show the advantage of making dynamic decisions that consider the interaction among edges on the given input sentence, we compare our results with a static feature selection approach on PTB section 23. The static algorithm does no pruning except by the length dictionary at the start. In each iteration, instead of running a fast parser and making decisions online, it simply adds the next group of feature templates to all edges. By forcing both algorithms to stop after each stage, we get the Pareto curves shown in Figure 5. For a given level of high accuracy, our dynamic approach (black) is much faster than its static counterpart (blue).

7 Conclusion

In this paper we present a dynamic feature selection algorithm for graph-based dependency parsing. We show that choosing feature templates adaptively for each edge in the dependency graph greatly reduces feature computation time and in some cases improves parsing accuracy. Our model also makes it practical to use an even larger feature set, since features are computed only when needed. In future, we are interested in training parsers favoring the dynamic feature selection setting, for example, parsers that are robust to missing features, or parsers optimized for different stages.

Semi-Supervised Representation Learning for Cross-Lingual Text Classification

Min Xiao and **Yuhong Guo**

Abstract

Cross-lingual adaptation aims to learn a prediction model in a label-scarce target language by exploiting labeled data from a label-rich source language. An effective cross-lingual adaptation system can substantially reduce the manual annotation effort required in many natural language processing tasks. In this paper, we propose a new cross-lingual adaptation approach for document classification based on learning cross-lingual discriminative distributed representations of words. Specifically, we propose to maximize the log-likelihood of the documents from both language domains under a cross-lingual log-bilinear document model, while minimizing the prediction log-losses of labeled documents. We conduct extensive experiments on cross-lingual sentiment classification tasks of Amazon product reviews. Our experimental results demonstrate the efficacy of the proposed cross-lingual adaptation approach.

1 Introduction

With the rapid development of linguistic resources in different languages, developing cross-lingual natural language processing (NLP) systems becomes increasingly important (Bel et al., 2003; Shanahan et al., 2004). Recently, cross-lingual adaptation methods have been studied to exploit labeled information from an existing *source* language domain where labeled training data is abundant for use in a *target* language domain where annotated training data is scarce (Prettenhofer and Stein, 2010). Previous work has shown that cross-lingual adaptation can greatly reduce labeling effort for a variety of cross language NLP tasks such as document categorization (Bel et al., 2003; Amini et al., 2009), genre classification (Petrenz and Webber, 2012), and sentiment classification (Shanahan et al., 2004; Wei and Pal, 2010; Prettenhofer and Stein, 2010).

The fundamental challenge of cross-lingual adaptation stems from a lack of overlap between the feature space of the source language data and that of the target language data. To address this challenge, previous work in the literature mainly relies on automatic machine translation tools. They first translate all the text data from one language domain into the other and then apply techniques such as domain adaptation (Wan et al., 2011; Rigutini and Maggini, 2005; Ling et al., 2008) and multi-view learning (Amini et al., 2009; Guo and Xiao, 2012b; Wan, 2009) to achieve cross-lingual adaptation. However, machine translation tools may not be freely available for all languages. Moreover, translating all the text data in one language into the other language is too time-consuming in reality. As an economic alternative solution, cross-lingual representation learning has recently been used in the literature to learn language-independent representations of the data for cross language text classification (Prettenhofer and Stein, 2010; Petrenz and Webber, 2012).

In this paper, we propose to tackle cross language text classification by inducing cross-lingual predictive data representations with both labeled and unlabeled documents from the two language domains. Specifically, we propose a cross-lingual log-bilinear document model to learn distributed representations of words, which can capture both the semantic sim-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1465–1475,
Seattle, Washington, USA, 18-21 October 2013.

ilarities of words across languages and the predictive information with respect to the target classification task. We conduct the representation learning by maximizing the log-likelihood of all documents from both language domains under the cross-lingual log-bilinear document model and minimizing the prediction log-losses of labeled documents. We formulate the learning problem as a joint non-convex minimization problem and solve it using a local optimization algorithm. To evaluate the effectiveness of the proposed approach, we conduct experiments on the task of cross language sentiment classification of Amazon product reviews. The empirical results show the proposed approach is very effective for cross-lingual document classification, and outperforms other comparison methods.

2 Related Work

Much work in the literature proposes to construct cross-lingual representations by using aligned parallel data. Basically, they first employ machine translation tools to translate documents from one language domain to the other one and then induce low dimensional latent representations as interlingual representations (Littman et al., 1998; Vinokourov et al., 2002; Platt et al., 2010; Pan et al., 2011; Guo and Xiao, 2012a). Littman et al. (1998) proposed a cross-language latent semantic indexing method to induce interlingual representations by performing latent semantic indexing over a dual-language document-term matrix, where each dual-language document contains its original words and the corresponding translation text. Vinokourov et al. (2002) proposed a cross-lingual kernel canonical correlation analysis method, which learns two projections (one for each language) by conducting kernel canonical correlation analysis over a paired bilingual corpus and then uses the two projections to project documents from language-specific feature spaces to the shared multilingual semantic feature space. Platt et al. (2010) employed oriented principal component analysis (Diamantaras and Kung, 1996) over concatenated parallel documents, which learns a multilingual projection by simultaneously minimizing the projected distance between parallel documents and maximizing the projected covariance of documents across different languages. Pan et al. (2011) proposed a bi-view non-negative matrix tri-factorization method for cross-lingual sentiment classification on the parallel training and test data. Guo and Xiao (2012a) developed a transductive subspace representation learning method for cross-lingual text classification based on non-negative matrix factorization. Some other works exploited parallel data by using multilingual topic models to extract cross-language latent topics as interlingual representations (Mimno et al., 2009; Ni et al., 2011; Platt et al., 2010; Smet et al., 2011) and using neural probabilistic language modes to learn word embeddings as cross-lingual distributed representations (Klementiev et al., 2012). Most of them were developed by applying the latent Dirichlet allocation (LDA) model (Blei et al., 2003) in a multilingual setting, including the polylingual topic model (Mimno et al., 2009), the bilingual LDA model (Smet et al., 2011), and the multilingual LDA model (Ni et al., 2011). Platt et al. (2010) extended the probabilistic latent semantic analysis (PLSA) model (Hofmann, 1999) and presented two variants of multilingual topic models: the joint PLSA model and the coupled PLSA model. Recently, Klementiev et al. (2012) extended the neural probabilistic language model (Bengio et al., 2000) to induce cross-lingual word distributed representations on a set of word-level aligned parallel sentences. The applicability of these approaches however is limited by the availability of parallel corpus. Translating the whole set of documents to produce parallel corpus is too time-consuming, expensive and even practically impossible for some language pairs. We thus do not evaluate those approaches in our empirical study.

Another group of works propose to use bilingual dictionaries to learn interlingual representations (Gliozzo, 2006; Prettenhofer and Stein, 2010). Gliozzo (2006) first translated each term from one language to the other using a bilingual dictionary and used the translated terms to augment original documents. Then they conducted latent semantic analysis (LSA) over the document-term matrix with concatenated vocabularies to obtain interlingual representations. Prettenhofer and Stein (2010) proposed a cross-language structural correspondence learning (CL-SCL) method to induce language-independent features by using word translation oracles. They first selected a subset of source

language features, which have the highest mutual information with respect to the class labels in the labeled documents from the source language domain, to translate them into the target language domain, and then used these pivot pairs to induce cross-lingual representations by modeling the correlations between pivot features and non-pivot features. Our proposed approach shares a similarity with the CL-SCL method in (Prettenhofer and Stein, 2010) on only requiring a small amount of word translations. But our approach performs representation learning in a semi-supervised manner by directly incorporating discriminative information with respect to the target prediction task, while CL-SCL only exploits labels when selecting pivot features and the structural correspondence learning process is conducted in a fully unsupervised fashion.

Some other bilingual resources, such as multilingual WordNet (Fellbaum, 1998) and universal part-of-speech (POS) tags (Petrov et al., 2012), have also been exploited in the literature for interlingual learning. Gliozzo (2006) proposed to use MultiWordNet to map words from different languages to a common synset-id as language-sharing terms. A similar work was proposed in A.R. et al. (2012), which transformed words from different languages to WordNet synset identifiers as interlingual sense-based representations. However, multilingual WordNet resources are not always available for different language pairs. Recently, Petrenz and Webber (2012) used language-specific POS taggers to tag each word and then mapped those language-specific POS tags to twelve universal POS tags as interlingual features for cross language fine-grained genre classification. This approach requires a POS tagger for each language and it may be adversely affected by the POS tagging accuracy.

3 Semi-Supervised Representation Learning for Cross-Lingual Text Classification

In this section, we introduce a semi-supervised cross-lingual representation learning method and then use it for cross language text classification.

Assume we have ℓ_s labeled and u_s unlabeled documents in the source language domain $\mathcal{S}$ and ℓ_t labeled and u_t unlabeled documents in the target language domain $\mathcal{T}$. We assume all the documents are independent and identically distributed in each language domain, and each document $\mathbf{x}_i$ is represented as a bag of words, $\mathbf{x}_i = \{w_{i1}, w_{i2}, \ldots, w_{iN_i}\}$. We use $(\mathbf{x}_i^\ell, y_i)$ to denote the i-th labeled document and its label, and consider exploiting the labeled documents in the source domain $\mathcal{S}$ for learning classifiers in the target domain $\mathcal{T}$.

To build connections between the two language domains, we first construct a set of critical bilingual word pairs $M = \{(w_i^s, w_j^t)\}_{i=1}^m$, where w_i^s is a critical word in the source language domain, w_j^t is its translation in the target language domain, and m is the number of word pairs. Here being critical means the word should be discriminative for the prediction task and occur frequently in both language domains. Following the work (Prettenhofer and Stein, 2010), we select bilingual word pairs in a heuristic way. First we select a subset of words from the source language domain, which have the highest mutual information with the class labels in labeled source documents. The mutual information is computed based on the empirical distributions of words and labels in the labeled source documents. Then we translate the selected words into the target language using a translation tool to produce word pairs. Finally we produce the M set by eliminating any candidate pair (w^s, w^t), if either w^s occurs less than a predefined threshold value ϕ in all source language documents or w^t occurs less than ϕ in all target language documents. Given the constructed bilingual word pair set M, the words appearing in the source language documents but not in M can be put together to form a source specific vocabulary set $V_s = \{w_1^s, \ldots, w_{v_s}^s\}$. Similarly, the words appearing in the target language documents but not in M can be put together to form a target specific vocabulary set $V_t = \{w_1^t, \ldots, w_{v_t}^t\}$. An overall cross-lingual vocabulary set can then be constructed as $V = V_s \cup V_t \cup M$, which has a total of $v = v_s + v_t + m$ entries. This cross-lingual vocabulary set covers all words appearing in both domains, while mapping each bilingual pair in M into the same entry.

To tackle cross language text classification, we then propose a cross-lingual log-bilinear document model to learn a predictive cross-lingual representation of words, which maps each entry in the vocabulary set V to one row vector in a word embed-

ding matrix $R \in \mathbb{R}^{v \times k}$. Similar to the log-bilinear language model (Mnih and Hinton, 2007) and the log-bilinear document model (Maas et al., 2011), our proposed model learns a dense feature vector for each word to capture semantic similarities between the vocabulary entries. But unlike the previous two models which only work with a monolingual language, our model also captures semantic similarities across different languages. Moreover, we explicitly incorporate the label information into our proposed approach, rendering the induced word embeddings more discriminative to the target prediction task.

3.1 Cross-Lingual Word Embeddings

As mentioned above, we assume a unified embedding matrix R which contains the distributed vector representations of words in the two language domains. However, even in a unified representation space, the distribution of words in the two domains will be different. To capture the distribution divergence of the two domains and facilitate cross-lingual learning, we split the word embedding matrix into three parts: source language specific part $R_s \in \mathbb{R}^{v \times k_s}$, common part $R_c \in \mathbb{R}^{v \times k_c}$ and target language specific part $R_t \in \mathbb{R}^{v \times k_t}$, such that $k = k_s + k_c + k_t$. Intuitively, we assume that source language words contain no target language specific representations and target language words contain no source language specific representations. Thus for words in the two language domains, we retrieve their distributed vector representations from the embedding matrix R using two mapping functions, $\Phi_{\mathcal{S}}$ and $\Phi_{\mathcal{T}}$, one for each language domain. The two mapping functions are defined as

$$\Phi_{\mathcal{S}}(w) = [R_s(w), R_c(w), \mathbf{0}_t]^T \quad (1)$$

$$\Phi_{\mathcal{T}}(w) = [\mathbf{0}_s, R_c(w), R_t(w)]^T \quad (2)$$

where $\mathbf{0}_t$ is a k_t-dimensional row vector of zeros, $\mathbf{0}_s$ is a k_s-dimensional row vector of zeros, $R_s(w)$ denotes the row vector of R_s matrix corresponding to the word w, $R_c(w)$ denotes the row vector of R_c matrix corresponding to the word w, and $R_t(w)$ denotes the row vector of R_t matrix corresponding to the word w. It is easy to see that each pair of words in M will share the same vector from R_c. To encode more information into the common part of representation for better knowledge transfer from the source language domain to the target language domain, we assume $k_c \geq k_s$ and $k_c \geq k_t$. The form of three part feature representations has been exploited in previous work of domain adaptation with heterogeneous feature spaces (Duan et al., 2012). However, their approach simply duplicates the original features as language-specific representations, while we will automatically learn those three part latent representations in our approach.

3.2 Semi-Supervised Cross-Lingual Representation Learning

Given the word representation scheme above, we conduct cross-lingual representation learning by simultaneously maximizing the log-likelihood of all documents and the conditional likelihood of labeled documents from the two language domains

$$\max_{\theta} \sum_{\mathcal{L} \in \{\mathcal{S}, \mathcal{T}\}} \sum_{\mathbf{x}_i \in \mathcal{L}} \sum_{j=1}^{N_i} \log P_{\mathcal{L}}(w_{ij}|\theta) + \alpha \sum_{\mathcal{L} \in \{\mathcal{S}, \mathcal{T}\}} \sum_{\mathbf{x}_i^{\ell} \in \mathcal{L}} \log P_{\mathcal{L}}(y_i|\mathbf{x}_i^{\ell}, \theta) \quad (3)$$

where θ denotes the model parameters and α is a trade-off parameter. The first part of the objective function captures the likelihood of the documents being generated with the learned representation R. $P_{\mathcal{L}}(w_{ij}|\theta)$ is the probability of word w_{ij} appearing in the document $\mathbf{x}_i$ from the language domain $\mathcal{L}$, and is defined as

$$P_{\mathcal{L}}(w_{ij}|\theta) = \frac{\exp\left(-E_{\mathcal{L}}(w_{ij}, \theta)\right)}{\sum_{w' \in V} \exp\left(-E_{\mathcal{L}}(w', \theta)\right)} \quad (4)$$

The term $E_{\mathcal{L}}(w_{ij}, \theta)$ is a log-bilinear energy function, defined as

$$E_{\mathcal{L}}(w_{ij}, \theta) = -\mathbf{d}_i^T \Phi_{\mathcal{L}}(w_{ij}) - b_{w_{ij}} \quad (5)$$

where $\mathbf{d}_i$ is a k-dimensional weight vector for document $\mathbf{x}_i$ and $b_{w_{ij}}$ is the bias for word w_{ij}. Below we will use $\mathbf{b}$ to denote a v-dimensional vector containing all words' biases.

The second part of the objective function in (3) takes the label information into account and aims to render the latent word representations more task-predictive. We use a logistic regression model to

compute the conditional probability of the class label given the document with the induced word representations, such that

$$P_{\mathcal{L}}(y_i|\mathbf{x}_i^{\ell},\theta) = \frac{1}{1+\exp\left(-y_i\left(\mathbf{w}^T\Psi_{\mathcal{L}}(\mathbf{x}_i^{\ell})+q\right)\right)} \tag{6}$$

where $\mathbf{w}, q$ are model parameters of the logistic regression model, $\Psi_{\mathcal{L}}(\mathbf{x}_i)$ is the k-dimensional vector representation of the document $\mathbf{x}_i$ in the language domain $\mathcal{L}$. We compute $\Psi_{\mathcal{L}}(\mathbf{x}_i)$ by taking average over all words in the document $\mathbf{x}_i$ such as

$$\Psi_{\mathcal{L}}(\mathbf{x}_i) = \frac{1}{N_i}\sum_{j=1}^{N_i}\Phi_{\mathcal{L}}(w_{ij}) \tag{7}$$

By summing over all descriptions above, we can see that the proposed semi-supervised representation learning has a set of model parameters, $\theta = \{R, \{\mathbf{d}_i\}, \mathbf{b}, \mathbf{w}, q\}$. In order to avoid overfitting, we add regularization terms for the parameters $R, \{\mathbf{d}_i\}$ and $\mathbf{w}$, which leads to the final optimization problem below

$$\begin{aligned}\max_{\theta} & \sum_{\mathcal{L}\in\{\mathcal{S},\mathcal{T}\}}\sum_{\mathbf{x}_i\in\mathcal{L}}\Big(\sum_{j=1}^{N_i}\log P_{\mathcal{L}}(w_{ij}|\theta) - \gamma\|\mathbf{d}_i\|_2^2\Big) \\ & + \alpha\sum_{\mathcal{L}\in\{\mathcal{S},\mathcal{T}\}}\sum_{\mathbf{x}_i^{\ell}\in\mathcal{L}}\log P_{\mathcal{L}}(y_i|\mathbf{x}_i^{\ell},\theta) \\ & - \beta\|R\|_F^2 - \eta\|\mathbf{w}\|_2^2 \end{aligned} \tag{8}$$

where β, γ, η are trade-off parameters, $\|\cdot\|_F$ denote the Frobenius norm and $\|\cdot\|_2$ denote the Euclidean-norm. This objective function is not jointly convex in all model parameters. We develop a gradient-based iterative optimization procedure to seek a local optimal solution. We first randomly initialize the model parameters $\{\mathbf{d}_i\}, R, \mathbf{w}$ and set $\mathbf{b}$ and q to zeros. Then we iteratively make gradient-based updates over the model parameters until reach a local optimal solution.

3.3 Cross-Lingual Document Classification

After solving (8), we obtain a word embedding matrix R. The distributed vector representation of any given document can then be computed using Eq. (7) based on Eq. (1) or Eq. (2). Under the distributed vector representations of the documents in both language domains, we perform cross-lingual document classification by training a supervised classification model using labeled data from both language domains and then applying it to classify test documents in the target language domain .

4 Experiments

We empirically evaluate the proposed approach using the cross language sentiment classification tasks of Amazon product reviews in four languages. In this section, we report our experimental results.

4.1 Dataset

We used the multilingual sentiment classification dataset[1] provided by Prettenhofer and Stein (2010), which contains Amazon product reviews in four different languages, English (E), French (F), German (G) and Japanese (J). The English product reviews were sampled from previous cross-domain sentiment classification datasets (Blitzer et al., 2007), while the other three language product reviews were crawled from Amazon by the authors in November 2009. In the dataset, each language contains three categories of product reviews, Books (B), DVD (D) and Music (M). Each language-category pair contains a balanced training set and test set, each of which consists of 1000 positive reviews and 1000 negative reviews. Each review is represented as a unigram bag-of-word feature vector with term-frequency values. Following the work (Prettenhofer and Stein, 2010), we used the original English reviews as the source language while treating the other three languages as target languages. Thus, we construct nine cross language sentiment classification tasks (GB, GD, GM, FB, FD, FM, JB, JD, JM), one for each target language-category pair. For example, the task *GB* means that the target language is *German* and the training and test data are samples from *Books* reviews.

4.2 Approaches

We compare our proposed semi-supervised cross-lingual representation learning (**CL-RL**) approach to the following approaches for cross-lingual document classification.

[1] http://www.webis.de/research/corpora/

Table 1: Average classification accuracies and standard deviations for the 9 cross-lingual sentiment classification tasks. The bold format indicates that the difference between the results of *CL-RL* and *MT* is significant with $p < 0.05$ under a McNemar paired test for labeling disagreements.

Task	TB	CL-Dict	CLD-LSA	CL-SCL	MT	CL-RL

- **TB:** This is a target baseline method, which trains a supervised monolingual classifier on the labeled training data from the target language domain without representation learning.
- **CL-Dict:** This is a simple baseline comparison method, which uses the bilingual word pairs directly to align features from different language domains into a unified feature dictionary and then trains a supervised classifier on this aligned feature space with labeled training data from both language domains.
- **CLD-LSA:** This is the cross-lingual representation learning method developed in (Gliozzo, 2006), which first translates each document from one language into the other language via a bilingual dictionary to produce augmenting features, and then performs latent semantic analysis (LSA) over the augmented bilingual document-term matrix.
- **CL-SCL:** This is the cross language structural correspondence learning method developed in (Prettenhofer and Stein, 2010).
- **MT:** This is a machine translation based comparison method, which first uses an existing machine translation tool (google translation) to translate the target language documents into the source language and then trains a monolingual classifier with labeled training data from both domains in the source language.

In all experiments, we used a linear support vector machine (SVM) for sentiment classification. For implementation, we used the liblinear package (Fan et al., 2008) with all of its default parameters. For the *CL-SCL* method, we used the same parameter setting as suggested in the paper (Prettenhofer and Stein, 2010): the number of pivot features is set as 450, the threshold value for selecting pivot features is 30, and the reduced dimensionality after singular value decomposition is 100. For the *CLD-LSA* method, we set the dimensionality of latent representation as 1000. Similarly, for our proposed approach, we built the cross-lingual vocabulary M by setting $m = 450$ and $\phi = 30$. For our representation learning, we set $\alpha = 1$, $\beta = \gamma = \eta = 1e^{-4}$, and set k_s, k_c, k_t to be 25, 50, 25, respectively. The values of α, β, γ and η are selected using the first cross language classification task GB. We selected the α value from the set $\{0.01, 0.1, 1, 10, 100\}$ and selected β, γ, η values from the set $\{1e^{-5}, 1e^{-4}, 1e^{-3}, 1e^{-2}, 1e^{-5}\}$ by repeating the experiment three times with random data partitions and choosing the parameter values that led to the best average classification accuracy.

4.3 Classification Accuracy

For each of the nine cross language sentiment classification tasks with different target language-category pairs, we used the training set in the source language domain (English) as labeled data while treating the test set in the source language domain as unlabeled.

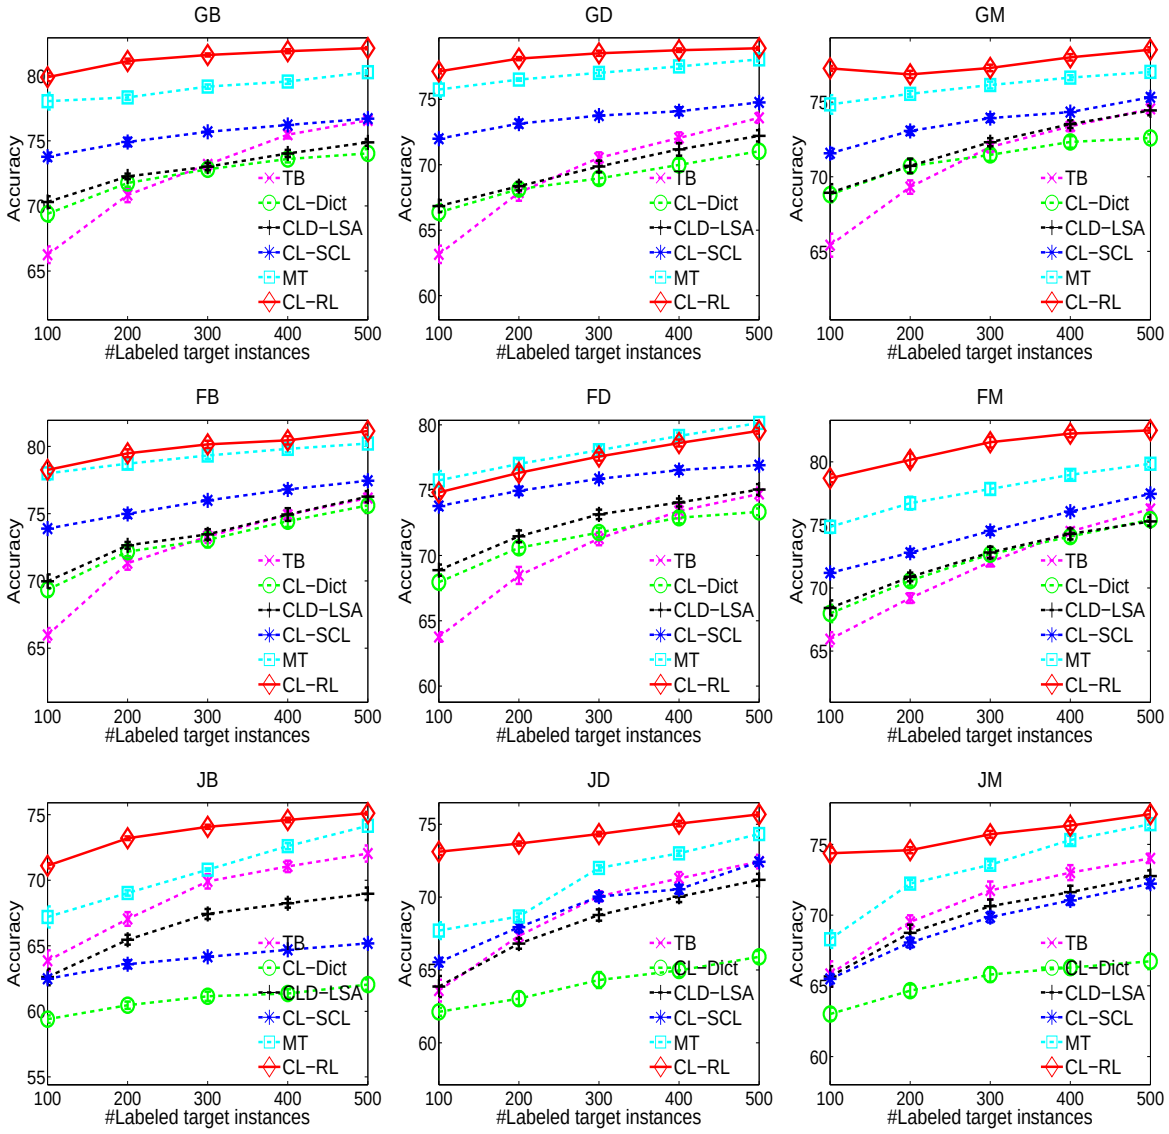

Figure 1: Average classification accuracies and standard deviations for 10 runs with respect to different numbers of labeled training documents in the target language domain.

For target language domain, we used the test set as test data while randomly selecting 100 documents from the training set as labeled data and treating the rest as unlabeled data. Thus, for each task, we have 2000 labeled documents and 2000 unlabeled documents from the source language domain, and 100 labeled and 1900 unlabeled documents from the target language domain for training. We have 2000 test documents from the target language domain as testing data. In each experiment, a classifier is produced by each approach with the training data and tested on the testing data. We repeated each experiment 10 times with different random selections of 100 labeled training documents from the target language domain. The average classification accuracies and standard deviations are reported in Table 1.

From Table 1, we can see that the proposed semi-supervised cross-lingual representation learning approach, CL-RL, clearly outperforms all other comparison methods on eight out of the nine tasks. The target baseline *TB* performs poorly on all the nine tasks, which suggests that 100 labeled instances from the target language is far from enough to obtain an accurate sentiment classifier in the target lan-

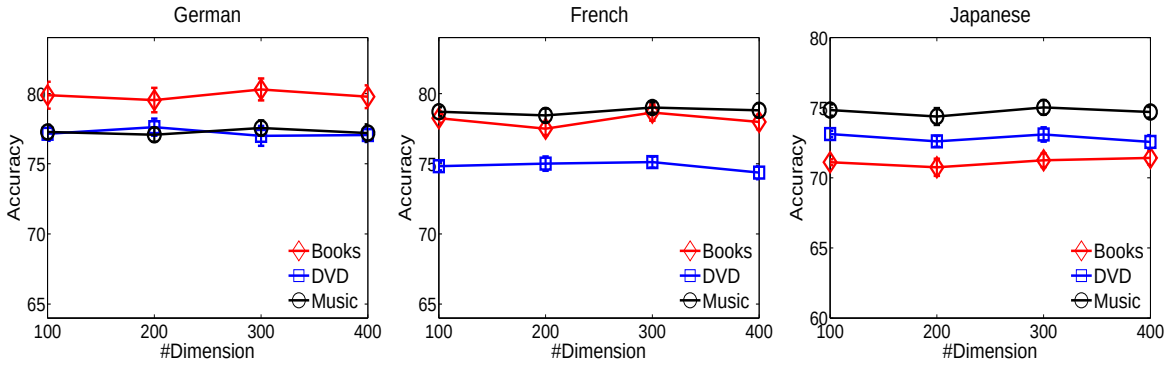

Figure 2: Average classification accuracy and standard deviation results for the proposed approach over 10 runs with respect to different dimensionality for the induced cross-lingual representations.

guage domain. By exploiting the large amount of labeled training data from the source language domain, even the simple cross-lingual adaptation approach, *CL-Dict*, produces effective improvements over *TB*. However, its performance is not consistent across the nine tasks. It has inferior performance than *TB* on the three tasks of adapting English to the Japanese language domain. This suggests the simple bilingual word-pair based feature space unification method is far from ideal for providing effective cross-lingual representations, especially when two languages (English, Japanese) are very different. With a better designed representation learning, *CLD-LSA* outperforms *CL-Dict* on all the nine tasks, but the improvements are very small on some tasks (e.g., GM). *CL-SCL* not only outperforms *CL-Dict* on all tasks, but also performs much better than *CLD-LSA* on most tasks. Its performance nevertheless is inferior to the method of *MT*. Though *MT* can greatly increase the test accuracies comparing to the other four methods, *TB*, *CL-Dict*, *CLD-LSA*, and *CL-SCL*, the benefit is obtained at the cost of whole document translations. In contrast, our proposed approach does not require whole document translations, but relies on the same simple word-pair translations used in *CL-Dict*. It however consistently and significantly outperforms *TB*, *CL-Dict*, *CLD-LSA*, and *CL-SCL* on all tasks, and outperforms *MT* on eight out of the nine tasks.

We also conduct significance tests for our proposed approach and *MT* using a McNemar paired test for labeling disagreements (Gillick and Cox, 1989). The results in bold format indicate that they are significant with $p < 0.05$. All these results demonstrate the efficacy of our cross-lingual representation learning method.

4.4 Classification Accuracy vs the Number of Labeled Target Documents

Next, we investigated the performance of the six approaches by varying the number of labeled training documents from the target language domain. We maintained the same experimental setting as before, but investigated a range of different values, $\ell_t = \{100, 200, 300, 400, 500\}$, as the number of labeled training documents from the target language domain. In each experiment, for a given value ℓ_t, we randomly selected ℓ_t documents from the training set of the target language domain as labeled data and used the rest as unlabeled data. We still performed prediction on the same 2000 test documents in the target language domain. We repeated each experiment 10 times based on different random selections of the labeled training data from the target language domain. The average classification accuracies and standard deviations across different ℓ_t values for all comparison methods on all the nine tasks are plotted in Figure 1.

We can see when the number of labeled target documents is small, *TB* performs poorly, especially for the first six tasks (GB, GD, GM, FB, FD, FM). By increasing the size of labeled target training data, *TB* can greatly increase its prediction accuracies and even outperform the *CL-Dict* method. The simple *CL-Dict* method has inconsistent performance across the nine tasks. Its performance is better than

TB when the labeled training data in the target language domain is very limited and is poor than *TB* when the labeled target data reaches 300 for the six tasks using German and French as target languages. Moreover, when adapting a system from English to a much more different target language (Japanese), *CL-Dict* produces much lower accuracies for all the three tasks comparing with *TB*. These results show that *CL-Dict* has very limited capacity on transferring labeled information from a related source language domain. Similar performance is observed for *CLD-LSA*. With a more sophisticated representation learning, the *CL-SCL* method consistently outperforms *CL-Dict*. However, it produces inferior performance than *CLD-LSA* on the tasks of *JB* and *JM*. By using more translation resources, the *MT* method outperforms *TB*, *CL-Dict*, *CLD-LSA*, *CL-SCL* in all the nine tasks across almost all scenarios. Our proposed method *CL-RL* significantly outperforms all the other five comparison methods across all experiments except on the task of FD, where *MT* produces similar performance. Moreover, it is especially important to notice that *CL-RL* achieves high test accuracies even when the number of labeled target instances is small. This is important for transferring knowledge from a source language to reduce the labeling effort in the target language.

4.5 Sensitivity Analysis

We also investigated the sensitivity of the proposed approach over the dimensionality of the induced cross-lingual representations. We used the same experimental setting as before, and conducted experiments with a set of different dimensionality values, $k = \{100, 200, 300, 400\}$. For each value k, we set $k_s = 0.25k, k_c = 0.5k, k_t = 0.25k$. We repeated each experiment for 10 times based on different random selections of labeled target training data and plotted the average prediction accuracies and standard deviations in Figure 2 for all the nine cross-lingual sentiment classification tasks. We can see the proposed approach produces stable accuracy results across the range of different k values. This suggests the proposed approach is not very sensitive to the dimensionality of the cross-lingual embedding features within the considered range of values, and with a small dimensionality of 100, the induced representation can already perform very well.

4.6 Cross-Lingual Word Representations

Finally, we used the first task *GB*, which adapts the *Books* reviews from English to German, to gain intuitive understandings over the learned cross-lingual word representations. Given an English word as seed word, we find its five closest neighboring English words and German words according to the Euclidean distances calculated in the induced cross-lingual representation space. We present a few results in Table 2. From Table 2, we can see that the retrieved words in both language domains are semantically close to the seed words, which indicates that our proposed method can capture semantic similarities of words not only in a monolingual setting but also in a multilingual setting.

5 Conclusion

In this paper, we proposed a semi-supervised cross-lingual representation learning approach to address cross-lingual text classification. The distributed word representation induced by the proposed approach can capture semantic similarities of words across languages while maintaining predictive information with respect to the target classification tasks. To evaluate the proposed approach, we conducted experiments on nine cross language sentiment classification tasks constructed from the Amazon product reviews in four languages, comparing to a number of comparison methods. The empirical results showed that the proposed approach can produce effective cross-lingual adaptation performance and significantly outperform other comparison methods.

Using crowdsourcing to get representations based on regular expressions

Abstract

Often the bottleneck in document classification is finding good representations that zoom in on the most important aspects of the documents. Most research uses n-gram representations, but relevant features often occur discontinuously, e.g., *not... good* in sentiment analysis. In this paper we present experiments getting experts to provide regular expressions, as well as crowdsourced annotation tasks from which regular expressions can be derived. Somewhat surprisingly, it turns out that these crowdsourced feature combinations outperform automatic feature combination methods, as well as expert features, by a very large margin and reduce error by 24-41% over n-gram representations.

1 Introduction

Finding good representations of classification problems is often glossed over in the literature. Several authors have emphasized the need to pay more attention to finding such representations (Wagstaff, 2012; Domingos, 2012), but in document classification most research still uses n-gram representations.

This paper considers two document classification problems where such representations seem inadequate. The problems are answer scoring (Burstein et al., 1998), on data from stackoverflow.com, and multi-attribute sentiment analysis (McAuley et al., 2012). We argue that in order to adequately represent such problems we need *discontinuous* features, i.e., regular expressions.

The problem with using regular expressions as features is of course that even with a finite vocabulary we can generate infinitely many regular expressions that match our documents. We suggest to use expert knowledge or crowdsourcing in the loop. In particular we present experiments where standard representations are augmented with features from a few hours of manual work, by machine learning experts or by turkers.

Somewhat surprisingly, we find that features derived from crowdsourced annotation tasks lead to the best results across the three datasets. While crowdsourcing of annotation tasks has become increasing popular in NLP, this is, to the best of our knowledge, the first attempt to crowdsource the problem of finding good representations.

1.1 Related work

Musat et al. (2012) design a collaborative two-player game for sentiment annotation and collecting a sentiment lexicon. One player guesses the sentiment of a text and picks a word from it that is representative of its sentiment. The other player also provides a guess observing only this word. If the two guesses agree, both players get a point. The idea of gamifying the problem of finding good representations goes beyond crowdsourcing, but is not considered here. Boyd-Graber et al. (2012) crowdsource the feature weighting problem, but using standard representations. The work most similar to ours is probably Tamuz et al. (2011), who learn a 'crowd kernel' by asking annotators to rate examples by similarity, providing an embedding that promotes feature combinations deemed relative when measuring similarity.

Table 1: Characteristics of the $n \times m$ data sets

2 Experiments

Data The three datasets used in our experiments come from two sources, namely stackoverflow.com and ratebeer.com. The two beer review datasets (TASTE and APPEARANCE) are described in McAuley et al. (2012) and available for download.[1] Each input example is an unstructured review text, and the associated label is the score assigned to taste or appearance by the reviewer. We randomly sample about 152k data points, as well as 500 examples for experiments with experts and turks.

We extracted the STACKOVERFLOW dataset from a publicly available data dump,[2], and we briefly describe our sampling process here. We select pairs of answers, where one is ranked higher than the other by stackoverflow.com users. Obviously the answers submitted first have a better chance of being ranked highly, so we also require that the highest ranked answer was submitted last. From this set of answer pairs, we randomly sample 97,519 pairs, as well as 500 examples for our experiments with experts and turks.

Our experiments are classification experiments using the same learning algorithm in all experiments, namely L_1-regularized logistic regression. We don't set any parameters The only differences between our systems are in the feature sets. Results are from 5-fold cross-validation. The four feature sets are described below: *BoW*, *HI*, *Exp* and *AMT*.

For motivating using regular expressions, consider the following sentence from a review of John Harvard's Grand Cru:

(1) Could have been more flavorful.

The only word carrying direct sentiment in this sentence is *flavorful*, which is positive, but the sentence is a negative evaluation of the Grand Cru's taste. The trigram *been more flavorful* seems negative at first, but in the context of negation or in a comparative, it can become positive again. However, note that this trigram may occur discontinuously, e.g., in *been less watery and more flavorful*. In order to match such occurrences, we need simple regular expressions, e.g.,:

```
been.*more.*flavorful
```

This is exactly the kind of regular expressions we asked experts to submit, and that we derived from the crowdsourced annotation tasks. Note that the sentence says nothing about the beer's appearance, so this feature is only relevant in TASTE, not in APPEARANCE.

BoW **and** *BoW+HI* Our most simple baseline approach is a bag-of-words model of unigram features (*BoW*). We lower-case our data, but leave in stop words. We also introduce a semantically enriched unigram model *(BoW)+HI*, where in addition to representing what words occur in a text, we also represent what Harvard Inquirer (HI)[3] word classes occur in it. The HI classes are used to generate features from the crowdsourced annotation tasks, so the semantically enriched unigram model is an important baseline in our experiments below.

BoW+Exp In order to collect regular expressions from experts, we set up a web interface for querying held-out portions of the datasets with regular expressions that reports how occurrences of the submitted regular expressions correlate with class. We used the Python `re` syntax for regular expressions after augmenting word forms with POS and semantic classes from the HI. Few of the experts made use of the POS tags, but many regular expressions included references to HI classes.

[1] http://snap.stanford.edu/data/web-RateBeer.html

[2] http://www.clearbits.net/torrents/2076-aug-2012

[3] http://www.wjh.harvard.edu/ inquirer/homecat.htm

Regular expressions submitted by participants were visible to other participants during the experiment, and participants were allowed to work together. Participants had 15 minutes to familiarize themselves with the syntax used in the experiments. Each query was executed in 2-30 seconds.

Seven researchers and graduate students spent five effective hours querying the datasets with regular expressions. In particular, they spent three hours on the Stack Exchange dataset, and one hour on each of the two RateBeer datasets. One had to leave an hour early. So, in total, we spent 20 person hours on Stack Exchange, and seven person hours on each of the RateBeer datasets. In the five hours, we collected 1,156 regular expressions for the STACKOVERFLOW dataset, and about 650 regular expressions for each of the two RateBeer datasets. *Exp* refers to these sets of regular expressions. In our experiments below we concatenate these with the *BoW* features to form *BoW+Exp*.

BoW+AMT For each dataset, we also had 500 held-out examples annotated by three turkers each, using Amazon Mechanical Turk,[4] obtaining 1,500 HITs for each dataset. The annotators were presented with each text, a review or an answer, twice: once as running text, once word-by-word with bullets to tick off words. The annotators were instructed to tick off words or phrases that they found predictive of the text's sentiment or answer quality. They were not informed about the class of the text. We chose this annotation task, because it is relatively easy for annotators to mark spans of text with a particular attribute. This set-up has been used in other applications, including NER (Finin et al., 2010) and error detection (Dahlmeier et al., 2013). The annotators were constrained to tick off at least three words, including one closed class item (closed class items were colored differently). Finally, we only used annotators with a track record of providing high-quality annotations in previous tasks. It was clear from the average time spent by annotators that annotating STACKOVERFLOW was harder than annotating the Ratebeer datasets. The average time spent on a Ratebeer HIT was 44s, while for STACKOVERFLOW it was 3m:8s. The mean number of words ticked off was between 5.6 and 7, with more words ticked off in STACKOVERFLOW. The maximum number of words ticked off by an annotator was 41. We spent $292.5 on the annotations, including a trial round. This was supposed to match, roughly, the cost of the experts consulted for *BoW+Exp*.

APPEARANCE	0.758	0.760	0.761	**0.859**

Table 2: Results using all features

The features generated from the annotations were constructed as follows: We use a sliding window of size 3 to extract trigrams over the possibly discontinuous words ticked off by the annotators. These trigrams were converted into regular expressions by placing Kleene stars between the words. This gives us a manually selected subset of skip trigrams. For each skip trigram, we add copies with one or more words replaced by one of their HI classes.

Feature combinations This subsection introduces some harder baselines for our experiments, considered in Experiment #2. The simplest possible way of combining unigram features is by considering n-gram models. An n-gram extracts features from a sliding window (of size n) over the text. We call this model *BoW*$(N = n)$. Our *BoW*$(N = 1)$ model takes word forms as features, and there are obviously more advanced ways of automatically combining such features.

Kernel representations We experimented with applying an approximate feature map for the additive χ^2-kernel. We used two sample steps, resulting in $4N + 1$ features. See Vedaldi and Zimmerman (2011) for details.

Deep features We also ran denoising autoencoders (Pascal et al., 2008), previously applied to a wide range of NLP tasks (Ranganath et al., 2009; Socher et al., 2011; Chen et al., 2012), with $2N$ nodes in the middle layer to obtain a deep representation of our datasets from χ^2-*BoW* input. The network was trained for 15 epochs. We set the drop-out rate to 0.0 and 0.3.

Summary of feature sets The feature sets – *BoW*,

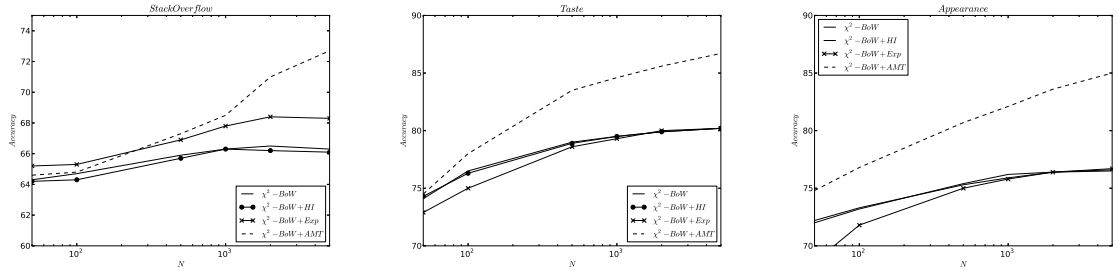

Figure 1: Results selecting N features using χ^2 (left to right): STACKOVERFLOW, TASTE, and APPEARANCE. The x-axis is logarithmic scale.

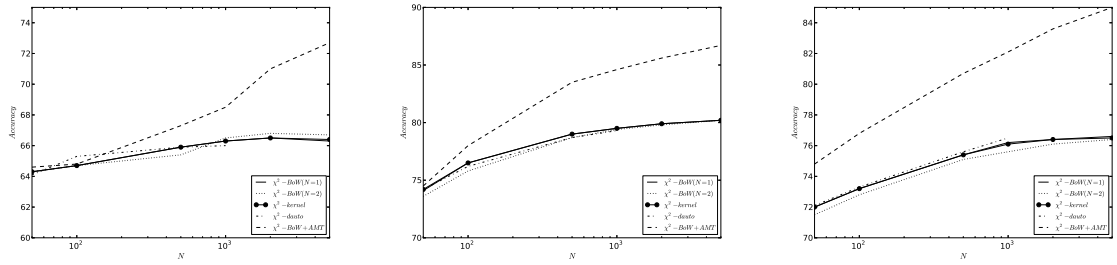

Figure 2: Results using different feature combination techniques (left to right): STACKOVERFLOW, TASTE, and APPEARANCE. The x-axis is logarithmic scale.

Exp and *AMT* – are very different. Their characteristics are presented in Table 1. $P(1)$ is the class distribution, e.g., the prior probability of positive class. n is the number of data points, m the number of features. Finally, μ_x is the average density of data points. One observation is of course that the expert feature set *Exp* is much smaller than *BoW* and *AMT*, but note also that the expert features fire about 150 times more often on average than the BoW features. *HI* is only a small set of additional features.

3 Results

Experiment #1: *BoW* **vs.** *Exp* **and** *AMT* We present results using all features, as well as results obtained after selecting k features as ranked by a simple χ^2 test. The results using all collected features are presented in Table 2. The error reduction on STACKOVERFLOW when adding crowdsourced features to our baseline model (*BoW+AMT*), is 24.3%. On TASTE, it is 34.2%. On APPEARANCE, it is 41.0%.

The *BoW+AMT* feature set is bigger than those of the other models. We therefore report results using the top-k features as ranked by a simple χ^2 test. The result curves are presented in the three plots in Fig. 1. With +500 features, *BoW+AMT* outperforms the other models by a large margin.

Experiment #2: *AMT* **vs. more baselines** The *BoW* baseline uses a standard representation that, while widely used, is usually thought of as a weak baseline. *BoW+HIT* did not provide a stronger baseline. We also show that bigram features, kernel-based decomposition and deep features do not provide much stronger baselines either. The result curves are presented in the three plots in Fig. 2. *BoW+AMT* is still significantly better than all other models with +500 features. Since autoencoders are consistently worse than denoising autoencoders (drop-out 0.3), we only plot denoising autoencoders.

4 Conclusion

We presented a new method for deriving feature representations from crowdsourced annotation tasks and showed how it leads to 24%-41% error reductions on answer scoring and multi-aspect sentiment analysis problems. We saw no significant improvements using features contributed by experts, kernel representations or learned deep representations.

Overcoming the Lack of Parallel Data in Sentence Compression

Abstract

A major challenge in supervised sentence compression is making use of rich feature representations because of very scarce parallel data. We address this problem and present a method to automatically build a compression corpus with hundreds of thousands of instances on which deletion-based algorithms can be trained. In our corpus, the syntactic trees of the compressions are subtrees of their uncompressed counterparts, and hence supervised systems which require a structural alignment between the input and output can be successfully trained. We also extend an existing unsupervised compression method with a learning module. The new system uses structured prediction to learn from lexical, syntactic and other features. An evaluation with human raters shows that the presented data harvesting method indeed produces a parallel corpus of high quality. Also, the supervised system trained on this corpus gets high scores both from human raters and in an automatic evaluation setting, significantly outperforming a strong baseline.

1 Introduction and related work

Sentence compression is a paraphrasing task where the goal is to generate sentences shorter than given while preserving the essential content. A robust compression system would be useful for mobile devices as well as a module in an extractive summarization system (Mani, 2001). Although a compression may differ lexically and structurally from the source sentence, to date most systems are extractive and proceed by deleting words from the input (Knight & Marcu, 2000; Dorr et al., 2003; Turner & Charniak, 2005; Clarke & Lapata, 2008; Berg-Kirkpatrick et al., 2011, inter alia). To decide which words, dependencies or phrases can be dropped, (i) rule-based approaches (Grefenstette, 1998; Jing & McKeown, 2000; Dorr et al., 2003; Zajic et al., 2007), (ii) supervised models trained on parallel data (Knight & Marcu, 2000; Turner & Charniak, 2005; McDonald, 2006; Gillick & Favre, 2009; Galanis & Androutsopoulos, 2010, inter alia) and (iii) unsupervised methods which make use of statistics collected from non-parallel data (Hori & Furui, 2004; Zajic et al., 2007; Clarke & Lapata, 2008; Filippova & Strube, 2008) have been investigated. Since it is infeasible to manually devise a set of accurate deletion rules with high coverage, recent research has been devoted to developing statistical methods and possibly augmenting them with a few linguistic rules to improve output readability (Clarke & Lapata, 2008; Nomoto, 2009).

Supervised models. A major problem for supervised deletion-based systems is very limited amount of parallel data. Many approaches make use of a small portion of the Ziff-Davis corpus which has about 1K sentence-compression pairs[1]. Other main sources of training data are the two manually crafted compression corpora from the University of Edinburgh ("written" and "spoken", each approx. 1.4K pairs). Galanis & Androutsopoulos (2011) attempt at getting more parallel data by applying a deletion-based compressor together with an automatic para-

[1]The method of Galley & McKeown (2007) could benefit from a larger number of sentences.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1481–1491,
Seattle, Washington, USA, 18-21 October 2013.

phraser and generating multiple alternative compressions. To our knowledge, this extended data set has not yet been used for successful training of compression systems.

Scarce parallel data makes it hard to go beyond a small set of features and explore lexicalization. For example, Knight & Marcu (2000) only induce non-lexicalized CFG rules, many of which occurred only once in the training data. The features of McDonald (2006) are formulated exclusively in terms of syntactic categories. Berg-Kirkpatrick et al. (2011) have as few as 13 features to decide whether a constituent can be dropped. Galanis & Androutsopoulos (2010) use many features when deciding which branches of the input dependency tree can be pruned but require a reranker to select most fluent compressions from a pool of candidates generated in the pruning phase, many of which are ungrammatical.

Even further data limitations exist for the algorithms which operate on syntactic trees and reformulate the compression task as a tree pruning one (Nomoto, 2008; Filippova & Strube, 2008; Cohn & Lapata, 2009; Galanis & Androutsopoulos, 2010, inter alia). These methods are sensitive to alignment errors, their performance degrades if the syntactic structure of the compression is very different from that of the input. For example, see Nomoto's 2009 analysis of the poor performance of the T3 system of Cohn & Lapata (2009) when retrained on a corpus of loosely similar RSS feeds and news.

Unsupervised models. Few approaches require no training data at all. The model of Hori & Furui (2004) combines scores estimated from monolingual corpora to generate compressions of transcribed speech. Adopting an integer linear programming (ILP) framework, Clarke & Lapata (2008) use hand-crafted syntactic constraints and an ngram language model, trained on uncompressed sentences, to find best compressions. The model of Filippova & Strube (2008) also uses ILP but the problem is formulated over dependencies and not ngrams. Conditional probabilities and word counts collected from a large treebank are combined in an ad hoc manner to assess grammatical importance and informativeness of dependencies. Similarly, Woodsend & Lapata (2010) formulate an ILP problem to generate news story highlights using precomputed scores. Again, an ad hoc combination of the scores learned independently of the task is used in the objective function.

Contributions of this paper. Our work is motivated by the obvious need for a large parallel corpus of sentences and compressions on which extractive systems can be trained. Furthermore, we want the compressions in the corpus to be structurally very close to the input. Ideally, in every pair, the compression should correspond to a subtree of the input. To this end, our contributions are three-fold:

- We describe an automatic procedure of constructing a parallel corpus of 250,000 sentence-compression pairs such that the dependency tree of the compression is a subtree of the source tree. An evaluation with human raters demonstrates high quality of the parallel data in terms of readability and informativeness.

- We successfully apply the acquired data to train a novel supervised compression system which produces readable and informative compressions without employing a separate reranker. In particular, we start with the unsupervised method of Filippova & Strube (2008) and replace the ad hoc edge weighting with a linear function over a rich feature representation. The parameter vector is learned from our corpus specifically for the compression task using structured prediction (Collins, 2002). The new system significantly outperforms the baseline and hence provides further evidence for the utility of the parallel data.

- We demonstrate that sparse lexical features are very useful for sentence compression, and that a large parallel corpus is a requirement for applying them successfully.

The compression framework we adopt and the unsupervised baseline are introduced in Section 2, the training algorithm for learning edge weights from parallel data is described in Section 3. In Section 4 we explain how to obtain the data and present an evaluation of its quality. In Section 5 we compare the baseline with our system and report the results of an experiment with humans as well as the results of an automatic evaluation.

2 Framework and baseline

We adopt the unsupervised compression framework of Filippova & Strube (2008) as our baseline and extend it to a supervised structured prediction problem. In the experiments reported by Filippova & Strube (2008), the system was evaluated on the Edinburgh corpora. It achieved an F-score (Riezler et al., 2003) higher than reported by other systems on the same data under an aggressive compression rate and thus presents a competitive baseline.

Tree pruning as optimization. In this framework, compressions are obtained by deleting edges of the source dependency structure so that (1) the retained edges form a valid syntactic tree, and (2) their total edge weight is maximized. The objective function is defined over set $X = \{x_e, e \in E\}$ of binary variables, corresponding to the set E of the source edges, subject to the structural and length constraints,

$$f(X) = \sum_{e \in E} x_e \times w(e) \quad (1)$$

Here, $w(e)$ denotes the weight of edge e. This constrained optimization problem is solved under the tree structure and length constraints using ILP. If x_e is resolved to 1, the respective edge is retained, otherwise it is deleted. The tree structure constraints enforce at most one parent for every node and structure connectivity (i.e., no disconnected subtrees). Given that $length(node(e))$ denotes the length of the node to which edge e points and α is the maximum permitted length for the compression, the length constraint is simply

$$\sum_{e \in E} x_e \times length(node(e)) \leq \alpha \quad (2)$$

Word limit is used in the original paper, whereas we use character length which is more appropriate for system comparisons (Napoles et al., 2011). If uniform weights are used in Eq. (1), the optimal solution would correspond to a subtree covering as many edges as possible while keeping the compression length under given limit.

The solution to the surface realization problem (Belz et al., 2011) is standard: the words in the compression subtree are put in the same order they are found in the source.

Due to space limitations, we refer the reader to (Filippova & Strube, 2008) for a detailed description on the method. Essential for the present discussion is that source dependency trees are transformed to dependency graphs in that (1) auxiliary, determiner, preposition, negation and possessive nodes are collapsed with their heads; (2) prepositions replace labels on the edges to their arguments; (3) the dummy root node is connected with every inflected verb. Figures 1(a)-1(b) illustrate most of the transformations. The transformations are deterministic and reversible, they can be implemented in a single top-down tree traversal[2].

The set E of edges in Eq. (1) is thus the set of edges of the *transformed dependency graph*, like in Fig. 1(b). A benefit of the transformations is that function words and negation appear in the compression if and only if their head words are present. Hence no separate constraints are required to ensure that negation or a determiner is preserved. The dummy root node makes constraint formulation easier and also allows for the generation of compressions from any finite clause of the source.

The described pruning optimization framework is used both for the unsupervised baseline and for our supervised system. The difference between the baseline and our system is in how edge weights, $w(e)$'s in Eq. (1), are instantiated.

Baseline edge weights. The precomputed edge weights reflect syntactic importance as well as informativeness of the nodes they point to. Given edge e from head node h to node n, the edge weight is the product of the syntactic and the informativeness weights,

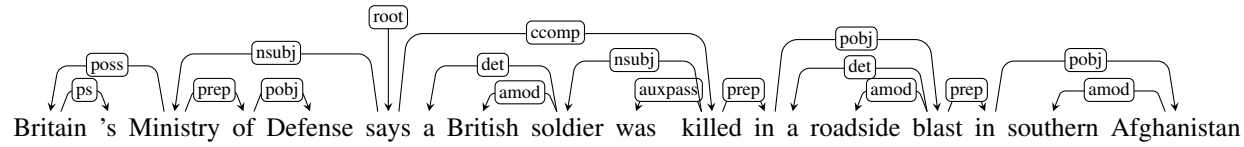
$$w(e) = w_{\text{synt}}(e) \times w_{\text{info}}(e) \quad (3)$$

The syntactic weight is defined as

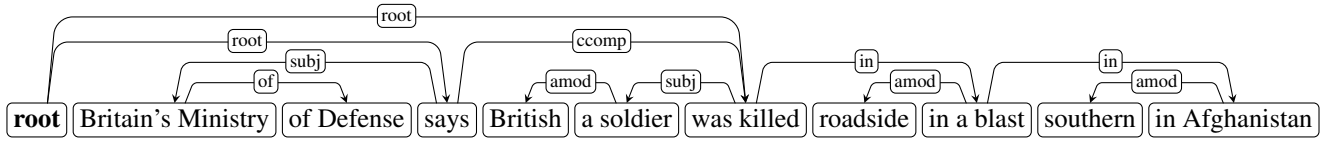
$$w_{\text{synt}}(e) = P(label(e)|lemma(h)) \quad (4)$$

For example, verb *kill* may have multiple arguments realized with dependency labels *subj*, *dobj*, *in*, etc. However, these argument labels are not equally likely, e.g., $P(\textit{subj}|\textit{kill}) > P(\textit{in}|\textit{kill})$. When forced to prune an edge, the system would prefer to keep

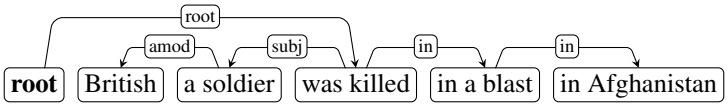
[2] Some of the transformations are comparable to what is implemented in the Stanford parser (de Marneffe et al., 2006).



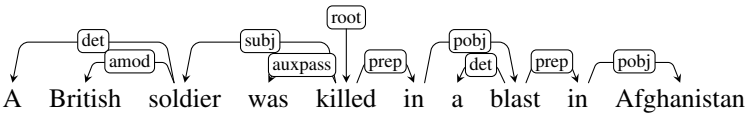
(a) Source dependency tree



(b) Transformed graph



(c) Tree of extracted headline *A British soldier was killed in a blast in Afghanistan*



(d) Tree of extracted headline with transformations undone

Figure 1: Source, transformed and extracted trees given headline *British soldier killed in Afghanistan*

the subject edge over the preposition-in edge since it contributes more weight to the objective function.

The informativeness score is inspired by Woodsend & Lapata (2012) and is defined as

$$w_{\text{info}}(e) = \frac{P_{\text{headline}}(lemma(n))}{P_{\text{article}}(lemma(n))} \quad (5)$$

This weight tells us how likely it is that a word from an article appears in the headline. For example, given two edges one of which points to verb *say* and another one to verb *kill*, the latter would be preferred over the former because *kill* is more "headliny" than *say*. When collecting counts for the syntactic and informativeness scores, we used 9M news articles crawled from the Internet, much more than Filippova & Strube (2008). As a result our estimates are probably more accurate than theirs.

Although both w_{synt} and w_{info} have a meaningful interpretation, there is no guarantee that product is the best way to combine the two when assigning edge weights. Also, it is unclear how to integrate other signals, such as distance to the root, node length or information about the siblings, which presumably all play a role in determining the overall edge importance.

3 Learning edge weights

Our supervised system differs from the unsupervised baseline in that instead of relying on precomputed scores, we define edge weight $w(e)$ in Eq. (1) with a linear function over a feature representation,

$$w(e) = \mathbf{w} \cdot \mathbf{f}(e) \quad (6)$$

Here $\mathbf{f}(e)$ is a vector of binary variables for every feature from the set of all possible but very infrequent features in the training set. $\mathbf{f}(e)$ has 1 for every feature extracted for edge *e* and zero otherwise.

Table 1 gives an overview of the feature types we use (edge *e* points from head *h* to node *n*). Note that syntactic, structural and semantic features are closed-class. For all the structural features but *char_length*, seven is used as maximum possible value; all possible character lengths are bucketed into six classes. All the features are local – for a given edge, contextual information is included about

syntactic	*label(e)*; for *e** to *h*, *label(e*)*; *pos(h)*; *pos(n)*
structural	*depth(n)*; *#children(n)*; *#children(h)*; *char_length(n)*; *#words_in(n)*
semantic	*NE_tag(h)*; *NE_tag(n)*; *is_negated(n)*
lexical	*lemma(n)*; *lemma(h)-label(e)*; for *e** to *n*'s siblings, *lemma(h)-label(e*)*

Table 1: Types of features extracted for edge *e* from *h* to *n*

the head and the target nodes, and the siblings as well as the children of the latter. The negation feature is only applicable to verb nodes which contain a negative particle, like *not*, after the tree transformations. Lexical features which combine lemmas and syntactic labels are inspired by the unsupervised baseline and are very sparse.

In what follows, our assumption is that we have a compression corpus at our disposal where for every input sentence there is a correct "oracle" compression such that its transformed parse tree matches a subtree of the transformed input graph. Given such a corpus, we can apply structured prediction methods to learn the parameter vector $\mathbf{w}$. In our study we employ an averaged variant of online structured perceptron (Collins, 2002). In the context of sentence fusion, a similar dependency structure pruning framework and a similar learning approach was adopted by Elsner & Santhanam (2011).

At every iteration, for every input graph, we find the optimal solution with ILP under the current parameter vector $\mathbf{w}$. The maximum permitted compression length is set to be the same as the length of the oracle compression. Since the oracle compression is a subtree of the input graph, it represents a feasible solution for ILP. The parameter vector is updated if there is a mismatch between the predicted and the oracle sets of edges for all the features with a non-zero net count. More formally, given an input graph with the set of edges E, oracle compression $C \subset E$ and compression $C_t \subseteq E$ predicted at iteration t , the parameter update vector at $t+1$ is given by

$$\mathbf{w_{t+1}} = \mathbf{w_t} + \sum_{e \in C \setminus C_t} \mathbf{f}(e) - \sum_{e \in C_t \setminus C} \mathbf{f}(e) \quad (7)$$

$\mathbf{w}$ is averaged over all the $\mathbf{w_t}$'s so that features whose weight fluctuated a lot during training are penalized (Freund & Shapire, 1999).

Of course, training a model with a large number of features, such as a lexicalized model, is only possible if there is a large compression corpus where the dependency tree of the compression is a subtree of the source sentence. In the next section we introduce our method of getting a sufficient amount of such data.

4 Acquiring parallel data automatically

In this section we explain how we obtained a parallel corpus of sentences and compressions. The underlying idea is to harvest news articles from the Internet where the headline appears to be similar to the first sentence and use it to find an extractive compression of the sentence.

Collecting headline-sentence pairs. Using a news crawler, we collected a corpus of news articles in English from the Internet. Similarly to previous work (Dolan et al., 2004; Wubben et al., 2009; Bejan & Harabagiu, 2010, inter alia), the Google News service[3] was used to identify news. From every article, the headline and the first sentence, which are known to be semantically similar (Dorr et al., 2003), were extracted. Predictably, very few headlines are extractive compressions of the first sentence, therefore simply looking for pairs where the headline is a subsequence of the words from the first sentence would not solve the problem of getting a large amount of parallel data. Importantly, headlines are syntactically quite different from "normal" sentences. For example, they may have no main verb, omit determiners and appear incomplete, making it hard for a supervised deletion-based system to learn useful rules. Moreover, we observed poor parsing accuracy for headlines which would make syntactic annotations for headlines hardly useful.

Thus, instead of taking the headline as it is, we use it to find a proper extractive compression of the sen-

[3] `http://news.google.com`, Jan-Dec 2012.

tence by matching lemmas of content words (*nouns, verbs, adjectives, adverbs*) and coreference IDs of entities from the headline with those of the sentence. The exact procedure is as follows (H, S and T stand for *headline*, *sentence* and *transformed graph* of the sentence):

PREPROCESSING H and S are preprocessed in a standard way: tokenized, lemmatized, PoS and NE tagged. Additionally, S is parsed with a dependency parser (Nivre, 2006) and transformed as described in Section 2 to obtain T. Finally, pronominal anaphora is resolved in S. Recall that S is the first sentence, so the antecedent must be located in a preceding, higher-level clause.

FILTERING To restrict the corpus to grammatical and informative headlines, we implemented a cascade of filters. Pair (H, S) is discarded if any of the questions in Table 2 is answered positively.

Is H a question?
Is H or S too short? (less than four word tokens)
Is H about as long as S? (min ratio: 1.5)
Does H lack a verb?
Does H begin with a verb?
Is there a *noun, verb, adj, adv* lemma from H not found in S?
Are the *noun, verb, adj, adv* lemmas from H found in S in a different order?

Table 2: Filters applied to candidate pair (H, S)

MATCHING Given the content words of H, a subset of nodes in T is selected based on lemma or coreference identity of the main (head) word in the nodes. For example, the main word of a collapsed node in T, which covers two words *was killed*, is *killed*; *was* is its child attached with label *aux* in the untransformed parse tree. This node is marked if H contains word *killed* or *killing* because of the lemma identity. In some cases there are multiple possible matches. For example, given S *Barack Obama said he will attend G20* and H mentioning *Obama*, both *Barack Obama* and *he* nodes are marked in T. Once all the nodes in T which match content words and entities from H are identified, a minimum subtree covering these nodes is found such that every word or entity from H occurs as many times in T as in H. So if *H* mentions *Obama* only once, then either *Barack Obama* or *he* must be covered by the subtree but not both. This minimum subtree corresponds to an **extractive headline**, H⋆, which we generate by ordering the surface forms of all the words in the subtree nodes by their offsets in S. Finally, the character length of H⋆ is compared with the length of H. If H⋆ is much longer than H, the pair (H, S) is discarded (max ratio 1.5).

As an illustration to the procedure, consider the example from Figure 1 with the extracted headline and its tree presented in Figure 1(c). Given the headline *British soldier killed in Afghanistan*, the extracted headline would be *A British soldier was killed in a blast in Afghanistan*. The lemmas *british, soldier, kill, afghanistan* from the headline match the nodes *British, a soldier, was killed, in Afghanistan* in the transformed graph. The node *in a blast* is added because it is on the path from *was killed* to *in Afghanistan*. Of course, it is possible to deterministically undo the transformations in order to obtain a standard dependency tree. In this case the extracted headline would still correspond to a subtree of the input (compare Fig. 1(d) with Fig. 1(a)). Also note that a similar procedure can be implemented for constituency parses.

The resulting corpus consists of 250K tuples (S, T, H, H⋆), Appendix provides more examples of source sentences, original headlines and extracted headlines. We did not attempt to tune the values for minimum/maximum length and ratio – lower thresholds may have produced comparable results.

Evaluating data quality. The described procedure produces a comparatively large compression corpus but how good are automatically constructed compressions? To answer this question, we randomly selected 50 tuples from the corpus and set up an experiment with human raters to validate and assess data quality in terms of *readability*[4] and *informativeness*[5] which are standard measures of compression quality (Clarke & Lapata, 2006). Raters were asked to read a sentence and a compression (original H or extracted H⋆ headline) and then rate the compression on two five-point scales. Three ratings were collected for every item. Table 3 gives

[4] Also called *grammaticality* and *fluency*.

[5] Also called *importance* and *representativeness*.

average ratings with standard deviation.

	AVG read	*AVG info*
ORIG. HEADLINE	4.36 (0.75)	3.86 (0.79)
EXTR. HEADLINE	4.26 (1.01)	3.70 (1.04)

Table 3: Results for two kinds of headlines

In terms of readability and informativeness the extracted headlines are comparable with human-written ones: at 95% confidence there is no statistically significant difference between the two.

Encouraged by the results of the validation experiment we proceeded to our next question: Can a supervised compression system be successfully trained on this corpus?

5 System evaluation and discussion

From the corpus of 250K tuples we used 100K to get pairs of *extracted* headlines and sentences for training (on the development set we did not observe much improvement from using more training data), 250 for development and the rest for testing. We ran the learning algorithm for 20 iterations, checking the performance on the development set. Features which applied to less than 20 edges were pruned, the size of the feature set is about 28K.

5.1 Evaluation with humans

50 pairs of *original* headlines and sentences (different from the data validation set in Sec. 4) were randomly selected for an evaluation with humans from the test data. As in the data quality validation experiment, we asked raters to assess the readability and informativeness of proposed compressions for the unsupervised system, our system and human-written headlines. The latter provide us with upper bounds on the evaluation criteria. Three ratings per item per parameter were collected. To get comparable results, the unsupervised and our systems used the same compression rate: for both, the requested maximum length was set to the length of the headline. Table 4 summarizes the results.

The results indicate that the trained model significantly outperforms the unsupervised system, getting particularly good marks for readability. The difference in readability between our system and *original* headlines is not statistically significant. Note that

	AVG read	*AVG info*
ORIG. HEADLINE	$4.66^{\dagger}$	$4.10^{\dagger\ddagger}$
OUR SYSTEM	$4.30^{\dagger}$	$3.52^{\dagger}$
UNSUP. SYSTEM	3.70	2.70

Table 4: Results for the systems and original headline: † and ‡ stand for *significantly better than Unsupervised* and *Our system at 95% confidence*, respectively

the unsupervised baseline is also capable of generating readable compressions but does a much poorer job in selecting most important information. Our trained model successfully learned to optimize both scores. We refer the reader to Appendix for input and compression examples. Note that the ratings for the human-written headlines in this experiment are slightly different from the ratings in the data validation experiment because a different data sample was used.

5.2 Automatic evaluation

Our automatic evaluation had the goal of explicitly addressing two relevant questions related to our claims about (1) the benefits of having a large parallel corpus and (2) employing a supervised approach with a rich feature representation.

1. Our primary motivation for collecting parallel data has been that having access to sparse lexical features, which considerably increase the feature space, would benefit compression systems. But is it really the case for sentence compression? Can a comparable performance be achieved with a closed, moderately sized set of dense, non-lexical features? If yes, then a large compression corpus is probably not needed. Furthermore, to demonstrate that a large corpus is not only sufficient but also necessary to learn weights for thousands of features, we need to compare the performance of the system when trained on the full data set and a small portion of it.

2. The syntactic and informativeness scores in Eq. (3) were calculated over millions of news articles and do provide us with meaninful statistics (see Sec. 2). Is there any benefit in replacing those scores with weights learned for

their feature counterparts? Recall that one of our feature types in Table 1 is the concatenation of *lemma(h)* (parent lemma) and *label(e)* which relies on the same information as $w_{\text{synt}} = P(label(e)|lemma(h))$. The feature counterpart of w_{info} defined in Eq. (5) is *lemma(n)*–the lemma of the node to which edge points. How would the supervised system perform against the unsupervised one, if it only extracted features of these two types?

To answer these questions, we sampled 1,000 tuples from the unused test data and measured F1 score (Riezler et al., 2003) by comparing the trees of the generated compression and the "correct", extracted headline. The systems we compared are the unsupervised baseline (UNSUP. SYSTEM) and the supervised model trained on three kinds of feature sets: (1) SYNT-INFO FEATURES, corresponding to the supervised training of the unsupervised baseline model (i.e., *lemma(h)-label(e)* and *lemma(n)*); (2) NON-LEX FEATURES, corresponding to a dense, non-lexical feature representation (i.e., all the feature types from Table 1 excluding the three involving *lemma*s); (3) ALL FEATURES (same as OUR SYSTEM). Additionally, we trained the system on 10% of the data–10K as opposed to 100K tuples, ALL FEATURES (10K)–for 20 iterations ignoring features which applied to less than three edges[6]. As before, the same compression rate was used for all the systems. The results are summarized in Table 5.

	F1 score	*#features*
UNSUP. SYSTEM	52.3	N.A.
SYNT-INFO FEATURES	75.0	12,490
NON-LEX FEATURES	79.6	330
ALL FEATURES	84.3	27,813
ALL FEATURES (10K)	81.4	22,529

Table 5: Results for the unsupervised baseline and the supervised system trained on three kinds of feature sets

Clearly, having more features, lexicalized and unlexicalized, is important: there is a significant improvement in going beyond the closed set of 330 non-lexical features to all, from 79.6 to 84.3 points. Moreover, successful training requires a large corpus since the performance of the system degrades if only 10K training instances are used. Note that this number already exceeds all the existing compression corpora taken together. Hence, sparse lexical features are useful for compression and a large parallel corpus is a requirement for successful supervised training.

Concerning our second question, learning feature weights from the data produces significantly better results than the hand-crafted way of making use of the same information, even if a much larger data set is used to collect statistics. We observed a dramatic increase from 52.3 to 75.0 points. Thus, we may conclude that training with dense and sparse features directly from data definitely improves the performance of the dependency pruning system.

5.3 Discussion

It is important to note that the data we used is challenging: first sentences in news articles tend to be long, in fact longer than other news sentences, which implies less reliable syntactic analysis and noisier input to the syntax-based systems. In the test set we used for the evaluation with humans, the mean sentence length is 165 characters. The average compression rate in characters is 0.46 ± 0.16 which is quite aggressive[7]. Recall that we used the very same framework for the unsupervised baseline and our system as well as the same compression rate. All the preprocessing errors affect both systems equally and the comparison of the two is fair. Predictably, wrong syntactic parses significantly increase chances of an ungrammatical compression, and parser errors seem to be a major source of readability deficiencies.

A property of the described compression framework is that a desired compression length is expected to be provided by the user. This can be seen both as a strength and as a weakness, depending on the application. In a scenario where mobile devices with a limited screen size are used, or in a summarization scenario where a total summary length is provided (see the DUC/TAC guidelines[8]), being able

[6]Recall from the beginning of the section that for the full (100K) training set the threshold was set to 20 with no tuning. For the 10K training set, we tried values of two, three, five and varied the number of iterations. The result we report is the highest we could get for 10K.

[7]We follow the standard terminology where smaller values imply *shorter* compressions.

[8]http://www.nist.gov/tac/

to specify a length is definitely an advantage. However, one can also think of other applications where the user does not have a strict length constraint but wants the text to be somewhat shorter. In this case, a reranker which compares compressions generated for a range of possible lengths can be employed to find a single compression (e.g., mean edge weight in the solution or a language model-based score).

6 Conclusions

We have addressed a major problem for supervised extractive compression models – the lack of a large parallel corpus. To this end, we presented a method to automatically build such a corpus from web documents available on the Internet. An evaluation with humans demonstrates that the quality of the corpus is high – the compressions are grammatical and informative. We also significantly improved a competitive unsupervised method achieving high readability and informativeness scores by incorporating thousands of features and learning the feature weights from our corpus. This result further confirms the practical utility of the automatically obtained data. We have shown that employing lexical features is important for sentence compression, and that our supervised module can successfully learn their weights from the corpus. To our knowledge, we are the first to empirically demonstrate that sparse features are useful for compression and that a large parallel corpus is a requirement for a successful learning of their weights. We believe that other supervised deletion-based systems can benefit from our work.

Fast Joint Compression and Summarization via Graph Cuts

Xian Qian and **Yang Liu**
The University of Texas at Dallas
800 W. Campbell Rd., Richardson, TX, USA
{qx,yangl}@hlt.utdallas.edu

Abstract

Extractive summarization typically uses sentences as summarization units. In contrast, joint compression and summarization can use smaller units such as words and phrases, resulting in summaries containing more information. The goal of compressive summarization is to find a subset of words that maximize the total score of concepts and cutting dependency arcs under the grammar constraints and summary length constraint. We propose an efficient decoding algorithm for fast compressive summarization using graph cuts. Our approach first relaxes the length constraint using Lagrangian relaxation. Then we propose to bound the relaxed objective function by the supermodular binary quadratic programming problem, which can be solved efficiently using graph max-flow/min-cut. Since finding the tightest lower bound suffers from local optimality, we use convex relaxation for initialization. Experimental results on TAC2008 dataset demonstrate our method achieves competitive ROUGE score and has good readability, while is much faster than the integer linear programming (ILP) method.

1 Introduction

Automatic multi-document summarization helps readers get the most important information from large amounts of texts. Summarization techniques can be roughly divided into two categories: extractive and abstractive. Extractive summarization casts the summarization task as a sentence selection problem: identifying important summary sentences from one or multiple documents. Many methods have been developed in the past decades, including supervised approaches that use classifiers to predict summary sentences, graph based approaches to rank the sentences, and recent global optimization methods such as integer linear programming (Gillick et al., 2008) (ILP) and submodular maximization methods (Lin and Bilmes, 2011). Though extractive summarization is popular because of its simplicity and high readability, it has limitations in that it selects each sentence as a whole, and thus may miss informative partial sentences.

To improve the informativeness, joint compression and summarization was proposed (Berg-Kirkpatrick et al., 2011), which uses words as summarization units, unlike extractive summarization where each sentence is a basic undecomposable unit. To achieve better readability, manually defined grammar constraints or automatically learned models based on syntax trees are added during the summarization process. Up to now, the state of the art compressive systems are based on integer linear programming (ILP). Because ILP suffers from exponential complexity, word-based compression summarization is an order of magnitude slower than sentence-based extraction.

One common way to solve an ILP problem is to use its LP relaxation and round the results. However Berg-Kirkpatrick et al. (2011) found that LP relaxation gave poor results, finding unacceptably suboptimal solutions. For speedup, they proposed a two stage method where they performed some sentence selection in the first step to reduce the number of candidates. Despite their empirical success, such

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1492–1502,
Seattle, Washington, USA, 18-21 October 2013.

a pruning approach has its inherent problem in that it may eliminate correct sentences in the first step. Recently, Almeida and Martins (2013) proposed a fast joint decoding algorithm based on dual decomposition. For fast convergence, they added quadratic penalty terms to alleviate the learning rate problem.

In this paper, we propose an efficient decoding algorithm for fast ILP based compressive summarization using graph cuts. Our assumption is that all concepts are word n-grams and non-negatively scored. The rationale for the non-negativity assumption is straightforward: the score of a concept reflects its informativeness, hence should be non-negative. Given a set of documents, each word is associated with a binary variable, indicating whether the word is selected in the summary. Our idea is to approximate the ILP as a binary quadratic programming problem where coefficients of all quadratic terms are non-negative. It is well known that such binary quadratic function is supermodular, and its maximum can be solved efficiently using graph max-flow/min-cut. Hence the key is to find the coefficients of the supermodular binary quadratic function (SBQF) so that its maximum is close to the optimal ILP objective function. Our solution consists of 3 steps. First, we show that the subtree deletion model and grammar constraints can be eliminated by adding SBQFs to the objective function. Second, we relax the summary length constraint using Lagrangian relaxation. Third, we propose a family of SBQFs that are lower bounds of the ILP objective function. Since finding the tightest lower bound suffers from local optimality, we choose to use convex relaxation for initialization. To demonstrate our technique, we conduct experiments on Text Analysis Conference (TAC) datasets using the same train/test splits as previous work (Berg-Kirkpatrick et al., 2011). We compare our approach with the state-of-the-art ILP based approach in terms of summary quality (ROUGE scores and sentence quality) and speed. Experimental results show that our proposed method achieves competitive performance with ILP, while about 100 times faster.

2 Compressive Summarization

2.1 Extractive Summarization

As our method is an approximation of ILP based method, we first briefly review the ILP based extractive summarization and compressive summarization. Gillick and Favre (2009) introduced the concept-based ILP for summarization. A concept is a basic semantic unit. They used word bigrams as such language concepts. Their system achieved the highest ROUGE score on the TAC 2009 evaluation. This approach selects sentences so that the total score of language concepts appearing in the summary is maximized. The association between the language concepts and sentences serves as the constraints, in addition to the summary length constraint.

Formally, given a set of sentences $\mathcal{S} = \{s_n\}_{n=1}^{N}$, extractive summarization can be represented by a binary vector $\mathbf{y}$, where y_n indicates whether sentence s_n is selected. Let $\mathcal{C} = \{c_1, \dots c_J\}$ denote the set of concepts in $\mathcal{S}$, e.g., word bigrams (Gillick and Favre, 2009). Each concept c_j is associated with a given score w_j and a binary variable v_j indicating if c_j is selected in the summary. Let n_{jk} denote the index of the sentence containing the k^{th} occurrence of concept c_j, and l_n denote the length of sentence s_n. The ILP based extractive summarization system can be formulated as below:

$$\begin{aligned} \max_{\mathbf{y},\mathbf{v}} \quad & \sum_{j=1}^{J} w_j v_j \\ \text{s.t.} \quad & v_j = \bigcup_{k} y_{n_{jk}} \qquad 1 \le j \le J \qquad (1) \\ & \sum_{i=1}^{N} y_n l_n \le L \\ & \mathbf{v}, \mathbf{y} \text{ are binary} \end{aligned}$$

The first constraint is imposed by the relation between concept selection and sentence selection: selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept only happens when it is present in at least one of the selected sentences. The second constraint is the summary length constraint.

As solving an ILP problem is generally NP-hard, pre-pruning of candidate concepts and sentences is necessary for efficient summarization. For exam-

ple, the ICSI system (Gillick et al., 2008) removed the sentences that are too short or have non-overlap with the queries, and concepts with document frequency less than 3, resulting in 95.8 sentences and about 80 concepts per topic on the TAC2009 dataset. Therefore the actual scale of ILP is rather small after pruning (e.g., 176 variables and 372 constraints per topic). Empirical studies showed that such small scale ILP can be solved within a few seconds (Gillick and Favre, 2009).

2.2 Compressive Summarization

The quality of sentence-based extractive summarization is limited by the informativeness of the original sentences and the summary length constraint. To remove the unimportant part from a long sentence, sentence compression is proposed to generate more informative summaries (Liu and Liu, 2009; Li et al., 2013a). Recent studies show that joint sentence compression and extraction, namely compressive summarization, outperforms pipeline systems that run extractive summarization on the compressed sentences or compress selected summary sentences (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Chali and Hasan, 2012). In Berg-Kirkpatrick et al. (2011), compressive summarization integrates the concept model for extractive summarization (Gillick and Favre, 2009) and subtree deletion model for sentence compression. The score of a compressive summary consists of two parts, scores of selected concepts, and scores of the broken arcs in the dependency parse trees. The selected words must satisfy the length constraint and grammar constraints that include subtree constraint and some manually defined hard constraints.

Formally, let $\mathbf{x} = x_1 \dots x_I$ denote the word sequence of documents, where $s_1 = x_1, \dots x_{l_1}$ corresponds to the first sentence, $s_2 = x_{l_1+1}, \dots, x_{l_1+l_2}$ corresponds to the second sentence, and so on. A compressive summary can be represented by a binary vector $\mathbf{z}$, where z_i indicates whether word x_i is selected in the summary. Let a_{hm} denote the arc $x_h \rightarrow x_m$ in the dependency parse tree of the corresponding sentence containing words x_h and x_m, and $\mathcal{A} = \{a_{hm}\}$ denote the set of dependency arcs. The subtree constraint ensures that word x_m is selected only if its head x_h is selected. In order to guarantee the readability, grammar constraints are added to prohibit the breaks of some specific arcs. For example, Clarke and Lapata (2008) never deleted an arc whose dependency label is *SUB, OBJ, PMOD, SBAR* or *VC*. In this paper, we use $\mathcal{B} \subseteq \mathcal{A}$ to denote the set of these arcs that must not be broken in summarization. We use o_{jk} to denote the indices of words corresponding to the k^{th} occurrence of c_j. For example, suppose the j^{th} concept *European Union* appears twice in the document: $x_{22}x_{23} = x_{50}x_{51}$ =*European Union*, then $o_{j1} = \{22, 23\}, o_{j2} = \{50, 51\}$.

The compressive summarization model can be formulated as an integer programming problem

$$
\begin{aligned}
\max_{\mathbf{z},\mathbf{v}} \quad & \sum_{j=1}^{J} w_j \cdot v_j + \sum_{a_{hm} \in \mathcal{A}} w_{a_{hm}} z_h (1 - z_m) \\
\text{s.t.} \quad & v_j = \bigcup_k \prod_{i \in o_{jk}} z_i \qquad \forall j \\
& \sum_i z_i \leq L \\
& z_h \geq z_m \quad \forall a_{hm} \in \mathcal{A} \\
& z_h = z_m \quad \forall a_{hm} \in \mathcal{B} \\
& \mathbf{z}, \mathbf{v} \text{ are binary}
\end{aligned} \tag{2}
$$

According to the subtree deletion model, the score of arc a_{hm} is included if $z_h = 1$ and $z_m = 0$, which can be formulated as $w_{a_{hm}} \cdot z_h(1 - z_m)$. The first constraint is similar to that in extractive summarization, that is, a concept is selected if and only if any of its occurrence is selected. The third and fourth constraints are the subtree constraints and manually defined grammar constraints respectively. In the rest of the paper, without loss of generality, we remove the fourth constraint by directly substituting one variable for the other.

Finding the optimal summary is generally NP-hard. Unlike extractive summarization where the scale of the problem (the number of sentences and concepts) is small, the number of variables in compressive summarization is linear in the number of words, which is usually thousands on the TAC datasets. Hence solving such a problem using ILP based decoding algorithms is not efficient especially when the document set is large.

3 Fast Decoding via Graph Cuts

In this section, we introduce our fast decoding algorithm. We assume that all the concepts are word n-grams, and their scores are non-negative. The non-negativity assumption can reduce the computational complexity, but is also reasonable: the score of a concept denotes its informativeness, hence should be non-negative. For example, Li et al. (2013b) proposed to use the estimated normalized frequencies of concepts as scores, which are essentially non-negative. The basic idea of our method is to approximate the above optimization problem (2) by the supermodular binary quadratic programming (SBQP) problem:

$$\begin{aligned} \max_{\mathbf{z}} \quad & \sum_i \beta_i z_i + \sum_{ij} \alpha_{ij} z_i z_j \\ \text{s.t.} \quad & \mathbf{z} \text{ is binary} \end{aligned} \tag{3}$$

where $\alpha_{ij} \geq 0$. It is known that such a binary quadratic function is supermodular, and its maximum can be solved efficiently using graph max-flow/min-cut (Billionnet and Minoux, 1985; Kolmogorov and Zabih, 2004). Now the problem is to find the optimal α, β for a good approximation.

3.1 Formulate Grammar Constraints and Subtree Deletion Model by SBQF

We show that the subtree deletion model can be formulated equivalently using SBQF. First, we can eliminate the constraint $z_h \geq z_m$ by adding a penalty term to the objective function. That is,

$$\begin{aligned} \max \quad & f(\mathbf{z}) \\ \text{s.t.} \quad & z_h \geq z_m \\ & \mathbf{z} \text{ is binary} \end{aligned}$$

is equivalent to

$$\begin{aligned} \max \quad & f(\mathbf{z}) - \infty(1 - z_h)z_m \\ \text{s.t.} \quad & \mathbf{z} \text{ is binary} \end{aligned}$$

We can see that the penalty term $-\infty(1-z_h)z_m$ excludes $z_h = 0$, $z_m = 1$ from the feasible set, and for $z_h \geq z_m$, both problems have the same objective function value. Hence the two problems are equivalent. Notice that the coefficient of quadratic term in $-\infty(1 - z_h)z_m$ is positive, hence the penalty term is supermodular.

Now we eliminate the third constraint in problem (2) using the penalized objective function described above. Note that the fourth constraint has been eliminated by variable substitution, we have

$$\begin{aligned} \max_{\mathbf{z},\mathbf{v}} \quad & \sum_{j=1}^{J} w_j \cdot v_j + \sum_{a_{hm} \in \mathcal{A}} w_{a_{hm}} z_h (1 - z_m) \\ & -\infty \sum_{a_{hm} \in \mathcal{A}} (1 - z_h) z_m \\ \text{s.t.} \quad & v_j = \bigcup_k \prod_{i \in o_{jk}} z_i \qquad \forall j \\ & \sum_i z_i \leq L \\ & \mathbf{z}, \mathbf{v} \text{ are binary} \end{aligned} \tag{4}$$

We can see that for each arc a_{hm}, there must be a positive quadratic term $+\infty z_h z_m$ in the objective function, which guarantees the supermodularity of the objective function, no matter what $w_{a_{hm}}$ is.

3.2 Eliminate Length Constraint Using Lagrangian Relaxation

Problem (4) is NP-hard, because for any feasible $\mathbf{v}$, it is a SBQP with a length constraint. Since size constrained minimum cut problem is generally NP-hard (Nagano et al., 2011), Problem (4) can not be cast as a SBQP as long as P $\neq$ NP. One popular way to deal with the size constrained optimization problem is Lagrangian relaxation. We introduce Lagrangian multiplier λ to the length constraint in Problem (4), and get

$$\begin{aligned} \min_{\lambda} \max_{\mathbf{z},\mathbf{v}} \quad & \sum_{j=1}^{J} w_j \cdot v_j + \sum_{a_{hm} \in \mathcal{A}} w_{a_{hm}} z_h (1 - z_m) \\ & -\infty \sum_{a_{hm} \in \mathcal{A}} (1 - z_h) z_m \\ & +\lambda (L - \sum_i z_i) \\ \text{s.t.} \quad & v_j = \bigcup_k \prod_{i \in o_{jk}} z_i \qquad \forall j \\ & \lambda \geq 0 \\ & \mathbf{z}, \mathbf{v} \text{ are binary} \end{aligned} \tag{5}$$

We solve the relaxed problem iteratively. In each iteration, we fix λ and solve the inner maximization problem (details described below). The score of

each word is penalized by λ — with larger λ, fewer words are selected. Hence the summary length can be adjusted by λ. The optimal λ can be found using binary search. We maintain an upper bound λ_{max} , and a lower bound λ_{min}, which is initially 0. In each iteration, we choose $\lambda = \frac{1}{2}(\lambda_{max} + \lambda_{min})$ and search the optimal $\mathbf{z}$. If the duality gap vanishes, i.e., $\lambda(L - \sum_i z_i) = 0$ and $\sum_i z_i \leq L$, then we get the global solution of Problem (4). Otherwise, if $\sum_i z_i > L$, then the current λ is too small, so we set $\lambda_{min} = \lambda$; otherwise, $\lambda > 0$ and $\sum_i z_i < L$, we set $\lambda_{max} = \lambda$. The search process terminates if $\lambda_{max} - \lambda_{min}$ is less than a predefined threshold.

3.3 Eliminate v Using Supermodular Relaxation

Now we consider the inner maximization Problem (5). It is still not a SBQP, since the objective function is not a linear function of $z_i z_j$. We propose to approximate the objective function using SBQP. Our solution consists of two steps. First we relax the first constraint of Problem (5) by bounding the objective function with a family of supermodular pseudo boolean functions (Boros and Hammer, 2002). Second we reformulate these pseudo boolean functions equivalently as quadratic functions.

Similar to the bounding strategy in (Qian and Liu, 2013), we relax the logical disjunction by linearization. Using the fact that for any binary vector $\mathbf{a}$, we have

$$\bigcup a_i = \max_{\mathbf{p}\in\Delta} \sum_i p_i a_i$$

where Δ denotes the probability simplex

$$\Delta = \{\mathbf{p} | \sum_k p_k = 1, p_k \geq 0\}$$

We have

$$\begin{aligned} v_j &= \bigcup_k \prod_{i\in o_{jk}} z_i \\ &= \max_{\mathbf{p}_j\in\Delta} \sum_k p_{jk} \prod_{i\in o_{jk}} z_i \end{aligned}$$

Plug the equation above into the objective function of Problem (5), we get the following optimization problem

$$\begin{aligned} \max_{\mathbf{z},\mathbf{p}} \quad & \sum_{j=1}^{J} \left(\sum_k p_{jk} w_j \prod_{i\in o_{jk}} z_i \right) \\ & + \sum_{a_{hm}\in\mathcal{A}} w_{a_{hm}} z_h (1 - z_m) \\ & -\infty \sum_{a_{hm}\in\mathcal{A}} (1 - z_h) z_m \\ & +\lambda(L - \sum_i z_i) \\ \text{s.t.} \quad & \mathbf{z} \text{ is binary} \\ & \mathbf{p}_j \in \Delta \qquad \forall j \end{aligned} \tag{6}$$

Let $Q(\mathbf{p}, \mathbf{z})$ denote the objective function of Problem (6). Given $\mathbf{p}$, we can see that Q is a supermodular pseudo boolean function because coefficients of all non-linear terms are non-negative. Using the fact that for any binary vector $\mathbf{a} = [a_1, \dots a_r]^T$, $a_i \in \{0, 1\}, 1 \leq i \leq r$,

$$\prod_{i=1}^{r} a_i = \max_{b\in\{0,1\}} \left(\sum_{i=1}^{r} a_i - r + 1 \right) b$$

(Freedman and Drineas, 2005), we get the following equivalent optimization problem of Problem (6)

$$\begin{aligned} \max_{\mathbf{z},\mathbf{p},\mathbf{q}} \quad & \sum_{j=1}^{J} \sum_k p_{jk} w_j q_{jk} \left(\sum_{i\in o_{jk}} z_i - |o_{jk}| + 1 \right) \\ & + \sum_{a_{hm}\in\mathcal{A}} w_{a_{hm}} z_h (1 - z_m) \\ & -\infty \sum_{a_{hm}\in\mathcal{A}} (1 - z_h) z_m \\ & +\lambda(L - \sum_i z_i) \\ \text{s.t.} \quad & \mathbf{z}, \mathbf{q} \text{ are binary} \\ & \mathbf{p}_j \in \Delta \qquad \forall j \end{aligned} \tag{7}$$

where $|o_{jk}|$ is the size of o_{jk}.

Let $R(\mathbf{z}, \mathbf{p}, \mathbf{q})$ denote the objective function of Problem (7), to search the optimal point, we alternatively update $\mathbf{p}$ and $\mathbf{z}, \mathbf{q}$. First we initialize $\mathbf{p} = \mathbf{p}(0)$. In each iteration, we first fix $\mathbf{p}$. It is obvious that Problem (7) is a SBQP, hence the optimal $\mathbf{z}, \mathbf{q}$ can be solved efficiently using max-flow/min-cut. Then we fix $\mathbf{z}, \mathbf{q}$, and update $\mathbf{p}$ using projected

subgradient. That is

$$\mathbf{p}_j^{\text{new}} = P_\Delta\left(\mathbf{p}_j + \frac{\partial R}{\partial \mathbf{p}_j}\alpha\right) \quad (8)$$

where $\alpha > 0$ is the step size in line search, and function $P_\Delta(q)$ denotes the projection of q onto the feasible set Δ

$$P_\Delta(\mathbf{q}) = \min_{\mathbf{p}\in\Delta} \|\mathbf{p} - \mathbf{q}\|_2$$

which can be solved efficiently by sorting (Duchi et al., 2008).

3.4 Initialize p Using Convex Relaxation

Since R is non-concave, searching its maximum using subgradient method suffers from local optimality. Though one can use techniques such as branch-and-bound for exact inference (Qian and Liu, 2013; Gormley and Eisner, 2013), here for fast decoding, we use convex relaxation to choose a good seed $\mathbf{p}(0)$. Recall that p_{jk} denotes the percentage of the k^{th} occurrence contributing to c_j. The larger p_{jk} is, the more likely the k^{th} occurrence is selected. To estimate such likelihood, we replace the binary constraint in extractive summarization (Problem (1)) by $\mathbf{0} \leq \mathbf{y}, \mathbf{v} \leq \mathbf{1}$, since solving a relaxed LP is much faster than ILP. Suppose $\mathbf{y}^*$ is the optimal solution for such a relaxed LP problem, we initialize $\mathbf{p}$ by

$$p_{jk} = \frac{y^*_{n_{jk}}}{\sum_k y^*_{n_{jk}}} \quad (9)$$

If for all k, $y^*_{n_{jk}} = 0$, then we initialize p_{jk} using uniform distribution

$$p_{jk} = \frac{1}{|o_j|}$$

where $|o_j|$ is the frequency of c_j.

3.5 Summary

For clarity, we summarize our decoding algorithm in Algorithm 1. Initial λ_{max} can be arbitrarily large. In our experiments, we set $\lambda_{max} = \sum_j w_j$, which empirically guarantees the summary length $\sum_i z_i \leq L$ when $\lambda = \lambda_{max}$. The choice of the step size for updating $\mathbf{p}$ is similar to the projected subgradient method in dual decomposition (Koo et al., 2010).

Algorithm 1 Compressive Summarization via Graph Cuts

Require: Scores of concepts $\{w_j\}$ and arcs $\{w_{a_{hm}}\}$, max summary length L.
Ensure: Compressive summarization $\mathbf{z}^*$, where z_i indicates whether the i^{th} word is selected.
Solve the relaxed LP of Problem (1) (replace the binary constraint by $\mathbf{0} \leq \mathbf{y}, \mathbf{v} \leq \mathbf{1}$) to get $\mathbf{y}$.
Initialize $\mathbf{p}(0)$ using Eq (9).
Initialize sufficient large λ_{max}, and $\lambda_{min} = 0$
while $\lambda_{max} - \lambda_{min} > \epsilon$ **do**
  Set $\lambda = \frac{1}{2}(\lambda_{min} + \lambda_{max})$
  Set $\mathbf{p} = \mathbf{p}(0)$.
  repeat
    Fix $\mathbf{p}$, solve Problem (7) to get $\mathbf{z}$ using max-flow/min-cut.
    Update $\mathbf{p}$ using Eq (8).
  until convergence
  if $\sum_i z_i > L$ **then**
    $\lambda_{min} = \lambda$
  else if $\sum_i z_i < L$ **then**
    $\lambda_{max} = \lambda$
  else
    break
  end if
end while

4 Features and Hard Constraints

We choose discriminative models to learn the scores of concepts and arcs. For concept c_j, its score is

$$w_j = \theta^T_{\text{concept}} \mathbf{f}_{\text{concept}}(c_j)$$

where $\mathbf{f}_{\text{concept}}(c_j)$ is the feature vector of c_j, and θ_{concept} is the corresponding weight vector of feature $\mathbf{f}_{\text{concept}}(c_j)$. Similarly, score $w_{a_{hm}}$ is defined as

$$w_{a_{hm}} = \theta^T_{\text{arc}} \mathbf{f}_{\text{arc}}(a_{hm})$$

Though our algorithm can handle general word n-gram concepts, we restrict the concepts to word bigrams, which have been widely used recently in the sentence-based ILP extractive summarization systems. For a concept c_j, we define the following features, some of which have been used in previous work (Brandow et al., 1995; Aker and Gaizauskas, 2009; Edmundson, 1969; Radev, 2001; Li et al., 2013b). All of these features are non-negative.

- Term frequency: the frequency of c_j in the given topic.

- Stop word ratio: ratio of stop words in c_j. The value can be $\{0, 0.5, 1\}$.
- Similarity with topic title: the number of common words in these two strings, divided by the length of the longer string.
- Document ratio: percentage of documents containing c_j.
- Sentence ratio: percentage of sentences containing c_j.
- Sentence-title similarity: word unigram/bigrams cosine similarity between the sentence containing c_j and the topic title. For concepts appearing in multiple sentences, we choose the maximal similarity.
- Sentence-query similarity: word unigram/bigram cosine similarity between the sentence containing c_j and the topic query (concatenation of topic title and description). For concepts appearing in multiple sentences, we choose the maximal similarity.
- Sentence position: position of the sentence containing c_j in the document. For concepts appearing in multiple sentences, we choose the minimum.
- Sentence length: length of the sentence containing c_j. For concepts appearing in multiple sentences, we choose the maximum.
- Paragraph starter: binary feature indicating whether c_j appears in the first sentence of a paragraph.

For subtree deletion model, we define the following features for arc a_{hm}.

- POS tags of head word x_h and child word x_m and their concatenations.
- Dependency label of arc a_{hm} and its parent arc.
- Word x_m if x_m is a conjunction word or preposition word. Word x_h if x_m is a conjunction word or preposition word.
- Binary feature indicating whether the modifier x_m is a temporal word such as *Friday*.

We also define some hard constraints for subtree deletion to improve the readability of the generated compressed sentences.

- **C0** Arc a_{hm} can be cut only if one of the two conditions holds: (1) there is a comma, colon, or semicolon between the head and the modifier; (2) the modifier word is a preposition (POS tag is *IN*) or a wh-word, such as *what, who, whose* (corresponds to POS tag *IN, WDT, WP, WP$, WRB*).
- **C1** Arcs with dependency labels *SUB, OBJ, PRD, SBAR* or *VC* can not be cut.
- **C2** Arcs in set phrases like *so far, more than, according to* can not be cut.
- **C3** All arcs in coordinate structures can not be cut, such as *cats and dogs*.

Note that compared with previous work, our compression is more conservative. Constraint C0 allows only a small portion of arcs to be cut. This is based on our observation of the sentence compression corpus: removing preposition phrases (PP) or sub-clauses can greatly reduce the length of sentence, while hurting the readability little. Cutting other arcs like *NMOD* usually removes only one or two words, and possibly affects the sentence's readability.

5 Experimental Results

5.1 Experimental Setup

Due to the lack of training data for compressive summarization, we learn the subtree deletion model and the concept model separately. Specifically, the sentence compression dataset (Clarke and Lapata, 2008) (referred as CL08) is used for subtree deletion model training (θ_{arc}). A sentence pair in the corpus is kept for training the subtree deletion model if the compressed sentence can be derived by deleting subtrees from the parse tree of the original sentence. There are $3,178$ out of $5,739$ such pairs. The concept model (θ_{concept}) is learned from the TAC2009 dataset. We create the oracle extractive summaries with the maximal bigram recall as the reference summary. TAC2010 data is used as

	Corpus	Sent.	Words	Topics
Train	TAC2009	4,216	117,304	44
	CL08	3,178	52,624	N/A
Develop	TAC2010	2,688	72,609	46
Test	TAC2008	4,518	123,946	48

Table 1: Corpus statistics. Training data consist of two parts, TAC2009 for learning the concept model, CL08 (Clarke and Lapata, 2008) for learning the subtree deletion model.

development set for various parameter tuning. Table 1 has the descriptions of all the data used.

We choose averaged perceptron for fast training. The number of iterations is tuned on the development data. Remind that our algorithm is based on the assumption that scores of concepts are non-negative, $\forall j, w_j \geq 0$. We assume that feature vector $\mathbf{f}_{\text{concept}}$ is non-negative (e.g., term frequency, n-gram features), then $\theta_{\text{concept}} \geq 0$ is required to guarantee the non-negativity of w_j. Therefore, we project θ_{concept} onto the non-negative space after each iteration. Since training is offline, we use ILP based exact inference for accurate learning. [1]

To control the contributions of the concept model and the subtree deletion model, we introduce a parameter μ, and modify the original maximization problem (Problem 2) to:

$$\max_{\mathbf{z},\mathbf{v}} \quad \sum_{j=1}^{J} w_j \cdot v_j + \mu \times \sum_{a_{hm} \in \mathcal{A}} w_{a_{hm}} z_h (1 - z_m)$$

We tune μ on TAC2010 dataset. For max-flow/min-cut, in our experiments, we implemented the improved shortest augmented path (SAP) method (Edmonds and Karp, 1972).

For performance measure of the summaries, we use both ROUGE and linguistic quality. ROUGE has been widely used for summarization performance and can measure the informativeness of the summaries (content match between system and reference summaries). Since joint compression and summarization tends to pick isolated words to maximize the information coverage in the system generated summaries, it may have poor readability. Therefore we conduct human evaluation for the linguistic quality for various systems. The linguistic quality consists of two parts. One evaluates the grammar quality within a sentence. Annotators marked if a compressed sentence is grammatically correct. Typical grammar errors include lack of verb or subordinate clause. The other evaluates the coherence between sentences, including the order of sentences and irrelevant sentences. For compressive summaries, we removed the sentences with grammar errors when evaluating coherence. The overall linguistic quality score is the combined score of the percentage of grammatically correct sentences and the correct ordering of the summary sentences. The score is scaled and ranges from 1 (bad) to 10 (good).

[1] we choose the GLPK as our ILP solver, which is used in (Berg-Kirkpatrick et al., 2011)

5.2 Results on the Development Set

We conducted a series of experiments on the development dataset to investigate the effect of the non-negative score assumption, SBQP approximation, and initialization. First, we build a standard ILP based compressive summarizer without the non-negative score assumption. We varied μ over $\{2^{-4}, 2^{-3}, \ldots 2^{4}\}$ and selected the optimal $\mu = 2^{-2}$ according to both ROUGE-2 score and linguistic quality. This interpolation weight is used in all the other experiments.

To study the impact of the non-negative score assumption, we build another summarizer by replacing the concept model with the one trained under the non-negative constraint. We also compared three different initialization strategies for $\mathbf{p}$. The first one is uniform initialization, i.e., $p_{jk} = \frac{1}{|o_j|}$. The second one is a greedy approach, where extractive summarization is obtained by greedy search (i.e., add the top ranked sentence iteratively), then we use the corresponding $\mathbf{y}$ and Eq (9) to initialize $\mathbf{p}$. The last one is our convex relaxation method described in Section 3.4.

Table 2 shows the comparison results. For comparison, we also include the sentence-based ILP extractive summarization results. We can see that the impact of initial $\mathbf{p}$ is substantial. Using convex relaxation helps our method to survive from local optimality. The non-negativity assumption has very little effect on the standard compressive summarization (comparing the first two rows). This empirical result demonstrates the appropriateness of the assumption we use in our proposed method.

System	R-2	LQ
ILP ($\mu = 2^{-2}$)	11.22	6.3
ILP (Non Neg.)	11.18	6.4
Graph Cut (uniform)	9.54	5.9
Graph Cut (greedy)	10.13	6.2
Graph Cut (LP)	11.06	6.1
Sent Extractive	10.11	7.3

Table 2: Experimental results on development dataset. R-2 and LQ are short for ROUGE-2 score multiplied by 100, and linguistic quality respectively.

5.3 Results on Test Dataset
