Table 3 shows the summarization results for various systems on the TAC2008 data set. We show both the summarization performance and the speed[2] of the system. The presented systems include our graph-cut based method, the ILP based compression and summarization, and the sentence-based extractive summarization. ILP 2-step refers to the 2-step fast decoding strategy proposed by (Berg-Kirkpatrick et al., 2011).

We also list the performance of some state-of-the-art systems, including the two ICSI systems (Gillick et al., 2008), the compressive summarization system of Berg-Kirkpatrick et al. (2011) (GBK'11), the multi-aspect ILP system of Woodsend and Lapata (2012)(WL'12) and the dual decomposition based system (Almeida and Martins, 2013) (AM'13). Note that for these referred systems since the linguistic quality results are not comparable due to different judgment methods. For our graph-cut based method, to study the tradeoff between the readability of the summary and the ROUGE scores, we present two versions for this method: one uses all the constraints (C0-C3), the other does not use C0.

We can see that our proposed method balanced speed and quality. Compared with ILP, we achieved competitive ROUGE scores, but with about 100x speedup. Our method is also faster than the 2-step ILP system. We also tried another state-of-the-art LP solver, Gurobi version 5.5[3], it achieves 0.17 seconds per topic, much faster than GLPK, but still slower than ours. Regarding the grammar constraints used in our system, from the two results for our graph-cut based method, we can see that adding constraint C0 significantly decreases the R-2 score but improves the language quality. This shows that word-based joint compression and summarization can improve ROUGE score; however, we need to keep in mind about linguistic quality and find a tradeoff between the ROUGE score and the linguistic quality. Almeida and Martins (2013) trained their model on extra corpora using multi-task learning, and achieved better results than ours. The results of our system and theirs showed that Lagrangian relaxation based method combined with combinatorial optimization algorithms such as dynamic programming or minimum cut can exploit the inner structure of problems and achieve significant speedup over ILP.

System	R-2	R-SU4	LQ	sec.
Graph Cut	11.74	14.54	6.5	0.056
Graph Cut w/o C0	12.05	14.71	5.4	0.053
ILP	11.86	14.62	6.6	5.5
ILP (Non Neg.)	11.82	14.60	6.6	5.2
ILP (2-step)	11.72	14.49	6.5	1.1
Sent Extractive	11.06	13.93	7.1	0.13
ICSI-1	11.0	13.4	-	$0.38^{\dagger}$
ICSI-2	11.1	14.3	-	-
BGK'11	11.70	14.38	$6.5^{\dagger}$	-
WL'12	11.37	14.47	-	-
AM'13	12.30^{+}	15.18^{+}	$4.2^{\dagger}$	$0.41^{\dagger}$

Table 3: Experimental results on TAC2008 dataset. Columns 2-5 are scores of ROUGE-2, ROUGE-SU4, linguistic quality, and speed (seconds per topic). ROUGE-2 and ROUGE-SU4 scores are multiplied by 100. All the experiments are conducted on the platform Intel Core i5-2500 CPU 3.30GHz. † numbers are not directly comparable due to different annotations or platforms. $^{+}$ extra resources are used.

Four example summaries produced by our system are shown below. Words in gray are not selected in the summary.

[2]For fair comparison, we only recode the running time for decoding. Other time costs like feature extraction, IO operations are excluded.

India's space agency is ready to send a man to space within seven years if the government gives the nod, while preparations have lready begun for the launch of an unmanned lunar mission, a top official said. India will launch more missions to the moon if its maiden unmanned spacecraft Chandrayaan-1, slated to be launched by 2008, is successful a top space fficial said Tuesday. The United States, the European Space Agency, China, Japan and India are all planning lunar missions during the ext decade.India is "a step ahead" of China in satellite technology and can surpass Beijing in space research by tapping the talent of its huge pool of young scientists, India's space research chief said Monday. The space agencies of India and France signed an agreement on Friday to cooperate in launching a satellite in four years that will help make climate predictions more accurate. The Indian Space Research Organization (ISRO) has short-listed experiments from five nations including the United States, Britain and Germany, for a slot on India's unmanned moon mission Chandrayaan-1 to be undertaken by 2006-2007, the Press Trust of India (PTI) reported Monday. A three-member Afghan delegation is in Bangalore seeking help to set up a high-tech telemedicine facility in 10 Afghan cities linked via Indian satellites, Indo-Asian News Service reported Saturday.

A woman was killed in Mississippi when a tree crashed on her car, becoming the 11th fatality blamed on the powerful Hurricane Katrina that slammed the US Gulf coast after pounding Florida, local TV reported Monday. The bill for the Hurricane Katrina disaster effort has so far reached 2.87 billion dollars, federal officials said on Tuesday. The official death toll from Hurricane Katrina has risen to 118 people in and around the swamped city of New Orleans, officials said Thursday. The Foreign Ministry on Friday reported the first confirmed death of a Guatemalan due to Hurricane Katrina in the United States. The Ugandan government has pledged 200,000 US dollars toward relief and rebuilding efforts in the aftermath of Hurricane Katrina, local press reported on Friday. Swiss Reinsurance Co., the world's second largest reinsurance company on Monday doubled to 40 billion US dollars its initial estimate of the global insured losses caused by Hurricane Katrina in the United States.

The A380 'superjumbo', which will be presented to the world in a lavish ceremony in southern France on Tuesday, will be profitable from 2008, its maker Airbus told the French financial newspaper La Tribune. The A380 will take over from the Boeing 747 as the biggest jet in the skies. An association of residents living near Paris's Charles-de-Gaulle airport on Wednesday denounced the noise pollution generated by the giant Airbus A380, after the new airliner's maiden flight. One problem that Airbus is encountering with its new A380 is that the craft pushes the envelope on the maximum size of a commercial airplane. With a whisper more than a roar, the largest passenger airliner ever built, the Airbus 380, took off on its maiden flight Wednesday.

"When she came in, she was in good spirits," a prison staffer told the New York Daily News. Martha Stewart, the American celebrity homemaker who had her own cooking and home improvement TV show, reported to a federal prison in Alderson, West Virginia, on Friday to serve a five-month sentence for lying about a stock sale. Home fashion guru Martha Stewart said on Friday that she has adjusted to prison life and is keeping busy behind bars since reporting a week ago to a federal penal camp in West Virginia, where she is serving a five-month sentence for lying about a stock sale. The lawyer said he did not know what she is writing, but Stewart has suggested since her conviction that she might write a book about her recent experience with the legal system. Walter Dellinger, the lawyer leading the appeal, said on NBC's "Today" that Stewart is exploring "innovative ways to do microwave cooking" The lawyer said he did not know with her fellow inmates. As Martha Stewart arrives at the red-brick federal prison in Alderson, W. Va., on Friday to begin a five-month sentence, the company she founded is focused both on life without her and on life once she returns.

In most cases, the removed phrases do not hurt the readability of the summaries. The errors are mainly caused by the break of sub-clauses or main clauses that are separated by commas, for example, the fourth sentence in the last summary, *The lawyer said he did not know what she is writing*. The compressed sentence is grammatically correct, but semantically incomplete. Other errors are due to the lack of verb, subject, or object, or incorrect removal of PP, such as the last sentence of the last summary.

6 Conclusion

In this paper, we propose a fast decoding algorithm for compressive summarization using graph cuts. Our idea is to approximate the original ILP problem using supermodular binary quadratic programming (SBQP) problem. Under the assumption that scores of concepts are non-negative, we eliminate subtree constraints and grammar constraints, and relax the length constraint and non-supermodular part of the problem step by step. Our experimental results showed that the graph cut based method achieved competitive performance compared to ILP, while about 100 times faster.

There are several possibilities for further research involving our graph cut algorithms. One idea is to apply it to the language model based compression method (Clarke and Lapata, 2008). The other is to adapt it to social media text summarization task, where text is much more noisy. As graph cut is a general method, applying it to other binary structured learning tasks is also an interesting direction.

Abstract

In a language generation system, a content planner selects which elements must be included in the output text and the ordering between them. Recent empirical approaches perform content selection without any ordering and have thus no means to ensure that the output is coherent. In this paper we focus on the problem of generating text from a database and present a trainable end-to-end generation system that includes both content selection and ordering. Content plans are represented intuitively by a set of grammar rules that operate on the document level and are acquired automatically from training data. We develop two approaches: the first one is inspired from Rhetorical Structure Theory and represents the document as a tree of discourse relations between database records; the second one requires little linguistic sophistication and uses tree structures to represent global patterns of database record sequences within a document. Experimental evaluation on two domains yields considerable improvements over the state of the art for both approaches.

1 Introduction

Concept-to-text generation broadly refers to the task of automatically producing textual output from non-linguistic input (Reiter and Dale, 2000). Depending on the application and the domain at hand, the input may assume various representations including databases, expert system knowledge bases, simulations of physical systems, or formal meaning representations. Generation systems typically follow a pipeline architecture consisting of three components: *content planning* (selecting and ordering the parts of the input to be mentioned in the output text), *sentence planning* (determining the structure and lexical content of individual sentences), and *surface realization* (verbalizing the chosen content in natural language). Traditionally, these components are hand-engineered in order to ensure output of high quality.

More recently there has been growing interest in the application of learning methods because of their promise to make generation more robust and adaptable. Examples include learning which content should be present in a document (Duboue and McKeown, 2002; Barzilay and Lapata, 2005), how it should be aligned to utterances (Liang et al., 2009), and how to select a sentence plan among many alternatives (Stent et al., 2004). Beyond isolated components, a few approaches have emerged that tackle concept-to-text generation end-to-end. Due to the complexity of the task, most models simplify the generation process, e.g., by treating sentence planning and surface realization as one component (Angeli et al., 2010), by implementing content selection without any document planning (Konstas and Lapata, 2012; Angeli et al., 2010; Kim and Mooney, 2010), or by eliminating content planning entirely (Belz, 2008; Wong and Mooney, 2007).

In this paper we present a trainable end-to-end generation system that captures all components of the traditional pipeline, including document planning. Rather than breaking up the generation process into a sequence of local decisions, each learned separately (Reiter et al., 2005; Belz, 2008; Chen and Mooney, 2008; Kim and Mooney, 2010), our model performs content planning (i.e., document planning and content selection), sentence planning (i.e., lex-

Output Text
Click start, point to settings, and then click control panel. Double-click users and passwords. On the advanced tab, click advanced.

(b) WINHELP

Figure 1: Database records and corresponding text for (a) weather forecasting and (b) Windows troubleshooting. Each record has a type (e.g., win-target), and a set of fields. Each field has a value, which can be categorical (in typewriter), an integer (in **bold**), or a literal string (in *italics*).

icalization of input entries), and surface realization jointly. We focus on the problem of generating text from a database. The input to our model is a set of database records and collocated descriptions, examples of which are shown in Figure 1.

Given this input, we define a probabilistic context-free grammar (PCFG) that captures the structure of the database and how it can be verbalized. Specifically, we extend the model of Konstas and Lapata (2012) which also uses a PCFG to perform content selection and surface realization, but does not capture any aspect of document planning. We represent content plans with grammar rules which operate on the document level and are embedded on top of the original PCFG. We essentially learn a discourse grammar following two approaches. The first one is linguistically naive but applicable to multiple languages and domains; it extracts rules representing global patterns of record sequences within a sentence and among sentences from a training corpus. The second approach learns document plans based on *Rhetorical Structure Theory* (RST; Mann and Thomson, 1988); it therefore has a solid linguistic foundation, but is resource intensive as it assumes access to a text-level discourse parser.

We learn document plans automatically using both representations and develop a tractable decoding algorithm for finding the best output, i.e., derivation in our grammar. To the best of our knowledge, this is the first data-driven model to incorporate document planning in a joint end-to-end system. Experimental evaluation on the WEATHERGOV (Liang et al., 2009) and WINHELP (Branavan et al., 2009) domains shows that our approach improves over Konstas and Lapata (2012) by a wide margin.

2 Related Work

Content planning is a fundamental component in a natural generation system. Not only does it determine which information-bearing units to talk about, but also arranges them into a structure that creates coherent output. It is therefore not surprising that many content planners have been based on theories of discourse coherence (Hovy, 1993; Scott and de Souza, 1990). Other work has relied on generic planners (Dale, 1988) or schemas (Duboue and McKeown, 2002). In all cases, content plans are created manually, sometimes through corpus analysis. A few researchers recognize that this top-down approach to planning is too inflexible and adopt a generate-and-rank architecture instead (Mellish et al., 1998; Karamanis, 2003; Kibble and Power, 2004). The idea is to produce a large set of candidate plans and select the best one according to a ranking function. The latter is typically developed manually taking into account constraints relating to discourse coherence and the semantics of the domain.

Duboue and McKeown (2001) present perhaps the first empirical approach to content planning. They use techniques from computational biology to learn the basic patterns contained within a plan and the ordering among them. Duboue and McKeown (2002) learn a tree-like planner from an aligned corpus of semantic inputs and corresponding human-authored outputs using evolutionary al-

gorithms. More recent data-driven work focuses on end-to-end systems rather than individual components, however without taking document planning into account. For example, Kim and Mooney (2010) first define a generative model similar to Liang et al. (2009) that selects which database records to talk about and then use an existing surface realizer (Wong and Mooney, 2007) to render the chosen records in natural language. Their content planner has no notion of coherence. Angeli et al. (2010) adopt a more unified approach that builds on top of the alignment model of Liang et al. (2009). They break record selection into a series of locally coherent decisions, by first deciding on what records to talk about. Each choice is based on a history of previous decisions, which is encoded in the form of discriminative features in a log-linear model. Analogously, they choose fields for each record, and finally verbalize the input using automatically extracted domain-specific templates from training data.

Konstas and Lapata (2012) propose a joint model, which recasts content selection and surface realization into a parsing problem. Their model optimizes the choice of records, fields and words simultaneously, however they still select and order records locally. We replace their content selection mechanism (which is based on a simple markovized chaining of records) with global document representations. A *plan* in our model is identified either as a sequence of sentences, each containing a sequence of records, or as a tree where the internal nodes denote discourse information and the leaf nodes correspond to records.

3 Problem Formulation

The generator takes as input a set of database records $\mathbf{d}$ and outputs a text g that verbalizes some of these records. Each record token $r_i \in \mathbf{d}$, with $1 \leq i \leq |\mathbf{d}|$, has a type $r_i.t$ and a set of fields f associated with it. Fields have different values $f.v$ and types $f.t$ (i.e., integer, categorical, or literal strings). For example, in Figure 1b, win-target is a record type with three fields: cmd (denotes the action the user must perform on an object on their screen, e.g., left-click), name (denotes the name of the object), and type (denotes the type of the object). The values of these fields are `dblclick`, *users and passwords*, and `item`; name is a literal string, the rest are categorical.

During training, our algorithm is given a corpus consisting of several *scenarios*, i.e., database records paired with texts w (see Figure 1). For each scenario, the model first decides on a *global document plan*, i.e., it selects which *types of records* belong to each sentence (or phrase) and how these sentences (or phrases) should be ordered. Then it selects appropriate record tokens for each type and progressively chooses the most relevant fields; then, based on the values of the fields, it generates the final text, word by word.

Grammar Rules
1. $\mathrm{S} \rightarrow \mathrm{R}(\mathrm{start})$
2. $\mathrm{R}(r_i.t) \rightarrow \mathrm{FS}(r_j, start)\ \mathrm{R}(r_j.t) \mid \mathrm{FS}(r_j, start)$
3. $\mathrm{FS}(r, r.f_i) \rightarrow \mathrm{F}(r, r.f_j)\ \mathrm{FS}(r, r.f_j) \mid \mathrm{F}(r, r.f_j)$
4. $\mathrm{F}(r, r.f) \rightarrow \mathrm{W}(r, r.f)\ \mathrm{F}(r, r.f) \mid \mathrm{W}(r, r.f)$
5. $\mathrm{W}(r, r.f) \rightarrow \alpha \mid \mathrm{g}(f.v)$

Figure 2: Grammar G of the original model. Parentheses denote features, and impose constraints on the grammar.

4 Original Model

Our work builds on the model developed by Konstas and Lapata (2012). The latter is essentially a PCFG which captures both the structure of the input database and the way it renders into natural language. This grammar-based approach lends itself well to the incorporation of document planning which has traditionally assumed tree-like representations. We first briefly describe the original model and then present our extensions in Section 5.

Grammar Grammar G in Figure 2 defines a set of non-recursive CFG rewrite rules that capture the structure of the database, i.e., the relationship between records, records and fields, fields and words. These rules are domain-independent and could be applied to any database provided it follows the same structure. Non-terminal symbols are in capitals, the terminal symbol α corresponds to the vocabulary of the training set and $g(f.v)$ is a function which generates integers given the field value $f.v$. Note that all non-terminals have features (in parentheses) which

act as constraints and impose non-recursion (e.g., in rule (2) $i \neq j$, so that a record cannot emit itself).

Rule (1) defines the expansion from the start symbol S to the first record R of type *start*. The rules in (2) implement content selection, by choosing appropriate records from the database and generating a sequence. $\mathrm{R}(r_i.t)$ is the source record, $\mathrm{R}(r_j.t)$ is the target record and $\mathrm{FS}(r_j.start)$ is a place-holder symbol for the set of fields of record token r_j. This method is locally optimal, since it only keeps track of the previous type of record for each re-write. The rules in (3) conclude content selection on the field level, i.e., after we have chosen a record, we select and order the corresponding fields. Finally, the rules in (4) and (5) correspond to surface realization. The former rule binarizes the sequence of words emitted by a particular field $r.f$ in an attempt to capture local dependencies between words, such as multi-word expressions (e.g., right click, radio button). The latter rule defines the emission of words and integer numbers[1], given a field type and its value. Note that the original model lexicalizes field values of categorical and integer type only.

Training The rules of grammar G are associated with weights that are learned using the EM algorithm (Dempster et al., 1977). During training, the records, fields and values of database $\mathbf{d}$ and the words w from the associated text are observed, and the model learns the mapping between them. Notice that we use w to denote the gold-standard text and g to refer to the words generated by the model. The mapping between the database and the observed text is unknown and thus the weights of the rules define a hidden correspondence h between records, fields and their values.

Decoding Given a trained grammar G and an input scenario from a database $\mathbf{d}$, the model generates text by finding the most likely derivation, i.e., sequence of rewrite rules for the input. Although resembling parsing, the generation task is subtly different. In parsing, we observe a string of words and our goal is to find the most probable syntactic structure, i.e., hidden correspondence $\hat{h}$. In generation, however, the string is not observed; instead, we must find the best text $\hat{g}$, by maximizing both over h and g, where $g = g_1 \dots g_N$ is a sequence of words licensed by G. More formally:

$$\hat{g} = f\Big(\arg\max_{g,h} P\big((g,h)\big)\Big) \tag{1}$$

where f is a function that takes as input a derivation tree (g,h) and returns $\hat{g}$. Konstas and Lapata (2012) use a modified version of the CYK parser (Kasami, 1965; Younger, 1967) to find $\hat{g}$. Specifically, they intersect grammar G with a n-gram language model and calculate the most probable generation $\hat{g}$ as:

$$\hat{g} = f\Big(\arg\max_{g,h} p(g) \cdot p(g,h \,|\, \mathbf{d})\Big) \tag{2}$$

where $p(g,h \,|\, \mathbf{d})$ is the decoding likelihood for a sequence of words $g = g_1 \dots g_N$ of length N and the hidden correspondence h that emits it, i.e., the likelihood of the grammar for a given database input scenario $\mathbf{d}$. $p(g)$ is a measure of the quality of each output and is provided by the n-gram language model.

5 Extensions

In this section we extend the model of Konstas and Lapata (2012) by developing two more sophisticated content selection approaches which are informed by a global plan of the document to be generated.

5.1 Planning with Record Sequences

Grammar Our key idea is to replace the content selection mechanism of the original model with a *document plan* which essentially defines a grammar on record types. We split a document into sentences, each terminated by a full-stop. Then a sentence is further split into a sequence of record types. Contrary to the original model, we observe a complete sequence[2] of record types, split into sentences. This way we learn domain-specific patterns of frequently occurring record type sequences among the sentences of a document, as well as more local structures within a sentence. We thus substitute rules (1)–(2) in Figure 2 with sub-grammar G_{RSE} based on record type sequences:

Definition 1 (G_{RSE} grammar)

$$G_{RSE} = \{\Sigma_R,\, N_{RSE},\, P_{RSE},\, D\}$$

[1] The function $g(f.v) : \mathbb{Z} \rightarrow \mathbb{Z}$, generates an integer in the following six ways (Liang et al., 2009): identical, rounding up/down to a multiple of 5, rounding off a multiple of 5 and adding or subtracting some noise modelled by a geometric distribution.

[2] Note that a sequence is different from a permutation, as we may allow repetitions or omissions of certain record types.

where Σ_R is a set of terminal symbols $R(r.t)$, and N_{RSE} is a set of non-terminal symbols:

$$N_{RSE} = \{D, SENT\}$$

where D represents the start symbol and $SENT$ a sequence of records. P_{RSE} is a set of production rules of the form:

(a) $D \rightarrow SENT(t_i, \ldots, t_j) \ \ldots \ SENT(t_l, \ldots, t_m)$

(b) $SENT(t_i, \ldots, t_j) \rightarrow R(r_a.t_i) \ \ldots \ R(r_k.t_j) \cdot$

where t is a record type, t_i, t_j, t_l and t_m may overlap and r_a, r_k are record tokens of type t_i and t_j respectively. The corresponding weights for the production rules P_{RSE} are:

Definition 2 (G_{RSE} weights)

(a) $p(t_i, \ldots, t_j, \ldots t_l, \ldots, t_m \mid D)$

(b) $p(t_i) \cdot \ldots \cdot p(t_j) = \frac{1}{|\mathbf{s}(t_i)|} \cdot \ldots \cdot \frac{1}{|\mathbf{s}(t_j)|}$

where $\mathbf{s}(t)$ is a function that returns the set of records with type t (Liang et al., 2009).

Rule (a) defines the expansion from the start symbol D to a sequence of sentences, each represented by the non-terminal $SENT$. Similarly to the original grammar G, we employ the use of features (in parentheses) to denote a sequence of record types. The same record types may recur in different sentences, but not in the same one. The weight of rule (a) is simply the joint probability of all the record types present, ordered and segmented appropriately into sentences in the document, given the start symbol.

Once record types have been selected (on a per sentence basis) we move on to rule (b) which describes how each non-terminal $SENT$ expands to an ordered sequence of records R, as they are observed within a sentence (see the terminal symbol '.' at the end of the rule). Notice that a record type t_i may correspond to several record tokens r_a. Rules (3)–(5) in grammar G make decisions on these tokens based on the overall content of the database and the field/value selection. The weight of this rule is the product of the weights of each record type. This is set to the uniform distribution over $\{1, ..., |\mathbf{s}(t)|\}$ for record type t, where $|\mathbf{s}(t)|$ is the number of records with that type.

Figure 3d shows an example tree for the database input in Figure 1b, using G_{RSE} and assuming that the alignments between records and text are given. The top level of the tree refers to the sequence of record types as they are observed in the text. The first sentence contains three records with types 'desktop', 'start' and 'start-target', each corresponding to the textual segments *click start*, *point to settings*, *and then click control panel*. The next level on the tree, denotes the choice of record tokens for each sentence, provided that we have decided on the choice and order of their types (see Figure 3b). In Figure 3d, the bottom-left sub-tree corresponds to the choice of the first three records of Figure 1b.

Training A straightforward way to train the extended model would be to embed the parameters of G_{RSE} in the original model and then run the EM algorithm using inside-outside at the E-step. Unfortunately, this method will induce a prohibitively large search space. Rule (a) enumerates all possible combinations of record type sequences and the number grows exponentially even for a few record types and a small sequence size. To tackle this problem, we extracted rules for G_{RSE} from the training data, based on the assumption that there will be far fewer unique sequences of record types per dataset than exhaustively enumerating all possibilities.

For each scenario, we obtain a word-by-word alignment between the database records and the corresponding text. In our experiments we used Liang et al.'s (2009) unsupervised model, however any other semi- or fully supervised method could be used. As we show in Section 7, the quality of the alignment inevitably correlates with the quality of the extracted grammar and the decoder's output. We then map the aligned record tokens to their corresponding types, merge adjacent words with the same type and segment on punctuation (see Figure 3b). Next, we create the corresponding tree according to G_{RSE} (Figure 3d) and binarize it. We experimented both with left and right binarization and adhered to the latter, as it obtained a more compact set of rules. Finally, we collectively count the rule weights on the resulting treebank and extract a rule set, discarding rules with frequency less than three.

Using the extracted (weighted) G_{RSE} rules, we run the EM algorithm via inside-outside and learn the weights for the remaining rules in G. Decoding remains the same as in Konstas and Lapata (2012); the only requirement is that the extracted grammar remains binarized in order to guarantee the cubic

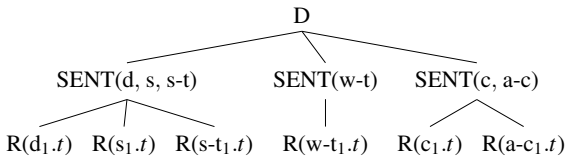
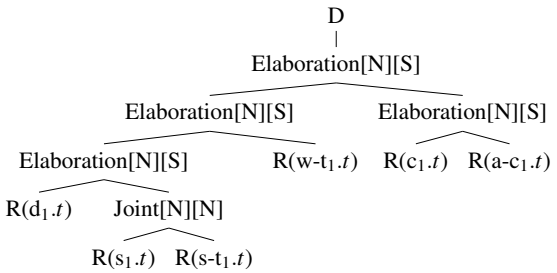
(c) Segmentation of text into EDUs



(d) Document plan using the G_{RSE} grammar



(e) Document plan using the G_{RST} grammar

Figure 3: Grammar extraction example from the WINHELP domain using G_{RSE} and G_{RST}. For G_{RSE}, we take the alignments of records on words and map them to their corresponding types (a); we then segment record types into sentences (b); and finally, create a tree using grammar G_{RSE} (c). For G_{RST}, we segment the text into EDUs based on the records they align to (d) and output the discourse tree (omitted here for brevity's sake); we build the document plan once we substitute the EDUs with their corresponding record types (e).

bound of the Viterbi search algorithm. Note that the original grammar is limited to the generation of categorical and integer values. We extend it to support the generation of strings. The following rule adds a simple verbatim lexicalization for string values:

$$\mathrm{W}(r, r.f) \rightarrow gen\_str(f.v, i)$$
$$gen\_str(f.v, i) : V \rightarrow V,\ f.v \in V$$

where V is the set of words for the fields of type string, and gen_str is a function that takes the value of a string-typed field $f.v$, and the position i in the string, and generates the corresponding word at that position. For example, gen_str(*users and passwords*, 3) = *passwords*. The weight of this rule is set to 1.

5.2 Planning with Rhetorical Structure Theory

Grammar RST (Mann and Thompson, 1988) is a theory of text organization which provides a framework for analyzing text. A basic tenet of the theory is that a text consists of hierarchically organized text spans or elementary discourse units (EDUs) that stand in various relations to one another (e.g., *Elaboration*, *Attribution*). These "rhetorical relations" hold between two adjacent parts of the text, where typically, one part is "nuclear" and one a "satellite". An analysis of a text consists in identifying the relations holding between successively larger parts of the text, yielding a natural hierarchical description of the rhetorical organization of the text. From its very inception, RST was conceived as a way to characterize text and textual relations for the purpose of text generation.

In order to create a RST-inspired document plan for our input (i.e., database records paired with texts), we make the following assumption: each record corresponds to a unique non-overlapping span in the collocated text, and can be therefore mapped to an EDU. Assuming the text has been segmented and aligned to a sequence of records, we can create a discourse tree with record types (in place of their corresponding EDUs) as leaf nodes. Again, we define a sub-grammar G_{RST} which replaces rules (1)–(2) from Figure 2:

Definition 3 (G_{RST} grammar)

$$G_{RST} = \{\Sigma_R, N_{RST}, P_{RST}, D\}$$

where Σ_R is the alphabet of leaf nodes as defined in Section 5.1, N_{RST} is a set of non-terminals corresponding to rhetorical relations augmented with nucleus-satellite information (e.g., *Elaboration[N][S]* stands for the elaboration relation between the nucleus EDU left-adjoining with the satellite EDU), P_{RST} is the set of production rules of the form $P_{RST} \subseteq N_{RST} \times \{N_{RST} \cup \Sigma_R\} \times \{N_{RST} \cup \Sigma_R\}$ associated with a weight for each rule, and $D \in N_{RST}$ is the root symbol. Figure 3e gives the discourse tree for the database input of Figure 1b, using G_{RST}.

Training In order to obtain the weighted productions of G_{RST}, we use an existing state-of-the-art discourse parser[3] (Feng and Hirst, 2012) trained on the RST-DT corpus (Carlson et al., 2001). The latter contains a selection of 385 Wall Street Journal articles which have been annotated using the framework of RST and an inventory of 78 rhetorical relations, classified into 18 coarse-grained categories (Carlson and Marcu, 2001). Figure 4 gives a comparison of the distribution of relations extracted for the two datasets we used, against the gold-standard annotation of RST-DT. The statistics for the RST-DT corpus are taken from Williams and Power (2008). The relative frequencies of relations on both datasets follow closely the distribution of those in RST-DT, thus empirically supporting the application of the RST framework to our data.

We segment each document in our training set into EDUs based on the record-to-text alignments given by the model of Liang et al. (2009) (see Figure 3c). We then run the discourse parser on the resulting EDUs, and retrieve the corresponding discourse tree; the internal nodes are labelled with one of the RST relations. Finally, we replace the leaf EDUs with their respective terminal symbols $R(r.t) \in \Sigma_R$ (Figure 3e) and collect the resulting grammar productions; their weights are calculated via maximum likelihood estimation based on their collective counts in the parse trees licensed by G_{RST}. Training and decoding of the extended generation model (after we embed G_{RST} in the original grammar G) is performed identically to Section 5.1.

6 Experimental Design

Data Since our aim was to evaluate the planning component of our model, we used datasets whose documents are at least a few sentences long. Specifically, we generated weather forecasts and troubleshooting guides for an operating system. For the first domain (henceforth WEATHERGOV) we used the dataset of Liang et al. (2009), which consists of 29,528 weather scenarios for 3,753 major US cities (collected over four days). The database has 12 record types, each scenario contains on average 36 records, 5.8 out of which are mentioned in the text. A document has 29.3 words and is four sentences long. The vocabulary is 345 words. We used 25,000 scenarios from WEATHERGOV for training, 1,000 scenarios for development and 3,528 scenarios for testing.

For the second domain (henceforth WINHELP) we used the dataset of Branavan et al. (2009), which consists of 128 scenarios. These are articles from Microsoft's Help and Support website[4] and contain step-by-step instructions on how to perform tasks on the Windows 2000 operating system. In its original format, the database provides a semantic representation of the textual guide, i.e., it represents the user's actions on the operating system's UI. We semi-automatically converted this representation into a schema of records, fields and values, following the conventions adopted in Branavan et al. (2009).[5] The final database has 13 record types. Each scenario has 9.2 records and each document 51.92 words with 4.3 sentences. The vocabulary is 629 words. We performed 10-fold cross-validation on the entire dataset for training and testing. Compared to WEATHERGOV, WINHELP documents are longer with a larger vocabulary. More importantly, due to the nature of the domain, i.e., giving instructions, content selection is critical not only in terms of what to say but also in what order.

Grammar Extraction and Parameter Setting We obtained alignments between database records and textual segments for both domains and grammars (G_{RSE} and G_{RST}) using the unsupervised model of Liang et al. (2009). On WEATHERGOV, we extracted a G_{RSE} grammar with 663 rules (after bi-

[4]`support.microsoft.com`

[5]The dataset can be downloaded from `http://homepages.inf.ed.ac.uk/ikonstas/index.php?page=resources`

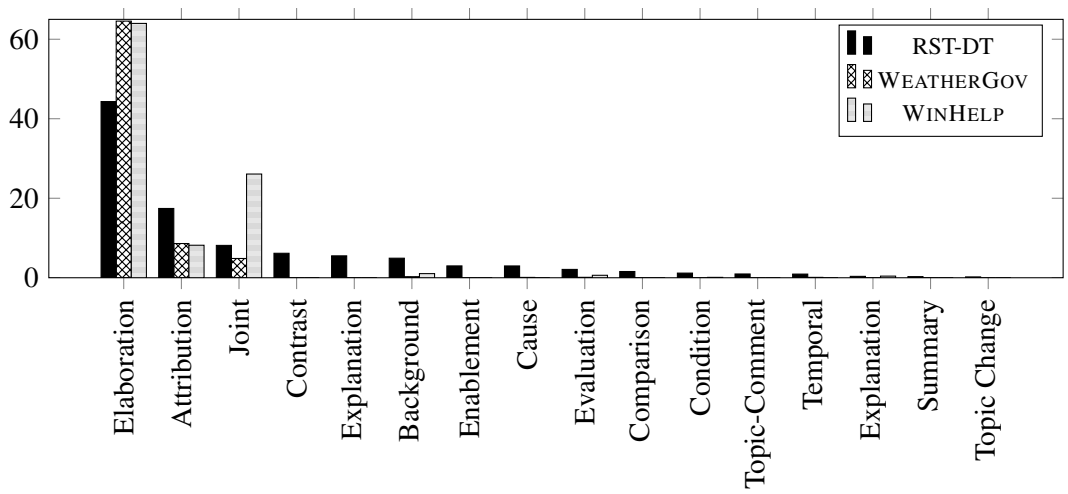

Figure 4: Distribution of RST relations on WEATHERGOV, WINHELP, and the RST-DT (Williams and Power, 2008).

narization). The WINHELP dataset is considerably smaller, and as a result the procedure described in Section 5.1 yields a very sparse grammar. To alleviate this, we *horizontally markovized* the right-hand side of each rule (Collins, 1999; Klein and Manning, 2003).[6] After markovization, we obtained a G_{RSE} grammar with 516 rules. On WEATHERGOV, we extracted 434 rules for G_{RST}. On WINHELP we could not follow the horizontal markovization procedure, since the discourse trees are already binarized. Instead, we performed *vertical markovization*, i.e., annotated each non-terminal with their parent node (Johnson, 1998) and obtained a G_{RST} grammar with 419 rules. The model of Konstas and Lapata (2012) has two parameters, namely the number of k-best lists to keep in each derivation, and the order of the language model. We tuned k experimentally on the development set and obtained best results with 60 for WEATHERGOV and 120 for WINHELP. We used a trigram model for both domains, trained on each training set.

Evaluation We compared two configurations of our system, one with a content planning component based on record type sequences (G_{RSE}) and another one based on RST (G_{RST}). In both cases content plans were extracted from (noisy) unsupervised alignments. As a baseline, we used the original model of Konstas and Lapata (2012). We also compared our model to Angeli et al.'s system (2010), which is state of the art on WEATHERGOV.

System output was evaluated automatically, using the BLEU modified precision score (Papineni et al., 2002) with the human-written text as reference. In addition, we evaluated the generated text by eliciting human judgments. Participants were presented with a scenario and its corresponding verbalization and were asked to rate the latter along three dimensions: fluency (is the text grammatical?), semantic correctness (does the meaning conveyed by the text correspond to the database input?) and coherence (is the text comprehensible and logically structured?). Participants used a five point rating scale where a high number indicates better performance. We randomly selected 12 documents from the test set (for each domain) and produced output with the system of Konstas and Lapata (2012) (henceforth K&L), our two models using G_{RSE} and G_{RST}, respectively, and Angeli et al. (2010) (henceforth ANGELI). We also included the original text (HUMAN) as gold-standard. We obtained ratings for 60 (12×5) scenario-text pairs for each domain. Examples of the documents shown to the participants are given in Table 1.

The study was conducted over the Internet us-

[6] When horizontally markovizing, we can encode an arbitrary amount of context in the intermediate non-terminals that result from this process; in our case we store h=1 horizontal siblings plus the mother left-hand side (LHS) non-terminal, in order to uniquely identify the Markov chain. For example, $A \rightarrow B\ C\ D$ becomes $A \rightarrow B\ \langle A \ldots B \rangle$, $\langle A \ldots B \rangle \rightarrow C\ \langle A \ldots C \rangle$, $\langle A \ldots C \rangle \rightarrow D$.

Right-click local area connection, and then click properties. Click to select the file and printer sharing for Microsoft networks check box. Click ok.

Table 1: Human-authored text and system output on WEATHERGOV and WINHELP.

ing Amazon Mechanical Turk[7], and involved 200 volunteers (100 for WEATHERGOV, and 100 for WINHELP), all self reported native English speakers. For WINHELP, we made sure participants were computer-literate and familiar with the Windows operating system by administering a short questionnaire prior to the experiment.

7 Results

The results of the automatic evaluation are summarized in Table 2. Overall, our models outperform K&L's system by a wide margin on both datasets. The two content planners (G_{RSE} and G_{RST}) perform comparably in terms of BLEU. This suggests that document plans induced solely from data are of similar quality to those informed by RST. This is an encouraging result given that RST-style discourse parsers are currently available only for English. ANGELI performs better on WEATHERGOV possibly due to better output quality on the surface level. Their system defines trigger patterns that specifically lexicalize record fields containing numbers. In contrast, on WINHELP it is difficult to explicitly specify such patterns, as none of the record fields are numeric; as a result their system performs poorly compared to the other models.

To assess the impact of the alignment on the content planner, we also extracted G_{RSE} from cleaner alignments which we obtained automatically via human-crafted heuristics for each domain. The heuristics performed mostly anchor matching between database records and words in the text (e.g., the value `Lkly` of the field rainChance, matches with the string *rain likely* in the text). Using these alignments, G_{RSE} obtained a BLEU score of 39.23 on WEATHERGOV and 41.35 on WINHELP. These results indicate that improved alignments would lead to more accurate grammar rules. WEATHERGOV seems more sensitive to the alignments than WINHELP. This is probably because the dataset shows more structural variations in the choice of record types at the document level, and therefore the grammar extracted from the unsupervised alignments is noisier. Unfortunately, performing this kind of analysis for G_{RST} would require gold standard segmentation of our training corpus into EDUs which we neither have nor can easily approximate via heuristics.

The results of our human evaluation study are shown in Table 3. We carried out an Analysis of Variance (ANOVA) to examine the effect of system

Model	WEATHERGOV	WINHELP
G_{RSE}	35.60	40.92
G_{RST}	36.54	40.65
K&L	33.70	38.26
ANGELI	38.40	32.21

Table 2: Automatic evaluation of system output using BLEU-4.

	WEATHERGOV			WINHELP		
Model	FL	SC	CO	FL	SC	CO
G_{RSE}	4.25	3.75	4.18	3.59	3.21	3.35
G_{RST}	4.10	3.68	4.10	3.45	3.29	3.22
K&L	3.73	3.25	3.59	3.27	2.97	2.93
ANGELI	3.90	3.44	3.82	3.44	2.79	2.97
HUMAN	4.22	3.72	4.11	4.20	4.41	4.25

Table 3: Mean ratings for fluency (FL), semantic correctness (SC) and coherence (CO) on system output elicited by humans.

type (G_{RSE}, G_{RST}, K&L, ANGELI, and HUMAN) on fluency, semantic correctness and coherence ratings. Means differences of 0.2 or more are significant at the 0.05 level using a post-hoc Tukey test. Interestingly, we observe that document planning improves system output overall, not only in terms of coherence. Across all dimensions our models are perceived better than K&L and ANGELI. As far as coherence is concerned, the two content planners are rated comparably (differences in the means are not significant). Both G_{RSE} and G_{RST} are significantly better than the comparison systems (ANGELI and K&L). Table 1 illustrates examples of system output along with the gold standard content selection for reference, for the WEATHERGOV and WINHELP domains, respectively.

In sum, we observe that integrating document planning either via G_{RSE} or G_{RST} boosts performance. Document plans induced from record sequences exhibit similar performance, compared to those generated using expert-derived linguistic knowledge. Our systems are consistently better than K&L both in terms of automatic and human evaluation and are close or better than the supervised model of Angeli et al. (2010). We also show that feeding the system with a grammar of better quality can achieve state-of-the-art performance, without further changes to the model.

8 Conclusions

In this paper, we have proposed an end-to-end system that generates text from database input and captures all components of the traditional generation pipeline, including document planning. Document plans are induced automatically from training data and are represented intuitively by PCFG rules capturing the structure of the database and the way it renders to text. We proposed two complementary approaches to inducing content planners. In a first linguistically naive approach, a document is modelled as a sequence of sentences and each sentence as a sequence of records. Our second approach draws inspiration from Rhetorical Structure Theory (Mann and Thomson, 1988) and represents a document as a tree with intermediate nodes corresponding to discourse relations, and leaf nodes to database records.

Experiments with both approaches demonstrate improvements over models that do not incorporate document planning. In the future, we would like to tackle more challenging domains, such as NFL recaps, financial articles and biographies (Howald et al., 2013; Schilder et al., 2013). Our models could also benefit from the development of more sophisticated planners either via grammar refinement or more expressive grammar formalisms (Cohn et al., 2010).

Acknowledgments

We are grateful to Percy Liang and Gabor Angeli for providing us with their code and data. Thanks to Giorgio Satta and Charles Sutton for helpful comments and suggestions. We also thank the members of the Probabilistic Models reading group at the University of Edinburgh for useful feedback.

Abstract

Recent studies on extractive text summarization formulate it as a combinatorial optimization problem such as a *Knapsack Problem*, a *Maximum Coverage Problem* or a *Budgeted Median Problem*. These methods successfully improved summarization quality, but they did not consider the rhetorical relations between the textual units of a source document. Thus, summaries generated by these methods may lack logical coherence. This paper proposes a single document summarization method based on the trimming of a discourse tree. This is a two-fold process. First, we propose rules for transforming a rhetorical structure theory-based discourse tree into a dependency-based discourse tree, which allows us to take a tree-trimming approach to summarization. Second, we formulate the problem of trimming a dependency-based discourse tree as a *Tree Knapsack Problem*, then solve it with integer linear programming (ILP). Evaluation results showed that our method improved ROUGE scores.

1 Introduction

State-of-the-art extractive text summarization methods regard a document (or a document set) as a set of textual units (e.g. sentences, clauses, phrases) and formulate summarization as a combinatorial optimization problem, *i.e.* selecting a subset of the set of textual units that maximizes an objective without violating a length constraint. For example, McDonald (2007) formulated text summarization as a *Knapsack Problem*, where he selects a set of textual units that maximize the sum of significance scores of each unit. Filatova et al. (2004) proposed a summarization method based on a *Maximum Coverage Problem*, in which they select a set of textual units that maximizes the weighted sum of the conceptual units (e.g. unigrams) contained in the set. Although, their greedy solution is only an approximation, Takamura et al. (2009a) extended it to obtain the exact solution. More recently, Takamura et al. (2009b) regarded summarization as a *Budgeted Median Problem* and obtain exact solutions with integer linear programming.

These methods successfully improved ROUGE (Lin, 2004) scores, but they still have one critical shortcoming. Since these methods are based on subset selection, the summaries they generate cannot preserve the rhetorical structure of the textual units of a source document. Thus, the resulting summary may lack coherence and may not include significant textual units from a source document.

One powerful and potential way to overcome the problem is to include discourse tree constraints in the summarization procedure. Marcu (1998) regarded a document as a Rhetorical Structure Theory (RST) (William Charles, Mann and Sandra Annear, Thompson, 1988)-based discourse tree (RST-DT) and selected textual units according to a preference ranking derived from the tree structure to make a summary. Daumé et al. (2002) proposed a document compression method that directly models the probability of a summary given an RST-DT by using a noisy-channel model. These methods generate well-organized summaries, however, since they do not formulate summarizations as combinatorial op-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1515–1520,
Seattle, Washington, USA, 18-21 October 2013.

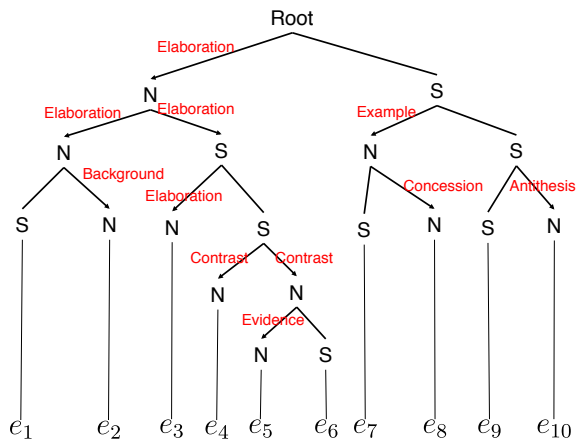

Figure 1: Example RST-DT from (Marcu, 1998).

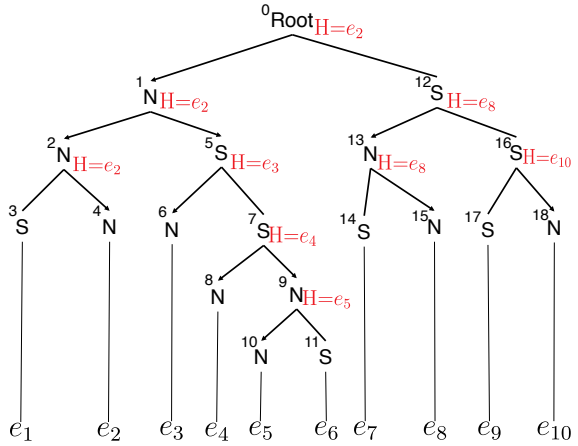

Figure 2: Heads of non-terminal nodes.

timization problems, the optimality of the generated summaries is not guaranteed.

In this paper, we propose a single document summarization method based on the trimming of a discourse tree based on the *Tree Knapsack Problem*. If a discourse tree explicitly represents parent-child relationships between textual units, we can apply the well-known tree-trimming approach to a discourse tree and reap the benefit of combinatorial optimization methods. In other words, to apply the tree-trimming approach, we need a tree whose all nodes represent textual units. Unfortunately, the RST-DT does not allow it, because textual units in the RST-DT are located only on leaf nodes and parent-child relationship between textual units are represented implicitly at higher positions in a tree. Therefore, we first propose rules that transform an RST-DT into a dependency-based discourse tree (DEP-DT) that explicitly defines the parent-child relationships. Second, we treat it as a rooted subtree selection, in other words, a *Tree Knapsack Problem* and formulate the problem as an ILP.

2 From RST-DT to DEP-DT

2.1 RST-DT

According to RST, a document is represented as an RST-DT whose terminal nodes correspond to elementary discourse units (EDU)s[1] and whose non-terminal nodes indicate the role of the contiguous EDUs namely, 'nucleus (N)' or 'satellite (S)'. A nucleus is more important than a satellite in terms of the writer's purpose. That is, a satellite is a child of a nucleus in the RST-DT. Some discourse relations such as 'Elaboration', 'Contrast' and 'Evidence' between a nucleus and a satellite or two nuclei are defined. Figure 1 shows an example of an RST-DT.

2.2 DEP-DT

An RST-DT is not suitable for tree trimming because it does not always explicitly define parent-child relationships between textual units. For example, if we consider how to trim the RST-DT in Figure 1, when we drop e_8, we have to drop e_7 because of the parent-child relationship defined between e_7 and e_8, *i.e.* e_7 is a satellite (child) of the nucleus (parent) e_8. On the other hand, we cannot judge whether we have to drop e_9 or e_{10} because the parent-child relationships are not explicitly defined between e_8 and e_9, e_8 and e_{10}. This view motivates us to produce a discourse tree that explicitly defines parent-child relationships and whose root node represents the most important EDU in a source document. If we can obtain such a tree, it is easy to formulate summarization as a *Tree Knapsack Problem*.

To construct a discourse tree that represents the parent-child relationships between EDUs, we propose rules for transforming an RST-DT to a dependency-based discourse tree (DEP-DT). The procedure is defined as follows:

1. For each non-terminal node excluding the par-

[1]EDUs roughly correspond to clauses.

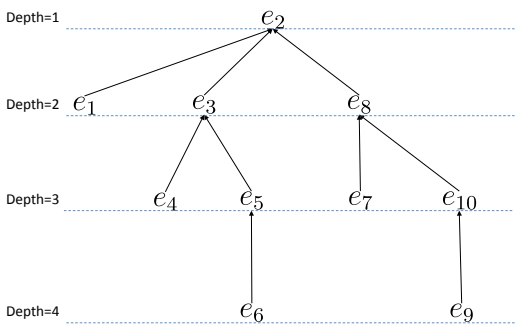

Figure 3: The DEP-DT obtained from the RST-DT in Figure 1.

ent of an EDU in the RST-DT, we define a 'head'. Here, a 'head' of a non-terminal node is the leftmost descendant EDU whose parent is N. In Figure 2, 'H' indicates the 'head' of each node.

2. For each EDU whose parent is N, we pick the nearest S with a 'head' from the EDU's ancestors and we add the EDU to the DEP-DT as a child of the head of the S's parent. If there is no nearest S, the EDU is the root of the DEP-DT. For example, in Figure 2, the nearest S to e_3 that has a head is node 5 and the head of node 5's parent is e_2. Thus, e_3 is a child of e_2.

3. For each EDU whose parent is S, we pick the nearest non-terminal with a 'head' from the ancestors and we add the EDU to the DEP-DT as a child of the head of the non-terminal node. For example, the nearest non-terminal node of e_9 that has a head is node 16 and the head of node 16 is e_{10}. Thus, e_9 is a child of e_{10}.

Figure 3 shows the DEP-DT obtained from the RST-DT in Figure 1. The DEP-DT expresses the parent-child relationship between the EDUs. Therefore, we have to drop e_7, e_9 and e_{10} when we drop e_8. Note that, by applying the rules, discourse relations defined between non-terminals of an RST-DT are eliminated. However, we believe that these relations are no needed for the summarization that we are attempting to realize.

3 Tree Knapsack Model for Single-Document Summarization

3.1 Formalization

We denote T as a set of all possible rooted subtrees obtained from a DEP-DT. $F(t)$ is the significance score for a rooted subtree $t \in T$ and L is the maximum number of words allowed in a summary. The optimal subtree t^* is defined as follows:

$$t^* = \arg\max_{t \in T} F(t) \quad (1)$$

$$s.t. \quad \text{Length}(t) \leq L. \quad (2)$$

Here, we define $F(t)$ as

$$F(t) = \sum_{e \in E(t)} \frac{\mathcal{W}(e)}{\text{Depth}(e)}. \quad (3)$$

$E(t)$ is the set of EDUs contained in t, $\text{Depth}(e)$ is the depth of an EDU e within the DEP-DT. For example, $\text{Depth}(e_2) = 1$, $\text{Depth}(e_6) = 4$ for the DEP-DT of Figure 3. $\mathcal{W}(e)$ is defined as follows:

$$\mathcal{W}(e) = \sum_{w \in W(e)} \text{tf}(w, D). \quad (4)$$

$W(e)$ is the set of words contained in e and $\text{tf}(w, D)$ is the term frequency of word w in a document D.

3.2 ILP Formulation

We formulate the optimization problem in the previous section as a *Tree Knapsack Problem*, which is a kind of *Precedence-Constrained Knapsack Problem* (Samphaiboon and Yamada, 2000) and we can obtain the optimal rooted subtree by solving the following ILP problem[2]:

$$\underset{\boldsymbol{x}}{\text{maximize}} \quad \sum_{i=1}^{N} \frac{\mathcal{W}(e_i)}{\text{Depth}(e_i)} x_i \quad (5)$$

$$s.t. \quad \sum_{i=1}^{N} \ell_i x_i \leq L \quad (6)$$

$$\forall i : x_{\text{parent}(i)} \geq x_i \quad (7)$$

$$\forall i : x_i \in \{0, 1\}, \quad (8)$$

[2]A similar approach has been applied to sentence compression (Filippova and Strube, 2008).

MCP	.279	.295^{H}	.073	.077
KP	.251	.266^{H}	.071	.075
LEAD	.255	.240	.092	.086

Table 1: ROUGE scores of the RST discourse treebank dataset. In the table, ^{G,H,K,L} indicate a method statistically significant against Marcu(G), Marcu(H), KP, LEAD, respectively.

where $\boldsymbol{x}$ is an N-dimensional binary vector that represents the summary, *i.e.* x_i=1 denotes that the i-th EDU is included in the summary. N is the number of EDUs in a document, ℓ_i is the length (the number of words) of the i-th EDU, and parent(i) indicates the ID of the parent of the i-th EDU in the DEP-DT. Constraint (6) ensures that the length of a summary is less than limit L. Constraint (7) ensures that a summary is a rooted subtree of the DEP-DT. Thus, $x_{\text{parent}(i)}$ is always 1 when the i-th EDU is included in the summary.

In general, the *Tree Knapsack Problem* is NP-hard, but fortunately we can obtain the optimal solution in a feasible time by using ILP solvers for documents of practical tree size. In addition, bottom-up DP (Lukes, 1974) and depth-first DP algorithms (Cho and Shaw, 1997) are known to find the optimal solution efficiently.

4 Experimental Evaluation

4.1 Settings

We conducted an experimental evaluation on the test collection for single document summarization evaluation contained in the RST Discourse Treebank (RST-DTB)(Carlson et al., 2001) distributed by the Linguistic Data Consortium (LDC)[3]. The RST-DTB Corpus includes 385 Wall Street Journal articles with RST annotation, and 30 of these documents also have one human-made reference summary. The average length of the reference summaries corresponds to about 10 % of the words in the source document.

We compared our method (TKP) with Marcu's method (Marcu) (Marcu, 1998), a simple knapsack model (KP), a maximum coverage model (MCP) and a lead method (LEAD). MCP is known to be a state-of-the-art method for multiple document summarization and we believe that MCP also performs well in terms of single document summarization. LEAD is also a widely used summarizer that simply takes the first K textual units of the document. Although this is a simple heuristic rule, it is known as a state-of-the-art summarizer (Nenkova and McKeown, 2011).

For our method, we examined two types of DEP-DT. One was obtained from the gold RST-DT. The other was obtained from the RST-DT produced by a state-of-the-art RST parser, HILDA (duVerle and Prendinger, 2009; Hernault et al., 2010). For Marcu's method, we examined both the gold RST-DT and HILDA's RST-DT. We re-implemented HILDA and re-trained it on the RST-DT Corpus excluding the 30 documents used in the evaluation. The F-score of the parser was around 0.5. For KP, we exclude constraint (7) from the ILP formulation of TKP and set the depth of all EDUs in equations (3) and (5) at 1. For MCP, we use tf (equation (4)) as the word weight.

We evaluated the summarization systems with ROUGE version 1.5.5 [4]. Performance metrics were the recall (R) and F-score (F) of ROUGE-1,2.

4.2 Results and Discussion

Table 1 shows the evaluation results. In the table, TKP(G) and TKP(H) denote methods with the DEP-DT obtained from the gold RST-DT and from HILDA, respectively. Marcu(G) and Marcu(H) denote Marcu's method described in (Marcu, 1998) with gold RST-DT and with HILDA, respectively. We performed a multiple comparison test for the differences among ROUGE scores, we calculated the p-values between systems with the Wilcoxon signed-rank test (Wilcoxon, 1945) and used the False Discovery Rate (FDR) (Benjamini and Hochberg, 1995) to calculate adjusted p-values, in order to limit false positive rate to 5%.

From the table, TKP(G) and Marcu(G) achieved

Reference:
The Fuji apple may one day replace the Red Delicious as the number one U.S. apple. Since the Red Delicious has been over-planted and prices have dropped to new lows, the apple industry seems ready for change. Along with growers, supermarkets are also trying different varieties of apples. Although the Fuji is smaller and not as perfectly shaped as the Red Delicious, it is much sweeter, less mealy and has a longer shelf life.

TKP(G):
We'll still have mom and apple pie. A Japanese apple called the Fuji. Some fruit visionaries say the Fuji could someday tumble the Red Delicious from the top of America's apple heap. It has a long shelf life. Now, even more radical changes seem afoot. The Delicious hegemony won't end anytime soon. New apple trees grow slowly. But the apple industry is ripe for change. There's a Fuji apple cult.

Marcu(G):
We'll still have mom and apple pie. On second thought, make that just mom. The Fuji could someday tumble the Red Delicious from the top of America's apple heap. Now, even more radical changes seem afoot. The Delicious hegemony won't end anytime soon. More than twice as many Red Delicious apples are grown as the Golden variety, America's No. 2 apple. But the apple industry is ripe for change.

MCP:
Called the Fuji. It has a long shelf life. New apple trees grow slowly. Its roots are patriotic. I'm going to have to get another job this year. Scowls. They still buy apples mainly for big, red good looks. Japanese researchers have bred dozens of strains of Fujis. Mr. Auvil, the Washington grower, says. Stores sell in summer. The " big boss " at a supermarket chain even rejected his Red Delicious recently. Many growers employ.

LEAD:
Soichiro Honda's picture now hangs with Henry Ford's in the U.S. Automotive Hall of Fame, and the game-show " Jeopardy " is soon to be Sony-owned. But no matter how much Japan gets under our skin, we'll still have mom and apple pie. On second thought, make that just mom. A Japanese apple called the Fuji is cropping up in orchards the way Hondas did on U.S. roads.

Figure 4: Summaries obtained from wsj_1128.

better results than MCP, KP and LEAD, although some of the comparisons are not significant. In particular, TKP(G) achieved the highest ROUGE scores on all measures. On ROUGE-1 Recall, TKP(G) significantly outperformed Marcu(G), Marcu(H), KP and LEAD. These results support the effectiveness of our method that utilizes the discourse structure. Comparing TKP(H) with Marcu(H), the former achieved higher scores with statistical significance on ROUGE-1. In addition, Marcu(H) was outperformed by MCP, KP and LEAD. The results confirm the effectiveness of our summarization model and trimming proposal for DEP-DT. Moreover, the difference between TKP(G) and TKP(H) was smaller than that between Marcu(G) and Marcu(H). This implies that our method is more robust against discourse parser error than Marcu's method.

Figure 4 shows the example summaries generated by TKP(G), Marcu(G), MCP and LEAD, respectively for an article, wsj_1128. Since TKP(G) and Marcu(G) utilize a discourse tree, the summary generated by TKP(G) is similar to that generated by Marcu(G) but it is different from those generated by MCP and LEAD.

5 Conclusion

This paper proposed rules for transforming an RST-DT to a DEP-DT to obtain the parent-child relationships between EDUs. We treated a single document summarization method as a *Tree Knapsack Problem*, *i.e.* the summarizer selects the best rooted subtree from a DEP-DT. To demonstrate the effectiveness of our method, we conducted an experimental evaluation using 30 documents selected from the RST Discourse Treebank Corpus. The results showed that our method achieved the highest ROUGE-1,2 scores.

Abstract

Social media like forums and microblogs have accumulated a huge amount of user generated content (UGC) containing human knowledge. Currently, most of UGC is listed as a whole or in pre-defined categories. This "list-based" approach is simple, but hinders users from browsing and learning knowledge of certain topics effectively. To address this problem, we propose a hierarchical entity-based approach for structuralizing UGC in social media. By using a large-scale entity repository, we design a three-step framework to organize UGC in a novel hierarchical structure called "cluster entity tree (CET)". With Yahoo! Answers as a test case, we conduct experiments and the results show the effectiveness of our framework in constructing CET. We further evaluate the performance of CET on UGC organization in both user and system aspects. From a user aspect, our user study demonstrates that, with CET-based structure, users perform significantly better in knowledge learning than using traditional list-based approach. From a system aspect, CET substantially boosts the performance of two information retrieval models (i.e., vector space model and query likelihood language model).

1 Introduction

With the development of Web 2.0, social media websites—such as online forums, blogs, microblogs, social networks, and community question answering (CQA) portals—have become the mainstream of web, where users create, share, and exchange information with each other. As a result, more and more UGC is accumulated, with social media websites retaining a huge amount of human knowledge and user experience. At present, most of UGC is organized in a list structure with extra information (e.g., category hierarchies in online forums), or without any other information.

Table 1: Sample questions about *Edinburgh*

1. Where can i buy a **hamburger** in **Edinburgh**?
2. Where can I get a **shawarma** in **Edinburgh**?
3. How long does it take to drive between **Glasgow** and **Edinburgh**?
4. Whats the difference between **Glasgow** and **Edinburgh**?
5. Good **hotels** in **London** and **Edinburgh**?
6. Looking for nice , clean cheap **hotel** in **Edinburgh**?
7. Does anyone know of a reasonably cheap **hotel** in **Edinburgh** that is near to **Niddry Street South** ?
8. Who can recommend a affordable **hotel** in **Edinburgh City Center**?

This "list-of-content" (list-based approach) is simple and straightforward, but ineffective for browsing and knowledge learning. Consider the following case: a user wants to spend his vacation in Edinburgh. He visits a CQA website to explore which aspects are mostly asked. In this scenario, he may browse some relevant categories like "Travel:United Kingdom:Edinburgh" to get useful information. He may also issue a query like "travel in Edinburgh" to search relevant questions. However, both the browsing and the searching give the user a list of relevant contents (e.g., questions shown in Table 1), not the direct knowledge. Thus, the user has to read these contents, understand them, classify them into various topics, and gain valuable

Seattle, Washington, USA, 18-21 October 2013.

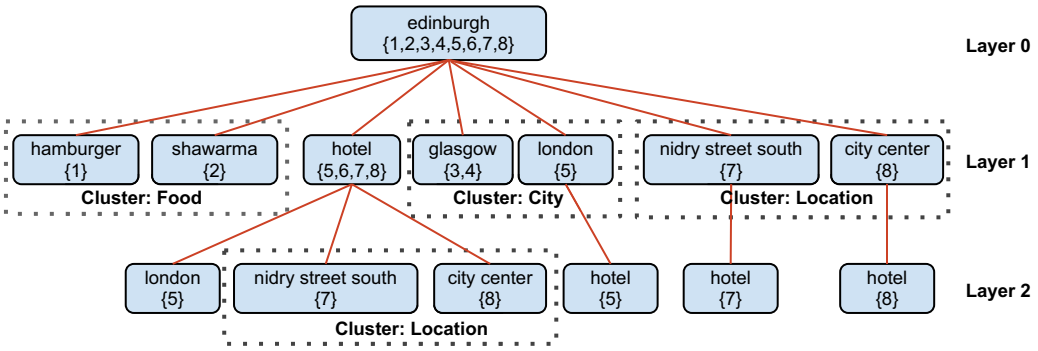

Figure 1: An CET constructed from questions about *Edinburgh*

knowledge himself. Obviously, it is ineffective and time-consuming.

The above problem calls for a new approach to structuralize UGC in social media, which facilitates users to seek knowledge (e.g., travel information about Edinburgh) more effectively. Traditionally, we can utilize topic models (Blei et al., 2003) or social tagging to structuralize UGC. However, for topic models, it is not easy to control the granularity of topics, and it is hard for users to interpret a topic only based on the multinomial distribution (Mei et al., 2007). For social tagging, it is not applicable in many sites and has sparsity problem (Shepitsen et al., 2008). Thus, both topic models and social tagging are not suitable for structuralizing UGC in social media.

In this paper, we propose a novel hierarchical entity-based approach, i.e., "cluster entity tree" or CET, to structuralize UGC in social media by leveraging an existing large-scale entity repository. Figure 1 shows how CET structuralizes UGC in Table 1. In this CET, each node contains one (named) entity and a set of question IDs. With "edinburgh" as the root entity, layer 1 includes all entities that co-occur with "edinburgh". Similarly, entities on layer 2 co-occur with their parent entities on layer 1 and the root entity "edinburgh". For example, "city center" co-occurs with "hotel" and "edinburgh" in Question 8. Deeper layers provide more specific topics about different aspects of Edinburgh (e.g., Edinburgh's hotels). As shown in Fig. 1, the corresponding question IDs are also attached in each node. In addition, entities which share the same parent are clustered to different groups (see dashed rectangles in Fig. 1)[1]. Through this hierarchical structure, we can easily browse corresponding questions and answers, and learn knowledge about Edinburgh more effectively, such as food and location. Moreover, since similar entities (and corresponding questions) are grouped in each layer, it also helps the system manage similar contents.

By utilizing a large-scale entity repository, CET avoids the granularity, interpretation, and sparsity problems. Entity repositories like Freebase[2] provide a large number of named entities across various pre-defined topics, which avoid the granularity and sparsity problems. In addition, they usually give descriptions of entities, which prevent the interpretation problem. Therefore, CET is more suitable for structuralizing UGC.

In this paper, we propose a three-step framework to construct CETs.

1. Entity extraction. In this step, we extract entities from documents using an existing entity repository.
2. Tree construction. we build the co-occurrence relationship between any two entities and construct hierarchical "entity trees (ETs)".
3. Hierarchical entity clustering. In an ET, some entities are more similar than other entities which share the same parents. Therefore, on each layer of the ET we cluster entities with the same parents (e.g., "london", "nidry street south", and "city center" on layer 2 of Fig. 1) and finally construct a CET.

We select Yahoo! Answers as a test case to evaluate 1) the performance of our framework for con-

[1]Single-node clusters are not surrounded by rectangles, like "hotel{5}" on layer 2.

[2]http://www.freebase.com/

structing CET and 2) the effectiveness of CET in UGC structuralization. Yahoo! Answers is a popular CQA portal, where users post questions and provide answers in different categories. Experimental results demonstrate the good performance of our framework for constructing CET. We further evaluate the effectiveness of CET in structuralizing UGC from both user and system aspects. From a user aspect, our user study show that, with CET-based organization, users perform significantly better in knowledge learning than using list-based approach. From a system aspect, CET boosts systems' information retrieval substantially: the mean reciprocal rank (MRR) of vector space model (VSM) and query likelihood language model (QLLM) are improved by 9.3% and 8.2%, respectively.

To summarize, our contributions are three-fold:

1. We propose a novel hierarchical entity-based approach to structuralize UGC in social media. To our knowledge, we are the first to utilize entities to structuralize UGC for content browsing and knowledge learning at a large scale;
2. We present a three-step framework to construct CETs and show its effectiveness from empirical results;
3. We demonstrate the significant advantages of our approach for both users and systems in knowledge learning and retrieval.

The paper proceeds as follows. We present related work in Section 2. We detail our framework to construct CETs and show empirical results in Section 3. Section 4 and Section 5 evaluate the effectiveness of CET on knowledge organization from user and system aspects respectively. We conclude the paper in Section 6.

2 Related Work

UGC organization in social media. Most UGC in social media is unstructured, or organized in a predefined category hierarchy. These categories give shallow semantics of UGC, and boosts the performance of information retrieval (Cao et al., 2008; Duan et al., 2008; Cao et al., 2012) and recommendation (Guo et al., 2008; Li et al., 2011). With new content kept adding into a hierarchy, we need to maintain category hierarchy (Yuan et al., 2012) to make content within the same category more topically cohesive.

Apart from category hierarchy, UGC can also be organized by topic models and tags. Topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003), are widely applied in document clustering and classification, However, it is not trivial to control the granularity of topics (Chen et al., 2011). What's more, it is generally difficult to understand a topic only from the multinomial distribution (Mei et al., 2007). Social tagging provides an alternative approach in document organization (Gupta et al., 2010). In some UGC websites like stackoverflow[3], users usually add tags to describe their contents. However, tags are not widely applicable and tags are usually sparse (Shepitsen et al., 2008). Our hierarchical entity-based approach prevents these problems by employing a large-scale entity repository. As the entity repository provides a unified set of entities across various of pre-defined topics, and gives descriptions of entities, CET avoids the granularity, interpretation and sparsity issues.

The work in (Zhu et al., 2013), which automatically generates and updates topic terms to organize UGC, is mostly related to our work. In this paper, given a root topic, subtopics and lower-level topics are extracted from UGC, which form a hierarchical structure to organize corresponding UGC. However, in (Zhu et al., 2013) more external sources are utilized to identify subtopics. In addition, relationships among subtopics which under the same parent are not investigated. The metro maps proposed in (Shahaf et al., 2013) are also related to our work. Different from (Shahaf et al., 2013), we employ a large-scale entity repository to extract more meaningful and interpretable key terms (entities), which make each subtopic much easier to understand.

Entity extraction. In our framework, we leverage an entity repository to extract named entities from UGC. A common approach is to utilize a Named Entity Recognition (NER) system like Stanford NER (Finkel et al., 2005), which recognizes the names of things (e.g., person and product names) from texts. For cross-domain NER, (Rüd et al., 2011) employed search engines. For short-text NER, (Liu et al., 2012) proposed a graphical model. However, most of above systems are restricted from

[3]http://stackoverflow.com/

producing labels for a few entity classes. To address the problem, (Ling and Weld, 2012) defined a fine-grained set of 112 tags based on Freebase for entity extraction. However, this approach still faces the "low-recall" problem in the real world. Our approach, which leverages a large-scale entity repository, addresses this issue.

Entity-based document classification and retrieval. Entity repository has been employed in other research areas, like document classification and retrieval. (Schonhofen, 2006) utilized Wikipedia to classify documents. (Yerva et al., 2012a) proposed an entity-based classification for tweets. In addition, entity-based retrieval models were proposed and applied in both QA archives (Singh, 2012a) and tweets (Yerva et al., 2012b). Besides, (Singh, 2012b) proposed an entity-based translation language model and demonstrated that it outperformed classical translation language model in question retrieval. However, to the best of our knowledge, no previous study leverages entities to organize UGC in social media.

3 CET Construction

In this section, we formulate the framework to construct CET and show the empirical results. Firstly, we provide the definitions of the entity repository and CET.

Definition 3.1 (Entity Repository) *Let $ER = \{R, g\}$ be an entity repository, where R is a set of named entities and $g : R \times R$ is a mapping function that defines the similarity of any two entities.*

Note that we do not require a hierarchical structure in an ER (like Freebase); only a similarity function is needed.

Definition 3.2 (Cluster Entity Tree) *Let D be a set of documents, $ER = \{R, g\}$ be an entity repository, e be an entity, a cluster entity tree $CET_e = (v_e, V, E, C)$ is defined as a tree structure, with the root node v_e, node set V, edge set E, and cluster set C. Each node $v_s \in V$ on CET_e includes an entity extracted from the set of documents $D_e \in D$ containing e, and a list $L(s)$ which stores the indexes of documents containing entity s and its superior entities. If v_s is v_t's parent node, entity t must co-occur with s and s's all superior entities at least once in the same document. Each element of C (one cluster) includes a set of nodes which share the same parent node, and the entities within a cluster are more similar to each other than the entities in other clusters.*

3.1 Framework

This section shows our three-step framework for constructing CET: entity extraction (Section 3.2.1), tree construction (Section 3.2.2), and hierarchical entity clustering (Section 3.2.3).

3.1.1 Entity Extraction

We adopt a simple entity repository based approach to extract entities, which address the "low-recall" problem for traditional NER methods (details are given in Section 3.3.2). This approach involves two phases: candidate entity extraction and entropy-based filtering.

Candidate entity extraction. We employ the Stanford Parser[4] to parse each document to a parse tree. Then, we extract all noun phrases, preprocess them (including stemming), and extract the noun phrases which are included in our entity repository. In our experiments, we adopt a large-scale enterprise entity repository (anonymized for blind reviews).

Entropy-based filtering. The candidate entities generated from the last step may contain many false examples, which are not relevant to the main semantics of documents, like "we", "how do i", etc. To filter them, we propose an entropy-based method. Given a document with a category label (or tags, which are available in most UGC sites), we get the distributions of each candidate entity over all top categories. The entropy of a candidate entity e_i is calculated as follows:

$$Entropy(e_i) = -\sum_{c=1}^{|C|} P_c(e_i) log P_c(e_i), \quad (1)$$

where $|C|$ is the number of top categories and $P_c(e_i)$ is the number of e_i in category c divided by all number of candidate entities in that category.

Top-ranked entities are general terms among categories. We set a threshold α and remove all candidate entities with entropy larger than α. The setting of α is a tradeoff: higher values will introduce more noise, while smaller values will lead to decreased

[4] http://nlp.stanford.edu/software/lex-parser.shtml

recall. In our experiments, we empirically set α as 1.5 since it provides the most satisfying results.

3.1.2 Tree Construction

Given an entity (e.g., "edinburgh"), we first search documents containing this entity and make the entity together with document ids as the root node. Then, from searched documents we find all entities that co-occur with the root entity. These entities and corresponding document ids form layer-1 nodes of the entity tree (see the example in Fig. 1). Afterwards, for each entity in layer-1 nodes, we search entities that co-occur with it and its superiors, combine them and corresponding document ids as new nodes, and put these new nodes under current node, which form layer-2 nodes. Iteratively, we construct the entity tree with the given entity as the root.

3.1.3 Hierarchical Entity Clustering

Under the same parent, some entities[5] may share similar topics. Therefore, the final step is to hierarchically cluster entities with the same parents at different layers of entity trees. This step not only facilitates knowledge learning but also reduces the width of a tree. In this paper, we follow the work in (Hu et al., 2012) and employ an agglomerative clustering algorithm for two reasons: 1) it is easy to implement and its time complexity is $O(N^2)$; 2) there is no need to set the number of clusters. Although the clustering results may be influenced by instance order, our empirical results demonstrate its effectiveness. Any other advanced algorithms like spectral clustering (Ng et al., 2002) can also be applied, but that is not the emphasis of this paper.

Algorithm. For a set of entities with the same parent, the agglomerative clustering algorithm works as follows:

1. Select one entity and create a new cluster which contains the entity;
2. Select the next entity e_i, create an empty candidate list, calculate the similarity between the entity and all existing clusters. Three strategies are employed[6]:
   - AC-MAX: If the similarity between entity e_i and entity e_j in one of the clusters (the first one) is larger than threshold θ_{max}, we put the cluster index and corresponding similarity in the candidate list.
   - AC-MIN: If the similarity between entity e_i and any entity e_j in one of the clusters is larger than threshold θ_{min}, we put the cluster index and corresponding similarity in the candidate list.
   - AC-AVG: If the mean similarity between entity e_i and any entity e_j in one of the clusters is larger than threshold θ_{avg}, we put the cluster index and corresponding similarity in the candidate list.
3. If the candidate list is not empty, put e_i in the cluster with highest similarly.
4. If the candidate list is empty, a new cluster with e_i as the element will be created.
5. Stop when all entities are clustered.

Similarity Function. In our entity repository, the similarity between two entities is computed using the approach in (Shi et al., 2010), which estimates the similarity of two terms according to their *first-order* and *second-order* co-occurrences. For example, "such as NP, NP" is a good pattern for detecting similar entities using *first-order* co-occurrences. In addition, if two entities usually co-occur with a third entity (*second-order* co-occurrence), these two entities are likely to be similar. To construct similarity functions, pattern-based approaches (Ohshima et al., 2006; Zhang et al., 2009) utilize *first-order* co-occurrences while distributional similarity approaches (Pasca et al., 2006; Pennacchiotti and Pantel, 2009) employ *second-order* co-occurrences. In the following, we briefly introduce the pattern-based approach (PB) and the distributional similarity approach (DS) in (Shi et al., 2010).

PB. Some well-designed patterns are leveraged to extract similar entities from a huge repository of webpages. The set of terms extracted by applying a pattern one time is called a raw semantic class (RASC). Given two entities t_a and t_b, PB calculates their similarity based on the number of RASCs containing both of them (Zhang et al., 2009):

$$Sim(t_a, t_b) = \log(1 + \sum_{i=1}^{r_{ab}} P_{ab_i})) \cdot \sqrt{idf(t_a) \cdot idf(t_b)}, \quad (2)$$

where $idf(t_a) = \log(1 + \frac{N}{C(t_a)})$, P_{ab_i} is a pattern which can generate RASC(s) containing both term

[5]Here we use the entity to represent the node.

[6]We modify the clustering algorithm in (Hu et al., 2012) slightly to assign a unique cluster for each entity.

t_a and term t_b, r_{ab} is the total number of such patterns, N is the total number of RASCs, and $C(t_a)$ is the number of RASCs containing t_a. The above similarity is normalized using the following function:

$$Sim_{PB}(t_a, t_b) == \frac{\log Sim(t_a, t_b)}{2 \log Sim(t_a, t_a)} + \frac{\log Sim(t_a, t_b)}{2 \log Sim(t_b, t_b)}. \quad (3)$$

DS. DS approach assumes that terms appearing in similar contexts tend to be similar. In this approach, a term is represented by a feature vector, with each feature corresponding to a context in which the term appears. The similarity between two terms is computed as the similarity between their corresponding feature vectors. Jaccard similarity is employed to estimate the similarity between two terms. Suppose the feature vector of t_a and t_b are **x** and **y** respectively,

$$Sim_{DS}(t_a, t_b) = \frac{\sum_i \min(x_i, y_i)}{\sum_i (x_i) + \sum_i (y_i) - \sum_i \min(x_i, y_i)}. \quad (4)$$

Shi et al. (Shi et al., 2010) found that PB performed better when dealing with proper nouns; while DS was relatively good at estimating similarity of other types of entities. The similarity function in our ER follows the suggestion of (Shi et al., 2010): if at least one entity is proper noun, PB is employed; otherwise DS is used.

3.2 Experiments

3.2.1 Setup

We evaluate the performance of our framework employing questions from Yahoo! Answers. 54.7 million questions are crawled from all 26 top categories in Yahoo! Answers, which consist of question titles and corresponding categories. From these questions, we construct the following two test sets for evaluating entity extraction and entity clustering:

Set EE. This set is employed to evaluate the performance of entity extraction. It contains 520 randomly sampled questions, 20 from each top category. One author is asked to label entities for each question.

Set EC. This set is constructed to automatically evaluate hierarchical entity clustering and select the best clustering strategy. The construction process is as follows. First, we map the four top categories of Yahoo! Answers to some categories of Freebase manually, as shown in Table 2. Second, from questions at each top category of Yahoo! Answers, we extract entities which appear exactly once in the corresponding Freebase categories. For instance, if an entity is extracted from questions in the category *Computers & Internet*, and it appears two or more times in *Computer* and *Internet* categories in Freebase, it will be filtered. Therefore, each entity is attached with a unique Freebase category label (i.e., the ground truth for clustering). Questions containing at least two entities are selected for Set EC. Table 3 reports the statistics. Intuitively, entities with a same Freebase category label should be in one cluster.

Table 2: Category mapping between Yahoo! Answers and FreeBase

Yahoo! Answers	FreeBase
Cars & Transportation	Aviation, Transportation, Boats Spaceflight, Automotive, Bicycles, Rail
Computers & Internet	Computer, Internet
Sports	Soccer, Olympics,Sports, American football, Baseball,Basketball,Ice Hockey,Martial Arts, Cricket,Tennis,Boxing,Skiing
Travel	Travel, Location, Transportation

Table 3: Number of questions and entities in Set EC

Category	Number of Questions	Number of Entities
Cars & Transportation	1,220,427	3,267,596
Computers & Internet	2,912,280	7,324,655
Sports	2,363,758	6,230,868
Travel	1,347,801	3,728,286

Note that Set EC only covers a small set of real entities and clustering on Set EC is partial clustering. However, it leverages Freebase labels and avoids manual labeling, which is time-consuming. Furthermore, partial clustering results are enough for evaluating different strategies' performance and choosing the best strategy.

Following the common practice, we evaluate entity extraction using precision, recall, and $F1$ score. For evaluating entity clustering results, we adopt B-cubed metrics. As reported in (Amigó et al., 2009), B-cubed metrics are more suitable than traditional metrics, such as NMI and purity.

Table 4: Entity extraction for various methods

Method	Precision	Recall	F1
Standord NER	0.750	0.155	0.257
FIGER	0.763	0.154	0.256
Freebase	0.644	0.595	0.619
Our	0.647	0.809	0.719

Table 5: Clustering results using AC-MAX (θ_{max}=0.1)

Level	*Travel*				*Cars & Transportation*				*Computer & Internet*				*Sports*			
	Count	P	R	F1	Count	P	R	F1	Count	P	R	F1	Count	P	R	F1
1	748	0.972	0.653	0.743	1281	0.948	0.868	0.897	3064	0.913	0.664	0.743	890	0.941	0.883	0.901
2	200	0.974	0.730	0.798	1202	0.989	0.956	0.965	11344	0.961	0.842	0.879	636	0.978	0.964	0.963
3	120	1.000	0.833	0.890	858	1.000	0.981	0.988	8184	0.978	0.899	0.920	492	0.965	0.882	0.899
4	NA	NA	NA	NA	1776	1.000	0.980	0.986	3648	0.990	0.908	0.934	1080	0.978	0.844	0.881
5	NA	NA	NA	NA	NA	NA	NA	NA	2520	1.000	0.952	0.968	NA	NA	NA	NA
Total	1068	0.976	0.688	0.770	5117	0.984	0.946	0.959	28760	0.968	0.857	0.891	3098	0.965	0.886	0.907

3.2.2 Results: Entity Extraction

Two ERs (i.e., ours and Freebase) are employed in entity extraction for comparison. In addition, we compare our approach with Stanford NER (Finkel et al., 2005) and fine-grained entity recognition (FIGER) (Ling and Weld, 2012). Table 4 reports the results of different methods. We can find that Stanford NER and FIGER get a relatively high precision in extracting entities. However, their recalls are very low and only about 15% of entities are recognized. With the help of entity repositories, recall is significantly improved with a small decrease of precision. Therefore, the $F1$s of entity-based approaches are much higher. This observation shows the great advantage of utilizing an entity repositories in entity extraction and the effectiveness of our approach. As our ER performs better than Freebase, we adopt it as our entity repository in the following evaluations.

3.2.3 Results: Hierarchical Entity Clustering

Table 5 reports the count of clusters, B-Cubed Precision, Recall, and F1 for different layers of clustering across four categories using **AC-MAX**. In our experiments, **AC-MAX** performed better than **AC-MIN** and **AC-AVG**. Due to space limitations, we only report the results of **AC-MAX** here. For **AC-MAX**, we changed the settings of θ from 0.01 to 0.9, and the best performance was achieved when θ_{max} was set at around 0.1. From Table 5 we can find that, although **AC-MAX**'s accuracy varies across categories (e.g., the $F1$ of *Transportation* is much higher than that of *Travel*), it performs well in general. Thus, we adopt **AC-MAX** with $\theta = 0.1$ for hierarchical entity clustering.

4 User Study

In this section, we investigate the influence of CET on users' content browsing and knowledge learning from a user study. In the study, we design 24 tasks in four popular Yahoo! Answers categories (see Table 2). For each category, we design three ***knowledge-learning*** tasks and three ***question-search*** tasks, as shown in Table A.1 in the supplementary material. A ***knowledge-learning*** task asks for some knowledge about a main entity from question texts. For instance, "find the games running on macbook pro" requires game names as the answer, where the main entity is "macbook pro". A ***question-search*** task, however, asks users to find similar questions to the question in the task. For example, "questions about who will win the MVP in NBA this year" asks for finding similar questions, and filling their question IDs as the answer. For each task, we give some suggested keywords (entities) to facilitate information gathering.

To evaluate user experience, we ask participants to fill out a questionnaire after each task. Following the work in (Kato et al., 2012), we collect information from 5 aspects: familiarity, easiness, satisfaction, adequate time, and helpfulness. A 5-point Likert scale is designed for each questionnaire. "5" means the participant totally agrees while "1" means the participant totally disagrees.

4.1 Setup

Programs. We develop two programs in our user study. One is CET-based, and the other is traditional list-based[7]. The list-based program searches questions by utilizing Apache Lucene[8]. The standard analyzer and the default search algorithm are adopted. For each query, top 200 most relevant questions are retrieved.

Data. We extract 70,195 questions which contain at least one of the 24 main entities (see Table A.1)

[7]The interface of CET-based program is provided in the supplementary material (see Fig. A.1). The interface of list-based program is similar, but the CET display area is replaced by a flat-ranked list.

[8]http://lucene.apache.org/core/

Table 6: User study results

	Knowledge-learning Tasks		*Question-search* Tasks	
	CET-based	List-based	CET-based	List-based
# Queries	2.99	4.47	2.56	3.38
# Answers	8.32	6.06	10.60	10.92
Precision	0.38	0.19	0.40	0.44
Time	136.44	121.87	103.71	87.75

Table 7: Questionnaire results

	Knowledge-learning Tasks		*Question-search* Tasks	
	CET-based	List-based	CET-based	List-based
Familiarity	3.18	3.22	3.07	3.28
Easiness	3.64	3.66	4.10	4.06
Satisfaction	3.70	2.94	3.86	3.44
Enough Time	3.87	3.83	4.44	4.54
Helpfulness	4.16	3.03	4.31	3.71

in the four categories. For each question, we extract the entities with the help of our entity repository. For each main entity, we build the corresponding CET from all extracted questions.

Participants. Sixteen volunteers are invited in the user study. They are first briefly informed of the research design and taught how to use two programs. To familiarize the participants with our programs promptly, we provide demonstrations using sample entities. Each volunteer is asked to finish 12 tasks (6 ***knowledge-learning*** tasks and 6 ***question-search*** tasks) using the CET-based program and 12 other tasks using the list-based program in random order. Thus, each task is finished by exactly 8 different participants using each program.

4.2 Results and Discussions

Table 6 reports the user study results, where we give the statistics for users' performance with the two programs. We evaluate from the number of queries issued, number of answers found, the precision of answers, and query time for each task. As our 24 tasks contain both knowledge-learning tasks and question-search tasks, we report their results separately. Z-tests are employed for significance tests.

From Table 6, we observe that more queries are issued in the knowledge-learning tasks than in the question-search tasks using both programs. However, the CET-based program reduces the number of queries substantially in both tasks. Because the CET-based program provides a series of clustered entities, it helpes users further refine queries through clicking on entities rather than reconstructing a new query. However, the list-based program only lists relevant questions, and users have to issue new queries according to returned questions.

By using the CET-based program, volunteers find more answers in knowledge-learning tasks ($z = 1.69, p < 0.05$). The reason is that the CET-based program clusters similar results in the same group, and if the user finds one answer she can easily get more answers. On the contrary, the list-based program returns a list of questions, and users need to find answers question-by-question. For question-search tasks, users of the list-based program find more answers, but the difference is not significant ($z = 0.19$). As the list-based program returns similar questions as top-ranked results, users are able to fill in answers easily. For CET-based program users, they have to find corresponding key entities in the CETs first. Therefore, they spend more time (the fourth row in Table 6) finding entities and less time filling answers. It is worth noting that our GUI prototype for CET is non-optimal, and users' searching time on CET-based program can be further reduced with better user interface.

The precision of answers from CET-based program users is twice of that from list-based program users ($z = 4.15, p < 0.0001$) in knowledge-learning tasks, which demonstrates the advantage of CET in helping knowledge-learning. For question-search tasks, CET-based program users perform slightly worse than list-based program users, but the difference is not significant ($z = 0.48$). Since users of the CET-based program spend more time finding entities, they have limited time to check the answers.

In both tasks, users spend more time on the CET-based program. According to users' post-user-study feedbacks, a few volunteers reported that they sometimes spent a considerable amount of time on finding entities from CETs; however, one positive observation is that most users find "the entity-based interface" very interesting, which stimulates them to spend more time on exploring answers.

The questionnaires reveal more about user experience on these two programs (see Table 7). Users' responses to task familiarity and easiness are similar. However, users of entity-based interface are more satisfied in both knowledge-learning tasks ($z = 3.98, p < 0.0001$) and question-search tasks ($z =$

1.38), and they feel that entity-based interface is more helpful in finding answers for both knowledge-learning tasks ($z = 6.47, p < 0.0001$) and question-search tasks ($z = 2.55, p < 0.01$). These promising observations show that CET helps knowledge learning greatly through structuralizing content.

5 CET-based Question Re-Ranking

In this section, we show that CET also helps systems to better retrieve information through re-ranking. In the following, we continue to use Yahoo! Answers as a test case.

Algorithm 1 CET-based search results re-ranking

Input: query q, question collection Q, a ranked list of k relevant questions $Q_q = \{q_1, q_2, ..., q_k\}$ to q, an entity repository ER, an empty list Θ.

Output: A new ranked list of questions.

1: Extract entities from each question of Q and construct a entity co-occurrence graph;
2: Get the PageRank score of each entity;
3: **if** There is no entity e in q **then**
4: return Q_q;
5: **else**
6: Identify the key entity e from q which has the highest PageRank score;
7: Construct the CET cet_e from Q based on ER;
8: **for** each question q_i **do**
9: For all entities in q_i, build a entity chain C in descending order of PageRank scores;
10: From C extract the first entity $\hat{e}$ that is not similar to e;
11: **if** $\hat{e}$ exists **then**
12: Put q_i in the corresponding cluster of nodes;
13: **else**
14: Put q_i in Θ;
15: **end if**
16: **end for**
17: **end if**
18: Rank all clusters on cet_e according to their first elements' original ranking;
19: Output the final ranking cluster by cluster and append the questions in Θ at the last.

Intuitively, questions sharing similar topics should be ranked similarly. However, traditional question retrieval models (Cao et al., 2010) such as QLLM and VSM do not capture key semantics and give more weights for entity terms. CET provides a feasible way to address this issue. By utilizing CET, entities are given more weight while trivial words are not. In addition, through clustering questions with similar topics, those questions which are ranked lower will be brought higher by their top-ranked neighbors.

Table 8: Re-ranking results for VSM and QLLM (* means that $p < 0.05$ in students' t-test)

	VSM	Re-ranking	QLLM	Re-ranking
MRR	0.3838	**0.4195*** (9.30%)	0.3593	**0.3889*** (8.24%)
MAP	0.3376	**0.3558*** (5.39%)	0.3326	**0.3479*** (4.60%)
Prec@1	0.2500	**0.3125*** (25.00%)	0.2438	**0.2688*** (10.25%)

Algorithm 1 illustrates the re-ranking algorithm in detail. We first extract entities from each question of the whole question collection, and construct a entity co-occurrence graph (Line 1). Then, we calculate the PageRank score of each entity (Line 2). Line 3-5 check whether q contains at least one entity. If the answer is no, we return the original ranking. Otherwise, we identify the key entity in q (Line 6) and construct the CET cet_e whose root entity is e (Line 7). Line 8-16 iteratively put questions in corresponding clusters of cet_e. In Line 8, we first build an entity chain for question q_i, in which entities of q_i are ranked according to their PageRank scores. Afterwards, the first entity $\hat{e}$, which is not similar to e (the similarity is calculated in Section 4.2.1 and the threshold of similarity is set to 0.1), is picked up as the main aspect of e, and q_i is grouped into the corresponding cluster on cet_e (Line 7-8). If $\hat{e}$ does not exist, we put q_i in a new cluster (Line 13-14). Then, we rank all clusters according to their first elements' original rankings (Line 18) and output the final re-ranked list (Line 19).

We perform our re-ranking on 160 randomly selected questions from *Computers & Internet* and *Travel* categories of our data set[9]. Each category contains 80 questions. All other questions in these two categories constitute the question collection Q. For each question, we utilize the VSM and QLLM[10] respectively to get the top 15 most relevant questions (excluding itself). The correct ranking is manually labeled and checked by two annotators. We firstly employed the VSM and QLLM respectively to retrieve the top 15 results and then obtained manual judgments. Given a retrieved question by VSM

[9]These 160 questions are not used for constructing the entity co-occurrence graph.

[10]Following (Zhai and Lafferty, 2004), we set λ to 0.2.

or QLLM, two assessors are asked to label it with "relevant" or "irrelevant". If their annotations are opposite, the third assessor is involved to determine the final label.

We re-rank these questions using Algorithm 1. Table 8 shows the results of MRR, mean average precision (MAP), and Precision@1. We can see that CET-based re-ranking improves the performance of standard retrieval models substantially. For VSM, our re-ranking boosts the MRR and MAP by 9.3% and 5.4%, respectively. It is worth noting that our re-ranking improves Prec@1 significantly: from 0.25 to 0.31. The reason is that traditional methods may give relatively low weights to the key terms (entities), while CET-based re-ranking addresses the problem. QLLM and re-ranking report similar results. Figures 2 and 3 illustrate the performance of various approaches across categories. We find that our re-ranking is neither category-biased nor algorithm-biased, yet it performs better than original models on both categories. The above results demonstrate that, by utilizing the hierarchical entity-based approach, CET greatly improves the retrieval performance of these two standard models.

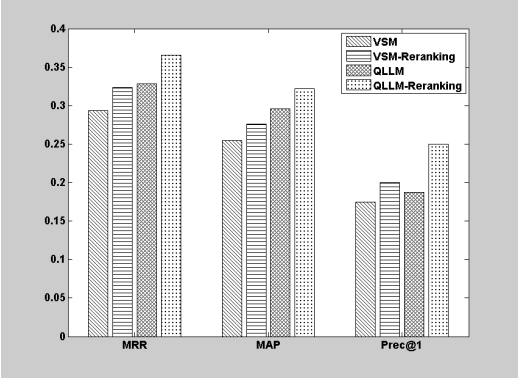

Figure 2: Re-ranking results of *Computer & Internet*

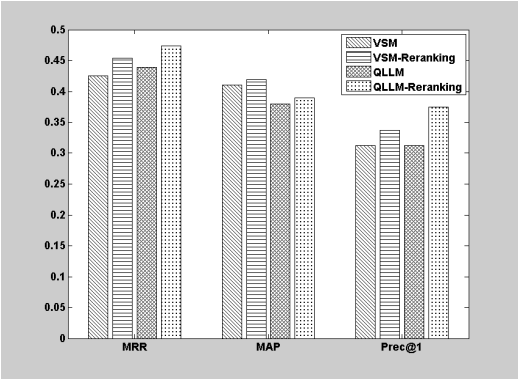

Figure 3: Re-ranking results of *Travel*

6 Conclusion and Future Work

Traditional list-based organization of UGC in social media is not effective for content browsing and knowledge learning due to large volume of documents. To address this problem, we propose a novel hierarchical entity-based approach to structuralize UGC in social media. By using a large-scale entity repository, we construct a three-step framework to organize knowledge in "cluster entity trees". Experimental results show the effectiveness of the framework in constructing CET. We further evaluate the performance of CET on knowledge organization from both user and system aspects. Our user study demonstrates that, with CET-based organization, users perform significantly better in knowledge learning than using list-based approach. In addition, CET boosts systems' content search performance substantially through re-ranking.

To our best knowledge, this work is the first attempt to utilize entities to structuralize UGC in social media, and there are some limitations to be improved in our future work. First, we employ Yahoo! Answers as our test data, in which questions (documents) are usually short. We observe that nearly 92% of all 54.7 million questions contain 1-4 entities, which means the depth of CETs are usually not so deep. However, long documents, such as Blog posts, will lead to deep CETs and hinder users' knowledge learning. Second, our current entity extraction focuses on named entities instead of canonical entities. In the future, we plan to employ document summarization techniques to shorten the depth of CETs. We also aim to incorporate semantic analysis and normalize named entities to canonical entities, which make CET more suitable for practical use.

Semantic Parsing on Freebase from Question-Answer Pairs

Jonathan Berant **Andrew Chou** **Roy Frostig** **Percy Liang**

{joberant,akchou}@stanford.edu {rf,pliang}@cs.stanford.edu

Abstract

In this paper, we train a semantic parser that scales up to Freebase. Instead of relying on annotated logical forms, which is especially expensive to obtain at large scale, we learn from question-answer pairs. The main challenge in this setting is narrowing down the huge number of possible logical predicates for a given question. We tackle this problem in two ways: First, we build a coarse mapping from phrases to predicates using a knowledge base and a large text corpus. Second, we use a *bridging* operation to generate additional predicates based on neighboring predicates. On the dataset of Cai and Yates (2013), despite not having annotated logical forms, our system outperforms their state-of-the-art parser. Additionally, we collected a more realistic and challenging dataset of question-answer pairs and improves over a natural baseline.

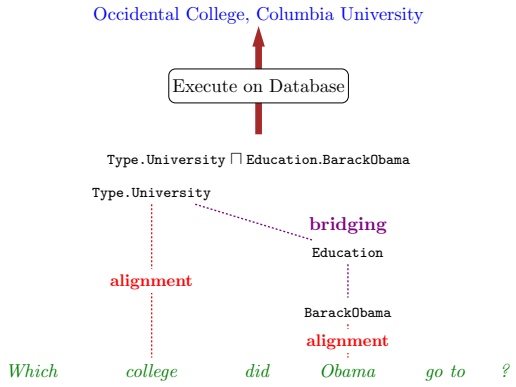

Figure 1: Our task is to map questions to answers via latent logical forms. To narrow down the space of logical predicates, we use a (i) coarse *alignment* based on Freebase and a text corpus and (ii) a *bridging* operation that generates predicates compatible with neighboring predicates.

1 Introduction

We focus on the problem of semantic parsing natural language utterances into logical forms that can be executed to produce denotations. Traditional semantic parsers (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Kwiatkowski et al., 2010) have two limitations: (i) they require annotated logical forms as supervision, and (ii) they operate in limited domains with a small number of logical predicates. Recent developments aim to lift these limitations, either by reducing the amount of supervision (Clarke et al., 2010; Liang et al., 2011; Goldwasser et al., 2011; Artzi and Zettlemoyer, 2011) or by increasing the number of logical predicates (Cai and Yates, 2013). The goal of this paper is to do both: learn a semantic parser without annotated logical forms that scales to the large number of predicates on Freebase.

At the lexical level, a major challenge in semantic parsing is mapping natural language phrases (e.g., *"attend"*) to logical predicates (e.g., `Education`). While limited-domain semantic parsers are able to learn the lexicon from per-example supervision (Kwiatkowski et al., 2011; Liang et al., 2011), at large scale they have inadequate coverage (Cai and Yates, 2013). Previous work on semantic parsing on Freebase uses a combination of manual rules (Yahya et al., 2012; Unger et al., 2012), distant supervision (Krishnamurthy and Mitchell, 2012), and schema

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1533–1544,
Seattle, Washington, USA, 18-21 October 2013.

matching (Cai and Yates, 2013). We use a large amount of web text and a knowledge base to build a coarse alignment between phrases and predicates—an approach similar in spirit to Cai and Yates (2013).

However, this alignment only allows us to generate a subset of the desired predicates. Aligning light verbs (e.g., *"go"*) and prepositions is not very informative due to polysemy, and rare predicates (e.g., *"cover price"*) are difficult to cover even given a large corpus. To improve coverage, we propose a new *bridging* operation that generates predicates based on adjacent predicates rather than on words.

At the compositional level, a semantic parser must combine the predicates into a coherent logical form. Previous work based on CCG requires manually specifying combination rules (Krishnamurthy and Mitchell, 2012) or inducing the rules from annotated logical forms (Kwiatkowski et al., 2010; Cai and Yates, 2013). We instead define a few simple composition rules which over-generate and then use model features to simulate soft rules and categories. In particular, we use POS tag features and features on the denotations of the predicted logical forms.

We experimented with two question answering datasets on Freebase. First, on the dataset of Cai and Yates (2013), we showed that our system outperforms their state-of-the-art system 62% to 59%, despite using no annotated logical forms. Second, we collected a new realistic dataset of questions by performing a breadth-first search using the Google Suggest API; these questions are then answered by Amazon Mechanical Turk workers. Although this dataset is much more challenging and noisy, we are still able to achieve 31.4% accuracy, a 4.5% absolute improvement over a natural baseline. Both datasets as well as the source code for SEMPRE, our semantic parser, are publicly released and can be downloaded from `http://nlp.stanford.edu/software/sempre/`.

2 Setup

Problem Statement Our task is as follows: Given (i) a knowledge base $\mathcal{K}$, and (ii) a training set of question-answer pairs $\{(x_i, y_i)\}_{i=1}^n$, output a semantic parser that maps new questions x to answers y via latent logical forms z and the knowledge base $\mathcal{K}$.

2.1 Knowledge base

Let $\mathcal{E}$ denote a set of *entities* (e.g., `BarackObama`), and let $\mathcal{P}$ denote a set of *properties* (e.g., `PlaceOfBirth`). A *knowledge base* $\mathcal{K}$ is a set of *assertions* $(e_1, p, e_2) \in \mathcal{E} \times \mathcal{P} \times \mathcal{E}$ (e.g., (`BarackObama`, `PlaceOfBirth`, `Honolulu`)).

We use the Freebase knowledge base (Google, 2013), which has 41M non-numeric entities, 19K properties, and 596M assertions.[1]

2.2 Logical forms

To query the knowledge base, we use a logical language called Lambda Dependency-Based Compositional Semantics (λ-DCS)—see Liang (2013) for details. For the purposes of this paper, we use a restricted subset called *simple λ-DCS*, which we will define below for the sake of completeness.

The chief motivation of λ-DCS is to produce logical forms that are simpler than lambda calculus forms. For example, $\lambda x.\exists a.p_1(x,a) \wedge \exists b.p_2(a,b) \wedge p_3(b,e)$ is expressed compactly in λ-DCS as $p_1.p_2.p_3.e$. Like DCS (Liang et al., 2011), λ-DCS makes existential quantification implicit, thereby reducing the number of variables. Variables are only used for anaphora and building composite binary predicates; these do not appear in simple λ-DCS.

Each logical form in simple λ-DCS is either a *unary* (which denotes a subset of $\mathcal{E}$) or a *binary* (which denotes a subset of $\mathcal{E} \times \mathcal{E}$). The basic λ-DCS logical forms z and their denotations $[\![z]\!]_{\mathcal{K}}$ are defined recursively as follows:

- Unary base case: If $e \in \mathcal{E}$ is an entity (e.g., `Seattle`), then e is a unary logical form with $[\![z]\!]_{\mathcal{K}} = \{e\}$.
- Binary base case: If $p \in \mathcal{P}$ is a property (e.g., `PlaceOfBirth`), then p is a binary logical form with $[\![p]\!]_{\mathcal{K}} = \{(e_1, e_2) : (e_1, p, e_2) \in \mathcal{K}\}$.[2]
- Join: If b is a binary and u is a unary, then $b.u$ (e.g., `PlaceOfBirth.Seattle`) is a unary denoting a join and project: $[\![b.u]\!]_{\mathcal{K}} = \{e_1 \in \mathcal{E} : \exists e_2.(e_1, e_2) \in [\![b]\!]_{\mathcal{K}} \wedge e_2 \in [\![u]\!]_{\mathcal{K}}\}$.

[1] In this paper, we condense Freebase names for readability (`/people/person` becomes `Person`).

[2] Binaries can be also built out of lambda abstractions (e.g., $\lambda x.$`Performance.Actor`$.x$), but as these constructions are not central to this paper, we defer to (Liang, 2013).

- Intersection: If u_1 and u_2 are both unaries, then $u_1 \sqcap u_2$ (e.g., `Profession.Scientist` $\sqcap$ `PlaceOfBirth.Seattle`) denotes set intersection: $[\![u_1 \sqcap u_2]\!]_{\mathcal{K}} = [\![u_1]\!]_{\mathcal{K}} \cap [\![u_2]\!]_{\mathcal{K}}$.
- Aggregation: If u is a unary, then `count`(u) denotes the cardinality: $[\![\texttt{count}(u)]\!]_{\mathcal{K}} = \{|[\![u]\!]_{\mathcal{K}}|\}$.

As a final example, *"number of dramas starring Tom Cruise"* in lambda calculus would be represented as `count`$(\lambda x.\texttt{Genre}(x, \texttt{Drama}) \wedge \exists y.\texttt{Performance}(x, y) \wedge \texttt{Actor}(y, \texttt{TomCruise}))$; in λ-DCS, it is simply `count`$(\texttt{Genre.Drama} \sqcap \texttt{Performance.Actor.TomCruise})$.

It is useful to think of the knowledge base $\mathcal{K}$ as a directed graph in which entities are nodes and properties are labels on the edges. Then simple λ-DCS unary logical forms are tree-like graph patterns which pick out a subset of the nodes.

2.3 Framework

Given an utterance x, our semantic parser constructs a distribution over possible derivations $D(x)$. Each *derivation* $d \in D(x)$ is a tree specifying the application of a set of combination rules that culminates in the logical form $d.z$ at the root of the tree—see Figure 2 for an example.

Composition Derivations are constructed recursively based on (i) a lexicon mapping natural language phrases to knowledge base predicates, and (ii) a small set of composition rules.

More specifically, we build a set of derivations for each span of the utterance. We first use the lexicon to generate single-predicate derivations for any matching span (e.g., *"born"* maps to `PeopleBornHere`). Then, given any logical form z_1 that has been constructed over the span $[i_1 : j_1]$ and z_2 over a non-overlapping span $[i_2 : j_2]$, we generate the following logical forms over the enclosing span $[\min(i_1, i_2) : \max(j_1, j_2)]$: intersection $z_1 \sqcap z_2$, join $z_1.z_2$, aggregation $z_1(z_2)$ (e.g., if $z_1 =$ count), or bridging $z_1 \sqcap p.z_2$ for any property $p \in \mathcal{P}$ (explained more in Section 3.2).[3]

Note that the construction of derivations $D(x)$ allows us to skip any words, and in general heavily over-generates. We instead rely on features and learning to guide us away from the bad derivations.

[3]We also discard logical forms are incompatible according to the Freebase types (e.g., `Profession.Politician` $\sqcap$ `Type.City` would be rejected).

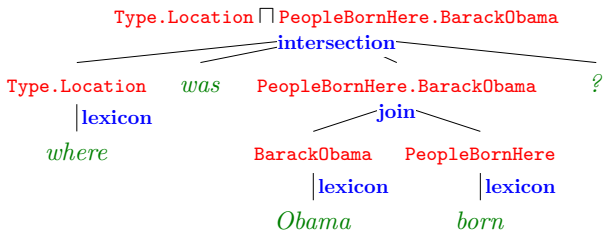

Figure 2: An example of a derivation d of the utterance *"Where was Obama born?"* and its sub-derivations, each labeled with composition rule (in blue) and logical form (in red). The derivation d skips the words *"was"* and *"?"*.

Modeling Following Zettlemoyer and Collins (2005) and Liang et al. (2011), we define a discriminative log-linear model over derivations $d \in D(x)$ given utterances x: $p_\theta(d \mid x) = \frac{\exp\{\phi(x,d)^\top \theta\}}{\sum_{d' \in D(x)} \exp\{\phi(x,d')^\top \theta\}}$, where $\phi(x, d)$ is a feature vector extracted from the utterance and the derivation, and $\theta \in \mathbb{R}^b$ is the vector of parameters to be learned. As our training data consists only of question-answer pairs (x_i, y_i), we maximize the log-likelihood of the correct answer ($[\![d.z]\!]_{\mathcal{K}} = y_i$), summing over the latent derivation d. Formally, our training objective is

$$\mathcal{O}(\theta) = \sum_{i=1}^{n} \log \sum_{d \in D(x): [\![d.z]\!]_{\mathcal{K}} = y_i} p_\theta(d \mid x_i). \quad (1)$$

Section 4 describes an approximation of this objective that we maximize to choose parameters θ.

3 Approach

Our knowledge base has more than 19,000 properties, so a major challenge is generating a manageable set of predicates for an utterance. We propose two strategies for doing this. First (Section 3.1), we construct a lexicon that maps natural language phrases to logical predicates by aligning a large text corpus to Freebase, reminiscent of Cai and Yates (2013). Second, we generate logical predicates compatible with neighboring predicates using the bridging operation (Section 3.2). Bridging is crucial when aligning phrases is difficult or even impossible. The derivations produced by combining these predicates

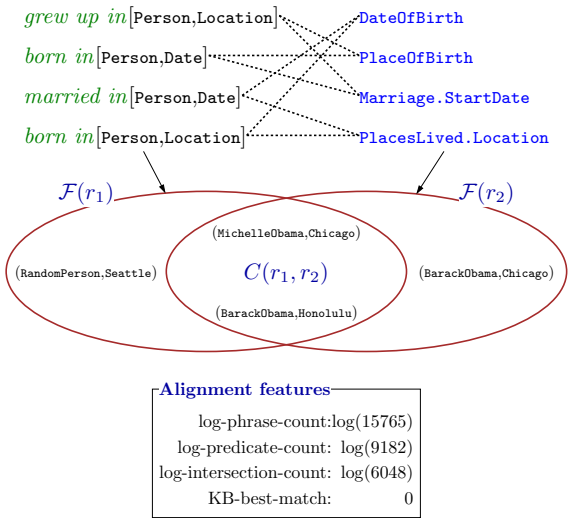

Figure 3: We construct a bipartite graph over phrases $\mathcal{R}_1$ and predicates $\mathcal{R}_2$. Each edge (r_1, r_2) is associated with alignment features.

are scored using features that capture lexical, syntactic and semantic regularities (Section 3.3).

3.1 Alignment

We now discuss the construction of a *lexicon* $\mathcal{L}$, which is a mapping from natural language phrases to logical predicates accompanied by a set of features. Specifically, for a phrase w (e.g., *"born in"*), $\mathcal{L}(w)$ is a set of entries (z, s), where z is a predicate and s is the set of features. A lexicon is constructed by alignment of a large text corpus to the knowledge base (KB). Intuitively, a phrase and a predicate align if they co-occur with many of the same entities.

Here is a summary of our alignment procedure: We construct a set of typed[4] phrases $\mathcal{R}_1$ (e.g., *"born in"*[Person,Location]) and predicates $\mathcal{R}_2$ (e.g., PlaceOfBirth). For each $r \in \mathcal{R}_1 \cup \mathcal{R}_2$, we create its *extension* $\mathcal{F}(r)$, which is a set of co-occurring entity-pairs (e.g., $\mathcal{F}$(*"born in"*[Person,Location]) $= \{$(BarackObama, Honolulu), ...$\}$. The lexicon is generated based on the overlap $\mathcal{F}(r_1) \cap \mathcal{F}(r_2)$, for $r_1 \in R_1$ and $r_2 \in R_2$.

Typed phrases 15 million triples (e_1, r, e_2) (e.g., (*"Obama"*, *"was also born in"*, *"August 1961"*)) were extracted from ClueWeb09 using the ReVerb open IE system (Fader et al., 2011). Lin et al. (2012) released a subset of these triples[5] where they were able to substitute the subject arguments with KB entities. We downloaded their dataset and heuristically replaced object arguments with KB entities by walking on the Freebase graph from subject KB entities and performing simple string matching. In addition, we normalized dates with SUTime (Chang and Manning, 2012).

We lemmatize and normalize each text phrase $r \in R_1$ and augment it with a type signature $[t_1, t_2]$ to deal with polysemy (*"born in"* could either map to PlaceOfBirth or DateOfBirth). We add an entity pair (e_1, e_2) to the extension of $\mathcal{F}(r[t_1, t_2])$ if the (Freebase) type of e_1 (e_2) is t_1 (t_2). For example, (BarackObama, 1961) is added to $\mathcal{F}$(*"born in"*[Person, Date]). We perform a similar procedure that uses a Hearst-like pattern (Hearst, 1992) to map phrases to unary predicates. If a text phrase $r \in R_1$ matches the pattern "(is|was a|the) x IN", where IN is a preposition, then we add e_1 to $\mathcal{F}(x)$. For (Honolulu, *"is a city in"*, Hawaii), we extract $x =$ *"city"* and add Honolulu to $\mathcal{F}$(*"city"*). From the initial 15M triples, we extracted 55,081 typed binary phrases (9,456 untyped) and 6,299 unary phrases.

Logical predicates Binary logical predicates contain (i) all KB properties[6] and (ii) concatenations of two properties $p_1.p_2$ if the intermediate type represents an event (e.g., the *married to* relation is represented by Marriage.Spouse). For unary predicates, we consider all logical forms Type.t and Profession.t for all (abstract) entities $t \in \mathcal{E}$ (e.g. Type.Book and Profession.Author). The types of logical predicates considered during alignment is restricted in this paper, but automatic induction of more compositional logical predicates is an interesting direction. Finally, we define the extension of a logical predicate $r \in \mathcal{R}_2$ to be its denotation, that is, the corresponding set of entities or entity pairs.

Lexicon construction Given typed phrases $\mathcal{R}_1$, logical predicates $\mathcal{R}_2$, and their extensions $\mathcal{F}$, we now generate the lexicon. It is useful to think of a

[4] Freebase associates each entity with a set of types using the Type property.

[6] We filter properties from the domains user and base.

Category	Description
Alignment	Log of # entity pairs that occur with the phrase r_1 ($\lvert\mathcal{F}(r_1)\rvert$) Log of # entity pairs that occur with the logical predicate r_2 ($\lvert\mathcal{F}(r_2)\rvert$) Log of # entity pairs that occur with both r_1 and r_2 ($\lvert\mathcal{F}(r_1) \cap \mathcal{F}(r_2)\rvert$) Whether r_2 is the best match for r_1 ($r_2 = \arg\max_r \lvert\mathcal{F}(r_1) \cap \mathcal{F}(r)\rvert$)
Lexicalized	Conjunction of phrase w and predicate z
Text similarity	Phrase r_1 is equal/prefix/suffix of s_2 Phrase overlap of r_1 and s_2
Bridging	Log of # entity pairs that occur with bridging predicate b ($\lvert\mathcal{F}(b)\rvert$) Kind of bridging (# unaries involved) The binary b injected
Composition	# of intersect/join/bridging operations POS tags in join/bridging and skipped words Size of denotation of logical form

Table 1: Full set of features. For the alignment and text similarity, r_1 is a phrase, r_2 is a predicate with Freebase name s_2, and b is a binary predicate with type signature (t_1, t_2).

bipartite graph with left nodes $\mathcal{R}_1$ and right nodes $\mathcal{R}_2$ (Figure 3). We add an edge (r_1, r_2) if (i) the type signatures of r_1 and r_2 match[7] and (ii) their extensions have non-empty overlap ($\mathcal{F}(r_1) \cap \mathcal{F}(r_2) \neq \emptyset$). Our final graph contains 109K edges for binary predicates and 294K edges for unary predicates.

Naturally, non-zero overlap by no means guarantees that r_1 should map to r_2. In our noisy data, even *"born in"* and `Marriage.EndDate` co-occur 4 times. Rather than thresholding based on some criterion, we compute a set of features, which are used by the model downstream in conjunction with other sources of information.

We compute three types of features (Table 1). *Alignment* features are unlexicalized and measure association based on argument overlap. *Lexicalized* features are standard conjunctions of the phrase w and the logical form z. *Text similarity* features compare the (untyped) phrase (e.g., *"born"*) to the Freebase name of the logical predicate (e.g., *"People born here"*): Given the phrase r_1 and the Freebase name s_2 of the predicate r_2, we compute string similarity features such as whether r_1 and s_2 are equal, as well as some other measures of token overlap.

[7]Each Freebase property has a designated type signature, which can be extended to composite predicates, e.g., sig(`Marriage.StartDate`) = (`Person`, `Date`).

3.2 Bridging

While alignment can cover many predicates, it is unreliable for cases where the predicates are expressed weakly or implicitly. For example, in *"What government does Chile have?"*, the predicate is expressed by the light verb *have*, in *"What actors are in Top Gun?"*, it is expressed by a highly ambiguous preposition, and in *"What is Italy money?"* [sic], it is omitted altogether. Since natural language doesn't offer much help here, let us turn elsewhere for guidance. Recall that at this point our main goal is to generate a manageable set of candidate logical forms to be scored by the log-linear model.

In the first example, suppose the phrases *"Chile"* and *"government"* are parsed as `Chile` and `Type.FormOfGovernment`, respectively, and we hypothesize a connecting binary. The two predicates impose strong type constraints on that binary, so we can afford to generate all the binary predicates that type check (see Table 2). More formally, given two unaries z_1 and z_2 with types t_1 and t_2, we generate a logical form $z_1 \sqcap b.z_2$ for each binary b whose type signature is (t_1, t_2). Figure 1 visualizes bridging of the unaries `Type.University` and `Obama`.

Now consider the example *"What is the cover price of X-men?"* Here, the binary `ComicBookCoverPrice` is expressed explicitly, but is not in our lexicon since the language use is rare. To handle this, we allow bridging to generate a binary based on a single unary; in this case, based on the unary `X-Men` (Table 2), we generate several binaries including `ComicBookCoverPrice`. Generically, given a unary z with type t, we construct a logical form $b.z$ for any predicate b with type $(*, t)$.

Finally, consider the question *"Who did Tom Cruise marry in 2006?"*. Suppose we parse the phrase *"Tom Cruise marry"* into `Marriage.Spouse.TomCruise`, or more explicitly, $\lambda x.\exists e.\texttt{Marriage}(x, e) \wedge \texttt{Spouse}(e, \texttt{TomCruise})$. Here, the neo-Davidsonian event variable e is an intermediate quantity, but needs to be further modified (in this case, by the temporal modifier *2006*). To handle this, we apply bridging to a unary and the intermediate event (see Table 2). Generically, given a logical form $p_1.p_2.z'$ where p_2 has type $(t_1, *)$, and a unary z with type t, bridging injects z and

#	Form 1	Form 2	Bridging
1	`Type.FormOfGovernment`	`Chile`	`Type.FormOfGovernment` $\sqcap$ **`GovernmentTypeOf`**`.Chile`
2		`X-Men`	**`ComicBookCoverPriceOf`**`.X-Men`
3	`Marriage.Spouse.TomCruise`	`2006`	`Marriage.(Spouse.TomCruise` $\sqcap$ **`StartDate`**`.2006)`

Table 2: Three examples of the bridging operation. The bridging binary predicate b is in boldface.

constructs a logical form $p_1.(p_2.z' \sqcap b.z)$ for each logical predicate b with type (t_1, t).

In each of the three examples, bridging generates a binary predicate based on neighboring logical predicates rather than on explicit lexical material. In a way, our *bridging* operation shares with bridging anaphora (Clark, 1975) the idea of establishing a novel relation between distinct parts of a sentence. Naturally, we need features to distinguish between the generated predicates, or decide whether bridging is even appropriate at all. Given a binary b, features include the log of the predicate count $\log |\mathcal{F}(b)|$, indicators for the kind of bridging, an indicator on the binary b for injections (Table 1). In addition, we add all text similarity features by comparing the Freebase name of b with content words in the question.

3.3 Composition

So far, we have mainly focused on the generation of predicates. We now discuss three classes of features pertaining to their composition.

Rule features Each derivation d is the result of applying some number of intersection, join, and bridging operations. To control this number, we define indicator features on each of these counts. This is in contrast to the norm of having a single feature whose value is equal to the count, which can only represent one-sided preferences for having more or fewer of a given operation. Indicator features stabilize the model, preferring derivations with a well-balanced inventory of operations.

Part-of-speech tag features To guide the composition of predicates, we use POS tags in two ways. First, we introduce features indicating when a word of a given POS tag is skipped, which could capture the fact that skipping auxiliaries is generally acceptable, while skipping proper nouns is not. Second, we introduce features on the POS tags involved in a composition, inspired by dependency parsing (McDonald et al., 2005). Specifically, when we combine logical forms z_1 and z_2 via a join or bridging, we include a feature on the POS tag of (the first word spanned by) z_1 conjoined with the POS tag corresponding to z_2. Rather than using head-modifier information from dependency trees (Branavan et al., 2012; Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013; Poon, 2013), we can learn the appropriate relationships tailored for downstream accuracy. For example, the phrase *"located"* is aligned to the predicate `ContainedBy`. POS features can detect that if *"located"* precedes a noun phrase (*"What is located in Beijing?"*), then the noun phrase is the object of the predicate, and if it follows the noun phrase (*"Where is Beijing located?"*), then it is in subject position.

Note that our three operations (intersection, join, and bridging) are quite permissive, and we rely on features, which encode soft, overlapping rules. In contrast, CCG-based methods (Kwiatkowski et al., 2010; Kwiatkowski et al., 2011) encode the combination preferences structurally in non-overlapping rules; these could be emulated with features with weights clamped to $-\infty$.

Denotation features While it is clear that learning from denotations rather than logical forms is a drawback since it provides less information, it is less obvious that working with denotations actually gives us additional information. Specifically, we include four features indicating whether the denotation of the predicted logical form has size 0, 1, 2, or at least 3. This feature encodes presupposition constraints in a soft way: when people ask a question, usually there is an answer and it is often unique. This allows us to favor logical forms with this property.

4 Experiments

We now evaluate our semantic parser empirically. In Section 4.1, we compare our approach to Cai and Yates (2013) on their recently released dataset (henceforth, FREE917) and present results on a new

dataset that we collected (henceforth, WEBQUESTIONS). In Section 4.2, we provide detailed experiments to provide additional insight on our system.

Setup We implemented a standard beam-based bottom-up parser which stores the k-best derivations for each span. We use $k = 500$ for all our experiments on FREE917 and $k = 200$ on WEBQUESTIONS. The root beam yields the candidate set $\tilde{D}(x)$ and is used to approximate the sum in the objective function $\mathcal{O}(\theta)$ in (1). In experiments on WEBQUESTIONS, $\tilde{D}(x)$ contained 197 derivations on average.

We write the approximate objective as $\mathcal{O}(\theta; \tilde{\theta}) = \sum_i \log \sum_{d \in \tilde{D}(x_i;\tilde{\theta}):[\![d.z]\!]_{\mathcal{K}}=y_i} p(d \mid x_i; \theta)$ to explicitly show dependence on the parameters $\tilde{\theta}$ used for beam search. We optimize the objective by initializing θ_0 to 0 and applying AdaGrad (stochastic gradient ascent with per-feature adaptive step size control) (Duchi et al., 2010), so that θ_{t+1} is set based on taking a stochastic approximation of $\frac{\partial \mathcal{O}(\theta;\theta_t)}{\partial \theta}\big|_{\theta=\theta_t}$. We make six passes over the training examples.

We used POS tagging and named-entity recognition to restrict what phrases in the utterance could be mapped by the lexicon. Entities must be named entities, proper nouns or a sequence of at least two tokens. Unaries must be a sequence of nouns, and binaries must be either a content word, or a verb followed by either a noun phrase or a particle. In addition, we used 17 hand-written rules to map question words such as *"where"* and *"how many"* to logical forms such as `Type.Location` and `Count`.

To compute denotations, we convert a logical form z into a SPARQL query and execute it on our copy of Freebase using the Virtuoso engine. On WEBQUESTIONS, a full run over the training examples involves approximately 600,000 queries. For evaluation, we predict the answer from the derivation with highest probability.

4.1 Main results

4.1.1 FREE917

Cai and Yates (2013) created a dataset consisting of 917 questions involving 635 Freebase relations, annotated with lambda calculus forms. We converted all 917 questions into simple λ-DCS, executed them on Freebase and used the resulting answers to train and evaluate. To map phrases to Freebase entities we used the manually-created entity lexicon used by Cai and Yates (2013), which contains 1,100 entries. Because entity disambiguation is a challenging problem in semantic parsing, the entity lexicon simplifies the problem.

Following Cai and Yates (2013), we held out 30% of the examples for the final test, and performed all development on the remaining 70%. During development, we split the data and used 512 examples (80%) for training and the remaining 129 (20%) for validation. All reported development numbers are averaged across 3 random splits. We evaluated using accuracy, the fraction of examples where the predicted answer exactly matched the correct answer.

Our main empirical result is that our system, which was trained only on question-answer pairs, obtained 62% accuracy on the test set, outperforming the 59% accuracy reported by Cai and Yates (2013), who trained on full logical forms.

4.1.2 WEBQUESTIONS

Dataset collection Because FREE917 requires logical forms, it is difficult to scale up due to the required expertise of annotating logical forms. We therefore created a new dataset, WEBQUESTIONS, of question-answer pairs obtained from non-experts.

To collect this dataset, we used the Google Suggest API to obtain questions that begin with a wh-word and contain exactly one entity. We started with the question *"Where was Barack Obama born?"* and performed a breadth-first search over questions (nodes), using the Google Suggest API supplying the edges of the graph. Specifically, we queried the question excluding the entity, the phrase before the entity, or the phrase after it; each query generates 5 candidate questions, which are added to the queue. We iterated until 1M questions were visited; a random 100K were submitted to Amazon Mechanical Turk (AMT).

The AMT task requested that workers answer the question using only the Freebase page of the questions' entity, or otherwise mark it as unanswerable by Freebase. The answer was restricted to be one of the possible entities, values, or list of entities on the page. As this list was long, we allowed the user to filter the list by typing. We paid the workers $0.03 per question. Out of 100K questions, 6,642 were annotated identically by at least two AMT workers.

We again held out a 35% random subset of the

Dataset	# examples	# word types
GeoQuery	880	279
ATIS	5,418	936
FREE917	917	2,036
WEBQUESTIONS	5,810	4,525

Table 3: Statistics on various semantic parsing datasets. Our new dataset, WEBQUESTIONS, is much larger than FREE917 and much more lexically diverse than ATIS.

System	FREE917	WebQ.
ALIGNMENT	38.0	30.6
BRIDGING	66.9	21.2
ALIGNMENT+BRIDGING	**71.3**	**32.9**

Table 4: Accuracies on the development set under different schemes of binary predicate generation. In ALIGNMENT, binaries are generated only via the alignment lexicon. In BRIDGING, binaries are generated through the bridging operation only. ALIGNMENT+BRIDGING corresponds to the full system.

questions for the final test, and performed all development on the remaining 65%, which was further divided into an 80%–20% split for training and validation. To map entities, we built a Lucene index over the 41M Freebase entities.

Table 3 provides some statistics about the new questions. One major difference in the datasets is the distribution of questions: FREE917 starts from Freebase properties and solicits questions about these properties; these questions tend to be tailored to the properties. WEBQUESTIONS starts from questions completely independent of Freebase, and therefore the questions tend to be more natural and varied. For example, for the Freebase property `ComicGenre`, FREE917 contains the question *"What genre is Doonesbury?"*, while WEBQUESTIONS for the property `MusicGenre` contains *"What music did Beethoven compose?"*.

The number of word types in WEBQUESTIONS is larger than in datasets such as ATIS and GeoQuery (Table 3), making lexical mapping much more challenging. On the other hand, in terms of structural complexity WEBQUESTIONS is simpler and many questions contain a unary, a binary and an entity.

In some questions, the answer provided by AMT workers is only roughly accurate, because workers are restricted to selecting answers from the Freebase page. For example, the answer given by workers to the question *"What is James Madison most famous for?"* is *"President of the United States"* rather than *"Authoring the Bill of Rights"*.

Results AMT workers sometimes provide partial answers, e.g., the answer to *"What movies does Taylor Lautner play in?"* is a set of 17 entities, out of which only 10 appear on the Freebase page. We therefore allow partial credit and score an answer using the F_1 measure, comparing the predicted set of entities to the annotated set of entities.

As a baseline, we omit from our system the main contributions presented in this paper—that is, we disallow bridging, and remove denotation and alignment features. The accuracy on the test set of this system is 26.9%, whereas our full system obtains 31.4%, a significant improvement.

Note that the number of possible derivations for questions in WEBQUESTIONS is quite large. In the question *"What kind of system of government does the United States have?"* the phrase *"United States"* maps to 231 entities in our lexicon, the verb *"have"* maps to 203 binaries, and the phrases *"kind"*, *"system"*, and *"government"* all map to many different unary and binary predicates. Parsing correctly involves skipping some words, mapping other words to predicates, while resolving many ambiguities in the way that the various predicates can combine.

4.2 Detailed analysis

We now delve deeper to explore the contributions of the various components of our system. All ablation results reported next were run on the development set (over 3 random splits).

Generation of binary predicates Recall that our system has two mechanisms for suggesting binaries: from the alignment lexicon or via the bridging operation. Table 4 shows accuracies when only one or both is used. Interestingly, alignment alone is better than bridging alone on WEBQUESTIONS, whereas for FREE917, it is the opposite. The reason for this is that FREE917 contains questions on rare predicates. These are often missing from the lexicon, but tend to have distinctive types and hence can be predicted from neighboring predicates. In contrast, WEBQUESTIONS contains questions that are commonly searched for and focuses on popular predicates, therefore exhibiting larger lexical variation.

System	FREE917	WebQ.
FULL	**71.3**	**32.9**
-POS	70.5	28.9
-DENOTATION	58.6	28.0

Table 5: Accuracies on the development set with features removed. POS and DENOTATION refer to the POS tag and denotation features from Section 3.3.

System	FREE917	WebQ.
ALIGNMENT	**71.3**	32.9
LEXICALIZED	68.5	34.2
LEXICALIZED+ALIGNMENT	69.0	**36.4**

Table 6: Accuracies on the development set using either unlexicalized alignment features (ALIGNMENT) or lexicalized features (LEXICALIZED).

For instance, when training without an alignment lexicon, the system errs on *"When did Nathan Smith die?"*. Bridging suggests binaries that are compatible with the common types `Person` and `Datetime`, and the binary `PlaceOfBirth` is chosen. On the other hand, without bridging, the system errs on *"In which comic book issue did Kitty Pryde first appear?"*, which refers to the rare predicate `ComicBookFirstAppearance`. With bridging, the parser can identify the correct binary, by linking the types `ComicBook` and `ComicBookCharacter`. On both datasets, best performance is achieved by combining the two sources of information.

Overall, running on WEBQUESTIONS, the parser constructs derivations that contain about 12,000 distinct binary predicates.

Feature variations Table 5 shows the results of feature ablation studies. Accuracy drops when POS tag features are omitted, e.g., in the question *"What number is Kevin Youkilis on the Boston Red Sox"* the parser happily skips the NNPs *"Kevin Youkilis"* and returns the numbers of all players on the Boston Red Sox. A significant loss is incurred without denotation features, largely due to the parser returning logical forms with empty denotations. For instance, the question *"How many people were at the 2006 FIFA world cup final?"* is answered with a logical form containing the property `PeopleInvolved` rather than `SoccerMatchAttendance`, resulting in an empty denotation.

Next we study the impact of lexicalized versus unlexicalized features (Table 6). In the large WEBQUESTIONS dataset, lexicalized features helped, and so we added those features to our model when running on the test set. In FREE917 lexicalized features result in overfitting due to the small number of training examples. Thus, we ran our final parser on the test set without lexicalized features.

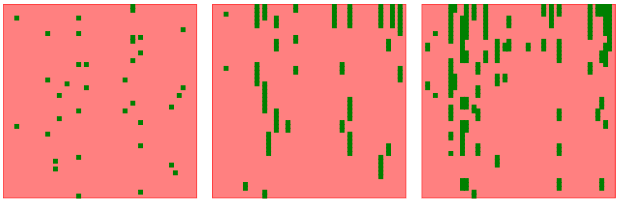

Figure 4: Beam of candidate derivations $\tilde{D}(x)$ for 50 WEBQUESTIONS examples. In each matrix, columns correspond to examples and rows correspond to beam position (ranked by decreasing model score). Green cells mark the positions of derivations with correct denotations. Note that both the number of good derivations and their positions improve as θ is optimized.

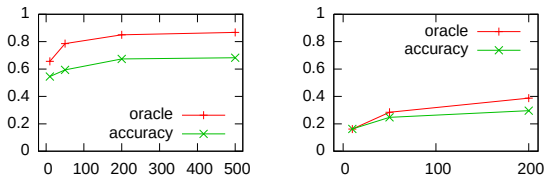

(a) FREE917 (b) WEBQUESTIONS

Figure 5: Accuracy and oracle as beam size k increases.

Effect of beam size An intrinsic challenge in semantic parsing is to handle the exponentially large set of possible derivations. We rely heavily on the k-best beam approximation in the parser keeping good derivations that lead to the correct answer. Recall that the set of candidate derivations $\tilde{D}(x)$ depends on the parameters θ. In the initial stages of learning, θ is far from optimal, so good derivations are likely to fall below the k-best cutoff of internal parser beams. As a result, $\tilde{D}(x)$ contains few derivations with the correct answer. Still, placing these few derivations on the beam allows the training procedure to bootstrap θ into a good solution. Figure 4 illustrates this improvement in $\tilde{D}(x)$ across early training iterations.

Smaller choices of k yield a coarser approxima-

tion in beam search. As we increase k (Figure 5), we see a tapering improvement in accuracy. We also see a widening gap between accuracy and oracle score,[8] as including a good derivation in $\tilde{D}(x)$ is made easier but the learning problem is made more difficult.

Error analysis The accuracy on WEBQUESTIONS is much lower than on FREE917. We analyzed WEBQUESTIONS examples and found several main causes of error: (i) Disambiguating entities in WEBQUESTIONS is much harder because the entity lexicon has 41M entities. For example, given *"Where did the battle of New Orleans start?"* the system identifies *"New Orleans"* as the target entity rather than its surrounding noun phrase. Recall that all FREE917 experiments used a carefully chosen entity lexicon. (ii) Bridging can often fail when the question's entity is compatible with many binaries. For example, in *"What did Charles Babbage make?"*, the system chooses a wrong binary compatible with the type `Person`. (iii) The system sometimes incorrectly draws verbs from subordinate clauses. For example, in *"Where did Walt Disney live before he died?"* it returns the place of death of Walt Disney, ignoring the matrix verb *live*.

5 Discussion

Our work intersects with two strands of work. The first involves learning models of semantics guided by denotations or interactions with the world. Besides semantic parsing for querying databases (Popescu et al., 2003; Clarke et al., 2010; Liang et al., 2011), previous work has looked at interpreting natural language for performing programming tasks (Kushman and Barzilay, 2013; Lei et al., 2013), playing computer games (Branavan et al., 2010; Branavan et al., 2011), following navigational instructions (Chen, 2012; Artzi and Zettlemoyer, 2013), and interacting in the real world via perception (Matuszek et al., 2012; Tellex et al., 2011; Krishnamurthy and Kollar, 2013). Our system uses denotations rather than logical forms as a training signal, but also benefits from denotation features, which becomes possible in the grounded setting.

The second body of work involves connecting natural language and open-domain databases. Several works perform relation extraction using distant supervision from a knowledge base (Riedel et al., 2010; Carlson et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). While similar in spirit to our alignment procedure for building the lexicon, one difference is that relation extraction cares about facts, aggregating over phrases, whereas a lexicon concerns specific phrases, thus aggregating over facts. On the question answering side, recent methods have made progress in building semantic parsers for the open domain, but still require a fair amount of manual effort (Yahya et al., 2012; Unger et al., 2012; Cai and Yates, 2013). Our system reduces the amount of supervision and has a more extensive evaluation on a new dataset.

Finally, although Freebase has thousands of properties, open information extraction (Banko et al., 2007; Fader et al., 2011; Masaum et al., 2012) and associated question answering systems (Fader et al., 2013) work over an even larger open-ended set of properties. The drawback of this regime is that the noise and the difficulty in canonicalization make it hard to perform reliable composition, thereby nullifying one of the key benefits of semantic parsing. An interesting midpoint involves keeping the structured knowledge base but augmenting the predicates, for example using random walks (Lao et al., 2011) or Markov logic (Zhang et al., 2012). This would allow us to map atomic words (e.g., *"wife"*) to composite predicates (e.g., $\lambda x.\texttt{Marriage.Spouse.}(\texttt{Gender.Female} \sqcap x)$). Learning these composite predicates would drastically increase the possible space of logical forms, but we believe that the methods proposed in this paper—alignment via distant supervision and bridging—can provide some traction on this problem.

Acknowledgments

We would like to thank Thomas Lin, Mausam and Oren Etzioni for providing us with open IE triples that are partially-linked to Freebase, and also Arun Chaganty for helpful comments. The authors gratefully acknowledge the support of the Defense Advanced Research Projects Agency (DARPA) Deep Exploration and Filtering of Text (DEFT) Program under Air Force Research Laboratory (AFRL) prime contract no. FA8750-13-2-0040.

[8] Oracle score is the fraction of examples for which $\tilde{D}(x)$ contains any derivation with the correct denotation.

Scaling Semantic Parsers with On-the-fly Ontology Matching

Abstract

We consider the challenge of learning semantic parsers that scale to large, open-domain problems, such as question answering with Freebase. In such settings, the sentences cover a wide variety of topics and include many phrases whose meaning is difficult to represent in a fixed target ontology. For example, even simple phrases such as 'daughter' and 'number of people living in' cannot be directly represented in Freebase, whose ontology instead encodes facts about gender, parenthood, and population. In this paper, we introduce a new semantic parsing approach that learns to resolve such ontological mismatches. The parser is learned from question-answer pairs, uses a probabilistic CCG to build linguistically motivated logical-form meaning representations, and includes an ontology matching model that adapts the output logical forms for each target ontology. Experiments demonstrate state-of-the-art performance on two benchmark semantic parsing datasets, including a nine point accuracy improvement on a recent Freebase QA corpus.

1 Introduction

Semantic parsers map sentences to formal representations of their underlying meaning. Recently, algorithms have been developed to learn such parsers for many applications, including question answering (QA) (Kwiatkowski et al., 2011; Liang et al., 2011), relation extraction (Krishnamurthy and Mitchell, 2012), robot control (Matuszek et al., 2012; Krishnamurthy and Kollar, 2013), interpreting instructions (Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013), and generating programs (Kushman and Barzilay, 2013).

In each case, the parser uses a predefined set of logical constants, or an ontology, to construct meaning representations. In practice, the choice of ontology significantly impacts learning. For example, consider the following questions (Q) and candidate meaning representations (MR):

Q1: What is the population of Seattle?
Q2: How many people live in Seattle?
MR1: $\lambda x.population(Seattle, x)$
MR2: $count(\lambda x.person(x) \wedge live(x, Seattle))$

A semantic parser might aim to construct MR1 for Q1 and MR2 for Q2; these pairings align constants ($count$, $person$, etc.) directly to phrases ('How many,' 'people,' etc.). Unfortunately, few ontologies have sufficient coverage to support both meaning representations, for example many QA databases would only include the population relation required for MR1. Most existing approaches would, given this deficiency, simply aim to produce MR1 for Q2, thereby introducing significant lexical ambiguity that complicates learning. Such ontological mismatches become increasingly common as domain and language complexity increases.

In this paper, we introduce a semantic parsing approach that supports scalable, open-domain ontological reasoning. The parser first constructs a linguistically motivated domain-independent meaning representation. For example, possibly producing MR1 for Q1 and MR2 for Q2 above. It then uses a learned ontology matching model to transform this represen-

Figure 1: Examples of sentences x, domain-independent underspecified logical forms l_0, fully specified logical forms y, and answers a drawn from the Freebase domain.

tation for the target domain. In our example, producing either MR1, MR2 or another more appropriate option, depending on the QA database schema. This two stage approach enables parsing without any domain-dependent lexicon that pairs words with logical constants. Instead, word meaning is filled in on-the-fly through ontology matching, enabling the parser to infer the meaning of previously unseen words and more easily transfer across domains. Figure 1 shows the desired outputs for two example Freebase sentences.

The first parsing stage uses a probabilistic combinatory categorial grammar (CCG) (Steedman, 2000; Clark and Curran, 2007) to map sentences to new, *underspecified* logical-form meaning representations containing generic logical constants that are not tied to any specific ontology. This approach enables us to share grammar structure across domains, instead of repeatedly re-learning different grammars for each target ontology. The ontology-matching step considers a large number of type-equivalent domain-specific meanings. It enables us to incorporate a number of cues, including the target ontology structure and lexical similarity between the names of the domain-independent and dependent constants, to construct the final logical forms.

During learning, we estimate a linear model over derivations that include all of the CCG parsing decisions and the choices for ontology matching. Following a number of recent approaches (Clarke et al., 2010; Liang et al., 2011), we treat all intermediate decisions as latent and learn from data containing only easily gathered question answer pairs. This approach aligns naturally with our two-stage parsing setup, where the final logical expression can be directly used to provide answers.

We report performance on two benchmark datasets: GeoQuery (Zelle and Mooney, 1996) and Freebase QA (FQ) (Cai and Yates, 2013a). GeoQuery includes a geography database with a small ontology and questions with relatively complex, compositional structure. FQ includes questions to Freebase, a large community-authored database that spans many sub-domains. Experiments demonstrate state-of-the-art performance in both cases, including a nine point improvement in recall for the FQ test.

2 Formal Overview

Task Let an ontology $\mathcal{O}$ be a set of logical constants and a knowledge base $\mathcal{K}$ be a collection of logical statements constructed with constants from $\mathcal{O}$. For example, $\mathcal{K}$ could be facts in Freebase (Bollacker et al., 2008) and $\mathcal{O}$ would define the set of entities and relation types used to encode those facts. Also, let y be a logical expression that can be executed against $\mathcal{K}$ to return an answer $a = \text{EXEC}(y, \mathcal{K})$. Figure 1 shows example queries and answers for Freebase. Our goal is to build a function $y = \text{PARSE}(x, \mathcal{O})$ for mapping a natural language sentence x to a domain-dependent logical form y.

Parsing We use a two-stage approach to define the space of possible parses $\text{GEN}(x, \mathcal{O})$ (Section 5). First, we use a CCG and word-class information from Wiktionary[1] to build domain-independent underspecified logical forms, which closely mirror the linguistic structure of the sentence but do not use constants from $\mathcal{O}$. For example, in Figure 1, l_0 denotes the underspecified logical forms paired with each sentence x. The parser then maps this intermediate representation to a logical form that uses constants from $\mathcal{O}$, such as the y seen in Figure 1.

[1] www.wiktionary.com

Learning We assume access to data containing question-answer pairs $\{(x_i, a_i) : i = 1 \dots n\}$ and a corresponding knowledge base $\mathcal{K}$. The learning algorithm (Section 7.1) estimates the parameters of a linear model for ranking the possible entires in $\text{GEN}(x, \mathcal{O})$. Unlike much previous work (e.g., Zettlemoyer and Collins (2005)), we do not induce a CCG lexicon. The lexicon is open domain, using no symbols from the ontology $\mathcal{O}$ for $\mathcal{K}$. This allows us to write a single set of lexical templates that are reused in every domain (Section 5.1). The burden of learning word meaning is shifted to the second, ontology matching, stage of parsing (Section 5.2), and modeled with a number of new features (Section 7.2) as part of the joint model.

Evaluation We evaluate on held out question-answer pairs in two benchmark domains, Freebase and GeoQuery. Following Cai and Yates (2013a), we also report a cross-domain evaluation where the Freebase data is divided by topics such as sports, film, and business. This condition ensures that the test data has a large percentage of previously unseen words, allowing us to measure the effectiveness of the real time ontology matching.

3 Related Work

Supervised approaches for learning semantic parsers have received significant attention, e.g. (Kate and Mooney, 2006; Wong and Mooney, 2007; Muresan, 2011; Kwiatkowski et al., 2010, 2011, 2012; Jones et al., 2012). However, these techniques require training data with hand-labeled domain-specific logical expressions. Recently, alternative forms of supervision were introduced, including learning from question-answer pairs (Clarke et al., 2010; Liang et al., 2011), from conversational logs (Artzi and Zettlemoyer, 2011), with distant supervision (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013b), and from sentences paired with system behavior (Goldwasser and Roth, 2011; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013). Our work adds to these efforts by demonstrating a new approach for learning with latent meaning representations that scales to large databases like Freebase.

Cai and Yates (2013a) present the most closely related work. They applied schema matching techniques to expand a CCG lexicon learned with the UBL algorithm (Kwiatkowski et al., 2010). This approach was one of the first to scale to Freebase, but required labeled logical forms and did not jointly model semantic parsing and ontological reasoning. This method serves as the state of the art for our comparison in Section 9.

We build on a number of existing algorithmic ideas, including using CCGs to build meaning representations (Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010, 2011), building derivations to transform the output of the CCG parser based on context (Zettlemoyer and Collins, 2009), and using weakly supervised margin-sensitive parameter updates (Artzi and Zettlemoyer, 2011, 2013). However, we introduce the idea of learning an open-domain CCG semantic parser; all previous methods suffered, to various degrees, from the ontological mismatch problem that motivates our work.

The challenge of ontological mismatch has been previously recognized in many settings. Hobbs (1985) describes the need for ontological promiscuity in general language understanding. Many previous hand-engineered natural language understanding systems (Grosz et al., 1987; Alshawi, 1992; Bos, 2008) are designed to build general meaning representations that are adapted for different domains. Recent efforts to build natural language interfaces to large databases, for example DBpedia (Yahya et al., 2012; Unger et al., 2012), have also used hand-engineered ontology matching techniques. Fader et al. (2013) recently presented a scalable approach to learning an open domain QA system, where ontological mismatches are resolved with learned paraphrases. Finally, the databases research community has a long history of developing schema matching techniques (Doan et al., 2004; Euzenat et al., 2007), which has inspired more recent work on distant supervision for relation extraction with Freebase (Zhang et al., 2012).

4 Background

Semantic Modeling We use the typed lambda calculus to build logical forms that represent the meanings of words, phrases and sentences. Logical forms contain constants, variables, lambda abstractions, and literals. In this paper, we use the term literal to refer to the application of a constant to a sequence of

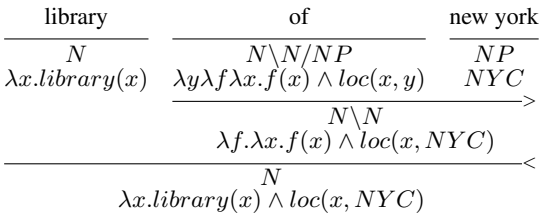

Figure 2: A sample CCG parse.

arguments. We include types for entities e, truth values t, numbers i, events ev, and higher-order functions, such as $\langle e, t\rangle$ and $\langle\langle e, t\rangle, e\rangle$. We use Davidsonian event semantics (Davidson, 1967) to explicitly represent events using event-typed variables and conjunctive modifiers to capture thematic roles.

Combinatory Categorial Grammars (CCG) CCGs are a linguistically-motivated formalism for modeling a wide range of language phenomena (Steedman, 1996, 2000). A CCG is defined by a lexicon and a set of combinators. The lexicon contains entries that pair words or phrases with CCG categories. For example, the lexical entry $\text{library} \vdash N : \lambda x.library(x)$ in Figure 2 pairs the word 'library' with the CCG category that has syntactic category N and meaning $\lambda x.library(x)$. A CCG parse starts from assigning lexical entries to words and phrases. These are then combined using the set of CCG combinators to build a logical form that captures the meaning of the entire sentence. We use the application, composition, and coordination combinators. Figure 2 shows an example parse.

5 Parsing Sentences to Meanings

The function $\text{GEN}(x, \mathcal{O})$ defines the set of possible derivations for an input sentence x. Each derivation $d = \langle \Pi, M\rangle$ builds a logical form y using constants from the ontology $\mathcal{O}$. Π is a CCG parse tree that maps x to an underspecified logical form l_0. M is an ontological match that maps l_0 onto the fully specified logical form y. This section describes, with reference to the example in Figure 3, the operations used by Π and M.

5.1 Domain Independent Parsing

Domain-independent CCG parse trees Π are built using a predefined set of 56 underspecified lexical categories, 49 domain-independent lexical items, and the combinatory rules introduced in Section 4.

An underspecified CCG lexical category has a syntactic category and a logical form containing no constants from the domain ontology $\mathcal{O}$. Instead, the logical form includes underspecified constants that are typed placeholders which will later be replaced during ontology matching. For example, a noun might be assigned the lexical category $\mathsf{N} : \lambda x.p(x)$, where p is an underspecified $\langle e, t\rangle$-type constant.

During parsing, lexical categories are created dynamically. We manually define a set of POS tags for each underspecified lexical category, and use Wiktionary as a tag dictionary to define the possible POS tags for words and phrases. Each phrase is assigned every matching lexical category. For example, the word 'visit' can be either a verb or a noun in Wiktionary. We accordingly assign it all underspecified categories for the classes, including:

$$\mathsf{N}:\lambda x.p(x) \;\;,\;\; \mathsf{S\backslash NP/NP}:\lambda x\lambda y\exists ev.p(y, x, ev)$$

for nouns and transitive verbs respectively.

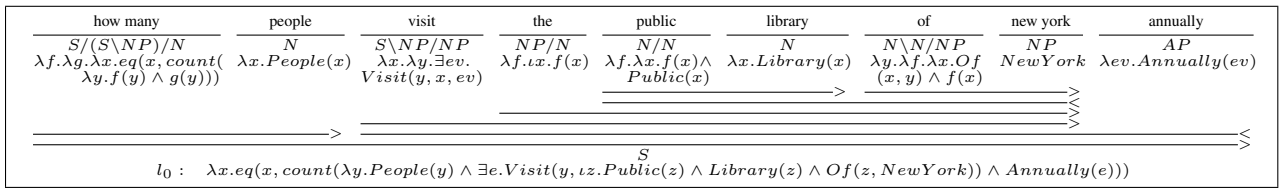
We also define domain-independent lexical items for function words such as 'what,' 'when,' and 'how many,' 'and,' and 'is.' These lexical items pair a word with a lexical category containing only domain-independent constants. For example, $\text{how many} \vdash \mathsf{S/(S\backslash NP)/N} : \lambda f.\lambda g.\lambda x.eq(x, count(\lambda y.f(y) \wedge g(y)))$ contains the function $count$ and the predicate eq.

Figure 3a shows the lexical categories and combinator applications used to construct the underspecified logical form l_0. Underspecified constants in this figure have been labeled with the words that they are associated with for readability.

5.2 Ontological Matching

The second, domain specific, step M maps the underspecified logical form l_0 onto the fully specified logical form y. The mapping from constants in l_0 to constants in y is not one-to-one. For example, in Figure 3, l_0 contains 11 constants but y contains only 2. The ontological match is a sequence of matching operations $M = \langle o_1 \ldots, o_n\rangle$ that can transform the structure of the logical form or replace underspecified constants with constants from $\mathcal{O}$.

(a) **Underspecified CCG parse Π:** Map words onto underspecified lexical categories as described in Section 5.1. Use the CCG combinators to combine lexical categories to give the full underpecified logical form l_0.



(b) **Structure Matching Steps in M:** Use the operators described in Section 5.2.1 and Figure 4 to transform l_0. In each step one of the operators is applied to a subexpression of the existing logical form to generate a modified logical form with a new underspecified constant marked in bold.

$$
\begin{aligned}
l_0 &: \lambda x.eq(x, count(\lambda y.People(y) \wedge \exists e.Visit(y, \iota z.Public(z) \wedge Library(z) \wedge Of(z, NewYork), e) \wedge Annually(e))) \\
l_1 &: \lambda x.eq(x, count(\lambda y.People(y) \wedge \exists e.Visit(y, \textbf{PublicLibraryOfNewYork}, e) \wedge Annually(e))) \\
l_2 &: \lambda x.\textbf{HowManyPeopleVisitAnnually}(x, PublicLibraryOfNewYork)))
\end{aligned}
$$

(c) **Constant Matching Steps in M:** Replace all underspecified constants in the transformed logical form with a similarly typed constant from $\mathcal{O}$, as described in Section 5.2.2. The underspecified constant to be replaced is marked in bold and constants from $\mathcal{O}$ are written in typeset.

$$
\begin{aligned}
& \lambda x.HowManyPeopleVisitAnnually(x, \textbf{PublicLibraryOfNewYork}) \\
l_3 : & \qquad \mapsto \lambda x.HowManyPeopleVisitAnnually(x, \texttt{new\_york\_public\_library}) \\
& \lambda x.\textbf{HowManyPeopleVisitAnnually}(x, \texttt{new\_york\_public\_library}) \\
y : & \qquad \mapsto \lambda x.\texttt{public\_library\_system.annual\_visits}(x, \texttt{new\_york\_public\_library})
\end{aligned}
$$

Figure 3: Example derivation for the query 'how many people visit the public library of new york annually.' Underspecified constants are labelled with the words from the query that they are associated with for readability. Constants from $\mathcal{O}$, written in typeset, are introduced in step (c).

	Operator	Definition and Conditions	Example
a.	Collapse Literal to Constant	$P(a_1, \ldots, a_n) \mapsto c$ s.t. $\texttt{type}(P(a_1, \ldots, a_n)) = \texttt{type}(c)$ $\texttt{type}(c) \in \{e, i\}$ $\texttt{freev}(P(a_1, \ldots, a_n)) = \emptyset$	$\iota z.Public(z) \wedge Library(z) \wedge Of(z, NewYork))$ $\mapsto \quad PublicLibraryOfNewYork$ Input and output have type e. e is allowed in $\mathcal{O}$. Input contains no free variables.
b.	Collapse Literal to Literal	$P(a_1, \ldots, a_n) \mapsto Q(b_1, \ldots, b_m)$ s.t. $\texttt{type}(P(a_1, \ldots, a_n)) = \texttt{type}(Q(b_1, \ldots, b_m))$ $\texttt{type}(Q) \in \{\texttt{type}(c) : c \in \mathcal{O}\}$ $\texttt{freev}(P(a_1, \ldots, a_n)) = \texttt{freev}(Q(b_1, \ldots, b_m))$ $\{b_1, \ldots, b_m\} \in \texttt{subexps}(P(a_1, \ldots, a_n))$	$eq(x, count(\lambda y.People(y) \wedge \exists e.Visit(y,$ $PublicLibraryOfNewYork) \wedge Annually(e)))$ $\mapsto CountPeopleVisitAnnually(x,$ $PublicLibraryOfNewYork)$ Input and output have type t. New constant has type $\langle i, \langle e, t\rangle\rangle$, allowed in $\mathcal{O}$. Input and output contain single free variable x. Arguments of output literal are subexpressions of input.
c.	Split Literal	$P(a_1, \ldots, a_k, x, a_{k+1}, \ldots, a_n)$ $\mapsto Q(b_1, \ldots, x, \ldots b_n) \wedge Q''(c_1, \ldots, x, \ldots c_m)$ s.t. $\texttt{type}(P(\ldots)) = t$ $\{\texttt{type}(Q), \texttt{type}(Q'')\} \in \{\texttt{type}(c) : c \in \mathcal{O}\}$ $\{b_1, \ldots, b_n, c_1, \ldots, c_m\} = \{a_1, \ldots, a_n\}$	$Dedicate(Mozart, Haydn, ev)$ $\mapsto Dedicate(Mozart, ev) \wedge Dedicate''(Haydn, ev)$ Input has type t. This matches output type by definition. New constants have allowed type $\langle e, \langle ev, t\rangle\rangle$. All arguments of input literal are preserved in output.

Figure 4: Definition of the operations used to transform the structure of the underspecified logical form l_0 to match the ontology $\mathcal{O}$. The function $\texttt{type}(c)$ calculates a constant c's type. The function $\texttt{freev}(lf)$ returns the set of variables that are free in lf (not bound by a lambda term or quantifier). The function $\texttt{subexps}(lf)$ generates the set of all subexpressions of the lambda calculus expression lf.

5.2.1 Structure Matching

Three structure matching operators, illustrated in Figure 4, are used to collapse or expand literals in l_0. Collapses merge a subexpression from l_0 to create a new underspecified constant, generating a logical form with fewer constants. Expansions split a subexpression from l_0 to generate a new logical form containing one extra constant.

Collapsing Operators The collapsing operator defined in Figure 4a merges all constants in a literal to generate a single constant of the same type. This operator is used to map $\iota z.Public(z) \wedge Library(z) \wedge Of(z,NewYork)$ to $PublicLibraryOfNewYork$ in Figure 3b. Its operation is limited to entity typed expressions that do not contain free variables.

The operator in Figure 4b, in contrast, can be used to collapse the expression $eq(x,count(\lambda y.People(y) \wedge \exists e.Visit(y,PublicLibraryOfNewYork,e)) \wedge Annually(e)))$, which contains free variable x onto a new expression $CountPeopleVisitAnnually(x,PublicLibraryOfNewYork)$. This is only possible when the type of the newly created constant is allowed in $\mathcal{O}$ and the variable x is free in the output expression. Subsets of conjuncts can be collapsed using the operator in Figure 4b by creating ad-hoc conjunctions that encapsulate them. Disjunctions are treated similarly.

Performing collapses on the underspecified logical form allows non-contiguous phrases to be represented in the collapsed form. In this example, the logical form representing the phrase 'how many people visit' has been merged with the logical form representing the non-adjacent adverb 'annually.' This generates a new underspecified constant that can be mapped onto the Freebase relation `public_library_system_annual_visits` that relates to both phrases.

The collapsing operations preserve semantic type, ensuring that all logical forms generated by the derivation sequence are well typed. The full set of allowed collapses of l_0 is given by the transitive closure of the collapsing operations. The size of this set is limited by the number of constants in l_0, since each collapse removes at least one constant. At each step, the number of possible collapses is polynomial in the number of constants in l_0 and exponential in the arity of the most complex type in $\mathcal{O}$. For domains of interest this arity is unlikely to be high and for triple stores such as Freebase it is 2.

Expansion Operators The fully specified logical form y can contain constants relating to multiple words in x. It can also use multiple constants to represent the meaning of a single word. For example, Freebase does not contain a relation representing the concept 'daughter', instead using two relations representing 'female' and 'child'. The expansion operator in Figure 4c allows a single predicate to be split into a pair of conjoined predicates sharing an argument variable. For example, in Figure 1, the constant for 'dedicate' is split in two to match its representation in Freebase. Underspecified constants from l_0 can be split once. For the experiments in Section 8, we constrain the expansion operator to work on event modifiers but the procedure generalizes to all predicates.

5.2.2 Constant Matching

To build an executable logical form y, all underspecified constants must be replaced with constants from $\mathcal{O}$. This is done through a sequence of constant replacement operations, each of which replaces a single underspecified constant with a constant of the same type from $\mathcal{O}$. Two example replacements are shown in Figure 3c. The output from the last replacement operation is a fully specified logical form.

6 Building and Scoring Derivations

This section introduces a dynamic program used to construct derivations and a linear scoring model.

6.1 Building Derivations

The space of derivations is too large to explicitly enumerate. However, each logical form (both final and interim) can be constructed with many different derivations, and we only need to find the highest scoring one. This allows us to develop a simple dynamic program for our two-stage semantic parser.

We use a CKY style chart parser to calculate the k-best logical forms output by parses of x. We then store each interim logical form generated by an operator in M once in a hyper-graph chart structure. The branching factor of this hypergraph is polynomial in the number of constants in l_0 and linear in the size of $\mathcal{O}$. Subsequently, there are too many possible logical forms to enumerate explicitly; we

prune as follows. We allow the top N scoring ontological matches for each original subexpression in l_0 and remove matches that differ from score from the maximum scoring match by more than a threshold τ. When building derivations, we apply constant matching operators as soon as they are applicable to new underspecified constants created by collapses and expansions. This allows the scoring function used by the pruning strategy to take advantage of all features defined in Section 7.2.

6.2 Ranking Derivations

Given feature vector ϕ and weight vector θ, the score of a derivation $d = \langle \Pi, M \rangle$ is a linear function that decomposes over the parse tree Π and the individual ontology-matching steps o.

$$\begin{aligned} \text{SCORE}(d) &= \phi(d)\theta \\ &= \phi(\Pi)\theta + \sum_{o \in M} \phi(o)\theta \end{aligned} \quad (1)$$

The function $\text{PARSE}(x, \mathcal{O})$ introduced as our goal in Section 2 returns the logical form associated with the highest scoring derivation of x:

$$\text{PARSE}(x, \mathcal{O}) = \arg \max_{d \in \text{GEN}(x, \mathcal{O})} (\text{SCORE}(d))$$

The features and learning algorithm used to estimate θ are defined in the next section.

7 Learning

This section describes an online learning algorithm for question-answering data, along with the domain-independent feature set.

7.1 Learning Model Parameters

Our learning algorithm estimates the parameters θ from a set $\{(x_i, a_i) : i = 1 \ldots n\}$ of questions x_i paired with answers a_i from the knowledge base $\mathcal{K}$. Each derivation d generated by the parser is associated with a fully specified logical form $y = \text{YIELD}(d)$ that can be executed in $\mathcal{K}$. A derivation d of x_i is correct if $\text{EXEC}(\text{YIELD}(d), \mathcal{K}) = a_i$. We use a perceptron to estimate a weight vector θ that support a separation of γ between correct and incorrect answers. Figure 5 presents the learning algorithm.

Input: Q/A pairs $\{(x_i, a_i) : i = 1 \ldots n\}$; Knowledge base $\mathcal{K}$; Ontology $\mathcal{O}$; Function $\text{GEN}(x, \mathcal{O})$ that computes derivations of x; Function $\text{YIELD}(d)$that returns logical form yield of derivation d; Function $\text{EXEC}(y, \mathcal{K})$ that calculates execution of y in $\mathcal{K}$; Margin γ; Number of iterations T.

Output: Linear model parameters θ.

Algorithm:

For $t = 1 \ldots T, i = 1 \ldots n$:

$C = \{d : d \in \text{GEN}(x_i, \mathcal{O}); \text{EXEC}(\text{YIELD}(d), \mathcal{K}) = a_i\}$

$W = \{d : d \in \text{GEN}(x_i, \mathcal{O}); \text{EXEC}(\text{YIELD}(d), \mathcal{K}) \neq a_i\}$

$C^* = \arg\max_{d \in C}(\phi(d)\theta)$

$W^* = \{d : d \in W;\ \exists c \in C^*\ s.t.\ \phi(c)\theta - \phi(d)\theta < \gamma)\}$

If $|C^*| > 0 \wedge |W^*| > 0$:

$\theta = \theta + \frac{1}{|C^*|} \sum_{c \in C^*} \phi(c) - \frac{1}{|W^*|} \sum_{e \in W^*} \phi(e)$

Figure 5: Parameter estimation from Q/A pairs.

7.2 Features

The feature vector $\phi(d)$ introduced in Section 6.2 decomposes over each of the derivation steps in d.

CCG Parse Features Each lexical item in Π has three indicator features. The first indicates the number of times each underspecified category is used. For example, the parse in Figure 3a uses the underspecified category $\mathsf{N} : \lambda x.p(x)$ twice. The second feature indicates (word, category) pairings — e.g. that $\mathsf{N} : \lambda x.p(x)$ is paired with 'library' and 'public' once each in Figure 3a. The final lexical feature indicates (part-of-speech, category) pairings for all parts of speech associated with the word.

Structural Features The structure matching operators (Section 5.2.1) in M generate new underspecified constants that define the types of constants in the output logical form y. These operators are scored using features that indicate the type of each complex-typed constant present in y and the identity of domain-independent functional constants in y. The logical form y generated in Figure 3 contains one complex typed constant with type $\langle i, \langle e, t \rangle \rangle$ and no domain-independent functional constants. Structural features allow the model to adapt to different knowledge bases $\mathcal{K}$. They allow it to determine, for example, whether a numeric quantity such as 'population' is likely to be explicitly listed in $\mathcal{K}$ or if it should be computed with the $count$ function.

Lexical Features Each constant replacement operator (Section 5.2.2) in M replaces an underspec-

ified constant c_u with a constant $c_\mathcal{O}$ from $\mathcal{O}$. The underspecified constant c_u is associated with the sequence of words $\vec{w}_u$ used in the CCG lexical entries that introduced it in Π. We assume that each of the constants c_O in $\mathcal{O}$ is associated with a string label $\vec{w}_O$. This allows us to introduce five domain-independent features that measure the similarity of $\vec{w}_u$ and $\vec{w}_O$.

The feature $\phi_{np}(c_u, c_O)$ signals the replacement of an entity-typed constant c_u with entity c_O that has label $\vec{w}_u$. For the second example in Figure 1 this feature indicates the replacement of the underspecified constant associated with the word 'mozart' with the Freebase entity `mozart`. Stem and synonymy features $\phi_{stem}(c_u, c_O)$ and $\phi_{syn}(c_u, c_O)$ signal the existence of words $w_u \in \vec{w_u}$ and $w_u \in \vec{w_O}$ that share a stem or synonym respectively. Stems are computed with the Porter stemmer and synonyms are extracted from Wiktionary. A single Freebase specific feature $\phi_{fp:stem}(c_u, c_O)$ indicates a word stem match between $w_u \in \vec{w_u}$ and the word filling the most specific position in $\vec{w_u}$ under Freebase's hierarchical naming schema.

A final feature $\phi_{gl}(c_u, c_O)$ calculates the overlap between Wiktionary definitions for $\vec{w_u}$ and $\vec{w_O}$. Let $\texttt{gl}(w)$ be the Wiktionary definition for w. Then:

$$\phi_{gl}(c_u, c_O) = \sum_{w_u \in \vec{w_u}; w_O \in \vec{w_O}} \frac{2 \cdot |\texttt{gl}(w_O) \cap \texttt{gl}(w_c)|}{|\vec{w_O}| \cdot |\vec{w_u}| \cdot |\texttt{gl}(w_O)| + |\texttt{gl}(w_c)|}$$

Domain-indepedent lexical features allow the model to reason about the meaning of unseen words. In small domains, however, the majority of word usages may be covered by training data. We make use of this fact in the GeoQuery domain with features $\phi_m(c_u, c_O)$ that indicate the pairing of $\vec{w_u}$ with c_O.

Knowledge Base Features Guided by the observation that we generally want to create queries y which have answers in knowledge base $\mathcal{K}$, we define features to signal whether each operation could build a logical form y with an answer in $\mathcal{K}$.

If a predicate-argument relation in y does not exist in $\mathcal{K}$, then the execution of y against $\mathcal{K}$ will not return an answer. Two features indicate whether predicate-argument relations in y exist in $\mathcal{K}$. $\phi_{direct}(y, \mathcal{K})$ indicates predicate-argument applications in y that exists in $\mathcal{K}$. For example, if the application of `dedicated_by` to `mozart` in Figure 1 exists in Freebase, $\phi_{direct}(y, \mathcal{K})$ will fire. $\phi_{join}(y, \mathcal{K})$ indicates entities separated from a predicate by one join in y, such as `mozart` and `dedicated_to` in Figure 1, that exist in the same relationship in $\mathcal{K}$.

If two predicates that share a variable in y do not share an argument in that position in $\mathcal{K}$ then the execution of y against $\mathcal{K}$ will fail. The predicate-predicate $\phi_{pp}(y, \mathcal{K})$ feature indicates pairs of predicates that share a variable in y but cannot occur in this relationship in $\mathcal{K}$. For example, since the subject of the Freebase property `date_of_birth` does not take arguments of type `location`, $\phi_{pp}(y, \mathcal{K})$ will fire if y contains the logical form $\lambda x \lambda y.\texttt{date\_of\_birth}(x, y) \wedge \texttt{location}(x)$.

Both the predicate-argument and predicate-predicate features operate on subexpressions of y. We also define the execution features: $\phi_{emp}(y, \mathcal{K})$ to signal an empty answer for y in $\mathcal{K}$; $\phi_0(y, \mathcal{K})$ to signal a zero-valued answer created by counting over an empty set; and $\phi_1(y, \mathcal{K})$ to signal a one-valued answer created by counting over a singleton set.

As with the lexical cues, we use knowledge base features as soft constraints since it is possible for natural language queries to refer to concepts that do not exist in $\mathcal{K}$.

8 Experimental Setup

Data We evaluate performance on the benchmark GeoQuery dataset (Zelle and Mooney, 1996), and a newly introduced Freebase Query (FQ) dataset (Cai and Yates, 2013a). FQ contains 917 questions labeled with logical form meaning representations for querying Freebase. We gathered question answer labels by executing the logical forms against Freebase, and manually correcting any inconsistencies.

Freebase (Bollacker et al., 2008) is a large, collaboratively authored database containing almost 40 million entities and two billion facts, covering more than 100 domains. We filter Freebase to cover the domains contained in the FQ dataset resulting in a database containing 18 million entities, 2072 relations, 635 types, 135 million facts and 81 domains, including for example film, sports, and business. We use this schema to define our target domain, allowing for a wider variety of queries than could be encoded with the 635 collapsed relations previously used to label the FQ data.

We report two different experiments on the FQ data: test results on the existing 642/275 train/test split and domain adaptation results where the data is split three ways, partitioning the topics so that the logical meaning expressions do not share any symbols across folds. We report on the standard 600/280 training/test split for GeoQuery.

Parameter Initialization and Training We initialize weights for ϕ_{np} and ϕ_{direct} to 10, and weights for ϕ_{stem} and ϕ_{join} to 5. This promotes the use of entities and relations named in sentences. We initialize weights for ϕ_{pp} and ϕ_{emp} to -1 to favour logical forms that have an interpretation in the knowledge base $\mathcal{K}$. All other feature weights are initialized to 0. We run the training algorithm for one iteration on the Freebase data, at which point performance on the development set had converged. This fast convergence is due to the very small number of matching parameters used (5 lexical features and 8 $\mathcal{K}$ features). For GeoQuery, we include the larger domain specific feature set introduced in Section 7.2 and train for 10 iterations. We set the pruning parameters from Section 6.1 as follows: $k = 5$ for Freebase, $k = 30$ for GeoQuery, $N = 50$, $\tau = 10$.

Comparison Systems We compare performance to state-of-the-art systems in both domains. On GeoQuery, we report results from DCS (Liang et al., 2011) without special initialization (DCS) and with an small hand-engineered lexicon (DCS with L^+). We also include results for the FUBL algorithm (Kwiatkowski et al., 2011), the CCG learning approach that is most closely related to our work. On FQ, we compare to Cai and Yates (2013a) (CY13).

Evaluation We evaluate by comparing the produced question answers to the labeled ones, with no partial credit. Because the parser can fail to produce a complete query, we report recall, the percent of total questions answered correctly, and precision, the percentage of produced queries with correct answers. CY13 and FUBL report fully correct logical forms, which is a close proxy to our numbers.

9 Results

Quantitative Analysis For FQ, we report results on the test set and in the cross-domain setting, as defined in Section 8. Figure 6 shows both results. Our approach outperforms the previous state of the art, achieving a nine point improvement in test recall, while not requiring labeled logical forms in training. We also see consistent improvements on both scenarios, indicating that our approach is generalizing well across topic domains. The learned ontology matching model is able to reason about previously unseen ontological subdomains as well as if it was provided explicit, in-domain training data.

Setting	System	R	P	F1
Test	Our Approach	68.0	76.7	72.1
	CY13	59	67	63
Cross Domain	Our Approach	67.9	73.5	71.5
	CY13	60	69	65

Figure 6: Results on the FQ dataset.

	R	P	F1
All Features	68.6	72.0	70.3
Without Wiktionary	67.2	70.7	68.9
Without $\mathcal{K}$ Features	61.8	62.5	62.1

Figure 7: Ablation Results

We also performed feature ablations with 5-fold cross validation on the training set, as seen in Figure 7. Both the Wiktionary features and knowledge base features were helpful. Without the Wiktionary features, the model must rely on word stem matches which, in combination with graph constraints, can still recover many of the correct queries. However, without the knowledge base constraints, the model produces many queries that return empty answers, and significantly impacts overall performance.

For GeoQuery, we report test results in Figure 8. Our approach outperforms the most closely related CCG model (FUBL) and DCS without initialization, but falls short of DCS with a small hand-built initial lexicon. Given the small size of the test set, it is fair to say that all algorithms are performing at state-of-the-art levels. This result demonstrates that our ap-

Figure 9: Example error cases, with associated frequencies, illustrating system output and gold standard references. 5% of the cases were miscellaneous or otherwise difficult to categorize.

proach can handle the high degree of lexical ambiguity in the FQ data, without sacrificing the ability to understanding the rich, compositional phenomena that are common in the GeoQuery data.

Qualitative Analysis We also did a qualitative analysis of errors in the FQ domain. The model learns to correctly produce complex forms that join multiple relations. However, there are a number of systematic error cases, grouped into four categories as seen in Figure 9.

The first and second examples show parse failures, where the underspecified CCG grammar did not have sufficient coverage. The third shows a failed structural match, where all of the correct logical constants are selected, but the argument order is reversed for one of the literals. The fourth and fifth examples demonstrate a failures due to database incompleteness. In both cases, the predicted queries would have returned the same answers as the gold-truth ones if Freebase contained all of the required facts. Developing models that are robust to database incompleteness is a challenging problem for future work. Finally, the last example demonstrates a lexical ambiguity, where the system was unable to determine if the query should include the opening date or the closing date for the exhibit.

10 Conclusion

We considered the problem of learning domain-independent semantic parsers, with application to QA against large knowledge bases. We introduced a new approach for learning a two-stage semantic parser that enables scalable, on-the-fly ontological matching. Experiments demonstrated state-of-the-art performance on benchmark datasets, including effective generalization to previously unseen words.

We would like to investigate more nuanced notions of semantic correctness, for example to support many of the essentially equivalent meaning representations we found in the error analysis. Although we focused exclusively on QA applications, the general two-stage analysis approach should allow for the reuse of learned grammars across a number of different domains, including robotics or dialog applications, where data is more challenging to gather.

Classifying Message Board Posts with an Extracted Lexicon of Patient Attributes

Ruihong Huang and Ellen Riloff

Abstract

The goal of our research is to distinguish veterinary message board posts that describe a case involving a specific patient from posts that ask a general question. We create a text classifier that incorporates automatically generated attribute lists for veterinary patients to tackle this problem. Using a small amount of annotated data, we train an information extraction (IE) system to identify veterinary patient attributes. We then apply the IE system to a large collection of unannotated texts to produce a lexicon of veterinary patient attribute terms. Our experimental results show that using the learned attribute lists to encode patient information in the text classifier yields improved performance on this task.

1 Introduction

Our research focuses on the problem of classifying message board posts in the domain of veterinary medicine. Most of the posts in our corpus discuss a case involving a specific patient, which we will call *patient-specific* posts. But there are also posts that ask a general question, for example to seek advice about different medications, information about new procedures, or how to perform a test. Our goal is to distinguish the patient-specific posts from general posts so that they can be automatically routed to different message board folders.

Distinguishing patient-specific posts from general posts is a challenging problem for two reasons. First, virtually any medical topic can appear in either type of post, so the vocabulary is very similar. Second, a highly skewed distribution exists between patient-specific posts and general posts. Almost 90% of the posts in our data are about specific patients.

With such a highly skewed distribution, it would seem logical to focus on recognizing instances of the minority class. But the distinguishing characteristic of a general post is the *absence* of a patient. Two nearly identical posts belong in different categories if one mentions a patient and the other does not. Consequently, our aim is to create features that identify references to a specific patient and use these to more accurately distinguish the two types of posts.

Our research explores the use of information extraction (IE) techniques to automatically identify common attributes of veterinary patients, which we use to encode patient information in a text classifier. Our approach involves three phases. First, we train a conditional random fields (CRF) tagger to identify seven common types of attributes that are often ascribed to veterinary patients: SPECIES/BREED, NAME, AGE, GENDER, WEIGHT, POSSESSOR, and DISEASE/SYMPTOM. Second, we apply the CRF tagger to a large set of unannotated message board posts, collect its extractions, and harvest the most frequently extracted terms to create a *Veterinary Patient Attribute (VPA) Lexicon*.

Finally, we define three types of features that exploit the harvested VPA lexicon. These features represent the patient attribute terms, types, and combinations of them to help the classifier determine whether a post is discussing a specific patient. We conduct experiments which show that the extracted patient attribute information improves text classification performance on this task.

Seattle, Washington, USA, 18-21 October 2013.

2 Related Work

Our work demonstrates the use of information extraction techniques to benefit a text classification application. There has been a great deal of research on text classification (e.g., (Borko and Bernick, 1963; Hoyle, 1973; Joachims, 1998; Nigam et al., 2000; Sebastiani, 2002)), which most commonly has used bag-of-word features. Researchers have also investigated clustering (Baker and McCallum, 1998), Latent Semantic Indexing (LSI) (Zelikovitz and Hirsh, 2001), Latent Dirichlet Allocation (LDA) (Br et al., 2008) and string kernels (Lodhi et al., 2001). Information extraction techniques have been used previously to create richer features for event-based text classification (Riloff and Lehnert, 1994) and web page classification (Furnkranz et al., 1998). Semantic information has also been incorporated for text classification. However, most previous work relies on existing semantic resources, such as Wordnet (Scott and Stan, 1998; Bloehdorn and Hotho, 2006) or Wikipedia (Wang et al., 2009).

There is also a rich history of automatic lexicon induction from text corpora (e.g., (Roark and Charniak, 1998; Riloff and Jones, 1999; McIntosh and Curran, 2009)), Wikipedia (e.g., (Vyas and Pantel, 2009)), and the Web (e.g., (Etzioni et al., 2005; Kozareva et al., 2008; Carlson et al., 2010)). The novel aspects of our work are in using an IE tagger to harvest a domain-specific lexicon from unannotated texts, and using the induced lexicon to encode domain-specific features for text classification.

3 Text Classification with Extracted Patient Attributes

This resesarch studies message board posts from the Veterinary Information Network (VIN), which is a web site (www.vin.com) for professionals in veterinary medicine. VIN hosts forums where veterinarians discuss medical issues, challenging cases, etc. We observed that patient-specific veterinary posts almost always include some basic facts about the patient, such as the animal's breed, age, or gender. It is also common to mention the patient's owner (e.g., *"a new client's cat"*) or a disease or symptom that the patient has (e.g., *"a diabetic cat"*). General posts almost never contain this information.

Although some of these terms can be found in existing resources such as Wordnet (Miller, 1990), our veterinary message board posts are filled with informal and unconventional vocabulary. For example, one might naively assume that *"male"* and *"female"* are sufficient to identify gender. But the gender of animals is often revealed by describing their spayed/neutered status, often indicated with shorthand notations. For example, *"m/n"* means male and neutered, *"fs"* means female spayed, *"castrated"* means neutered and implies male. Shorthand terms and informal jargon are also frequently used for breeds (e.g., *"doxy"* for dachsund, *"labx"* for labrador cross, *"gshep"* for German Shepherd) and ages (e.g., *"3-yr-old"*, *"3yo"*, *"3mo"*). A particularly creative age expression describes an animal as (say) *"a 1999 model"* (i.e., born in 1999). To recognize the idiosyncratic vocabulary in these texts, we use information extraction techniques to identify terms corresponding to seven attributes of veterinary patients: SPECIES/BREED, NAME, AGE, WEIGHT, GENDER, POSSESSOR, and DISEASE/SYMPTOM.

Figure 1 illustrates our overall approach, which consists of three steps. First, we train a sequential IE tagger to label veterinary patient attributes using supervised learning. Second, we apply the tagger to 10,000 unannotated message board posts to automatically create a Veterinary Patient Attribute (VPA) Lexicon. Third, we use the VPA Lexicon to encode patient attribute features in a document classifier.

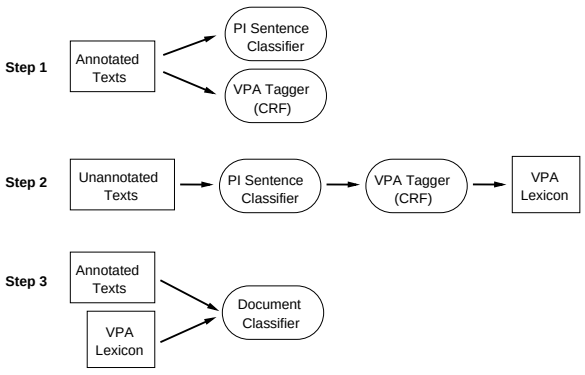

Figure 1: Flowchart for Creating a Patient-Specific vs. General Document Classifier

3.1 Patient Attribute Tagger

The first component of our system is a tagger that labels veterinary patient attributes. To train the tagger, we need texts labeled with patient attributes.

The message board posts can be long and tedious to read (i.e., they are often filled with medical history and test results), so manually annotating every word would be arduous. However, the patient is usually described at the beginning of a post, most commonly in 1-2 "introductory" sentences. Therefore we adopted a two stage process, both for manual and automatic tagging of patient attributes.

First, we created annotation guidelines to identify "patient introductory" (PI) sentences, which we defined as sentences that introduce a patient to the reader by providing a general (non-medical) description of the animal (e.g., *"I was presented with a m/n Siamese cat that is lethargic."*) We randomly selected 300 posts from our text collection and asked two human annotators to manually identify the PI sentences. We measured their inter-annotator agreement using Cohen's kappa (κ) and their agreement was κ=.93. The two annotators then adjudicated their differences to create our gold standard set of PI sentence annotations. 269 of the 300 posts contained at least one PI sentence , indicating that 89.7% of the posts mention a specific patient. The remaining 31 posts (10.3%) are general in nature.

Second, the annotators manually labeled the words in these PI sentences with respect to the 7 veterinary patient attributes. On 50 randomly selected texts, the annotators achieved an inter-annotator agreement of κ = .89. The remaining 250 posts were then annotated with patient attributes (in the PI sentences), providing us with gold standard attribute annotations for all 300 posts. To illustrate, the sentence below would have the following labels:

$$\text{Daisy}_{name} \text{ is a } \text{10yr}_{age} \text{ old}_{age} \text{ lab}_{species}$$

We used these 300 annotated posts to train both a PI sentence classifier and a patient attribute tagger. The PI sentence classifier is a support vector machine (SVM) with a linear kernel (Keerthi and DeCoste, 2005), unigram and bigram features, and binary feature values. The PI sentences are the positive training instances, and the sentences in the general posts are negative training instances.

For the tagger, we trained a single conditional random fields (CRF) model to label all 7 types of patient attributes using the CRF++ package (Lafferty et al., 2001). We defined features for the word string and the part-of-speech tags of the targeted word, two words on its left, and two words on its right.

Given new texts to process, we first apply the PI sentence classifier to identify sentences that introduce a patient. These sentences are given to the patient attribute tagger, which labels the words in those sentences for the 7 patient attribute categories.

To evaluate the performance of the patient attribute tagger, we randomly sampled 200 of the 300 annotated documents to use as training data and used the remaining 100 documents for testing. For this experiment, we only applied the CRF tagger to the gold standard PI sentences, to eliminate any confounding factors from the PI sentence classifier. Table 1 shows the performance of the CRF tagger in terms of Recall (%), Precision (%), and F Score (%). Its precision is consistently high, averaging 91% across all seven attributes. But the average recall is only 47%, with only one attribute (AGE) achieving recall $\geq$ 80%. Nevertheless, the CRF's high precision justifies our plan to use the CRF tagger to harvest additional attribute terms from a large collection of unannotated texts. As we will see in Section 4, the additional terms harvested from the unannotated texts provide substantially more attribute information for the document classifier to use.

Attribute	Rec	Prec	F
SPECIES/BREED	59	93	72
NAME	62	100	76
POSSESSOR	12	100	21
AGE	80	91	85
GENDER	59	81	68
WEIGHT	19	100	32
DISEASE/SYMPTOM	35	73	47
Average	47	91	62

Table 1: Patient Attribute Tagger Evaluation

3.2 Creating a Veterinary Patient Attribute (VPA) Lexicon

The patient attribute tagger was trained with supervised learning, so its ability to recognize important words is limited by the scope of its training set. Since we had an additional 10,000 unannotated veterinary message board posts, we used the tagger to acquire a large lexicon of patient attribute terms.

We applied the PI sentence classifier to all 10,000 texts and then applied the patient attribute tagger to each PI sentence. The patient attribute tagger is not

perfect, so we assumed that words tagged with the same attribute value at least five times[1] are most likely to be correct and harvested them to create a veterinary patient attribute (VPA) lexicon. This produced a VPA lexicon of 592 words. Table 2 shows examples of learned terms for each attribute, with the total number of learned words in parentheses.

Species/Breed (177): DSH, Schnauzer, kitty, Bengal, pug, Labrador, siamese, Shep, miniature, golden, lab, Spaniel, Westie, springer, Chow, cat, Beagle, Mix, ...
Name (53): Lucky, Shadow, Toby, Ginger, Boo, Max, Baby, Buddy, Tucker, Gracie, Maggie, Willie, Tiger, Sasha, Rusty, Beau, Kiki, Oscar, Harley, Scooter, ...
Age (59): #-year, adult, young, YO, y/o, model, wk, y.o., yr-old, yrs, y, #-yr, #-month, #m, mo, mth, ...
Gender (39): F/s, speyed, neutered, spayed, N/M, FN, CM, F, mc, mn, SF, male, fs, M/N, Female, S, S/F, m/n, m/c, intact, M, NM, castrated, ...
Weight (5): lb, lbs, pound, pounds, kg
Possessor (7): my, owner, client, technician, ...
Disease/Symptom (252): abscess, fever, edema, hepatic, inappetance, sneezing, blindness, pain, persistent, mass, insufficiency, acute, poor, ...

3.3 Text Classification with Patient Attributes

Our ultimate goal is to incorporate patient attribute information into a text classifier to help it distinguish between patient-specific posts and general posts. We designed three sets of features:

Attribute Types: We create one feature for each attribute type, indicating whether a word of that attribute type appeared or not.

Attribute Types with Neighbor: For each word labeled as a patient attribute, we create two features by pairing its Attribute Type with a preceding or following word. For example, given the sentence: *"The tiny Siamese kitten was lethargic."*, if "Siamese" has attribute type SPECIES then we create two features: <*tiny*, SPECIES> and <SPECIES, *kitten*>.

Attribute Pairs: We create features for all pairs of patient attribute words that occur in the same sentence. For each pair, we create one feature representing the words themselves and one feature representing the attribute types of the words.

4 Evaluation

To create a blind test set for evaluation, our annotators labeled an additional 500 posts as *patient-specific* or *general*. Specifically, they labeled those 500 posts with PI sentences. The absence of a PI sentence meant that the post was general. Of the 500 texts, 48 (9.6%) were labeled as general posts. We evaluated the performance of the PI sentence classifier on this test set and found that it achieved 88% accuracy at identifying patient introductory sentences.

We then conducted a series of experiments for the document classification task: distinguishing patient-specific message board posts from general posts. All of our experiments used support vector machine (SVM) classifiers with a linear kernel, and ran 10-fold cross validation on our blind test set of 500 posts. We report Recall (%), Precision (%), and F score (%) results for the patient-specific posts and general posts separately, and for the macro-averaged score across both classes. For the sake of completeness, we also show overall Accuracy (%) results. However, we will focus attention on the results for the general posts, since our main goal is to improve performance at recognizing this minority class.

As a baseline, we created SVM classifiers using unigram features.[2] We tried binary, frequency, and tf-idf feature values. The first three rows of Table 3 show that binary feature values performed the best, yielding a macro-averaged F score of 81% but identifying only 54% of the general posts.

The middle section of Table 3 shows the performance of SVM classifiers using our patient attribute features. We conducted three experiments: applying the CRF tagger to PI sentences (per its design), and labeling words with the VPA lexicon either on all sentences or only on PI sentences (as identified by the PI sentence classifier). The CRF features produced extremely low recall and precision on the general posts. The VPA lexicon performed best when applied only to PI sentences and produced much higher recall than all of the other classifiers, although with lower precision than the two

[1] After our text classification experiments were done, we reran the experiments with the unigrams+lexicon classifier using thresholds ranging from 1 to 10 for lexicon creation, just to see how much difference this threshold made. We found that values ≥ 5 produced nearly identical classification results.

[2] We also tried unigrams + bigrams, but they did not perform better.

Method	Patient-Specific Posts			General Posts			Macro Avg			
	Rec	Prec	F	Rec	Prec	F	Rec	Prec	F	Acc
Unigram Features										
Unigrams (freq)	96	96	96	58	60	59	77	76	77	92
Unigrams (tf-idf)	99	93	96	33	84	48	66	89	76	93
Unigrams (binary)	98	95	97	54	79	64	76	87	81	94
Patient Attribute Features										
CRF Features (PI Sents)	99	91	95	02	25	04	51	58	54	90
VPA Lexicon Features (All Sents)	96	96	96	60	63	62	78	79	79	93
VPA Lexicon Features (PI Sents)	96	98	97	81	66	73	88	82	85	94
Unigram & Patient Attribute Features										
CRF Features (PI Sents)	97	96	97	60	71	65	79	83	81	94
VPA Lexicon Features (PI Sents)	98	98	**98**	79	78	**78**	88	88	**88**	**96**

Table 3: Experimental Results

best unigram-based SVMs.

The bottom section of Table 3 shows results for classifiers with both unigrams (binary) and patient attribute features. Using the CRF features increases recall on the general posts from 54 → 60, but decreases precision from 79 → 71. Using the patient attribute features from the VPA lexicon yields a substantial improvement. Recall improves from 54 → 79 and precision is just one point lower. Overall, the macro-averaged F score across the two categories jumps from 81% to 88%.

We performed paired bootstrap testing (Berg-Kirkpatrick et al., 2012)) to determine whether the SVM with unigrams and VPA lexicon features is statistically significantly better than the best SVM with only unigram features (binary). The SVM with unigrams and VPA lexicon features produces significantly better F scores at the $p < 0.05$ level for general post classification as well as the macro average. The F score for patient-specific classification and overall accuracy are statistically significant at the $p < 0.10$ level.

Attribute	CRF Tagger	VPA Lexicon
SPECIES/BREED	270	1045
NAME	36	43
POSSESSOR	12	233
AGE	545	1773
GENDER	153	338
WEIGHT	27	83
DISEASE/SYMPTOM	220	2673

Table 4: Number of Attributes Labeled in Test Set

Finally, we did an analysis to understand why the VPA lexicon was so much more effective than the CRF tagger when used to create features for text classification. Table 4 shows the number of words in PI sentences (identified by the classifier) of the test set that were labeled as patient attributes by the CRF tagger or the VPA lexicon. The VPA lexicon clearly labeled many more terms, and the additional coverage made a big difference for the text classifier.

5 Conclusions

This work demonstrated how annotated data can be leveraged to automatically harvest a domain-specific lexicon from a large collection of unannotated texts. Our induced VPA lexicon was then used to create patient attribute features that improved the ability of a document classifier to distinguish between patient-specific message board posts and general posts. We believe that this approach could also be used to create specialized lexicons for many other domains and applications. A key benefit of inducing lexicons from unannotated texts is that they provide additional vocabulary coverage beyond the terms found in annotated data sets, which are usually small.

Abstract

Lexical chains provide a representation of the lexical cohesion structure of a text. In this paper, we propose two lexical chain based cohesion models to incorporate lexical cohesion into document-level statistical machine translation: 1) a count cohesion model that rewards a hypothesis whenever a chain word occurs in the hypothesis, 2) and a probability cohesion model that further takes chain word translation probabilities into account. We compute lexical chains for each source document to be translated and generate target lexical chains based on the computed source chains via maximum entropy classifiers. We then use the generated target chains to provide constraints for word selection in document-level machine translation through the two proposed lexical chain based cohesion models. We verify the effectiveness of the two models using a hierarchical phrase-based translation system. Experiments on large-scale training data show that they can substantially improve translation quality in terms of BLEU and that the probability cohesion model outperforms previous models based on lexical cohesion devices.

1 Introduction

Given a source document, traditionally most statistical machine translation (SMT) systems translate the document sentence by sentence. In such a translation scheme, sentences are translated independent of any other sentences. However, a text is normally written cohesively, in which sentences are connected to each other via syntactic and lexical devices. This linguistic phenomenon is called as *textual cohesion* (Halliday and Hasan, 1976).

Cohesion is a surface-level property of well-formed texts. It deals with five categories of relationships between text units, namely co-reference, ellipsis, substitution, conjunction and lexical cohesion that is realized via semantically related words. The former four cohesion relations can be grouped as grammatical cohesion. Generally speaking, grammatical cohesion is less common and harder to identify than lexical cohesion (Barzilay and Elhadad, 1997).

As most SMT systems translate a text in a sentence-by-sentence fashion, they tend to build less lexical cohesion than human translators (Wong and Kit, 2012). We therefore study lexical cohesion for document-level translation. We use lexical chains (Morris and Hirst, 1991) to capture lexical cohesion in a text. Lexical chains are connected graphs that represent the lexical cohesion structure of a text. They have been successfully used for information retrieval (Stairmand, 1996), document summarization (Barzilay and Elhadad, 1997) and so on. In this paper, we investigate how lexical chains can be used to incorporate lexical cohesion into document-level translation.

Our basic assumption is that the lexical chains of a target document are direct correspondences of the lexical chains of its counterpart source document. This assumption is reasonable as the target document translation should be faithful to the source document in terms of both text meaning and structure. Based on this assumption, we propose a framework

to incorporate lexical cohesion into target document translation via lexical chains, which works as follows.

- Compute lexical chains for each source document that is to be translated;
- Project the computed source lexical chains onto the corresponding target document by translating source chain words into target chain words using maximum entropy classifiers;
- Incorporate lexical cohesion into the target document translation via cohesion models built on the projected target lexical chains .

We build two lexical chain based cohesion models. The first model is a count model that rewards a hypothesis whenever a word in the projected target lexical chains occur in the hypothesis. As a source chain word may be translated into many different target words, we further extend the count model to a second cohesion model: a probability model that takes chain word translation probabilities into account.

We test the two lexical chain based cohesion models on a hierarchical phrase-based SMT system that is trained with large-scale Chinese-English bilingual data. Experiment results show that our lexical chain based cohesion models can achieve substantial improvements over the baseline. Furthermore, the probability cohesion model is better than the count model and it also outperforms previous cohesion models based on lexical cohesion devices (Xiong et al., 2013).

To the best of our knowledge, this is the first attempt to explore lexical chains for statistical machine translation. The remainder of this paper is organized as follows. Section 2 discusses related work and highlights the differences between our method and previous work. Section 3 briefly introduces lexical chains and algorithms that compute lexical chains. Section 4 elaborates the proposed lexical chain based framework, including details on source lexical chain computation, target lexical chain generation and the two lexical chain based cohesion models. Section 5 presents our large-scale experiments and results. Finally, we conclude with future directions in Section 6.

2 Related Work

Recent years have witnessed growing research interests in document-level statistical machine translation. Such research efforts can be roughly divided into two groups: 1) general document-level machine translation that does not explore or explores very little linguistic discourse information; 2) linguistically-motivated document-level machine translation that incorporates discourse information such as cohesion and coherence into SMT. Recent studies (Guillou, 2013; Beigman Klebanov and Flor, 2013) show that this discourse information is very important for document-level machine translation.

General Document-Level Machine Translation Tiedemann (2010) propose cache-based language and translation models for document-level machine translation. These models are built on recently translated sentences. Following this cache-based approach, Gong et al. (2011) further introduce two additional caches. They use a static cache to store bilingual phrases extracted from documents in training data that are similar to the document being translated. They also adopt a topic cache with target language topic words. Xiao et al. (2011) study the translation consistency issue in document-level machine translation. They use a hard constraint to consistently translate ambiguous source words into the most frequent translation options. Ture et al. (2012) soften this consistency constraint by integrating three counting features into decoder.

Using Lexical Cohesion Devices in Document-Level SMT Lexical cohesion devices are semantically related words, including word repetition, synonyms/near-synonyms, hyponyms and so on. They are also the cohesion-building elements in lexical chains.

Wong and Kit (2012) use lexical cohesion device based metrics to improve machine translation evaluation at the document level. These metrics measure the proportion of content words that are used as lexical cohesion devices in machine-generated translations. Hardmeier et al. (2012) propose a document-wide phrase-based decoder and integrate a semantic language model into the decoder. They argue that their semantic language model can capture lexical cohesion by exploring n-grams that cross sentence

boundaries.

Most recently Xiong et al. (2013) integrate three categories of lexical cohesion devices into document-level machine translation. They define three cohesion models based on lexical cohesion devices: a direct reward model, a conditional probability model and a mutual information trigger model. The latter two models measure the strength of lexical cohesion relation between two lexical items. They are incorporated into SMT to calculate how appropriately lexical cohesion devices are used in document translation. As lexical chains capture lexical cohesion relations among sequences of related words rather than those only between two words, experiments in Section 5 show that our lexical chain based probability cohesion model is better than the lexical cohesion device based trigger model, which is the best among the three cohesion models proposed by Xiong et al. (2013).

Modeling Coherence in Document-Level SMT In discourse analysis, cohesion is often studied together with *coherence* which is another dimension of the linguistic structure of a text (Barzilay and Elhadad, 1997). Cohesion is related to the surface structure of a text while coherence is concerned with the underlying meaning connectedness in a text (Vasconcellos, 1989). Compared with cohesion, coherence is not easy to be detected. Even so, various models have been proposed to explore coherence for document summarization and generation (Barzilay and Lapata, 2008; Louis and Nenkova, 2012). Following this line, Xiong and Zhang (2013) integrate a topic-based coherence model into document-level machine translation, where coherence is defined as a continuous sentence topic transition.

Our lexical chain based cohesion models are also related to previous work on using word and phrase sense disambiguation for lexical choice in SMT (Carpuat and Wu, 2007b; Carpuat and Wu, 2007a; Chan et al., 2007). The difference is that we use document-wide lexical chains to build our cohesion models rather than sentence-level context features. In our framework, lexical choice is performed to make the selected words consistent with the lexical cohesion structure of a document.

Carpuat (2009) explores the principle of one sense per discourse (Gale et al., 1992) in the context of SMT and imposes the constraint of one translation per discourse on document translation. We also use the one sense per discourse principle to perform word sense disambiguation on the source side in our lexical chaining algorithm (See Section 4.1).

3 Background: Lexical Chain and Chain Computation

Lexical chains are sequences of semantically related words (Morris and Hirst, 1991). They represent the lexical cohesion structure of a text. Figure 2 displays six lexical chains computed from the Chinese news article shown in Figure 1. Words in these lexical chains have lexical cohesion relations such as repetition, synonym, which may range over the entire text. For example, in the lexical chain LC^1 of Figure 2, the same word "déguó" (Germany) repeats 9 times. In the lexical chain LC^3, the two words "zǒngcái" (president) and "zhǔxí" (chairman) are synonym words. Generally, a text can have many different lexical chains, each of which represents a thread of cohesion through the text.

Several lexical chaining algorithms have been proposed to compute lexical chains from texts. Normally they need an ontology to obtain semantic relations between words. Word sense disambiguation (WSD) is also used to determine the sense of each word in a text. Generally a lexical chain computation algorithm completes the following three subtasks:

- Building a representation of a text with a set of candidate words and assigning semantic relations between the candidate words according to the ontology;
- Choosing the right sense for each candidate word via WSD;
- Building chains over the semantically related and disambiguated candidate words.

These three sub-tasks can be done separately or simultaneously.

Morris and Hirst (Morris and Hirst, 1991) define the first lexical chain computation algorithm that adopts a greedy strategy to immediately disambiguate a word at its first occurrence. This algorithm runs in linear time but suffers from inaccurate disambiguation. Barzilay and Elhadad (Barzilay and Elhadad, 1997) significantly improve WSD

accuracy by processing all possible combinations of word senses in a text to disambiguate words. Unfortunately, their algorithm runs slowly in quadratic time. Galley and Mckeown (2003) present an algorithm that are better than the former two algorithms both in terms of running efficiency and WSD accuracy. They separate the WSD sub-task from the task of lexical chain building and impose a "one sense per discourse" constraint in the WSD step.

4 Translating Documents Using Lexical Chains

In this section, we describe how we incorporate lexical cohesion into document-level machine translation using lexical chains. We divide the lexical chain based document-level machine translation process into three steps: (1) computing lexical chains for source documents with a source language ontology, (2) generating target lexical chains from the computed source lexical chains, and finally (3) incorporating lexical cohesion encoded in the generated target lexical chains into document-level translation via lexical chain based cohesion models. The remainder of this section will elaborate these three steps.

4.1 Source Lexical Chains Computation

We follow the chain computation algorithm introduced by Galley and McKeown (2003) to build lexical chains on source (Chinese) documents. In the algorithm, the chaining process includes three steps: choosing candidate words to build a disambiguation graph (Galley and McKeown, 2003) for each document, disambiguating the candidate words and finally building lexical chains over the disambiguated candidate words.

The disambiguation graph can be considered as a representation of all possible interpretations of its corresponding text. In the graph, nodes are candidate words with different senses and edges between word senses are weighted according to their semantic relations, such as synonym, hypernym and so on. We use an extended version of a Chinese thesaurus *Tongyici Cilin* (Cilin for short) to define word senses and semantic relations between senses. The ex-

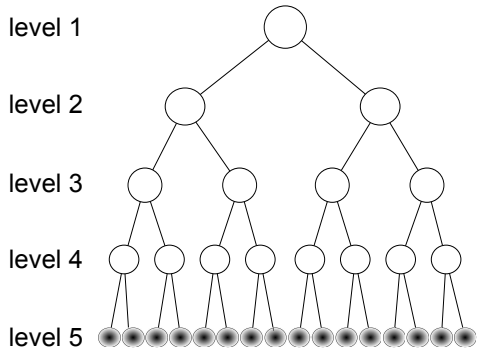

Figure 3: The architecture of the extended Cilin. For simplicity, we only draw a binary tree to represent the hierarchical structure of Cilin. This doesn't mean that each semantic class at level i has only two sub-classes at level $i+1$. Actually, they have multiple sub-classes.

tended Cilin contains 77,343 Chinese words, which are organized in a hierarchical structure containing 5 levels as shown in Figure 3. In the 5th level, each node represents an atomic concept which consists of a set of synonyms. These atomic concepts are just like *synsets* in WordNet. We use them to represent senses of words in the disambiguation graph.

We select nouns, verbs, abbreviations and idioms as candidate words for the disambiguation graph. These words are identified by a Chinese part-to-speech tagger LTP (Che et al., 2010) in a preprocessing step. In order to build the disambiguation graph, we first build an array indexed by the atomic concepts of Cilin, then insert a copy of each candidate word into its all concept (sense) entries in the array. After that, we create all semantic links among senses of different candidate words in the disambiguation graph following Galley and McKeown (2003).

In the second step, we use the principle of one sense per discourse to perform WSD for each candidate word in the disambiguation graph. We sum the weights of all semantic links under the different senses of the candidate word in question. The sense with the highest sum of weights is considered as the most probable sense for this word. We then assign this sense to all occurrences of the word in the document by adopting the constraint of one sense per discourse.

Once all candidate words are disambiguated, we can build lexical chains over these words by removing all semantic links that connect those unselected word senses. The six lexical chains shown in Figure 2 are computed from the Chinese document in Figure 1 exactly following the algorithm of Galley and McKeown (2003). The only difference is that we use Cilin rather than WordNet as the ontology.

4.2 Target Lexical Chains Generation

Since a faithful target document translation should follow the same cohesion structure as that in its corresponding source document, we generate target lexical chains from the computed source lexical chains. Given a source lexical chain $LC_s = \{s_i^j\}$ where the ith chain word s_i^j is from the jth sentence of the source document D_s, we generate a target lexical chain $LC_t = \{t_i^j\}$ using maximum entropy (MaxEnt) classifiers. Particularly, we translate a word s_i^j in the source lexical chain into a target word t_i^j in the target lexical chain using a corresponding MaxEnt classifier as follows[1].

$$P(t_i^j|\mathcal{C}(s_i^j)) = \frac{exp(\sum_k \theta_k f_k(t_i^j, \mathcal{C}(s_i^j)))}{\sum_t exp(\sum_k \theta_k f_k(t, \mathcal{C}(s_i^j)))} \quad (1)$$

where f_k are binary features, θ_k are weights of these features, and $\mathcal{C}(s_i^j)$ is the surrounding context of chain word s_i^j.

We train one MaxEnt classifier per unique source chain word. For each classifier, we define two groups of binary features: 1) the preceding and succeeding two words of s_i^j in the jth sentence ($\{w_{-2}, w_{-1}, s_i^j, w_{+1}, w_{+2}\}$); 2) the preceding and succeeding one word of s_i^j in the lexical chain LC_s ($\{s_{i-1}^p, s_i^j, s_{i+1}^q\}$). All features are in the following binary form.

$$f(t_i^j, \mathcal{C}(s_i^j)) = \begin{cases} 1, & \text{if } t_i^j = \clubsuit \text{ and } \mathcal{C}(s_i^j).\heartsuit = \spadesuit \\ 0, & \text{else} \end{cases} \quad (2)$$

where the symbol $\clubsuit$ is a placeholder for a possible target word, the symbol $\heartsuit$ indicates a contextual element for the chain word s_i^j (e.g., the preceding word in the jth sentence or the succeeding word in the lexical chain LC_s), and the symbol $\spadesuit$ represents the value of $\heartsuit$.

Given a source document D_s and its N lexical chains $\{LC_s^k\}_{k=1}^N$ computed from the document as

[1]We collect training instances from word-aligned bilingual data to train the MaxEnt classifier.

described in Section 4.1, we can generate the N target lexical chains $\{LC_t^k\}_{k=1}^N$ using our MaxEnt classifiers. Each target word t_i^j in the target lexical chain LC_t^k is the translation of its corresponding source word s_i^j in the source lexical chain LC_s^k with the highest probability $P(t_i^j|\mathcal{C}(s_i^j))$ according to Eq. (1).

As we know, the MaxEnt classifier can generate multiple translations for each source word. In order to incorporate these multiple chain word translations, we can generate a *super target lexical chain* ${}_\epsilon LC_t$ from a source lexical chain LC_s, where ϵ is a pre-defined threshold used to select multiple translations. For example, given a source lexical chain $LC_s = \{a, b, c\}$, we can have the corresponding super target lexical chain ${}_\epsilon LC_t = \{\{a_t^1, a_t^2...\}, \{b_t^1, b_t^2...\}, \{c_t^1, c_t^2...\}\}$, where x_t^i is the translation of x with a translation probability $P(x_t^i|\mathcal{C}(x)) \geq \epsilon$ according to Eq. (1). Integrating multiple translations for each source chain word, we can reduce the error propagation of the MaxEnt classifier to some extent. Our experiments also confirm that the super target lexical chains with multiple translation options for each chain word are better than the target lexical chains with only one translation per chain word. Therefore we build our cohesion models based on the super target lexical chains, which will be described in the next section.

4.3 Lexical Chain Based Cohesion Models

Once we generate the super target lexical chains $\{{}_\epsilon LC_t^k\}_{k=1}^N$ for the target document D_t, we can use them to provide constraints for the target document translation. Our key interest is to make the target document translation T_{D_t} as cohesive as possible. We therefore propose lexical chain based cohesion models to measure the cohesion of the target document translation. The basic idea is to reward a translation hypothesis if a word from the super target lexical chains occurs in the hypothesis. According to the difference in the reward strategy, we have two cohesion models: a *count cohesion model* and a *probability cohesion model*.

Count Cohesion Model $M_c(T_{D_t}, \{{}_\epsilon LC_t^k\}_{k=1}^N)$: This model rewards a translation hypothesis of the jth sentence in the document whenever a lexical chain word t_i^j occurs in the hypothesis. The model maintains a counter and accumulates the counter when necessary. It is factorized into the sentence cohesion metric $M_c(T_j, \{{}_\epsilon LC_t^k\}_{k=1}^N)$, where T_j is the translation of the jth sentence in the target document. $M_c(T_j, \{{}_\epsilon LC_t^k\}_{k=1}^N)$ is formulated as follows.

$$M_c(T_j, \{{}_\epsilon LC_t^k\}_{k=1}^N) = \prod_{w \in T_j} \prod_{t_i^j \in \mathbf{C}} e^{\delta(w, t_i^j)} \quad (3)$$

where $\mathbf{C}$ represents $\{{}_\epsilon LC_t^k\}_{k=1}^N$, and the δ function is defined as follows.

$$\delta(w, t_i^j) = \begin{cases} 1, & \text{if } t_i^j = w \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

Probability Cohesion Model $M_p(T_{D_t}, \{{}_\epsilon LC_t^k\}_{k=1}^N)$: This model rewards a translation hypothesis according to the translation probability of a chain word that occurs in the hypothesis. The translation probability is computed by Eq. (1). The model is also factorized into the sentence cohesion metric $M_p(T_j, \{{}_\epsilon LC_t^k\}_{k=1}^N)$ which is formulated as follows.

$$M_p(T_j, \{{}_\epsilon LC_t^k\}_{k=1}^M) = \prod_{w \in T_j} \prod_{t_i^j \in \mathbf{C}} e^{\delta(w, t_i^j)} \times P(t_i^j|\mathcal{C}(s_i^j)) \quad (5)$$

where $P(t_i^j|\mathcal{C}(s_i^j)$ is the translation probability computed according to Eq. (1).

4.4 Decoding

The proposed lexical chain based cohesion models are integrated into the log-linear translation framework of SMT as a cohesion feature. Before translating a source document, we compute lexical chains for the source document as described in Section 4.1. We then generate the super target lexical chains. In order to efficiently calculate our lexical chain based cohesion models, we reorganize words in the super target lexical chains into vectors. We associate each source sentence S_j a vector to store target lexical chain words that are to occur in the corresponding target sentence T_j.

Although we still translate a source document sentence by sentence, we capture the global cohesion structure of the document via lexical chains and use the lexical chain based cohesion models to constrain word selection in document translation. Figure 4 shows the architecture of an SMT system with the lexical chain based cohesion model.

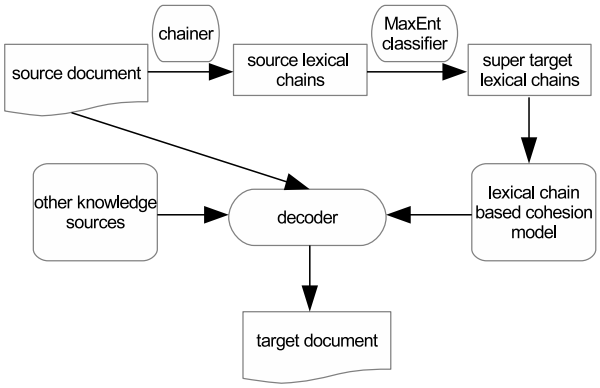

Figure 4: Architecture of an SMT system with the lexical chain based cohesion model.

5 Experiments

In this section, we conducted a series of experiments to validate the effectiveness of the proposed lexical chain based cohesion models for Chinese-to-English document-level machine translation. We used a hierarchical phrased-based SMT system (Chiang, 2007) trained on large-scale data. In particular, we aim at:

- Measuring the impact of the threshold ϵ on the probability cohesion model and selecting the best threshold on a development test set.
- Investigating the effect of the two lexical-chain based cohesion models.
- Comparing our lexical chain based cohesion models against the previous lexical cohesion device based models (Xiong et al., 2013).

5.1 Setup

We collected our bilingual training data from LDC, which includes the corpus LDC2002E18, LDC2003E07, LDC2003E14, LDC2004E12, LDC2004T07, LDC2004T08 (Only Hong Kong News), LDC2005T06 and LDC2005T10. The collected bilingual training data contains 3.8M sentence pairs with 96.9M Chinese words and 109.5M English words. We trained a 4-gram language model on the Xinhua portion of the English Gigaword corpus (306 million words) via the SRILM toolkit (Stolcke, 2002) with Kneser-Ney smoothing.

	Training	**MT05**	**MT06**	**MT08**
#Doc	103,236	100	79	109
#Sent	2.80M	1,082	1,664	1,357
#Chain	3.52M	1700	2172	1693
#AvgC	35.72	17	27.49	15.53
#AvgW	14.81	5.89	6.89	5.63

Table 1: Statistics of the training, development and test sets, which show the number of documents (#Doc) and sentences (#Sent), the number of lexical chains extracted from the source documents (#Chain), the average number of lexical chains per document (#AvgC) and the average number of words per lexical chain (#AvgW).

In order to build the lexical chain based cohesion models, we selected corpora with document boundaries explicitly provided from the bilingual training data together with the whole Hong Kong parallel text corpus as the cohesion model training data[2]. We show the statistics of these selected corpora in Table 1. They contain 103,236 documents and 2.80M sentences. Averagely, each document consists of 28.4 sentences. From the source documents of the selected corpora, we extract 3.52M lexical chains. On average, there are 35.72 lexical chains per document and 14.81 words per lexical chain.

We used the off-the-shelf MaxEnt toolkit[3] to train one MaxEnt classifier per unique source lexical chain word (61,121 different source chain words in total). We performed 100 iterations of the L-BFGS algorithm implemented in the training toolkit for each chain word with both Gaussian prior and event cutoff set to 1 to avoid overfitting. After event cutoff, we have an average of 17.75 different classes (target translations) per source chain word.

We used the NIST MT05 as the tuning set for the minimum error rate training (MERT) [Och, 2003], the NIST MT06 as the development test set and the MT08 as the final test set. The numbers of documents/sentences in the NIST MT05, MT06 and MT08 are 100/1082, 79/1664 and 109/1357 respectively. They contain 17, 27.49 and 15.53 lexical chains per document respectively.

We used the case-insensitive BLEU-4 (Papineni

[2]The training data includes LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hong Kong Hansards/Laws/News).

et al., 2002) as our evaluation metric. As MERT is normally instable, we ran the tuning process three times for all our experiments and presented the average BLEU scores on the three MERT runs as suggested by Clark et al (2011).

5.2 Setting the Threshold ϵ

As the two lexical chain based cohesion models are built on the super target lexical chains that are associated with a parameter ϵ, we need to tune the threshold parameter ϵ on the development test set NIST MT06. We conducted a group of experiments using the probability cohesion model defined in Eq. (5) to find the best threshold. Experiment results are shown in Table 2.

If we set the threshold too small (e.g., 0.05), the super target lexical chains may contain too many noisy words that are not the translations of source lexical chain words, which may jeopardise the quality of the super target lexical chains. The cohesion model built on these noisy super target lexical chains may select incorrect words rather than the proper lexical chain words. On the other hand, if we set the threshold too large (e.g., 0.3 or 0.4), we may take the risk of not selecting the appropriate chain word translations into the super target lexical chains. It seems that the best threshold is 0.1 as we obtained the highest BLEU score 31.64 on the NIST MT06 with this threshold. Therefore we set the threshold ϵ to 0.1 in all experiments thereafter.

5.3 Effect of the Count and Probability Cohesion Model

After we found the best threshold, we carried out experiments to test the effect of the two lexical chain based cohesion models: the count and probability cohesion model. We compared them against the baseline system that does not integrate any lexical chain information. We also compared the count cohesion model (LexChainCount(top1)) built on the target lexical chains where each target chain word is the best translation of its corresponding source lexical chain word according to Eq. (1). Experiment results are shown in Table 3.

From Table 3, we can observe that

- Our lexical chain based cohesion models are able to substantially improve the translation quality in terms of BLEU score. We achieve an average improvement of up to 1.21 BLEU points over the baseline on the two test sets MT06 and MT08.
- The count cohesion model built on the super target lexical chains is better than that based on the target lexical chains only with top one translations (27.07 vs. 26.99). This shows the advantage of the super target lexical chains $\{_\epsilon LC_t^k\}_{k=1}^N$ over the standard target lexical chians $\{LC_t^k\}_{k=1}^N$.
- Finally, the probability cohesion model is much better than the count cohesion model (28.09 vs. 27.07). This suggests that we should take into account chain word translation probabilities when we reward hypotheses where target lexical chain words occur.

5.4 Lexical Chains vs. Lexical Cohesion Devices

As we have mentioned in Section 2, lexical cohesion devices can be also used to build lexical cohesion models to capture lexical cohesion relations in a text. We therefore want to compare our lexical chain based cohesion models with the lexical cohesion device based cohesion models.

System	MT06	MT08	Avg
Baseline	30.43	23.32	26.88
LexDeviceTrigger	31.35	24.11	27.73
LexChainProb	31.64	24.54	28.09

Table 4: The lexical chain based probability cohesion model (LexChainProb) vs. the lexical cohesion device based trigger model (LexDeviceTrigger).

We re-implemented the mutual information trigger model that is the best lexical cohesion model based on lexical cohesion devices among the three models proposed by Xiong et al. (2013). The mutual information trigger model measures the association strength of two lexical cohesion items x and y in a lexical cohesion relation xRy. In the model, it is required that x occurs in a sentence preceding the sentence where y occurs and that the two items have a lexical cohesion relation such as word repetition, synonym. The model treats x as the trigger and y as the triggered item. The mutual information between the trigger x and the triggered item y estimates how possible y will occur given x is mentioned in a text.

The comparison results are reported in Table 4. Our lexical chain based probability cohesion model outperforms the lexical cohesion device based trigger model by 0.36 BLEU points. The reason for this superiority of our cohesion model over the trigger model may be that the former model captures lexical cohesion relations among sequences of words through lexical chains while the latter model captures lexical cohesion relations only between two related words.

6 Conclusions

We have presented two lexical chain based cohesion models that incorporate the lexical cohesion structure of a text into document-level machine translation. We project the lexical chains of a source document to the corresponding target document by translating each word in each source lexical chain into their counterparts via MaxEnt classifiers. The projected target lexical chains provide a representation of the lexical cohesion structure of the target document that is to be generated. We build two cohesion models based on the projected target lexical chains: a count model that rewards a hypothesis according to the time of occurrence of target lexical chain words in the hypothesis and a probability model that further takes translation probabilities into account when rewarding hypotheses. These two cohesion models are used to constrain word selection for document translation so that the generated document is consistent with the projected lexical cohesion structure.

We have integrated the two proposed cohesion models into a hierarchical phrase-based SMT system. Experiment results on large-scale data validate that

- The lexical chain based cohesion models are able to substantially improve translation quality in terms of BLEU.
- The probability cohesion model is better than the count cohesion model.
- The lexical chain based probability cohesion model is better than the previous mutual information trigger model that adopts lexical cohesion devices to capture lexical cohesion relations between two related words.

As we mentioned in Section 2, cohesion is closely connected to coherence. It provides a surface indicator for coherence identification (Barzilay and Elhadad, 1997). In the future, we would like to use lexical chains to identify coherence and incorporate both cohesion and coherence into document-level machine translation.

Abstract

The IBM translation models have been hugely influential in statistical machine translation; they are the basis of the alignment models used in modern translation systems. Excluding IBM Model 1, the IBM translation models, and practically all variants proposed in the literature, have relied on the optimization of likelihood functions or similar functions that are non-convex, and hence have multiple local optima. In this paper we introduce a convex relaxation of IBM Model 2, and describe an optimization algorithm for the relaxation based on a subgradient method combined with exponentiated-gradient updates. Our approach gives the same level of alignment accuracy as IBM Model 2.

1 Introduction

The IBM translation models (Brown et al., 1993) have been tremendously important in statistical machine translation (SMT). The IBM models were the first generation of SMT systems; in recent work, they play a central role in deriving alignments used within many modern SMT approaches, for example phrase-based translation models (Koehn, 2008) and syntax-based translation systems (e.g., (Chiang, 2005; Marcu et al., 2006)). Since the original IBM paper, there has been a large amount of research exploring the original IBM models and modern variants (e.g., (Moore, 2004; Liang et al., 2006; Toutanova and Galley, 2011; Riley and Gildea, 2012; Vogel et al., 1996)).

Excluding IBM Model 1, the IBM translation models, and practically all variants proposed in the literature, have relied on the optimization of likelihood functions or similar functions that are non-convex. Unfortunately, non-convex objective functions have multiple local optima, and finding a global optimum of a non-convex function is typically a computationally intractible problem. Typically, an EM algorithm is used, which often runs in a reasonable amount of time, but with no guarantees of finding a global optima (or for that matter, even a near-optimal solution).

In this paper we make the following contributions:

- We introduce a convex relaxation of IBM Model 2. At a very high level, the relaxation is derived by replacing the product $t(f_j|e_i) \times d(i|j)$ with a relaxation that is commonly used in the linear programming literature (e.g., see (Bertsimas, 1997; Bertsimas and Tsitsiklis, 1997; Martins et al., 2010)). (Here $t(f|e)$ are the translation parameters of the model, and $d(i|j)$ are the distortion parameters; the product is non-linear, effectively introducing non-convexity into the problem.)
- We describe an optimization algorithm for the relaxed objective, based on a combination of stochastic subgradient methods with the exponentiated-gradient (EG) algorithm (Kivinen and Warmuth, 1997; Beck and Teboulle, 2003).
- We describe experiments with the method on standard alignment datasets, showing that the EG algorithm converges in only a few passes over the data, and that our method achieves accuracies that are very similar to those of IBM Model 2.

Framing the unsupervised learning of alignment models as a convex optimization problem, with guaranteed convergence to a global optimum, has several clear advantages. First, the method is easier to analyze, as the objective function is being truly maximized. Second, there is no need for initialization heuristics with the approach, given that the method will always converge to a global optimum. Finally, we expect that our convexity-based approach may facilitate the further development of more convex models. There has been a rich

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1574–1583,
Seattle, Washington, USA, 18-21 October 2013.

interplay between convex and non-convex methods in machine learning: as one example consider the literature on classification problems, with early work on the perceptron (linear/convex), then work on neural networks with back-propagation (non-linear/non-convex), then the introduction of support vector machines (non-linear/convex), and finally recent work on deep belief networks (non-linear/non-convex). In view of these developments, the lack of convex methods in translation alignment models has been noticeable, and we hope that our work will open up new directions and lead to further progress in this area.

Notation. Throughout this paper, for any integer N, we use $[N]$ to denote $\{1 \dots N\}$ and $[N]_0$ to denote $\{0 \dots N\}$.

2 Related Work

(Brown et al., 1993) introduced IBM Models 1 through 5, and optimization methods for these models based on the EM algorithm. While the models were originally introduced for full translation, they are now mainly used to derive alignments which are then used by phrase-based and other modern SMT systems. Since the original IBM models were introduced, many variants have been introduced in the literature. (Vogel et al., 1996) introduced a model, sometimes referred to as IBM 2.5, which uses a parameterization that is similar to a hidden Markov model, and which allows the value of each alignment variable to be conditioned on a previous alignment variable. (Liang et al., 2006) describe a method that explicitly incorporates agreement preferences during training. (Och and Ney, 2003) give a systematic comparison of several alignment models in the literature. (Moore, 2004) gives a detailed study of IBM Model 1, showing various steps that can be used to improve its performance. (Ganchev et al., 2010) describes a method based on posterior regularization that incorporates additional constraints within the EM algorithm for estimation of IBM models. All of these approaches are unsupervised, in that they do not require labeled alignment data; however several authors have considered supervised models (e.g., see (Lacoste-Julien et al., 2006; Taskar et al., 2005; Haghighi et al., 2009)). The focus of the current paper is on unsupervised learning; the unsupervised variants described above all make use of non-convex objective functions during training, with the usual problems with multiple local maxima.

3 The IBM Model 1 and Model 2 Optimization Problems

In this section we give a brief review of IBM Models 1 and 2, and the optimization problems arising from these models. The standard approach for optimization within these models is the EM algorithm.

Throughout this section, and the remainder of the paper, we assume that our set of training examples is $(e^{(k)}, f^{(k)})$ for $k = 1 \dots n$, where $e^{(k)}$ is the k'th English sentence and $f^{(k)}$ is the k'th French sentence. Following standard convention, we assume the task is to translate from *French* (the "source" language) into *English* (the "target" language). We use E to denote the English vocabulary (set of possible English words), and F to denote the French vocabulary. The k'th English sentence is a sequence of words $e_1^{(k)} \dots e_{l_k}^{(k)}$ where l_k is the length of the k'th English sentence, and each $e_i^{(k)} \in E$; similarly the k'th French sentence is a sequence $f_1^{(k)} \dots f_{m_k}^{(k)}$ where each $f_j^{(k)} \in F$. We define $e_0^{(k)}$ for $k = 1 \dots n$ to be a special NULL word (note that E contains the NULL word). Finally, we define $L = \max_{k=1}^{n} l_k$ and $M = \max_{k=1}^{n} m_k$.

For each English word $e \in E$, we will assume that $D(e)$ is a *dictionary* specifying the set of possible French words that can be translations of e. The set $D(e)$ is a subset of F. In practice, $D(e)$ can be derived in various ways; in our experiments we simply define $D(e)$ to include all French words f such that e and f are seen in a translation pair.

Given these definitions, the IBM model 2 optimization problem is given in Figure 1. The parameters in this problem are $t(f|e)$ and $d(i|j)$. The $t(f|e)$ parameters are *translation* parameters specifying the probability of English word e being translated as French word f. The *distortion* parameters $d(i|j)$ specify the probability of the j'th French word in a sentence being aligned to the i'th English word. We use a variant of IBM Model 2 where the distortion variables are shared across all sentence lengths (similar variants have been used in (Liang et al., 2006) and (Koehn, 2008)). The objective function is then

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 3.

Parameters:
• A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
• A parameter $d(i|j)$ for each $i \in [L]_0, j \in [M]$.

Constraints:

$$\forall e \in E, f \in D(e), \quad t(f|e) \geq 0 \quad (1)$$

$$\forall e \in E, \quad \sum_{f \in D(e)} t(f|e) = 1 \quad (2)$$

$$\forall i \in [L]_0, j \in [M], \quad d(i|j) \geq 0 \quad (3)$$

$$\forall j \in [M], \quad \sum_{i \in [L]_0} d(i|j) = 1 \quad (4)$$

Objective: Maximize

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \log \sum_{i=0}^{l_k} t(f_j^{(k)}|e_i^{(k)}) d(i|j) \quad (5)$$

with respect to the $t(f|e)$ and $d(i|j)$ parameters.

Figure 1: The IBM Model 2 Optimization Problem.

the log-likelihood of the training data (see Eq. 5):

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \log p(f_j^{(k)}|e^{(k)}) \ ,$$

where

$$p(f_j^{(k)}|e^{(k)}) = \sum_{i=0}^{l_k} t(f_j^{(k)}|e_i^{(k)}) d(i|j) \ .$$

Crucially, while the constraints in the IBM Model 2 optimization problem are linear, the objective function in Eq. 5 is non-convex. Therefore, optimization methods for IBM Model 2, in particular the EM algorithm, are typically only guaranteed to reach a local maximum of the objective function.

For completeness, Figure 2 shows the optimization problem for IBM Model 1. In IBM Model 1 the distortion parameters $d(i|j)$ are all fixed to be the uniform distribution (i.e., $1/(L+1)$). The objective function for IBM Model 1 is actually convex, so the EM algorithm will converge to a global maximum. However IBM Model 1 is much weaker than model 2, and typically gives far worse performance.

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 3.

Parameters:
• A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.

Constraints:

$$\forall e \in E, f \in D(e), \quad t(f|e) \geq 0 \quad (6)$$

$$\forall e \in E, \quad \sum_{f \in D(e)} t(f|e) = 1 \quad (7)$$

Objective: Maximize

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \log \sum_{i=0}^{l_k} \frac{t(f_j^{(k)}|e_i^{(k)})}{(L+1)} \quad (8)$$

with respect to the $t(f|e)$ parameters.

Figure 2: The IBM Model 1 Optimization Problem.

A common heuristic is to initialize the $t(f|e)$ parameters in EM optimization of IBM Model 2 using the output from IBM Model 1. The intuition behind this heuristic is that the IBM Model 1 values for $t(f|e)$ will be a reasonable starting point, and the EM algorithm will climb to a "good" local optimum. We are not aware of any guarantees for this initialization heuristic, however.

4 A Convex Relaxation of IBM Model 2

We now introduce a convex optimization problem, the I2CR (IBM 2 Convex Relaxation) problem. As its name suggests, this optimization problem is closely related to IBM Model 2, but is convex. Because of this it will be relatively easy to derive an optimization algorithm that is guaranteed to converge to a global optimum. Our experiments show that the relaxation gives very similar performance to the original IBM 2 optimization problem, as described in the previous section.

We first describe an optimization problem, I2CR-1, that illustrates the basic idea behind the convex relaxation. We then describe a refined relaxation, I2CR-2, that introduces a couple of modifications, and which performs well in experiments.

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 3.

Parameters:

- A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
- A parameter $d(i|j)$ for each $i \in [L]_0, j \in [M]$.
- A parameter $q(i, j, k)$ for each $k \in [n]$, $i \in [l_k]_0$, $j \in [m_k]$.

Constraints:

$$\forall e \in E, f \in D(e), \quad t(f|e) \geq 0 \tag{9}$$

$$\forall e \in E, \quad \sum_{f \in D(e)} t(f|e) = 1 \tag{10}$$

$$\forall i \in [L]_0, j \in [M], \quad d(i|j) \geq 0 \tag{11}$$

$$\forall j \in [M], \quad \sum_{i \in [L]_0} d(i|j) = 1 \tag{12}$$

$$\forall i, j, k, \quad q(i, j, k) \geq 0 \tag{13}$$

$$\forall i, j, k, \quad q(i, j, k) \leq d(i|j) \tag{14}$$

$$\forall i, j, k, \quad q(i, j, k) \leq t(f_j^{(k)}|e_i^{(k)}) \tag{15}$$

Objective: Maximize

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \log \sum_{i=0}^{l_k} q(i, j, k) \tag{16}$$

with respect to the $q(i, j, k)$, $t(f|e)$ and $d(i|j)$ parameters.

Figure 3: The I2CR-1 (IBM 2 Convex Relaxation) Problem, version 1.

4.1 The I2CR-1 Problem

The I2CR-1 problem is shown in Figure 3. A first key idea is to introduce a new variable $q(i, j, k)$ for each $k \in [n]$, $i \in [l_k]_0$, $j \in [m_k]$: that is, a new variable for each triple (i, j, k) specifying a sentence pair, and a specific English and French position in that sentence. Each q variable must satisfy the constraints in Eqs. 13-15, repeated here for convenience:

$$\begin{aligned} &\forall i, j, k, \quad q(i, j, k) \geq 0 \, , \\ &\forall i, j, k, \quad q(i, j, k) \leq d(i|j) \, , \\ &\forall i, j, k, \quad q(i, j, k) \leq t(f_j^{(k)}|e_i^{(k)}) \, . \end{aligned}$$

The objective function is

$$\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \log \sum_{i=0}^{l_k} q(i, j, k)$$

which is similar to the objective function in Figure 1, but where $t(f_j^{(k)}|e_i^{(k)}) \times d(i|j)$ has been replaced by $q(i, j, k)$. The intuition behind the new problem is as follows. If, instead of the constraints in Eqs. 13-15, we had the constraint

$$q(i, j, k) = t(f_j^{(k)}|e_i^{(k)}) \times d(i|j) \, , \tag{17}$$

then the I2CR-1 problem would clearly be identical to the IBM Model 2 optimization problem. We have used a standard relaxation of the non-linear constraint $x = y \times z$ where x, y, z are all variables in the range $[0, 1]$, namely

$$\begin{aligned} x &\leq y \, , \\ x &\leq z \, , \\ x &\geq y + z - 1 \, . \end{aligned}$$

These inequalites are a relaxation in the sense that any (x, y, z) triple that satisfies $x = y \times z$ also satisfies these constraints. Applying this relaxation to Eq. 17 gives

$$\begin{aligned} q(i, j, k) &\leq t(f_j^{(k)}|e_i^{(k)}) \, , \\ q(i, j, k) &\leq d(i|j) \, , \\ q(i, j, k) &\geq t(f_j^{(k)}|e_i^{(k)}) + d(i|j) - 1 \, . \end{aligned} \tag{18}$$

The final thing to note is that the constraint in Eq. 18 can be omitted in the I2CR-1 problem. This is because the task is to maximize the objective with respect to the q variables and the objective is strictly increasing as the q values increase—thus lower bounds on their values are redundant in the I2CR-1 problem.

It is easily verified that the constraints in the I2CR-1 problem are linear, and that the objective function is convex. In Section 5 of this paper we describe an optimization method for the problem.

Note that because the objective function is being maximized, and the objective increases monotonically as the q values increase, at the global optimum[1]

[1] More precisely, at *any* global optimum: the objective function may not be strictly convex, in which case there will be multiple global optima.

Input: Same as in I2CR-1 (Figure 4).
Parameters: Same as in I2CR-1 (Figure 4).

Constraints: Same as in I2CR-1 (Figure 4).
Objective: Maximize

$$\frac{1}{2n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log'\sum_{i=0}^{l_k}q(i,j,k) + \frac{1}{2n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log'\sum_{i=0}^{l_k}\frac{t(f_j^{(k)}|e_i^{(k)})}{(L+1)}$$

with respect to the $q(i,j,k)$, $t(f|e)$ and $d(i|j)$ parameters.

Figure 4: The I2CR-2 (IBM 2 Convex Relaxation) Problem, version 2. The problem is identical to the I2CR-1 problem, but it also includes a term in the objective function that is identical to the IBM Model 1 objective. We define $\log'(z) = \log(z+\lambda)$ where λ is a small positive constant.

we have

$$q(i,j,k) = \min\{t(f_j^{(k)}|e_i^{(k)}), d(i|j)\}\ ,$$

where $\min\{x,y\}$ returns the minimum of the two values x and y. Thus, we could actually eliminate the q variables and write an optimization problem that is identical to the IBM Model 2 optimization problem, but with the objective function

$$\frac{1}{n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log\sum_{i=0}^{l_k}\min\{t(f_j^{(k)}|e_i^{(k)}), d(i|j)\}\ .$$

It will turn out that both views of the I2CR-1 problem—with and without the q variables—are helpful, so we have included both in this paper.

4.2 The I2CR-2 Problem

Figure 4 shows the refined optimization problem, which we call I2CR-2. The problem incorporates two modifications. First, we modify the objective function to be

$$\frac{1}{2n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log'\sum_{i=0}^{l_k}q(i,j,k) + \frac{1}{2n}\sum_{k=1}^{n}\sum_{j=1}^{m_k}\log'\sum_{i=0}^{l_k}\frac{t(f_j^{(k)}|e_i^{(k)})}{(L+1)}\ .$$

Thus the objective function includes a second term that is identical to the objective function for IBM Model 1 (see Figure 2). In preliminary experiments with the I2CR-1 optimization problem, we found that the I2CR-1 objective was not sufficiently dependent on the t parameters: intuitively, if the d parameters achieve the $\min$ on many training examples, the values for the t variables become unimportant. The addition of the IBM Model 1 objective fixed this problem by introducing a term that depends on the t values alone.

Second, we replace $\log$ by $\log'$, where $\log'(z) = \log(z+\lambda)$, and λ is a small positive constant (in our experiments we used $\lambda = 0.001$). Under this definition the derivatives of $\log'$ are upper-bounded by $1/\lambda$, in contrast to $\log$, where the derivatives can diverge to infinity. The optimization methods we use are gradient-based methods (or more precisely, *subgradient*-based methods), and we have found them to be considerably more stable when the values for gradients do not diverge to infinity.

The modified objective remains convex.

5 A Stochastic Exponentiated-Gradient Algorithm for Optimization

We now describe an algorithm for optimizing the I2CR-2 problem in Figure 4. The algorithm is closely related to stochastic gradient ascent, but with two modifications:

- First, because the $t(f|e)$ and $d(i|j)$ parameters have simplex constraints (see Figure 1), we use *exponentiated gradient* (EG) updates. EG algorithms are gradient-based methods that maintain simplex constraints; see for example: (Kivinen and Warmuth, 1997; Beck and Teboulle, 2003; Collins et al., 2008).

- Second, the objective function in the I2CR-2 problem is convex, but is not differentiable (the gradient may not exist at all points). For this reason we use *subgradients* in the place of gradients. In spite of the non-differentiability of the objective function, subgradient methods still have strong convergence guarantees when combined with EG updates (e.g., the convergence proofs in (Beck and Teboulle, 2003)

go through with minor modifications; see also (Bertsekas, 1999)).

To derive the updates, recall that we are maximizing the following objective function:

$$\begin{aligned} & h(t,d) \\ = & \frac{1}{2|\mathcal{T}|} \sum_{k \in \mathcal{T}} \sum_{j=1}^{m_k} \log' \sum_{i=0}^{l_k} \min \left\{ t(f_j^{(k)} | e_i^{(k)}), d(i|j) \right\} \\ + & \frac{1}{2|\mathcal{T}|} \sum_{k \in \mathcal{T}} \sum_{j=1}^{m_k} \log' \sum_{i=0}^{l_k} \frac{t(f_j^{(k)} | e_i^{(k)})}{(L+1)} \, . \end{aligned} \quad (19)$$

Here we use $\mathcal{T}$ to denote the set $\{1 \ldots n\}$; we will see shortly why this notation is convenient. We use t and d to refer to the full set of t and d parameters respectively; $h(t,d)$ is the function to be maximized. Recall that $\log'(z) = \log(z + \lambda)$ where λ is a small positive parameter.

Given a concave function $f(x)$ where $x \in \mathbb{R}^d$, a subgradient of $f(x)$ at x is any vector $g(x) \in \mathbb{R}^d$ such that for any $y \in \mathbb{R}^d$,

$$f(y) \leq f(x) + g(x) \cdot (y - x) \, ,$$

where $u \cdot v$ is the inner product between vectors u and v. Subgradients are similar to gradients for differentiable concave functions, in that gradients satisfy the above property. Subgradients can be used in the place of gradients in many optimization algorithms (see for example (Bertsekas, 1999)).

The subgradients for the objective function in Eq. 19 take a simple form. First, define

$$\begin{aligned} R(j,k) &= \lambda + \sum_{i=0}^{l_k} t(f_j^{(k)} | e_i^{(k)}) \, , \\ Q(j,k) &= \lambda + \sum_{i=0}^{l_k} \min\{ t(f_j^{(k)} | e_i^{(k)}), d(i|j) \} \, , \end{aligned}$$

and

$$I(i,j,k) = \begin{cases} 1 & \text{if } t(f_j^{(k)} | e_i^{(k)}) \leq d(i|j) \\ 0 & \text{otherwise} \, . \end{cases}$$

Then the subgradients[2] are

$$\nabla t(f|e) = \frac{1}{2|\mathcal{T}|} \sum_{\substack{i,j,k: \\ f_j^{(k)} = f \\ e_i^{(k)} = e}} \left(\frac{1}{R(j,k)} + \frac{I(i,j,k)}{Q(j,k)} \right)$$

and

$$\nabla d(i|j) = \frac{1}{2|\mathcal{T}|} \sum_{k: i \leq l_k, j \leq m_k} \frac{1 - I(i,j,k)}{Q(j,k)} \, .$$

Exponentiated-gradient updates then take the following form:

$$t(f|e) \leftarrow \frac{t(f|e) \times \exp\{\gamma \times \nabla t(f|e)\}}{\sum_f t(f|e) \times \exp\{\gamma \times \nabla t(f|e)\}} \quad (20)$$

and

$$d(i|j) \leftarrow \frac{d(i|j) \times \exp\{\gamma \times \nabla d(i|j)\}}{\sum_i d(i|j) \times \exp\{\gamma \times \nabla d(i|j)\}} \, , \quad (21)$$

where $\gamma > 0$ is a constant step size in the algorithm. Note that the EG updates make use of subgradients, but maintain the simplex constraints on the t and d variables.

The method just described is a *batch* gradient method, where the entire training set $\mathcal{T} = \{1 \ldots n\}$ is used to derive the subgradients before the updates in Eqs. 20 and 21 are made. Many results in machine learning and NLP have shown that *stochastic gradient methods*, where a subset of the training examples is used before each gradient-based update, can converge much more quickly than batch gradient methods. In our notation, this simply involves replacing $\mathcal{T}$ by some subset $\mathcal{T}'$ of the training examples in the above definitions, where $|\mathcal{T}'|$ is typically much smaller than $|\mathcal{T}|$.

Figure 5 shows our final algorithm, a stochastic version of the exponentiated-gradient method. The method takes S passes over the data. For each pass, it randomly partitions the training set into mini-batches $\mathcal{T}_1 \ldots \mathcal{T}_K$ of size B, where B is an integer specifying the size of each mini-batch (in our experiments we used $B = 125$ or $B = 250$). The algorithm then performs EG updates using each mini-batch $\mathcal{T}_1 \ldots \mathcal{T}_K$ in turn. As can be seen in Table 3, our experiments show that the algorithm makes very significant progress in the first pass over the data, and takes very few iterations to converge to a good solution even though we initialized with uniform parameter values.

6 Experiments

In this section we describe experiments using the I2CR-2 optimization problem combined with the

[2] We set $\nabla t(f|e)$ and $\nabla d(i|j)$ as the subgradients for the objective function in Eq. 19 with respect to $t(f|e)$ and $d(i|j)$ respectively.

Input: Define E, F, L, M, $(e^{(k)}, f^{(k)}, l_k, m_k)$ for $k = 1 \ldots n$, $D(e)$ for $e \in E$ as in Section 3. An integer B specifying the batch size. An integer S specifying the number of passes over the data. A step size $\gamma > 0$. A parameter $\lambda > 0$ used in the definition of $\log'$.

Parameters:

- A parameter $t(f|e)$ for each $e \in E, f \in D(e)$.
- A parameter $d(i|j)$ for each $i \in [L]_0, j \in [M]$.

Definitions:

$$R(j,k) = \lambda + \sum_{i=0}^{l_k} t(f_j^{(k)}|e_i^{(k)})$$

$$Q(j,k) = \lambda + \sum_{i=0}^{l_k} \min\{t(f_j^{(k)}|e_i^{(k)}), d(i|j)\}$$

Initialization:

- $\forall e \in E,\ f \in D(e),\ t(f|e) = 1/|D(e)|$
- $\forall j \in [M],\ i \in [L]_0,\ d(i|j) = 1/(L+1)$

Algorithm:

for all $s = 1$ to S **do**
  Randomly partition $[n]$ into subsets $\mathcal{T}_1 \ldots \mathcal{T}_K$ of size B where $K = n/B$.
  for all $b = 1$ to K **do**
    $\forall e \in E,\ f \in D(e),\ \alpha(e,f) = 0$
    $\forall j \in [M],\ i \in [L]_0,\ \beta(i,j) = 0$
    for all $k \in \mathcal{T}_b$ **do**
      for all $j = 1$ to m_k **do**
        for all $i = 0$ to l_k **do**
          $\alpha(e_i^{(k)}, f_j^{(k)})$ += $1/(2R(j,k))$
          if $t(f_j^{(k)}|e_i^{(k)}) \leq d(i|j)$ **then**
            $\alpha(e_i^{(k)}, f_j^{(k)})$ += $1/(2Q(j,k))$
          else
            $\beta(i,j)$ += $1/(2Q(j,k))$
    $\forall e, f,\ t(f|e) = t(f|e) \exp(\gamma \times \alpha(e,f)/B)$
    $\forall i, j, d(i|j) = d(i|j) \exp(\gamma \times \beta(i,j)/B)$
    Renormalize t and d parameters to satisfy $\sum_f t(f|e) = 1$ and $\sum_i d(i|j) = 1$.

Output: t and d parameters.

Figure 5: The stochastic exponentiated-gradient algorithm for optimization of I2CR-2.

stochastic EG algorithm for parameter estimation. We first describe the data sets we use, and then describe experiments with the method, comparing our approach to results from IBM Model 2. We compare the various algorithms in terms of their accuracy in recovering alignments, using metrics such as F-measure and AER.

6.1 Data Sets

We use data from the bilingual word alignment workshop held at HLT-NAACL 2003 (Michalcea and Pederson, 2003). As a first dataset, we use the Canadian Hansards bilingual corpus, with 247,878 English-French sentence pairs as training data, 37 sentences of development data, and 447 sentences of test data (note that we use a randomly chosen subset of the original training set of 1.1 million sentences, similar to the setting used in (Moore, 2004)). The development and test data have been manually aligned at the word level, annotating alignments between source and target words in the corpus as either "sure" (S) or "possible" (P) alignments, as described in (Och and Ney, 2003).

As a second data set, we used the Romanian-English data from the HLT-NAACL 2003 workshop. This consisted of a training set of 48,706 Romanian-English sentence-pairs, a development set of 17 sentence pairs, and a test set of 248 sentence pairs.

6.2 Methodology

For each of the models—IBM Model 1, IBM Model 2, and I2CR-2—we follow convention in applying the following methodology: first, we estimate the t and d parameters using models in both source-target and target-source directions; second, we find the most likely alignment for each development or test data sentence in each direction; third, we take the intersection of the two alignments as the final output from the model.

For the EG algorithm we use a batch size $B = 250$ and step size $\gamma = 0.5$ on the Hansards data, and $B = 125$ and $\gamma = 0.5$ for the Romanian-English data.

We report the performance of the models in terms of *Precision*, *Recall*, *AER*, and *F-Measure* as defined by (Och and Ney, 2003). If A is the set of alignments produced by an algorithm, S is the set of sure alignments as annotated in test data, and P is the set of possible alignments, then these quantities are defined as

$$\text{Recall} = \frac{|A \cap S|}{|S|} ,$$

$$\text{Precision} = \frac{|A \cap S|}{|A|} ,$$

$$\text{AER} = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|} ,$$

$$\text{F-Measure} = \frac{1}{\frac{.5}{\text{Recall}} + \frac{.5}{\text{Precision}}} .$$

Note that we report results in both AER and F-measure; however there is evidence (Fraser and Marcu, 2004) that F-measure is better correlated with translation quality when the alignments are used in a full system.

In training IBM Model 1 we follow (Moore, 2004) in running EM for 15 iterations. In training IBM Model 2 we first train IBM Model 1 for 15 iterations to initialize the t parameters, then train IBM Model 2 for a further 10 iterations. For the EG algorithm, we use 10 iterations over the training data for the Hansards data, and 15 iterations on the Romanian-English data (on the latter dataset results on the trial data showed that the method took slightly longer to converge). We report F-measure and AER results for each of the iterations under the IBM Model 2 and I2CR-2 models. See Table 1 for the results on the Hansards data, and Table 2 for the results on the English-Romanian dataset. It can be seen that both I2CR-2 and IBM Model 2 converge to a fairly stable result after 2-3 iterations. The two models give very similar levels of performance, for example after 10 iterations on the Hansard data IBM Model 2 gives 14.22 AER and 0.7516 F-Measure versus 14.60 AER and 0.7506 F-Measure for I2CR-2.

On the right, Table 3 shows the values of the objective function at each iteration when using the EG algorithm to optimize the I2CR-2 objective. The method makes a large amount of progress on the first iteration and then continues to improve. Finally, we note that the memory requirements for I2CR-2 and IBM2 are about the same, but that the time for one iteration of I2CR-2 on the Hansards data is approximately one hour, while the time for one iteration of IBM2 was approximately 10 minutes.

7 Conclusions and Future Work

We have introduced the first convex model for unsupervised learning of alignments in statistical machine translation with performance comparable to

Pair Language Models for Deriving Alternative Pronunciations and Spellings from Pronunciation Dictionaries

Abstract

Pronunciation dictionaries provide a readily available parallel corpus for learning to transduce between character strings and phoneme strings or vice versa. Translation models can be used to derive character-level paraphrases on either side of this transduction, allowing for the automatic derivation of alternative pronunciations or spellings. We examine finite-state and SMT-based methods for these related tasks, and demonstrate that the tasks have different characteristics – finding alternative spellings is harder than alternative pronunciations and benefits from round-trip algorithms when the other does not. We also show that we can increase accuracy by modeling syllable stress.

1 Introduction

Robust processing of speech and language requires dealing with variation in language production, either in terms of pronunciation in the spoken domain or spelling in the written domain. Predicting the intended words of an acoustic or textual sequence is an important recognition task, often required for downstream processing such as spoken language understanding or knowledge extraction. Informal text genres, such as those found in social media, share some characteristics with speech; in fact such text is often informed by pronunciation variation. For example, consider the following tweet:

> He aint gotta question my loyalty, cuz he knw wen sh!t get real. Ill be right here!

where several tokens (e.g. "cuz", "wen") represent spelling alternations related to pronunciation. Work in text normalization and spelling correction – e.g., Toutanova and Moore (2002); Li and Liu (2012) – has included pronunciation information to improve recognition of the intended word, via grapheme to phoneme (g2p) conversion modeling derived from pronunciation dictionaries.

Pronunciation dictionaries provide natural parallel corpora, with strings of characters paired to strings of phones. Thus, standard lexicons have been used in recent years with machine translation systems such as Moses (Koehn et al., 2007), to train g2p systems (Laurent et al., 2009; Gerosa and Federico, 2009). Further, other algorithms using such dictionaries also use translation phrase tables, but not for translation tasks. For example, data-driven paraphrasing methods (Bannard and Callison-Burch, 2005) use translation phrase-tables as a "pivot" to learn sets of phrases which translated to the same target phrase. In a similar manner, with a pronunciation dictionary instead of a phrsetable, pivoting can be used to learn alternative pronunciations (Karanasou and Lamel, 2010), i.e., direct phoneme-to-phoneme (p2p) "translation" systems that yield alternative pronunciations. Alternatively, round-trip translation could be used, e.g., to map from letter strings to phone strings in one step, then from the resulting phone strings to letter strings in a second step, as the means to find alternative spellings (Li and Liu, 2012).

In this study, we explore dictionary-derived models to find either alternative pronunciations or alternative spellings, using either direct (p2p or g2g) or round-trip algorithms (p2g2p or g2p2g). We compare methods based on weighted finite-state transducers (WFST) with phrase-based models trained with Moses. Our main interest is to evaluate Karanasou and Lamel (2010) methods – shown to be useful for deriving alternative pronunciations – for deriving alternative spellings, and thus to determine the relative difficulty of these two tasks. We also examine when, if ever, round-trip processing yields benefits over direct transduction. Our results indicate that real alternative pronunciations are substantially easier to find than real alternative spellings, partic-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1584–1589,
Seattle, Washington, USA, 18-21 October 2013.

ularly when pronunciation features such as syllable stress are available. Second, round trip translation yields no gain (and some loss) over direct transduction for finding alternative pronunciations, yet yields some modest gains for finding alternative spellings. Further, WFST methods perform as well as or better than Moses trained models. Finally, combining the methods yields further gains, indicating that the models are learning complementary sets of patterns.

The primary contribution of this work is to introduce a competitive method of building and using pair language model WFSTs for generating alternative spellings and pronunciations which reflect real-world variability. This could improve results for downstream processes, e.g., epidemiological studies (Chew and Eysenbach, 2010) or sentiment analysis (Barbosa and Feng, 2010) derived from social media text. Further, we present a controlled comparison between the two tasks, and demonstrate that they differ in terms of task difficulty

2 Related work

Text normalization has been a major focus in text-to-speech (TTS) research for many years. Notably, Sproat et al. (2001) deemed it a problem in itself, rather than *ad hoc* preparatory work, and defined many of the issues involved, as well as offering a variety of initial solutions. Similar approaches apply to automatic spelling correction, where Toutanova and Moore (2002) extended the noisy channel spelling correction method of Brill and Moore (2000), by modeling pronunciation alternations to infer from misspellings to correct spellings. Similarly, Li and Liu (2012) extended the character-based translation approach to text normalization of Pennell and Liu (2011), by adding an additional round-trip translation to-and-from pronunciations. Karanasou and Lamel (2010) used Moses to generate alternative pronunciations from an English dictionary, using both direct and round-trip methods. They validated their systems on a set of words with multiple pronunciations, measuring the degree to which alternative pronunciations are generated from one of the given pronunciations. Our task and method of evaluation is similar to theirs, though we also look at alternative spellings.

3 Methods

To generate alternative spellings and pronunciations, we built phrase-based translation and finite-state transduction models from a parallel corpus. When pronunciations were part of the model – i.e., not direct grapheme-to-grapheme – we included conditions with and without vowel stress.

3.1 Corpus

Our training corpus is the CMU Pronouncing Dictionary[1], which contains nearly 130k entries. From this corpus, we identified homophone sets, i.e., sets of multiple spellings sharing the same pronunciation, such as "colonel" and "kernel". We found 9,977 such sets, and randomly selected 1000 for testing; the rest we used for training. Each set had, on average, 2.46 members. We also identified homograph sets, i.e., sets of multiple pronunciations all spelled the same, such as potato (/potato/ and /pəteto/). We found 8,216 such homograph sets, and randomly selected 1000 for testing; the rest we used for training. These sets averaged 2.13 members.

We construct seven parallel training corpora from the lexicon, each disjoint from its relevant test set. For round-trip models, the parallel corpus is each grapheme string in the lexicon aligned with its phoneme string, if neither the grapheme string nor phoneme string appear in the test set. There are four such corpora, corresponding to these options: stress or no stress, and g2p2g or p2g2p. The g2p2g and p2g2g conditions require different corpora because they are differently partitioned for testing. For direct grapheme-to-grapheme training sets, non-homophone words are self-aligned; for homophones, from each homophone set, each possible pair of spellings are aligned. For example, for a pronunciation with four spellings—a, b, c, and d—there would be six alignments: a:b, a:c, a:d, b:c, b:d, c:d. Similarly for direct phoneme-to-phoneme training sets, non-homograph words are self-aligned; words from the training homograph sets are pairwise aligned in all pairings. There are two direct p2p corpora: with and without stress.

3.2 Phrase-based translation models

As a baseline system, we used the Moses statistical machine translation package (Koehn et al., 2007) to build grapheme-based and phoneme-based translation systems, using a bigram language model.[2] These are trained on the parallel corpus resulting from the homophone or homograph sets detailed in

[1] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

[2] Higher order language models yielded no improvements.

the previous section for the direct methods. For this paper, we did not perform round-trip translation with Moses, rather present it as a baseline for the direct approach.

3.3 Pair language models

Our weighted finite-state transducer approach is based on pair language models (Bisani and Ney, 2008; Deligne and Bimbot, 1997; Ghoshal et al., 2009), or, more recently, (Sagae et al., 2012).) The basic idea in a pair LM is to align strings, then train a language model over sequences whose symbols are the input:output pairs of the alignment. This language model can then be converted to transducers. For a g2g example, homophones "their" and "there" are aligned via the standard Levenshtein edit distance algorithm as "t:t h:h e:e i:ϵ r:r ϵ:e". A trigram model over these x:y strings would use standard n-gram modeling to estimate, for example, P(ϵ:e | i:ϵ r:r); i.e., the probability of a silent "r" in a given context.

Building the pair language model transducers requires two phases. In the first phase we create new corpora by aligning the elements of the parallel corpora outlined above. In the second phase we use these corpora of string alignments to build a pair language model.

3.3.1 Alignment and Corpora Building

We use extensions to the Levenshtein edit distance algorithm to align g2g, p2p and g2p strings, with substitution matrices created to provide useful alignments (Wagner and Fischer, 1974). As in Brill and Moore (2000), we allow for certain multi-symbol strings to be substituted with a single cost, e.g., substituting 'th' with /θ/ in g2p alignment. For g2g alignment, our substitution cost is 0 for identity and 2 for a few pairs of commonly interchangeable graphemes, such as 'c' and 'k'. Other substitutions are not permitted, and delete and insertion have cost 10. For p2p alignment there are two conditions, with and without stress. Without vowel stress, no substitutions other than identity are allowed; with vowel stress, substitution cost is 2.5 for the same vowel with differing stress; and 5.0 if substituting a vowel with another vowel. Other substitutions are not permitted, and, again, delete and insertion have cost 10.

For training round-trip models, we have to perform g2p and p2g alignment, with differing alphabets on the input and output of the alignment. We begin with a basic substitution table that allows graphemes and their most likely phonemes to align. We then re-estimate the substitution costs based on relative frequency estimation (-logP), and also aggregate sequences of consecutively deleted graphemes so that they collectively map to a single phoneme. For example, given the alignment 'o:/a/ u:/ϵ/ g:/ϵ/ h:/ϵ/ t:/t/', ('ought', /at/), we make a new rule: ough:/a/, and give it a cost based on its relative frequency. Grapheme strings that appear sufficiently often with a given phoneme will thus accumulate sufficient probability mass to compete.

Each alignment produced as described above is a string in a training corpus for creating a pair language model. As such, each alignment pair (e.g. a:/ə/) is a token.

3.3.2 From Corpora to WFSTs

We use the open source OpenGrm NGram library (Roark et al., 2012) to build 5-gram language models from the strings of input:output pairs. These langauge models are encoded as weighted finite-state acceptors in the OpenFst format (Allauzen et al., 2007). We shrink the models with the `ngramshrink` command, using the relative entropy method (Stolcke, 1998), with the "theta" threshold set at $1.0e-6$. These finite state acceptors are then converted into transducers by modifying the arcs: split the labels of each arc, x:y, making x the input label for that arc, and y the output label. Thus traversing such an arc will consume an x a return a y. Such pair language models we use for all WFST methods discussed here.

3.4 Producing k-best output

Each tested input string, spelling or pronunciation, is encoded as a cost-free linear chain WFST and composed with a pair language model transducer described in the previous section. The resulting lattice is converted to an acceptor by projecting onto its output labels, i.e., for each arc, the input label is set to the value of the output label. Epsilons are then removed and the result is determinized. The k-best paths are extracted using the shortest path algorithm in the OpenFst library.

For direct models (g2g and p2p), the k-best output from this first transduction is our result, ranked according the probability of each path. For round-trip methods (e.g. g2p2g), however, we do a second transduction in the other direction. For example, for

g2p2g, the first transduction would have transduced from a spelling to a set of candidate pronunciations; the second transduction will transduce from pronunciations to spellings. For this second transduction, we take each string s from the k-best list from the first transduction, and process them as we did in the first transduction, now using the inverse transducer. So, for each s in the first k-best list, we now have a k-best list from the second transduction. Thus, for the original input string, we have up to k^2 alternatives. Finally, we score each alternative by combining their scores from both transductions.

Let $\bar{p}$ represent a phoneme string, and $\bar{g}$ a grapheme string. If we perform a transduction from $\bar{p}$ to $\bar{g}$, the weights from the transducer provide the (negative log) joint probability $\mathrm{P}(\bar{p}, \bar{g})$. By performing a soft-max normalization over the k-best list output, we obtain the (negative log) conditional probability $\mathrm{P}(\bar{g} \mid \bar{p})$. For round-trip methods, we take the product of the conditional probability in each direction, and marginalize out the intermediate grapheme sequence, i.e.,

$$\mathrm{P}(\bar{p}_2 \mid \bar{p}_1) \;=\; \sum_{\bar{g}} \mathrm{P}(\bar{p}_2 \mid \bar{g})\, \mathrm{P}(\bar{g} \mid \bar{p}_1).$$

4 Experimental results

For evaluation purposes, we reserved a set of 1000 test homophone sets and 1000 test homograph sets, as described in Section 3.1. From each set, we generate alternatives from the longest set member (ties broken alphabetically) and examine the resulting k-best list for presence of other members of the set. Note that the input string itself is not a target, and, before evaluation, is removed from the k-best list. Recall is the proportion of the k-best list returned by the system:

$$\text{Recall}(\{\text{k-best}\}) \;=\; \frac{\mid \{\text{k-best}\} \cap \{\text{gold-list}\} \mid}{\mid \{\text{gold-list}\} \mid}$$

.

Results for generating alternative pronunciations are listed in Table 1; those for generating alternative spellings are in Table 2. For alternative spellings, we also present results that combine the outputs of direct, round-trip (no stress) and Moses into a single list using a simple ranked voting scheme (simple Borda count).

A noteworthy result is the apparent usefulness of stress modeling for predicting pronunciation variation using WFSTs with the direct method; this is seen in the first two data columns of 1. This suggests that stress has an effect on phoneme alteration, something we discuss in more detail in Section 5.

Recall: Alternative Pronunciations						
k-best size	pair language model				Moses	
	Direct		Roundtrip		Direct	
	stress	none	stress	none	stress	none
1	0.43	0.54	0.38	0.37	0.44	0.46
3	0.77	0.71	0.59	0.58	0.60	0.62
5	0.82	0.77	0.66	0.66	0.64	0.65
10	0.86	0.80	0.73	0.76	0.68	0.69

Table 1: Recall for generating alternative pronunciations

However, while providing a large gain in the p2p condition, pronunciation modeling gives small or negative effects elsewhere. In the round trip methods, the effects of stress are lost: stress has little influence of how a particular phoneme is spelled. Thus, graphemes do not retain much stress information, hence any pass through the orthographic domain will shed it.

Recall is higher for alternative pronunciations than for alternative spellings. One reason for this is that spellings in our test set average eight letters, whereas the pronunciations average around five phonemes. Furthermore, the average Levenshtein distance between original spellings and their target alternatives, is 2.6, while for pronunciations, it is 2.2. Combining these factors, we see that, for spellings, more edit operations are required, and there are more symbols to which to apply them. Therefore, for spellings, there are more incorrect candidates.

The results also show gains resulting from the roundtrip method when applied to finding alternative spellings, but no such gains when roundtrip methods are applied to alternative pronunciations. Suppose, when seeking alternatives for some spelling, we alter grapheme g_1 to g_2. With a direct method, we must have instances of g_1 mapping to g_2 in the training set. The roundtrip method, however, is less constrained: there must exist some phoneme p_1 in the training set such that g_1 maps to p_1, and p_1 maps to g_2; thus, the set of possible alternations at testing are $\{g_1 \rightarrow p_1\} \times \{p_1 \rightarrow g_2\}$. This argument also applies to finding alternative pronunciations. Thus the roundtrip method offers more possible mappings. These extra possible mappings may be helpful or harmful, depending on how likely they are compared to the possible mappings they displace. Why are they helpful for alternative spellings, but not for al-

Recall: Alternative Spellings

Table 2: Recall for generating alternative spellings

ternative pronunciations? We discuss one possible explanation in Section 5.

Comparing Moses to the pair language model methods, Moses does slightly better for smaller n ($n = 1, 3$), and slightly worse for larger n ($n = 10$). Our only partial explanation for this is that Moses does well at weighing alternatives but, possibly, does not generate a large number of viable alternatives. System combination yields solid gains in finding alternative spellings, demonstrating that these different systems are coming up with diverse options.

Finally, we note that many of the false positive pronunciations given by the WFST system are plausibly correct although they are not included in the CMU dictionary. For example, for the spelling, *adequate*, the CMU dictionary provides two pronunciations: /ædəkwət/ and /ædəkwet/. Meanwhile, the p2p WFST system (with stress modeling) produces /ædəkwIt/. This suggests that we can learn from CMU dictionary to predict actual pronunciations that CMU dictionary does not itself list.

5 Discussion and Summary

The experimental results demonstrated the utility of stress modeling for generating alternative pronunciations, which we suggested was due to the impact of stress on phoneme alternation. To examine this more closely, we looked at each phoneme, stress class, (ph, s)—e.g. (/ə/, primary)—and determined how likely is an occurrence of (ph, s) to have an alternative phoneme in a homograph set. We found that primary and secondary stressed vowels had an alteration probability of 0.017, while non-stressed vowels had an alteration probability of 0.036. This difference should be picked up in the transition probabilities of our WFSTs, resulting in a preference for alterations of unstressed vowels. This is analogous to results found in (Greenberg et al., 2002) for spontaneous American English discourse. A further analysis of the system output might shed more light on relationships between stress and phoneme choice.

Why are round-trip methods useful for finding alternative spellings but not for finding alternative pronunciations? One possible explanation is that the variety of orthographic alternations is greater than that of pronunciation alternations. Thus, the training set for spelling may provide less relative coverage of the alternations in its test set than the training set for pronunciation provides for *its* test set. This is supported by the fact that pronunciation recall exceeds spelling recall. The roundtrip method allows for finding mappings not seen in training. These extra mappings might be no better for spelling than they are for pronunciation, but for spelling, the mappings they replace in the k-best list are worse, so they yield an improvement. For pronunciation, the mappings they replace in the k-best list are better, so they yield a loss. Further research is required to validate this explanation.

Ultimately, we would like to apply these methods to the normalization of social media text, especially to find alternative spellings based on alternative pronunciations. To apply such methods to, say, Twitter normalization requires a sizable corpus mapping canonical spellings to non-standard spellings. To assess domain portability, we applied a model built from the CMU dictionary to just over 100 alternative spellings observed in a small Twitter collection. Using the direct g2g method, we generated alternative spellings from the canonical spelling of each term, and measured the recall of the output, i.e., whether the observed alternatives were present in the k-best list. Recall was extremely low (less than 5%), suggesting that the type of orthographic alterations that are found in dictionary pronunciations are very different from the orthographic variations found on Twitter, and that those differences have a profound effect on our ability to recover alternatives.

In sum, we have presented a small study of the utility of pronunciation dictionaries for finding spelling and pronunciation alternatives, demonstrating key differences between these tasks.

Abstract

Recent work has shown that compositional-distributional models using element-wise operations on contextual word vectors benefit from the introduction of a prior disambiguation step. The purpose of this paper is to generalise these ideas to tensor-based models, where relational words such as verbs and adjectives are represented by linear maps (higher order tensors) acting on a number of arguments (vectors). We propose disambiguation algorithms for a number of tensor-based models, which we then test on a variety of tasks. The results show that disambiguation can provide better compositional representation even for the case of tensor-based models. Furthermore, we confirm previous findings regarding the positive effect of disambiguation on vector mixture models, and we compare the effectiveness of the two approaches.

1 Introduction

Distributional models of meaning have been proved extremely useful for a number of natural language processing tasks, ranging from thesaurus extraction (Curran, 2004) to topic modelling (Landauer and Dumais, 1997) and information retrieval (Manning et al., 2008), to name just a few. These models are based on the *distributional hypothesis* of Harris (1968), which states that the meaning of a word depends on its context. This idea allows the words to be represented by vectors of statistics collected from a sufficiently large corpus of text; each element of the vector reflects how many times a word co-occurs in the same context with another word of the vocabulary. However, due to the generative power of natural language, which is able to produce infinite new structures from a finite set of resources (words), no text corpus, regardless of its size, can provide reliable distributional representations for anything longer than single words or perhaps very short phrases consisting of two words; in other words, this technique cannot scale up to the phrase or sentence level.

Much research activity has been recently dedicated to provide a solution to this problem: although the direct construction of a sentence vector is not possible, we might still be able to synthetically create such a vectorial representation by somehow *composing* the vectors of the words that comprise the sentence. Towards this goal, researchers have employed a variety of approaches that roughly fall into two general categories. Following an influential work (Mitchell and Lapata, 2008), the models in the first category compute a sentence vector as a mixture of the original word vectors, using simple operations such as element-wise multiplication and addition; we refer to these models as *vector mixtures*. The main characteristic of these models is that they do not distinguish between the type-logical identities of the different words: an intransitive verb, for example, is of the same order as its subject (a noun), and both will contribute equally to the composite sentence vector.

However, this symmetric treatment of composition seems unjustified from a formal semantics point of view. Words with special meanings, such as verbs and adjectives, are usually seen as functions acting on, hence modifying, a number of arguments rather than lexical units of the same order as them; an adjective, for example, is a function that returns a modified version of its input noun. Inspired from

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1590–1601,
Seattle, Washington, USA, 18-21 October 2013.

this more-aligned-to-formal-semantics view, a second research direction aims to represent relational words as linear maps (tensors of various orders) that can be applied to one or more arguments (vectors). Baroni and Zamparelli (2010), for example, model adjectives as matrices which, when matrix-multiplied with a noun vector, will produce a vectorial representation of the specific adjective-noun compound. The notion of a framework where relational words are entities living in vector spaces of higher order than nouns, which are simple vectors, has been formalized by Coecke et al. (2010) in the context of the abstract mathematical framework of compact closed categories. We refer to this class of models as *tensor-based*.

Regardless of the way they approach the representation of relational words and their composition operation, however, most current compositional-distributional models do share a common feature: they all rely on ambiguous vector representations, where all the senses of a polysemous word, such as the verb 'file' (which can mean *register* or *smooth*), are merged into the same vector or tensor. At least for the vector mixture approach, this practice has been proved suboptimal: Reddy et al. (2011) and Kartsaklis et al. (2013) test a number of simple multiplicative and additive models using disambiguated vector representations on various tasks, showing that the introduction of a disambiguation step prior to actual composition can indeed increase the quality of the composite vectors. However, the fact that disambiguation can be beneficial for models based on vector mixtures is not very surprising. Both additive and multiplicative compositions are but a kind of average of the vectors of the words in the sentence, hence can directly benefit from the provision of more accurate starting points. Perhaps a more interesting question, and one that the current paper aims to address, is to what extent disambiguation can also provide benefits for tensor-based approaches, which in general constitute more powerful models for natural language (see discussion in Section 2).

Specifically, this paper aims to: (a) propose disambiguation algorithms for a number of tensor-based distributional models; (b) examine the effect of disambiguation on tensors for relational words; and (c) meaningfully compare the effectiveness of tensor-based against vector mixture models in a number of tasks. Based on the generic procedure of Schütze (1998), we propose algorithms for a number of tensor-based models, where the composition is modelled as the application of linear maps (tensor contractions). Following Mitchell and Lapata (2008) and many others, we test our models on two disambiguation tasks similar to that of Kintsch (2001), and on the phrase similarity task introduced in (Mitchell and Lapata, 2010). In almost every case, the results show that disambiguation can make a great difference in the case of tensor-based models; they also reconfirm previous findings regarding the effectiveness of the method for simple vector mixture models.

2 Vectors vs tensors

The simple models of Mitchell and Lapata (2008) constitute the easiest and perhaps the most intuitive way of composing two or more vectors: each element of the resulting vector is computed as the sum or the product of the corresponding elements in the input vectors (left part in Figure 1). In the case of addition, the components of the output vector are simply the cumulative scores of the corresponding input components. So in a sense the output element embraces both input elements, resembling a *union* of the input features. On the other hand, the element-wise multiplication of two vectors can be seen as the *intersection* of their features: a zero element in one of the input vectors will eliminate the corresponding feature in the output, no matter how high the other input component was. In addition to failing to identify the special roles of words in a sentence, vector mixture models disregard grammar in another way: the commutativity of operators make them a bag-of-words approach, where the meaning of sentence 'dog bites man' is equated to that of 'man bites dog'.

On the contrary to the above element-wise treatment, a compositional approach based on linear maps computes each element of the resulting vec-

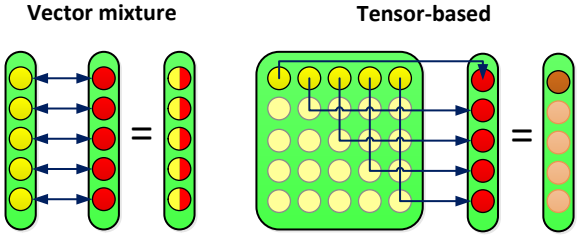

Figure 1: Vector mixture and tensor-based models for composition. In the latter approach, the ith element of the output vector is the linear combination of the input vector with the ith row of the matrix.

tor via a linear combination of *all* the elements of the input vector (right part of Figure 1); in other words, possible interdependencies between different features are also taken into account, offering (in principle) more power. Furthermore, by design, the bag-of-words problem is not present here. Overall, tensor-based models offer a more complete and linguistically motivated solution to the problem of composition. For example, one can consider building linear maps for prepositions and logical words, rather than treating them as noise and discard them, as commonly done in the vector mixture models.

3 Disambiguation in vector mixtures

For a compositional model based on vector mixtures, polysemy of words can be a critical factor. Pulman (2013) and Kartsaklis et al. (2013) point out that the element-wise combination of "ambiguous" vectors produces results that are hard to interpret; the composed vector is not a purely compositional representation but a product of two tasks that take place in parallel: composition and *some* amount of disambiguation that emerges as a side-effect of the compositional process, leaving the resulting vector in an intermediate state.

This effect is demonstrated in Figure 2, which shows the composition of the ambiguous verb 'run' (with meanings *moving fast* and *dissolving*) with the subject 'horse'. The first three components of our toy vector space are related to the *dissolving* meaning, while the last three of them to the *moving fast* meaning. An ambiguous vector for 'run' will have non-zero values for every component. On the other hand, we would expect the vector for 'horse' to have high values for the 'race', 'gallop', and 'move' components, and very low values (but not necessarily zero) for the dissolving-related ones—it is always possible for the word 'horse' to appear in the same context with the word 'painting', for example. The left part of Figure 2 shows what happens when the ambiguous 'run' vector is used; the multiplication with the 'horse' vector will produce an impure result, half affected by composition and half by disambiguation. However, what we really want is a vector where all the dissolving-related components will be eliminated, since they are irrelevant to the way the word 'run' is used in the sentence. In order to achieve this, we have to introduce a disambiguation step prior to composition (right part of Figure 2).

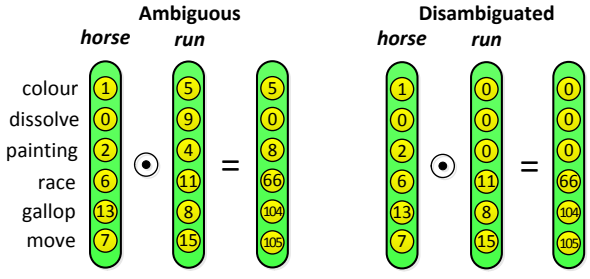

Figure 2: The effect of disambiguation on vector composition. The numbers are (artificial) co-occurrence counts of each target word with the 6 basis words on the left.

These ideas are experimentally verified in the works of Reddy et al. (2011) and Kartsaklis et al. (2013); Pulman (2013) also presents a comprehensive analysis of the problem. What remains to be seen is if disambiguation can also provide benefits for the linguistically motivated setting of tensor-based models, the principles of which are shortly discussed in the next section.

4 Tensors as multilinear maps

A *tensor* is a geometric object that can be seen as the generalization of the familiar notion of a vector in higher dimensions. The *order* of a tensor is the number of its dimensions; in other words, the number of indices we need to fully describe a random element of the tensor. Hence, a vector is a tensor of order 1, a matrix is a tensor of order 2, and so on. Tensors and multilinear maps stand in one-to-one correspondence, as stated by the following well-known "map-state" isomorphism (Bourbaki, 1989):

$$f : V_1 \rightarrow \ldots \rightarrow V_j \rightarrow V_k \cong V_k \otimes V_j \otimes \ldots \otimes V_1 \quad (1)$$

This offers an elegant way to adopt a formal semantics view of natural language in vector spaces. Let nouns live in a basic vector space $N \in \mathbb{R}^D$; returning to our previous example, an adjective then can be seen as a map $f : N \rightarrow N$ which is isomorphic to $N \otimes N$ (that is, to a matrix). In general, the order of the tensor is equal to the number of arguments plus one dimension that carries the result; so a unary function (e.g. adjectives, intransitive verbs) is represented by a tensor of order 2 (a matrix), a binary function (e.g. a transitive verb) as an order 3 tensor, and so on. Due to the above isomorphism, function application (and hence our compositional operation) becomes a generalisation of matrix multiplication, formalised in terms of the inner product. In the case of a unary relational word, such as an adjective, this is nothing more than the usual notion

of matrix multiplication between a matrix and a vector. The generalization of this process to tensors of higher order is known as *tensor contraction*. Given two tensors of orders n and m, the tensor contraction operation will always produce a tensor of order $n + m - 2$.

Let us see an example of how this works for a simple transitive sentence. Let $\mathcal{V} \in \mathbb{R}^{I \times J \times K}$ be the tensor of order 3 for the verb and $\mathcal{S} \in \mathbb{R}^I$, $\mathcal{O} \in \mathbb{R}^K$ the tensors of order 1 (vectors) for the subject and the object of the verb, respectively. Then $\mathcal{V} \times \mathcal{O}$ will return a new tensor living in $\mathbb{R}^{I \times J}$ (i.e. a matrix)[1]; a further interaction of this result with the subject will return a vector for the whole transitive sentence living in $\mathbb{R}^J$. We should note that the order in which the verb is applied to its arguments is not important; so in general the meaning of a transitive sentence is given by:

$$(\mathcal{V} \times \mathcal{O})^{\mathsf{T}} \times \mathcal{S} = (\mathcal{V}^{\mathsf{T}} \times \mathcal{S}) \times \mathcal{O} \qquad (2)$$

where T denotes a transpose and makes indices match, since subject precedes the verb.

5 Creating verb tensors

In this section we review a number of proposals regarding concrete methods of constructing tensors for relational words in the context of the frameworks of Coecke et al. (2010) and Baroni and Zamparelli (2010), which both comply to the setting of Section 4.[2]

Relational Following ideas from the set-theoretic view of formal semantics, Grefenstette and Sadrzadeh (2011a) suggest that the meaning of a relational word should be represented as the sum of its arguments. The meaning of adjective 'red', for example, becomes the sum of the vectors of all the nouns that 'red' modifies in the corpus; so $\overrightarrow{red} = \sum_i \overrightarrow{noun_i}$, where i iterates through all the occurrences of 'red'. This can be generalised to relational words of any arity, by summing the tensor product of their arguments. So for a transitive verb we have:

$$\overline{verb}^2 = \sum_i (\overrightarrow{subj}_i \otimes \overrightarrow{obj}_i) \qquad (3)$$

where i again iterates over all occurrences of the specific verb in the corpus and the superscript denotes the order of the tensor.

In order to achieve a more expressive representation for the sentences, the authors used the convention that the arity of the head word in a sentence will also determine the order of the sentence space; that is, the space of intransitive sentences will be of order 1, of transitive ones will be of order 2, and so on. Recall from Section 4 that for the transitive case this increases the order of the verb tensor to 4 (2 dimensions for the arguments plus another 2 for the result). In spite of this, however, note that the method of Equation 3 produces a matrix. The other two dimensions of the tensor remain empty (filled with zeros), a fact that simplifies the calculations but also considerably weakens the expressive power of the model. This simplification transforms Equation 2 to the following:

$$\overline{subj\ verb\ obj}^2 = (\overrightarrow{subj} \otimes \overrightarrow{obj}) \odot \overline{verb}^2 \qquad (4)$$

where $\otimes$ denotes the tensor product and $\odot$ element-wise multiplication.

Kronecker In a subsequent work (Grefenstette and Sadrzadeh, 2011b), the same team proposes the creation of a verb matrix as the Kronecker product of the verb's contextual vector with itself:

$$\overline{verb}^2 = \overrightarrow{verb} \otimes \overrightarrow{verb} \qquad (5)$$

Again in this model the sentence space is of order 2, and the meaning of a transitive sentence is calculated using Equation 4.

Frobenius The previous models bring the important limitation that only sentences of the same structure can be meaningfully compared; it is not possible, for example, to compare an intransitive sentence (e.g. 'kids play') with a transitive one ('children play football'), since the former is a vector and the latter a matrix. Using Frobenius algebras, Kartsaklis et al. (2012) provide a unified sentence space for every sentence regardless of its type. These models turn the matrix of Equation 3 to a tensor of order 3 (as required by the type-logical identities) by copying one of the existing dimensions. When the dimension of rows (corresponding to subjects) is copied, the calculation of a vector for a transitive sentence becomes:

$$\overrightarrow{subj\ verb\ obj} = \overrightarrow{subj} \odot (\overline{verb}^2 \times \overrightarrow{obj}) \qquad (6)$$

[1] The symbol $\times$ denotes tensor contraction.

[2] In what follows we use the case of a transitive verb as an example; however the descriptions apply to any relational word of any arity. A vector (an order-1 tensor) is denoted as $\overrightarrow{x}$; tensors of order $n > 1$ are shown as $\overline{x}^n$ for clarity.

Copying the column dimension (objects) gives:

$$\overrightarrow{subj\ verb\ obj} = \overrightarrow{obj} \odot \left((\overrightarrow{verb}^2)^{\mathsf{T}} \times \overrightarrow{subj} \right) \quad (7)$$

Linear regression None of the above models create tensors that are fully populated: one or more dimensions will always remain empty. Following an idea first introduced by Baroni and Zamparelli (2010) for the creation of adjective matrices, Grefenstette et al. (2013) use linear regression in order to learn full tensors of order 3 for transitive verbs. Linear regression is a supervised method of learning, so it needs a number of exemplar data points. In the case of the adjective 'red', for example, we would need a set of the form $\langle \overrightarrow{car}, \overrightarrow{red\ car} \rangle, \langle \overrightarrow{shirt}, \overrightarrow{red\ shirt} \rangle, \langle \overrightarrow{shoe}, \overrightarrow{red\ shoe} \rangle$ and so on, where the second vector in each pair is the contextual vector of the whole phrase created exactly as if it were a single word. The goal of the learning process is to find the parameters $\overline{adj}^2$ and $\overrightarrow{b}$ such that:

$$\overrightarrow{adj\ noun} \approx \overline{adj}^2 \times \overrightarrow{noun} + \overrightarrow{b} \quad (8)$$

for all nouns modified by the specific adjective. In practice, the bias $\overrightarrow{b}$ is embedded in $\overline{adj}^2$, hence the above procedure provides us with a matrix for the adjective. One can generalize this procedure to tensors of higher order by proceeding step-wise, as done by Grefenstette et al. (2013). For the case of a transitive verb, they first use exemplar pairs of the form $\langle \overrightarrow{subj}, \overrightarrow{subj\ verb\ obj} \rangle$ to learn a matrix $\overline{verb\ obj}^2$ for the verb phrase; then, they perform a new training session with exemplars of the form $\langle \overrightarrow{obj}, \overline{verb\ obj}^2 \rangle$, the result of which is an order 3 tensor for the verb.

6 Generic context-based disambiguation

In all of the models of Section 5, the training of a relational word tensor is based on the set of contexts where this word occurs. Hence, in these models the problem of creating disambiguated versions of tensors can be recasted to that of further breaking the set of contexts in a way that each subset reflects a different sense of the word in the corpus. If, for example, S is the whole set of sentences for a word w that occurs in the corpus under n different senses, then the goal is to create n subsets $S_1, \ldots S_n$ such that S_1 contains the sentences where w appears under the first sense, S_2 the sentences where w occurs under the second sense, and so on. Each one of these subsets can then be used to train a tensor for a specific sense of the target relational word.

Towards this purpose we use a variation of the effective procedure of Schütze (1998): first, each context for a target word w_t is represented by a *context vector* of the form $\frac{1}{n}(\overrightarrow{w_1} + \ldots + \overrightarrow{w_n})$, where $\overrightarrow{w_i}$ is the lexical vector of some other word $w_i \neq w_t$ in the same context. Next, we apply a clustering method on this set of vectors in order to discover the latent senses of w_t. The assumption is that the contexts of w_t will vary according to the specific sense this word is used: 'bank' as a financial institution should appear in quite different contexts than as land.

The above procedure will give us a number of clusters, each consisting of context vectors; we use the centroid of each cluster as a vectorial representation of the corresponding sense. So in our model each word w is initially represented by a tuple $\langle \overrightarrow{w}, S \rangle$, where $\overrightarrow{w}$ is the lexical vector of the word as created by the usual distributional practice, and S is a set of sense vectors (centroids of context vector clusters) produced by the above procedure. The disambiguation of a new word w under a context C can now be accomplished as follows: we create a context vector $\overrightarrow{c}$ for C as above, and we compare it with every sense vector of w; the word is assigned to the sense corresponding to the closest sense vector. Specifically, if S_w is the set of sense vectors for w, $\overrightarrow{c}$ the context vector for C, and $d(\overrightarrow{v}, \overrightarrow{u})$ our vector distance measure, the preferred sense $\hat{s}$ is given by:

$$\hat{s} = \underset{\overrightarrow{v_s} \in S_w}{\arg\min}\ d(\overrightarrow{v_s}, \overrightarrow{c}) \quad (9)$$

For the actual clustering step we follow the setting of Kartsaklis et al. (2013), which worked well in tasks very similar to ours. Specifically, we perform hierarchical agglomerative clustering (HAC) using Ward's method as the inter-cluster distance, while the distance between vectors is measured with Pearson's correlation.[3] In the above work, this configuration has been found to return the highest V-measure (Rosenberg and Hirschberg, 2007) on the noun set of SEMEVAL 2010 Word Sense Induction & Disambiguation Task (Manandhar et al., 2010). As context for a word, we consider the sentence in which this word occurs. The output of HAC is a *dendrogram* embedding all the possible partitionings of the

[3] Informal experimentation with more robust probabilistic techniques, such as Dirichlet process gaussian mixture models, revealed no significant benefits for our setting.

data. In order to select the optimal partitioning, we rely on the Caliński/Harabasz index (Caliński and Harabasz, 1974), also known as variance ratio criterion (VRC). VRC is calculated as the ratio of the sum of the inter-cluster variances over the sum of the intra-cluster variances, bearing the intuition that the optimal partitioning should be the one that results in the most compact and maximally separated clusters. We compute the VRC for a range of different partitionings (from 2 to 10 clusters) and keep the partitioning with the highest score.

7 Constructing unambiguous verb tensors

The procedure described in Section 6 provides us with n clusters of context vectors for a target word. Since in our case each context vector corresponds to a distinct sentence, the output of the clustering scheme can also be seen as n subsets of sentences, where the word appears under different senses. It is now quite straightforward to use this partitioning of the training corpus in order to learn unambiguous versions of verb tensors, as detailed below.

Relational/Frobenius Both the Relational and the Frobenius models use the same way of creating an initial verb matrix (Equation 3) which then they expand to a higher order tensor. Let $S_1 \dots S_n$ be the sets of sentences returned by the clustering step for a verb. Then, the verb tensor for the ith sense is:

$$\overline{verb}_i^2 = \sum_{s \in S_i} (\overrightarrow{subj_s} \otimes \overrightarrow{obj_s}) \tag{10}$$

where $subj_s$ and obj_s refer to the subject/object pair that occurred with the verb in sentence s. This can be generalized to any arity n as follows:

$$\overline{word}_i^n = \sum_{s \in S_i} \bigotimes_{k=1}^{n} \overrightarrow{arg_{k,s}} \tag{11}$$

where $arg_{k,s}$ denotes the kth argument of the target word in sentence s.

Kronecker For a given verb v in a context C, let $\overrightarrow{v_i}$ be the sense vector of v given C corresponding to the sense i returned by Equation 9. Then we have:

$$\overline{verb}_i^2 = \overrightarrow{v_i} \otimes \overrightarrow{v_i} \tag{12}$$

The generalized version to arity n is given by:

$$\overline{word}_i^n = \bigotimes_{k=1}^{n} \overrightarrow{v_i} \tag{13}$$

Linear regression Creating unambiguous full tensors using linear regression is also quite straightforward. Let us assume again that the clustering step for a verb v returns n sets of sentences $S_1 \dots S_n$, where each sentence set corresponds to a different sense. Then, we have n different regression problems, each one of which will be trained on exemplar pairs derived exclusively from the sentences of the corresponding set. This will result in n verb tensors, which will correspond to the different senses of the verb. Generalization to higher arities is a straightforward extension of the step-wise process in Section 5 for transitive verbs.

8 Experiments

In this section we will test the effect of disambiguation on the models of Section 5 in a variety of tasks. Due to the significant methodological differences of the linear regression model from the other approaches and the variety of its set of parameters, we decided that it would be better if this was left as the subject of a distinct work.

Experimental setting We train our vectors using ukWaC (Ferraresi et al., 2008), a corpus of English text with 2 billion words (100m sentences). We use 2000 dimensions, with weights calculated as the ratio of the probability of the context word given the target word to the probability of the context word overall. The context here is a 5-word window on both sides of the target word. The vectors are disambiguated both syntactically and semantically: first, separate vectors have been created for different syntactic usages of the same word in the corpus; for example, the word 'book' has two vectors, one for its noun sense and one for its verb sense. Furthermore, each word is semantically disambiguated according to the method of Section 6.

Models We compare the tensor-based models of Section 5 with the multiplicative and additive models of Mitchell and Lapata (2008), reporting results for both ambiguous and disambiguated versions. For all the disambiguated models, the best sense for each word in the sentence or phrase is first selected by applying the procedure of Section 6 and Equation 9. If the model is based on a vector mixture, the sense vectors corresponding to these senses are multiplied or added to form the composite representation for the sentence or phrase. For the tensor-based models, the composite meanings are calculated ac-

cording to the equations of Section 5, using verb tensors created by the procedures of Section 7. The semantic similarity of two phrases or sentences is measured as the cosine distance between their composite vectors. For models that return a matrix (e.g. Relational, Kronecker), the distance is based on the Frobenius inner product.

Implementation details Our code is mainly written in Python and C++, and for the actual clustering step we use the Python interface of the efficient FASTCLUSTER library (Müllner, 2013). In a shared 24-core Xeon machine with 72 GB of memory, and with a fair amount of parallelism applied, the average processing time per word was about 4 minutes; this is roughly translated to 12-13 hours of training on average per dataset.

8.1 Verb disambiguation task

Perhaps surprisingly, one of the most popular tasks for testing compositionality in distributional models is based on disambiguation. This task, originally introduced by Kintsch (2001), has been adopted by Mitchell and Lapata (2008) and others for evaluating the quality of composition in vector spaces. Given an ambiguous verb such as 'file', the goal is to find out to what extent the presence of an appropriate context will disambiguate its intended meaning. The context (e.g. a subject/object pair) is composed with two landmark verbs corresponding to the different senses ('smooth' and 'register') to create simple sentences. The assumption is that a good compositional model should be able to reflect that 'woman files application' is closer to 'woman registers application' than to 'woman smooths application'.

In this paper we test our models on two different datasets of transitive sentences, that of Grefenstette and Sadrzadeh (2011a) and Kartsaklis et al. (2013)[4]. Specific details about the creation of the datasets can be found in the above papers; for the purposes of the current work it is sufficient to mention that their main difference is that in the former the verbs and their alternative meanings have been selected automatically using the JCN metric of semantic similarity (Jiang and Conrath, 1997), while in the latter the selection was based on human judgements from the work of Pickering and Frisson (2001). So, while in the first dataset many verbs cannot be considered as genuinely ambiguous (e.g. 'say' with meanings *state* and *allege* or 'write' with meanings *publish* and *spell*), the landmarks in the second dataset correspond to clearly separated senses (e.g. 'file' with meanings *register* and *smooth* or 'charge' with meanings *accuse* and *bill*). Furthermore, subjects and objects of this latter case are modified by appropriate adjectives, overall creating a richer and more linguistically balanced dataset.

In both cases the evaluation methodology is the same: each entry of the dataset has the form ⟨subject, verb, object, high-sim landmark, low-sim landmark⟩. The context is combined with the verb and the two landmarks, creating three simple transitive sentences. The main-verb sentence is paired with both the landmark sentences, and these pairs are randomly presented to human evaluators, the duty of which is to evaluate the similarity of the sentences within a pair in a scale from 1 to 7. The scores of the compositional models are the cosine distances (or the Frobenius inner products, in the case of matrices) between the composite representations of the sentences of each pair. As an overall score for each model, we report its Spearman's ρ correlation with the human judgements. Both datasets consist of 200 pairs of sentences (10 main verbs $\times$ 2 landmarks $\times$ 10 contexts).

Results The results for the G&S dataset are shown in Table 1.[5] The verbs-only model (BL) refers to a non-compositional evaluation, where the similarity between two sentences is solely based on the distance between the two verbs, without applying any compositional step with subject and object.

The tensor-based models present much better performance than the vector mixture ones, with the disambiguated version of the copy-object model significantly higher than the relational model. By design, the copy-object model retains more information about the objects; so this result confirms previous findings, that in this certain dataset the role of objects is more important than that of subjects (Kartsaklis et al., 2012). In general, the disambiguation step improves the results of all the tensor-based models except Kronecker; the effect is reversed for the vector mixture models, where the disambiguated versions present much worse performance (these

findings are further discussed in Section 9).

The result of disambiguation is clearer for the dataset of Kartsaklis et al. (Table 2). The longer context in combination with genuinely ambiguous verbs produces two effects: first, disambiguation is now helpful for all models, either vector mixtures or tensor-based; second, the disambiguation of just the verb (verbs-only model), without any interaction with the context, is sufficient to provide the best score (0.22) with a difference statistically significant from the second model (0.19 for disambiguated additive). In fact, further composition of the verb with the context decreases performance, confirming the results reported by Kartsaklis et al. (2013) for vectors trained using BNC. Given the nature of the specific task, which is designed around the ambiguity of the verb, this result is not surprising: a direct disambiguation of the verb based on the rest of the context should naturally constitute the best method to achieve top performance—no composition is necessary for this task to be successful.

However, when one *does* use a task like this in order to evaluate compositional models (as we do here and as is commonly the case), they implicitly correlate the strength of the disambiguation effect that takes place during the composition with the quality of composition, essentially assuming that the stronger the disambiguation, the better the compositional model that produced this side-effect. Unfortunately, the extent to which this assumption is valid or not is still not quite clear; the subject is addressed in more detail in (Kartsaklis et al., 2013). Keeping a note of this observation, we now proceed to examine the performance of our models in a task that does not use disambiguation as a criterion of composition.

8.2 Phrase/sentence similarity task

Our second set of experiments is based on the phrase similarity task of Mitchell and Lapata (2010). On the contrary with the task of Section 8.1, this one does not involve any assumptions about disambiguation, and thus it seems like a more genuine test of models aiming to provide appropriate phrasal or sentential semantic representations; the only criterion is the degree to which these models correctly evaluate the *similarity* between pairs of sentences or phrases. We work on the verb-phrase part of the dataset, consisting of 72 short verb phrases (verb-object structures). These 72 phrases have been paired in three different ways to form groups exhibiting various degrees of similarity: the first group contains 36 pairs of highly similar phrases (e.g. *produce effect-achieve result*), the pairs of the second group are of medium similarity (e.g. *write book-hear word*), while a last group contains low-similarity pairs (*use knowledge-provide system*). The task is again to compare the similarity scores given by the various models for each phrase pair with those of human annotators. Additionally to the verb phrases task, we also perform a richer version of the experiment using transitive sentences.

Verb phrases It can be shown that for simple verb phrases the relational model reduces itself to the copy-subject model; for both of these methods, the meaning of the verb phrase is calculated according to Equation 6. Furthermore, according to the copy-object model the meaning of a verb phrase computed by a verb matrix $\sum_{ij} v_{ij}(\overrightarrow{n_i} \otimes \overrightarrow{n_j})$ and an object vector $\sum_j o_j \overrightarrow{n_j}$ becomes:

$$\overrightarrow{verb\ object}^2 = \sum_{ij} v_{ij} o_j (\overrightarrow{n_i} \otimes \overrightarrow{n_j}) \qquad (14)$$

Finally, the Kronecker model has no meaning for verb phrases, since the vector of a verb phrase will become $(\overrightarrow{v_s} \otimes \overrightarrow{v_s}) \times \overrightarrow{obj}$, which is equal to $\langle \overrightarrow{v_s} | \overrightarrow{obj} \rangle \overrightarrow{v_s}$, where $\langle \overrightarrow{v_s} | \overrightarrow{obj} \rangle$ denotes the inner product between vectors of verb and object. Hence, the

Table 3: Results for the original M&L task.

meaning of a verb phrase becomes a scalar multiplication of the meaning of its verb. As a result, the cosine distance (used for measuring similarity) between the meanings of two verb phrases is reduced to the distance between the vectors of their verbs, completely dismissing the role of their objects.

Hence our models are limited to those of Table 3. The effects of disambiguation for this task are quite impressive: the differences between the scores of all disambiguated models and those of the ambiguous versions are highly statistically significant (with $p < 0.001$), while 4 of the 5 models present an improvement greater than 10 units of correlation. The models that benefit the most from disambiguation are the vector mixtures; both of these approaches perform significantly better than the best tensor-based model (copy-object). In fact, the score of M1 (0.45) is quite high, given that the inter-annotator agreement is 0.55 (best score reported by Mitchell and Lapata was 0.41 for their LDA-dilation model).

Transitive sentences The second part of this experiment aims to examine the extent to which the above picture can change for the case of text structures longer than verb phrases. In order to achieve this, we extend each one of the 72 verb phrases to a full transitive sentence by adding an appropriate subject such that the similarity relationships of the original dataset are retained as much as possible, so the human judgements for the verb phrase pairs could as well be used for the transitive cases. We worked pair-wise: for each pair of verb phrases, we first selected one of the 5 most frequent subjects for the first phrase; then, the subject of the other phrase was selected by a list of synonyms of the first subject in a way that the new pair of transitive sentences constitutes the least more specific version of the given verb-phrase pair. So, for example, the pair *produce effect/achieve result* became *drug produce effect/medication achieve result*, while the pair *pose problem/address question* became *study pose problem/paper address question*.[6]

The restrictions of the verb-phrase version do not hold here, so we evaluate on the full set of models (Table 4). Once more disambiguation produces better results in all cases, with highly statistically significant differences for all but one model. Furthermore, now the best score is delivered by one of the tensor-based models (Kronecker), with a difference *not* statistically significant from disambiguated additive. In any case, the result suggests that as the length of the text segments increases, the performance of vector mixtures and tensor-based models converges. Indeed, note how the performance of the vector mixture models are significantly decreased compared to the verb phrase task.

9 Discussion

The purpose of this work was twofold: our main objective was to investigate how disambiguation can affect the compositional models which are based on higher order vector spaces; a second, but not less important goal, was to compare this more linguistically motivated approach to the simpler vector mixture methods. Based on the experimental work presented here, we can say with enough confidence that disambiguation as an additional step prior to composition is indeed very beneficial for tensor-based models. Furthermore, our experiments confirm and strengthen previous work (Reddy et al., 2011; Kartsaklis et al., 2013) that showed better performance of disambiguated vector mixture models compared to their ambiguous versions. The positive effect of disambiguation is more evident for the vector mixture models (especially for the additive model) than for

[6]The dataset will be available at `http://www.cs.ox.ac.uk/activities/compdistmeaning/`.

the tensor-based ones. This is expected: composite representations created by element-wise operations are averages, and a prior step of disambiguation can make a great difference.

From a task perspective, the effect of disambiguation was much more definite in the phrase/sentence similarity task. This observation is really interesting, since the words of that dataset were *not* selected in order to be ambiguous in any way. The superior performance of the disambiguated models, therefore, implies that the proposed methodology can improve tasks based on phrase or sentence similarity *regardless* of the level of ambiguity in the vocabulary. For these cases, the proposed disambiguation algorithm acts as a fine-tuning process, the outcome of which seems to be always positive; it can only produce better composite representations, not worse. In general, the positive effect of disambiguation in the phrase/sentence similarity task is quite encouraging, especially given the fact that this task constitutes a more appropriate test for evaluating compositional models, avoiding the pitfalls of disambiguation-based experiments (as shortly discussed in Section 8.1).

For disambiguation-based tasks similar to those of Section 8.1, the form of dataset is very important; hence the inferior performance of disambiguated models in the G&S dataset, compared to the dataset of Kartsaklis et al.. In fact, the G&S dataset was the only one where disambiguation was not helpful for some cases (specifically, for vector mixtures and the Kronecker model). We believe the reason behind this lies in the fact that the automatic selection of landmark verbs using the JCN metric (as done with the G&S dataset) was not very efficient for certain cases. Note, for example, that the bare baseline of comparing just ambiguous versions of verbs (without any composition) in that dataset already achieves a very high correlation of 0.198 with human judgements (Table 1).[7]. This number is only 0.15 for the Kartsaklis et al. dataset, due to the more efficient verb selection procedure. In general, we consider the results gained by this latter experiment more reliable for the specific task, the successful evaluation of which requires genuinely ambiguous verbs.

The results are less conclusive for the second question we posed in the beginning of this section, regarding the comparison of the two classes of models. Despite the obvious benefits of the tensor-based approaches, this work suggests for one more time that vector mixture models might constitute a hard-to-beat baseline; similar observations have been made, for example, in the comparative study of Blacoe and Lapata (2012). However, when trying to interpret the mixing results regarding the effectiveness of the tensor-based models compared to vector mixtures, we need to take into account that the tensor-based models tested in this work were all "hybrid", in the sense that they all involved some element of point-wise operation; in other words, they constituted a trade-off between transformational power and complexity.

Even with this compromise, though, the study presented in Section 8.2 implies that the effectiveness of each method depends to some extent on the length of the text segment: when more words are involved, vector mixture models tend to be less effective; on the contrary, the performance of tensor-based models seems to be proportional to the length of the phrase or sentence—the more, the better. These observations comply with the nature of the approaches: "averaging" larger numbers of points results in more general (hence less accurate) representations; on the other hand, a larger number of arguments makes a function (such as a verb) more accurate.

10 Conclusion and future work

In the present paper we showed how to improve a number of tensor-based compositional distributional models of meaning by introducing a step of disambiguation prior to composition. Our simple algorithm (based on the procedure of Schütze (1998)) creates unambiguous versions of tensors before these are composed with vectors of nouns in order to construct vectors for sentences and phrases. This algorithm is quite generic, and can be applied to any model that follows the tensor contraction process described in Section 4. As for future work, we aim to investigate the application of this procedure to the regression model of Grefenstette et al. (2013).

Abstract

We present Multi-Relational Latent Semantic Analysis (MRLSA) which generalizes Latent Semantic Analysis (LSA). MRLSA provides an elegant approach to combining multiple relations between words by constructing a 3-way tensor. Similar to LSA, a low-rank approximation of the tensor is derived using a tensor decomposition. Each word in the vocabulary is thus represented by a vector in the latent semantic space and each relation is captured by a latent square matrix. The degree of two words having a specific relation can then be measured through simple linear algebraic operations. We demonstrate that by integrating multiple relations from both homogeneous and heterogeneous information sources, MRLSA achieves state-of-the-art performance on existing benchmark datasets for two relations, *antonymy* and *is-a*.

1 Introduction

Continuous semantic space representations have proven successful in a wide variety of NLP and IR applications, such as document clustering (Xu et al., 2003) and cross-lingual document retrieval (Dumais et al., 1997; Platt et al., 2010) at the document level and sentential semantics (Guo and Diab, 2012; Guo and Diab, 2013) and syntactic parsing (Socher et al., 2013) at the sentence level. Such representations also play an important role in applications for lexical semantics, such as word sense disambiguation (Boyd-Graber et al., 2007), measuring word similarity (Deerwester et al., 1990) and relational similarity (Turney, 2006; Zhila et al., 2013; Mikolov et al., 2013). In many of these applications, Latent Semantic Analysis (LSA) (Deerwester et al., 1990) has been widely used, serving as a fundamental component or as a strong baseline.

LSA operates by mapping text objects, typically documents and words, to a latent semantic space. The proximity of the vectors in this space implies that the original text objects are semantically related. However, one well-known limitation of LSA is that it is unable to differentiate fine-grained relations. For instance, when applied to lexical semantics, synonyms and antonyms may both be assigned high similarity scores (Landauer and Laham, 1998; Landauer, 2002). Asymmetric relations like hyponyms and hypernyms also cannot be differentiated. Although there exists some recent work, such as PILSA which tries to overcome this weakness of LSA by introducing the notion of polarity (Yih et al., 2012). This extension, however, can only handle two opposing relations (e.g., synonyms and antonyms), leaving open the challenge of encoding multiple relations.

In this paper, we propose Multi-Relational Latent Semantic Analysis (MRLSA), which strictly generalizes LSA to incorporate information of multiple relations concurrently. Similar to LSA or PILSA when applied to lexical semantics, each word is still mapped to a vector in the latent space. However, when measuring whether two words have a specific relation (e.g., antonymy or *is-a*), the word vectors will be mapped to a new space according to the relation where the degree of having this relation will be

*Work conducted while interning at Microsoft Research.

Seattle, Washington, USA, 18-21 October 2013.

judged by cosine similarity. The raw data construction in MRLSA is straightforward and similar to the document-term matrix in LSA. However, instead of using one matrix to capture all relations, we extend the representation to a 3-way tensor. Each slice corresponds to the document-term matrix in the original LSA design but for a specific relation. Analogous to LSA, the whole linear transformation mapping is derived through tensor decomposition, which provides a low-rank approximation of the original tensor. As a result, previously unseen relations between two words can be discovered, and the information encoded in other relations can influence the construction of the latent representations, and thus potentially improves the overall quality. In addition, the information in different slices can come from heterogeneous sources (conceptually similar to (Riedel et al., 2013)), which not only improves the model, but also extends the word coverage in a reliable way.

We provide empirical evidence that MRLSA is effective using two different word relations: *antonymy* and *is-a*. We use the benchmark GRE test of closest-opposites (Mohammad et al., 2008) to show that MRLSA performs comparably to PILSA, which was the pervious state-of-the-art approach on this problem, when given the same amount of information. In addition, when other words and relations are available, potentially from additional resources, MRLSA is able to outperform previous methods significantly. We use the *is-a* relation to demonstrate that MRLSA is capable of handling asymmetric relations. We take the list of word pairs from the *Class-Inclusion* (i.e., *is-a*) relations in SemEval-2012 Task 2 (Jurgens et al., 2012), and use our model to measure the degree of two words have this relation. The measures derived from our model correlate with human judgement better than the best system that participated in the task.

The rest of this paper is organized as follows. We first survey some related work in Section 2, followed by a more detailed description of LSA and PILSA in Section 3. Our proposed model, MRLSA, is presented in Section 4. Section 5 presents our experimental results. Finally, Section 6 concludes the paper.

2 Related Work

MRLSA can be viewed as a model that derives general continuous space *representations* for capturing *lexical semantics*, with the help of *tensor decomposition* techniques. We highlight some recent work related to our approach.

The most commonly used continuous space representation of text is arguably the vector space model (VSM) (Turney and Pantel, 2010). In this representation, each text object can be represented by a high-dimensional sparse vector, such as a term-vector or a document-vector that denotes the statistics of term occurrences (Salton et al., 1975) in a large corpus. The text can also be represented by a low-dimensional dense vector derived by linear projection models like latent semantic analysis (LSA) (Deerwester et al., 1990), by discriminative learning methods like Siamese neural networks (Yih et al., 2011), recurrent neural networks (Mikolov et al., 2013) and recursive neural networks (Socher et al., 2011), or by graphical models such as probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) and latent Dirichlet allocation (LDA) (Blei et al., 2003). As a generalization of LSA, MRLSA is also a linear projection model. However, while the words are represented by vectors as well, multiple relations between words are captured separately by matrices.

In the context of lexical semantics, VSMs provide a natural way of measuring semantic word relatedness by computing the distance between the corresponding vectors, which has been a standard approach (Agirre et al., 2009; Reisinger and Mooney, 2010; Yih and Qazvinian, 2012). These approaches do not apply directly to the problem of modeling other types of relations. Existing methods that do handle multiple relations often use a model combination scheme to integrate signals from various types of information sources. For instance, morphological variations discovered from the Google n-gram corpus have been combined with information from thesauri and vector-based word relatedness models for detecting antonyms (Mohammad et al., 2008). An alternative approach proposed by Turney (2008) that handles synonyms, antonyms and associations is to use a uniform approach by first reducing the problem to determining whether two

pairs of words can be analogous, and then predicting it using a supervised model with features based on the frequencies of patterns in the corpus. Similarly, to measure whether two word pairs have the same relation, Zhila et al. (2013) proposed to combine heterogeneous models, which achieved state-of-the-art performance. In comparison, MRLSA models multiple lexical relations holistically. The degree that two words having a particular relation is estimated using the same linear function of the corresponding vectors and matrix.

Tensor decomposition generalizes matrix factorization and has been applied to several NLP applications recently. For example, Cohen et al. (2013) proposed an approximation algorithm for PCFG parsing that relies on Kruskal decomposition. Van de Cruys et al. (2013) modeled the composition of subject-verb-object triples using Tucker decomposition, which results in a better similarity measure for transitive phrases. Similar to this construction but used in the community-based question answering (CQA) scenario, Qiu et al. (2013) represented triples of question title, question content and answer as a tensor and applied 3-mode SVD to derive latent semantic representations for question matching. The construction of MRLSA bears some resemblance to the work that use tensors to capture triples. However, our goal of modeling different relations for lexical semantics is very different from the intended usage of tensor decomposition in the existing work.

3 Latent Semantic Analysis

Latent Semantic Analysis (LSA) (Deerwester et al., 1990) is a widely used continuous vector space model that maps words and documents into a low dimensional space. LSA consists of two main steps. First, taking a collection of d documents that contains words from a vocabulary list of size n, it first constructs a $d \times n$ document-term matrix $\mathbf{W}$ to encode the occurrence information of a word in a document. For instance, in its simplest form, the element $\mathbf{W}_{i,j}$ can be the term frequency of the j-th word in the i-th document. In practice, a weighting scheme that better captures the importance of a word in the document, such as TF×IDF (Salton et al., 1975), is often used instead. Notice that "document" here simply means a group of words and has been applied to various texts including news articles, sentences and bags of words. Once the matrix is constructed, the second step is to apply singular value decomposition (SVD) to $\mathbf{W}$ in order to derive a low-rank approximation. To have a rank-k approximation, $\mathbf{X}$ is the reconstruction matrix of $\mathbf{W}$, defined as

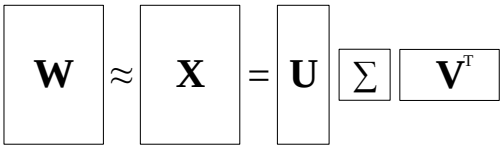

Figure 1: SVD applied to a $d \times n$ document-term matrix $\mathbf{W}$. The rank-k approximation, $\mathbf{X}$, is the multiplication of $\mathbf{U}$, $\mathbf{\Sigma}$ and $\mathbf{V}^T$, where $\mathbf{U}$ and $\mathbf{V}$ are $d \times k$ and $n \times k$ orthonormal matrices and $\mathbf{\Sigma}$ is a $k \times k$ diagonal matrix. The column vectors of $\mathbf{V}^T$ multiplied by the singular values $\mathbf{\Sigma}$ represent words in the latent semantic space.

$$\mathbf{W} \approx \mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T \quad (1)$$

where the dimensions of $\mathbf{U}$ and $\mathbf{V}$ are $d \times k$ and $n \times k$, respectively, and $\mathbf{\Sigma}$ is a $k \times k$ diagonal matrix. In addition, the columns in $\mathbf{U}$ and $\mathbf{V}$ are orthonormal and the elements in $\mathbf{\Sigma}$ are the singular values and are conventionally reverse-ordered. Figure 1 illustrates this decomposition.

LSA can be used to compute the similarity between two documents or two words in the latent space. For instance, to compare the u-th and v-th words in the vocabulary, one can compute the cosine similarity of the u-th and v-th column vectors of $\mathbf{X}$, the reconstruction matrix of $\mathbf{W}$. In contrast to a direct lexical matching via the columns of $\mathbf{W}$, the similarity measure computed as a result of the SVD may have a nonzero similarity score even if these two words do not co-occur in any documents. This is due to the fact that those words can share some latent components.

An alternative view of using LSA is to treat the column vectors of $\mathbf{\Sigma}\mathbf{V}^T$ as a representation of the words in a new k-dimensional latent space. This comes from the observation that the inner product of every two column vectors in $\mathbf{X}$ is the inner product of the corresponding column vectors of $\mathbf{\Sigma}\mathbf{V}^T$,

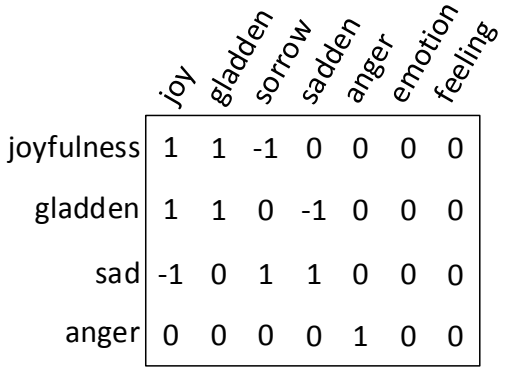

Figure 2: The matrix construction of PILSA. The vocabulary is {joy, gladden, sorrow, sadden, anger, emotion, feeling} and target words are {joyfulness, gladden, sad, anger}. For ease of presentation, we show the numbers with 0-1 values instead of TF×IDF scores. The polarity (i.e., sign) indicates whether the term in the vocabulary is a synonym or antonym of the target word.

which can be derived from the equations below.

$$\begin{aligned}\mathbf{X}^T\mathbf{X} &= (\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T)^T(\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T) \\ &= \mathbf{V}\mathbf{\Sigma}\mathbf{U}^T\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T \quad (\mathbf{\Sigma} \text{ is diagonal}) \\ &= \mathbf{V}\mathbf{\Sigma}^2\mathbf{V}^T \quad (\text{Columns of } \mathbf{U} \text{ are orthonormal}) \\ &= (\mathbf{\Sigma}\mathbf{V}^T)^T(\mathbf{\Sigma}\mathbf{V}^T) \end{aligned} \tag{2}$$

Thus, the semantic relatedness between the i-th and j-th words can be computed by cosine similarity[1]:

$$\cos(\mathbf{X}_{:,i}, \mathbf{X}_{:,j}) \tag{3}$$

When used to compare words, one well-known limitation of LSA is that the score captures the general notion of semantic similarity, and is unable to distinguish fine-grained word relations, such as antonyms (Landauer and Laham, 1998; Landauer, 2002). This is due to the fact that the raw matrix representation only records the occurrences of words in documents without knowing the specific relation between the word and document. To address this issue, Yih et al. (2012) proposed a polarity inducing latent semantic analysis model recently, which we introduce next.

[1]Cosine similarity is equivalent to the inner product of the normalized vectors.

3.1 Polarity Inducing Latent Semantic Analysis

In order to distinguish antonyms from synonyms, the polarity inducing LSA (PILSA) model (Yih et al., 2012) takes a thesaurus as input. Synonyms and antonyms of the same target word are grouped together as a "document" and a document-term matrix is constructed accordingly as done in LSA. Because each word in a group belongs to either one of the two opposite relations, *synonymy* and *antonymy*, the *polarity* information is induced by flipping the signs of antonyms. While the absolute value of each element in the matrix is still the same TF×IDF score, the elements that correspond to the antonyms become negative.

This design has an intriguing effect. When comparing two words using the cosine similarity (or simply inner product) of their corresponding column vectors in the matrix, the score of a synonym pair remains positive, but the score of an antonym pair becomes negative. Figure 2 illustrates this design using a simplified matrix as example.

Once the matrix is constructed, PILSA applies SVD as done in LSA, which generalizes the model to go beyond lexical matching. The sign of the cosine score of the column vectors of any two words indicates whether they are close to synonyms or to antonyms and the absolute value reflects the degree of the relation. When all the column vectors are normalized to unit vectors, it can also be viewed as synonyms are clustered together and antonyms lie on the opposite sides of a unit sphere. Although PILSA successfully extends LSA to handle not just one single *occurrence* relation, the extension is limited to encoding two opposing relations

4 Multi-Relational Latent Semantic Analysis

The fundamental reason why it is difficult to handle multiple relations is due to the 2-dimensional matrix representation. In order to overcome this, we encode the raw data in a 3-way tensor. Each slice captures a particular relation and is in the format of the document-term matrix in LSA. Just as in LSA, where the low-rank approximation by SVD helps generalize the representation and discover unseen relations, we apply a tensor decomposition method,

(a) Synonym layer (b) Antonym layer (c) Hypernym layer

Figure 3: The three slices of MRLSA raw tensor $\mathcal{W}$ for an example with vocabulary {joy, gladden, sorrow, sadden, anger, emotion, feeling} and target words {joyfulness, gladden, sad, anger}. Figures 3(a), 3(b), 3(c) show the matrices $\mathcal{W}_{:,:,\text{syn}}$, $\mathcal{W}_{:,:,\text{ant}}$, $\mathcal{W}_{:,:,\text{hyper}}$, respectively. Rows represent documents (see definition in text), and columns represent words. For ease of presentation, we show numbers with 0-1 values instead of TF×IDF scores.

the Tucker decomposition, to the tensor.

4.1 Representing Multi-Relational Data in Tensors

A tensor is simply a multi-dimensional array. In this work, we use a 3-way tensor $\mathcal{W}$ to encode multiple word relations. An element of $\mathcal{W}$ is denoted by $\mathcal{W}_{i,j,k}$ using its indices, and $\mathcal{W}_{:,:,k}$ represents the k-th *slice* of $\mathcal{W}$ (a slice of a 3-way tensor is a matrix, obtained by fixing the third index). Following (Kolda and Bader, 2009), a *fiber* of a tensor $\mathcal{W}_{:,j,k}$ is a vector, which is a high order analog of a matrix row or column.

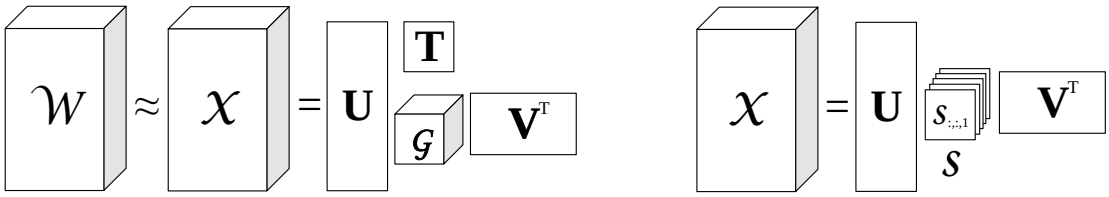
When constructing the raw tensor $\mathcal{W}$ in MRLSA, each slice is analogous to the document-term matrix in LSA, but created based on the data of a particular relation, such as synonyms. With a slight abuse of notation, we sometimes use the value rather than index when there is no confusion. For instance, $\mathcal{W}_{:,\text{“word”},k}$ represents the fiber corresponding to the “word” in slice k, and $\mathcal{W}_{:,:,\text{syn}}$ refers to the slice that encodes the synonymy relation. Below we use an example to compare this construction to the raw matrix in PILSA, and discuss how it extends LSA.

Suppose we are interested in representing two relations, synonymy and antonymy. The raw tensor in MRLSA would then consist of two slices, $\mathcal{W}_{:,:,\text{syn}}$ and $\mathcal{W}_{:,:,\text{ant}}$, to encode synonyms and antonyms of target words from a knowledge source (e.g., a thesaurus). Each row in $\mathcal{W}_{:,:,\text{syn}}$ represents the synonyms of a target word, and the corresponding row in $\mathcal{W}_{:,:,\text{ant}}$ encodes its antonyms. Figures 3(a) and 3(b) illustrate an example, where “joy”, ”gladden” are synonyms of the target word “joyfulness” and “sorrow” is its antonym. Therefore, the values of the corresponding entries are 1. Notice that the matrix $\mathbf{W}' = \mathcal{W}_{:,:,\text{syn}} - \mathcal{W}_{:,:,\text{ant}}$ is identical to the PILSA raw matrix. We can extend the construction above to enable MRLSA to utilize other semantic relations (e.g., *hypernymy*) by adding a slice corresponding to each relation of interest. Fig. 3(c) demonstrates how to add another slice $\mathcal{W}_{:,:,\text{hyper}}$ to the tensor for encoding hypernyms.

4.2 Tensor Decomposition

The MRLSA raw tensor encodes relations in one or more data resources, such as thesauri. However, the knowledge from a thesaurus is usually noisy and incomplete. In this section, we derive a low-rank approximation of the tensor to generalize the knowledge. This step is analogous to the rank-k approximation in LSA.

Various tensor decomposition methods have been proposed in literature. Among them, Tucker decomposition (Tucker, 1966) is recognized as a multi-dimensional extension of SVD and has been widely used in many applications. An illustration of this method is in Fig. 4(a). In Tucker decomposition, a $d \times n \times m$ tensor $\mathcal{W}$ is decomposed into four components $\mathcal{G}, \mathbf{U}, \mathbf{V}, \mathbf{T}$. A low-rank approximation



(a) Tucker Tensor Decomposition (b) Our Reformulation

Figure 4: Fig. 4(a) illustrates the Tucker tensor decomposition method which factors a 3-way tensor $\mathcal{W}$ to three orthogonal matrices, $\mathbf{U}, \mathbf{V}, \mathbf{T}$, and a core tensor $\mathcal{G}$. We further apply a n-mode matrix product on the core tensor $\mathcal{G}$ with $\mathbf{T}$. Consequently, each slice of the resulted core tensor $\mathcal{S}$ (a square matrix) captures a semantic relation type, and each column of $\mathbf{V}^T$ is a vector representing a word.

$\mathcal{X}$ of $\mathcal{W}$ is defined by

$$\mathcal{W}_{i,j,k} \approx \mathcal{X}_{i,j,k} = \sum_{r_1=1}^{R_1} \sum_{r_2=1}^{R_2} \sum_{r_3=1}^{R_3} \mathcal{G}_{r_1,r_2,r_3} \mathbf{U}_{i,r_1} \mathbf{V}_{j,r_2} \mathbf{T}_{k,r_3},$$

where $\mathcal{G}$ is a core tensor with dimensions $R_1 \times R_2 \times R_3$ and $\mathbf{U}, \mathbf{V}, \mathbf{T}$ are orthogonal matrices with dimensions $d \times R_1, n \times R_2, m \times R_3$, respectively. The rank parameters $R_1 \leq d, R_2 \leq n, R_3 \leq m$ are given as input to the algorithm. In MRLSA, m (the number of relations) is usually small, while d and n are typically large (often in the scale of hundreds of thousands). Therefore, we choose $R_1 = R_2 = \tau$, $\tau \ll d, n$ and $R_3 = m$, where τ is typically less than 1000.

To make the analogy to SVD clear, we rewrite the results of Tucker decomposition by performing a n-mode matrix product over the core tensor $\mathcal{G}$ with the matrix $\mathbf{T}$. This produces a tensor $\mathcal{S}$ where each slice is a linear combination of the slices of $\mathcal{G}$ with coefficients given by $\mathbf{T}$ (see (Kolda and Bader, 2009) for detail). That is, we have

$$\mathcal{S}_{:,:,k} = \sum_{t=1}^{m} \mathbf{T}_{t,k} \mathcal{G}_{:,:,t}, \quad \forall k.$$

An illustration is shown in Fig. 4(b), Then, a straightforward calculation shows that k-th slice of tensor $\mathcal{W}$ is approximated by

$$\mathcal{W}_{:,:,k} \approx \mathcal{X}_{:,:,k} = \mathbf{U} \mathcal{S}_{:,:,k} \mathbf{V}^T. \tag{4}$$

Comparing Eq. (4) to Eq. (1), one can observe that matrices $\mathbf{U}$ and $\mathbf{V}$ play similar roles here, and each slice of the core tensor $\mathcal{S}$ is analogous to Σ. However, the square matrix $\mathcal{G}_{:,:,k}$ is not necessary to be diagonal. As in SVD, the column vectors of $\mathcal{G}_{:,:,k}\mathbf{V}^T$ (capture both word and relation information) behave similarly to the column vectors of the original tensor slice $\mathcal{W}_{:,:,k}$.

4.3 Measuring the Degrees of Word Relations

In principle, the raw information in the input tensor $\mathcal{W}$ can be used for computing lexical similarity using the cosine score between the column vectors for two words from the same slice of the tensor. To measure the degree of other relations, however, our approach requires one to specify a *pivot* slice. The key role of the pivot slice is to expand the lexical coverage of the relation of interest to additional lexical entries and, for this reason, the pivot slice should be chosen to capture the equivalence of the lexical entries. In this paper, we use the synonymy relation as our pivot slice. First we consider measuring the degree of a relation *rel* holding between the i-th and j-th words using the raw tensor $\mathcal{W}$, which can be computed as

$$\cos\left(\mathcal{W}_{:,i,\text{syn}}, \mathcal{W}_{:,j,rel}\right). \tag{5}$$

This measurement can be motivated from the logical rule: $\text{syn}(\text{word}_i, \text{target}) \wedge rel(\text{target}, \text{word}_j) \rightarrow rel(\text{word}_i, \text{word}_j)$, where the pivot relation *syn* expands the coverage of the relation of interest *rel*.

Turning to the use of the tensor decomposition, we use a similar derivation to Eq. (3), and measure the degree of relation *rel* between two words by

$$\cos\left(\mathcal{S}_{:,:,\text{syn}} \mathbf{V}_{i,:}^T, \mathcal{S}_{:,:,rel} \mathbf{V}_{j,:}^T\right). \tag{6}$$

For instance, the degree of antonymy between "joy" and "sorrow" is measured by the cosine similarity between the respective fibers $\cos(\mathcal{X}_{:,\text{"joy"},\text{syn}}, \mathcal{X}_{:,\text{"sorrow"},\text{ant}})$. We can encode both symmetric relations (e.g., *antonymy* and *synonymy*) and asymmetric relations (e.g., *hypernymy* and *hyponymy*) in the same tensor representation. For a symmetric relation, we use both $\cos(\mathcal{X}_{:,i,\text{syn}}, \mathcal{X}_{:,j,rel})$ and $\cos(\mathcal{X}_{:,j,\text{syn}}, \mathcal{X}_{:,i,rel})$ and measure the degree of a symmetric relation by the average of these two cosine similarity scores. However, for asymmetric relations, we use only $\cos(\mathcal{X}_{:,i,\text{syn}}, \mathcal{X}_{:,j,rel})$.

5 Experiments

We evaluate MRLSA on two tasks: answering the closest-opposite GRE questions and measuring degrees of various class-inclusion (i.e., *is-a*) relations. In both tasks, we design the experiments to empirically validate the following claims. When encoding two opposite relations from the same source, MRLSA performs comparably to PILSA. However, MRLSA generalizes LSA to model multiple relations, which could be obtained from both homogeneous and heterogeneous data sources. As a result, the performance of a target task can be further improved.

5.1 Experimental Setup

We construct the raw tensors to encode a particular relation in each slice based on two data sources.

Encarta The Encarta thesaurus is developed by Bloomsbury Publishing Plc[2]. For each target word, it provides a list of synonyms and antonyms. We use the same version of the thesaurus as in (Yih et al., 2012), which contains about 47k words and a vocabulary list of approximately 50k words.

WordNet We use four types of relations from WordNet: synonymy, antonymy, hypernymy and hyponymy. The number of target words and the size of the vocabulary in our version are 117,791 and 149,400, respectively. WordNet has better vocabulary coverage, but fewer antonym pairs. For instance, the WordNet antonym slice contains only 46,945 nonzero entries, while the Encarta antonym slice has 129,733.

[2]http://www.bloomsbury.com

We apply a memory-efficient Tucker decomposition algorithm (Kolda and Sun, 2008) implemented in *tensor_toolbox v2.5* (Bader et al., 2012)[3] to factor the tensor. The largest tensor considered in this paper can be decomposed in about 3 hours using less than 4GB of memory with a commodity PC.

5.2 Answering GRE Antonym Questions

The first task is to answer the closest-opposite questions from the GRE test provided by Mohammad et al. (2008)[4]. Each question in this test consists of a target word and five candidate words, where the goal is to pick the candidate word that has the most opposite meaning to the target word. In order to have a fair comparison, we use the same data split as in (Mohammad et al., 2008), with 162 questions used for the development set and 950 for test. Following (Mohammad et al., 2008; Yih et al., 2012), we report the results in precision (accuracy of the questions that the system attempts to answer), recall (percentage of the questions answered correctly over all questions) and F_1 (the harmonic mean of precision and recall).

We tune two sets of parameters using the development set: (1) the rank parameter τ in the tensor decomposition and (2) the scaling factors of different slices of the tensor. The rank parameter specifies the number of dimensions of the latent space. In the experiments, We pick the best value of τ from $\{100, 200, 300, 500, 750, 1000\}$. The scaling factors adjust the values of each slice of the tensor. The elements of each slice are multiplied by the scaling factor before factorization. This is important because Tucker decomposition minimizes the reconstruction error (the Frobenius norm of the residual tensor). As a result, the slice with a larger range of values becomes more influential to $\mathbf{U}$ and $\mathbf{V}$. In this work, we fix $\mathcal{W}_{:,:,\text{ant}}$, and search for the scaling factor of $\mathcal{W}_{:,:,\text{syn}}$ in $\{0.25, 0.5, 1, 2, 4\}$ and the factors of $\mathcal{W}_{:,:,\text{hyper}}$ and $\mathcal{W}_{:,:,\text{hypo}}$ in $\{0.0625, 0.125, 0.25\}$.

Table 1 summarizes the results of training

[3]`http://www.sandia.gov/~tgkolda/TensorToolbox`. The Tucker decomposition involves performing SVD on a large matrix. We modify the MATLAB code of *tensor_toolbox* to use the built-in `svd` function instead of `svds`. This modification reduces both the running time and memory usage.

Table 1: GRE antonym test results of models based on Encarta and WordNet data in precision, recall and F_1. RawTensor evaluates the performance of the tensor with 2 slices encoding synonyms and antonyms before decomposition (see Eq. (5)), which is comparable to checking the original data directly (Lookup). MRLSA:Syn+Ant applies Tucker decomposition to the raw tensor and measures the degree of antonymy using Eq. (6). The result is similar to that of PILSA (see Sec. 3.1). MRLSA:4-layers adds hypernyms and hyponyms from WordNet; MRLSA:WordNet+Encarta consists of synonyms/antonyms from Encarta and hypernyms/hyponyms from WordNet, where the target words are aligned using the synonymy relations. Both models demonstrate the advantage of encoding more relations, from either the same or different resources.

MRLSA using two different corpora, Encarta and WordNet. The performance of the MRLSA raw tensor is close to that of looking up the thesaurus. This indicates the tensor representation is able to capture the word relations explicitly described in the thesaurus. After conducting tensor decomposition, MRLSA:Syn+Ant achieves similar results to PILSA. This confirms our claim that when giving the same among of information, MRLSA performs at least comparably to PILSA. However, the true power of MRLSA is its ability to incorporate other semantic relations to boost the performance of the target task. For example, when we add the hypernymy and hyponymy relations to the tensor, these class-inclusion relations provide a weak signal to help resolve antonymy. We suspect that this is due to the fact that antonyms typically share the same properties but only have the opposite meaning on one particular semantic dimension. For instance, the antonyms "sadness" and "happiness" are different forms of emotion. When two words are hyponyms of a target word, the likelihood that they are antonyms should thus be increased. We show that the target relations and these auxiliary semantic relations can be collected from the same data source (e.g., WordNet MRLSA:4-layers) or from multiple, heterogeneous sources (e.g., MRLSA:WordNET+Encarta). In both cases, the performance of the model improves as more relations are incorporated. Moreover, our experiments show that adding the hypernym and hyponym layers from WordNet improves modeling antonym relations based on the Encarta thesaurus. This suggests that the weak signal from a resource with a large vocabulary (e.g., WordNet) can help predict relations between out-of-vocabulary words and thus improve the recall.

To better understand the model, we examine the top antonyms for three question words from the GRE test. The lists below show antonyms and their MRLSA scores for each of the GRE question words as determined by the MRLSA:WordNET+Encarta model. Antonyms that can be found directly in the Encarta thesaurus are in italics.

inanimate *alive* (0.91), living (0.90), *bodily* (0.90), in-the-flesh (0.89), *incarnate* (0.89)

alleviate exacerbate (0.68), make-worse (0.67), inflame (0.66), amplify (0.65), stir-up (0.64)

relish detest (0.33), abhor (0.33), abominate (0.33), despise (0.33), loathe (0.31)

We can see that from these examples, MRLSA not

Table 2: Results of measuring the class-inclusion (*is-a*) relations in MaxDiff accuracy (see text for detail). RawTensor has synonym and hyponym slices and measures the degree of *is-a* relation using Eq. (5). MRLSA:Syn+Hypo factors the raw tensor and judges the relation by Eq. (6). The constructions of MRLSA:4-layers and MRLSA:WordNet+Encarta are the same as in Sec. 5.2 (see the caption of Table 1 for detail). For MRLSA models, numbers shown in the parentheses are the results when parameters are tuned using the test sets. UTD_{NB} is the results of the best performing system in SemEval-2012 Task 2.

only preserves the antonyms in the thesaurus, but also discovers additional ones, such as *exacerbate* and *inflame* for "alleviate". Another interesting finding is that while the scores are useful in ranking the candidate words, they might not be comparable across different question words. This could be an issue for some applications, which need to make a binary decision on whether two words are antonyms.

5.3 Measuring degrees of *Is-A* relations

We evaluate MRLSA using the class-inclusion portion of SemEval-2012 Task 2 data (Jurgens et al., 2012). Here the goal is to measure the degree of two words having the *is-a* relation. Five annotated datasets are provided for different subcategories of this relation: 1a-taxonomic, 1b-functional, 1c-singular, 1d-plural, 1e-class individual. We omit 1e because it focuses on real world entities (e.g., queen:Elizabeth, river:Nile), which are not included in WordNet.

Each dataset contains about 100 questions based on approximately 40 word pairs. The question consists of 4 randomly chosen word pairs and asks the best and worst pairs that exemplify the specific *is-a* relation. The performance is measured by the average prediction accuracy, also called the MaxDiff accuracy (Louviere and Woodworth, 1991).

Because the questions are generated from the same set of word pairs, these questions are not mutually independent. Therefore, it is not proper to split the data of each subcategory into the development and test sets. Alternatively, we follow the setting of SemEval-2012 Task 2 and use the first subcategory (1a-taxonomy) to tune the model and evaluate its performance based on the results on other datasets. Since the models are tuned and tested on different types of subcategories, they might not be the optimal ones when evaluated on the test sets. Therefore, we show results using the best parameters tuned on the development set and those tuned on the test set, where the latter suggests a performance upper-bound. Besides the rank parameter, we tune the scaling factors of the synonym, hypernym and hyponym slices from $\{4, 16, 64\}$. The scaling factor of the antonym slice is fixed to 1.

Table 2 shows the performance in MaxDiff accuracy. Results show that even the raw tensor representation (RawTensor) performs better than WordNet lookup. We suspect that this is because the tensor representation can capture the fact that the hyponyms of a word are usually synonymous to each other. By performing Tucker decomposition on the raw Tensor, MRLSA achieves better performance. MRLSA:4-layers further leverages the information from antonyms and hypernyms and thus improves the model. As we notice in the GRE antonym test, models based on the Encarta thesaurus perform better in predicting antonyms. Therefore, it is interesting to check if combining synonyms and antonyms from Encarta helps. As a result, MRLSA:WordNet+Encarta improves over MRLSA:4-layers significantly. This demonstrates again that MRLSA can leverage knowledge stored in heterogeneous resources. Notably, MRLSA outper-

forms the best system participated in the SemEval-2012 task with a large margin, with a difference of 21.4 in MaxDiff accuracy.

Next we examine the top words that have the *is-a* relation relative to three question words from the task. The lists below show the hyponyms and their respective MRLSA scores for each of the question words as determined by MRLSA:4-layers.

bird ostrich (0.75), gamecock (0.75), nighthawk (0.75), amazon (0.74), parrot (0.74)

automobile minivan (0.48), wagon (0.48), taxi (0.46), minicab (0.45), gypsy cab (0.45)

vegetable buttercrunch (0.61), yellow turnip (0.61), romaine (0.61), chipotle (0.61), chilli (0.61)

Although the model in general does a good job finding hyponyms, we observe that some suggested words, such as *buttercrunch* (a mild lettuce) vs. "vegetable", do not seem intuitive (e.g., compared to *carrot*). Having one additional slice to capture the general term co-occurrence relation may help improve the model in this respect.

6 Conclusions

In this paper, we propose Multi-Relational Latent Semantic Analysis (MRLSA) which generalizes Latent Semantic Analysis (LSA) for lexical semantics. MRLSA models multiple word relations by leveraging a 3-way tensor, where each slice captures one particular relation. A low-rank approximation of the tensor is then derived using a tensor decomposition. Consequently, words in the vocabulary are represented by vectors in the latent semantic space, and each relation is captured by a latent square matrix. Given two words, MRLSA not only can measure their degree of having a specific relation, but also can discover unknown relations between them. These advantages have been demonstrated in our experiments. By encoding relations from both homogeneous or heterogeneous data sources, MRLSA achieves state-of-the-art performance on existing benchmark datasets for two relations, *antonymy* and *is-a*.

For future work, we plan to explore directions that aim for improving both the quality and word coverage of the model. For instance, the knowledge encoded by MRLSA can be enriched by adding more relations from a variety of linguistic resources, including the co-occurrence relations from large corpora. On model refinement, we notice that MRLSA can be viewed as a 3-layer neural network without applying the sigmoid function. Following the strategy of using Siamese neural networks to enhance PILSA (Yih et al., 2012), training MRLSA with a multi-task discriminative learning setting can be a promising approach as well.

Abstract

We present a new language pair agnostic approach to inducing bilingual vector spaces from non-parallel data without any other resource in a bootstrapping fashion. The paper systematically introduces and describes all key elements of the bootstrapping procedure: (1) starting point or seed lexicon, (2) the confidence estimation and selection of new dimensions of the space, and (3) convergence. We test the quality of the induced bilingual vector spaces, and analyze the influence of the different components of the bootstrapping approach in the task of bilingual lexicon extraction (BLE) for two language pairs. Results reveal that, contrary to conclusions from prior work, the seeding of the bootstrapping process has a heavy impact on the quality of the learned lexicons. We also show that our approach outperforms the best performing fully corpus-based BLE methods on these test sets.

1 Introduction

Bilingual lexicons serve as an indispensable source of knowledge for various cross-lingual tasks such as cross-lingual information retrieval (Lavrenko et al., 2002; Levow et al., 2005) or statistical machine translation (Och and Ney, 2003). Additionally, they are a crucial component in cross-lingual knowledge transfer, where the knowledge about utterances in one language may be transferred to another. The utility of the transfer or annotation projection by means of bilingual lexicons has already been proven in various tasks such as semantic role labeling (Padó and Lapata, 2009; van der Plas et al., 2011), parsing (Zhao et al., 2009; Durrett et al., 2012; Täckström et al., 2013b), POS tagging (Yarowsky and Ngai, 2001; Das and Petrov, 2011; Täckström et al., 2013a), etc.

Techniques for automatic bilingual lexicon extraction (BLE) from parallel corpora on the basis of word alignment models are well established (Och and Ney, 2003). However, due to a relative scarceness of parallel data for many language pairs and domains, alternative approaches that rely on comparable corpora have also gained much interest (e.g., Fung and Yee (1998); Rapp (1999)).

The models that rely on non-parallel data typically represent each word by a high-dimensional vector in a feature vector space, where the dimensions of the vector are its *context features*. The context features are typically words co-occurring with the word in a predefined context.[1] The similarity of two words, w_1^S given in the source language L_S with vocabulary V^S and w_2^T in the target language L_T with vocabulary V^T is then computed as $sim(w_1^S, w_2^T) = SF(cv(w_1^S), cv(w_2^T))$. $cv(w_1^S) = [sc_1^S(c_1), \ldots, sc_1^S(c_N)]$ is a context vector for w_1^S with N context features c_k, where $sc_1^S(c_k)$ denotes the score for w_1^S associated with context feature c_k (similar for w_2^T). SF is a similarity function (e.g., cosine, the Kullback-Leibler divergence, the Jaccard index) operating on the context vectors (Lee, 1999).

When operating with 2 languages, the context features cannot be compared directly. Therefore, in order to compare the feature vectors $cv(w_1^S)$ and $cv(w_2^T)$, the context features need to span a shared

[1] The context may be a document, a paragraph, a window of predefined size around each occurrence of w_i^S in $\mathcal{C}_S$, etc. For an overview, see, e.g., (Tamura et al., 2012).

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1613–1624,
Seattle, Washington, USA, 18-21 October 2013.

bilingual vector space. The standard way of building a bilingual vector space is to use *bilingual lexicon entries* (Rapp, 1999; Fung and Cheung, 2004; Gaussier et al., 2004) as dimensions of the space. However, there seems to be an apparent flaw in logic, since the methods assume that there exist readily available bilingual lexicons that are then used to induce bilingual lexicons! Therefore, the focus of the researchers has turned to designing BLE methods that do not rely on any external translation resources such as machine-readable bilingual lexicons and parallel corpora (Haghighi et al., 2008; Vulić et al., 2011).

In order to circumvent this issue, one line of recent work aims to *bootstrap high-quality bilingual vector spaces from a small initial seed lexicon*. The seed lexicon is constructed by harvesting identical or similarly spelled words across languages (Koehn and Knight, 2002; Peirsman and Padó, 2010), and it spans the initial bilingual vector space. *The space is then gradually enriched with new dimensions/axes during the bootstrapping procedure*. The bootstrapping process has already proven its validity in inducing bilingual lexicons for closely similar languages such as Spanish-Portuguese or Croatian-Slovene (Fišer and Ljubešić, 2011), but it still lacks further generalization to more distant language pairs.

The main goal of this paper is to shed new light on the bootstrapping approaches to bilingual lexicon extraction, and to construct a language pair agnostic bootstrapping method that is able to build high-quality bilingual vector spaces that consequently lead to high-quality bilingual lexicons for more distant language pairs where orthographic similarity is not sufficient to seed bilingual vector spaces. We aim to answer the following key questions:

- How to seed bilingual vector spaces besides using only orthographically similar words?
- Is it better to seed bilingual spaces with translation pairs/dimensions that are frequent in the corpus, and does the frequency matter at all? Does the size of the initial seed lexicon matter?
- How to enrich bilingual vector spaces with only highly reliable dimensions in order to prevent semantic drift?

With respect to these questions, the main contributions of this article are:

- We present a complete overview of the framework of bootstrapping bilingual vector spaces from non-parallel data without any additional resources. We dissect the bootstrapping process and describe all its key components.
- We introduce a new way of seeding the bootstrapping procedure that does not rely on any orthographic clues and that yields bilingual vector spaces of higher quality. We analyze the impact of different seed lexicons on the quality of induced bilingual vector spaces.
- We show that in the setting without any external translation resources, our bootstrapping approach yields lexicons that outperform the best performing corpus-based BLE methods on standard test datasets for 2 language pairs.

2 Boostrapping Bilingual Vector Spaces: A General Overview

This section presents the complete bootstrapping procedure that starts with an initial seed lexicon which spans the initial bilingual vector space, while as the output in each iteration of the procedure it produces an updated bilingual vector space that can be used to extract a bilingual lexicon.

2.1 General Framework

We assume that we are solely in possession of a (non-parallel) bilingual corpus $\mathcal{C}$ that is composed of a sub-corpus $\mathcal{C}_S$ given in the source language L_S, and a sub-corpus $\mathcal{C}_T$ in the target language L_T. All word types that occur in $\mathcal{C}_S$ constitute a set V^S. All word types in $\mathcal{C}_T$ constitute a set V^T. The goal is to build a bilingual vector space using only corpus $\mathcal{C}$.

Assumption 1. *Dimensions of the bilingual vector space are one-to-one word translation pairs*. For instance, dimensions of a Spanish-English space are pairs like *(perro, dog)*, *(ciencia, science)*, etc. The *one-to-one constraint* (Melamed, 2000), although not valid in general, simplifies the construction of the bootstrapping procedure. $\mathcal{Z}$ denotes the set of translation pairs that are the dimensions of the space.

Computing cross-lingual word similarity in a bilingual vector space. Now, assume that our bilingual vector space consists of N one-to-one word translation pairs $c_k = (c_k^S, c_k^T), k = 1, \ldots, N$. For each word $w_i^S \in V^S$, we compute the similarity of

that word with each word $w_j^T \in V^T$ by computing the similarity between their context vectors $cv(w_i^S)$ and $cv(w_j^T)$, which are actually their representations in the N-dimensional bilingual vector space.

The cross-lingual similarity is computed following the standard procedure (Gaussier et al., 2004):
(1) For each source word $w_i^S \in V^S$, build its N-dimensional context vector $cv(w_i^S)$ that consists of association scores $sc_k^S(c_k^S)$, that is, we compute the strength of association with the "source" part of each dimension c_k that constitutes the N-dimensional bilingual space. The association is dependent on the co-occurrence of w_i^S and c_k^S in a predefined context. Various functions such as the log-likelihood ratio (LLR) (Rapp, 1999; Ismail and Manandhar, 2010), TF-IDF (Fung and Yee, 1998), or pointwise mutual information (PMI) (Bullinaria and Levy, 2007; Shezaf and Rappoport, 2010) are typically used as *weighting functions* to quantify the strength of the association.
(2) Repeat step (1) for each target word $w_j^T \in V^T$ and build context vectors $cv(w_j^T)$ that consist of scores $sc_k^T(c_k^T)$.
(3) Since c_k^S and c_k^T address the same dimension c_k in the bilingual vector space for each $k = 1, \ldots, N$, we are able to compute the similarity between $cv(w_i^S)$ and $cv(w_j^T)$ using any similarity measure such as the Jaccard index, the Kullback-Leibler or the Jensen-Shannon divergence, the cosine measure, or others (Lee, 1999; Cha, 2007).

The similarity score for two words w_i^S and w_j^T is $sim(w_i^S, w_j^T)$. For each source word w_i^S, we can build a *ranked list* $RL(w_i^S)$ that consists of all words $w_j^T \in V^T$ ranked according to their respective similarity scores $sim(w_i^S, w_j^T)$. In the similar fashion, we can build a ranked list $RL(w_j^T)$, for each target word w_j^T. We call the top scoring target word w_j^T for some source word w_i^S its *translation candidate*, and write $TC(w_i^S) = w_j^T$. Additionally, we label the ranked list $RL(w_i^S)$ that is pruned at position M as $RL_M(w_i^S)$.

Bootstrapping. The key idea of the bootstrapping approach relies on an insight that *highly reliable translation pairs* (w_1^S, w_2^T) that are encountered using the N-dimensional bilingual vector space might be added as new dimensions of the space. By adding these new dimensions, it might be possible to extract more highly reliable translation pairs that were previously not used as dimensions of the space, and the iterative procedure repeats until no new dimensions are found. The induced bilingual vector space may then be observed as a bilingual lexicon *per se*, but it may also be used to find translation equivalents for other words which are not used to span the space.

Algorithm 1: Bootstrapping a bilingual vector space

Input : Bilingual corpus $\mathcal{C} = \mathcal{C}_S \cup \mathcal{C}_T$
Initialize: (1) Obtain a one-to-one seed lexicon. The entries from the lexicon are initial dimensions of the space: $\mathcal{Z}_0$; (2) $s = 0$;
Bootstrap:
repeat
1: For each $w_i^S \in V^S$: compute $RL(w_i^S)$ using $\mathcal{Z}_s$;
2: For each $w_j^T \in V^T$: compute $RL(w_j^T)$ using $\mathcal{Z}_s$;
3: For each $w_i^S \in V^S$ and $w_j^T \in V^T$: score each translation pair $(w_i^S, TC(w_i^S))$ and $(TC(w_j^T), w_j^T)$ and add them to a *pool of candidate dimensions* ;
4: Choose *the best candidates* from the pool and add them as new dimensions: $\mathcal{Z}_{s+1} \leftarrow \mathcal{Z}_s \cup \{best\}$;
5: Resolve collisions in $\mathcal{Z}_{s+1}$;
6: $s \leftarrow s + 1$;
until *no new dimensions are found (convergence)* ;
Output: One-to-one translation pairs $\rightarrow$ Dimensions of a bilingual vector space $\mathcal{Z}_{final}$

The overview of the procedure as given by alg. 1 reveals these crucial points in the procedure: (Q1) how to provide initial dimensions of the space? (the initialization step), (Q2) how to score each translation pair, estimate their confidence, and how to choose the best candidates from the pool of candidates? (steps 3 and 4), and (Q3) how to resolve potential collisions that violate the one-to-one constraint? (step 5). We will discuss (Q1) and (Q2) in more detail later, while we resolve (Q3) following a simple heuristic as follows:

Assumption 2. *In case of collision, dimensions/pairs that are found at later stages of the bootstrapping process overwrite previous dimensions.*

The intuition here is that we expect for the quality of the space to increase at each stage of the bootstrapping process, and newer translation pairs should be more confident than the older ones. For instance, if 2 out of N dimensions of a Spanish-English bilingual space are pairs *(piedra,wall)* and *(tapia,stone)*, but then if during the bootstrapping process we extract a new candidate pair *(piedra,stone)*, we will delete the former two dimensions and add the latter.

2.2 Initializing Bilingual Vector Spaces

Seeding or initializing a bootstrapping procedure is often a critical step regardless of the actual task (McIntosh and Curran, 2009; Kozareva and Hovy, 2010), and it decides whether the complete process will end as a success or a failure. However, Peirsman and Padó (2011) argue that the initialization step is not crucial when dealing with bootstrapping bilingual vector spaces. Here, we present two different strategies of initializing the bilingual vector space.

Identical words and cognates. Previous work relies exclusively on identical and similarly spelled words to build the initial set of dimensions $\mathcal{Z}_0$ (Koehn and Knight, 2002; Peirsman and Padó, 2010; Fišer and Ljubešić, 2011). This strategy yields promising results for closely similar language pairs, but is of limited use for other language pairs.

High-frequency seeds. Another problem with using only identical words and cognates as seeds lies in the fact that many of them might be infrequent in the corpus, and as a consequence the expressiveness of a bilingual vector space might be limited. On the other hand, high-frequency words offer a lot of evidence in the corpus that could be exploited in the bootstrapping approach. In order to induce initial translation pairs, we rely on the framework of *multilingual probabilistic topic modeling* (MuPTM) (Boyd-Graber and Blei, 2009; De Smet and Moens, 2009; Mimno et al., 2009; Zhang et al., 2010), that does not require a bilingual lexicon, it operates with non-parallel data, and is able to produce highly confident translation pairs for high-frequency words (Mimno et al., 2009; Vulić and Moens, 2013).[2] Therefore, we can construct the initial seed lexicon as follows:

(1) Train a multilingual topic model on the corpus.

(2) Obtain one-to-one translation pairs using any of the MuPTM-based models of cross-lingual similarity, e.g., (Vulić et al., 2011; Vulić and Moens, 2013).

(3) Retain only *symmetric* translation pairs. This step ensures that only highly confident pairs are used as seed translation pairs.

(4) Rank translation pairs according to their frequency in the corpus and use a subset of the most frequent symmetric pairs as seeds.

2.3 Estimating Confidence of New Dimensions

Another crucial step in the bootstrapping procedure is the estimation of confidence in a translation pair/candidate dimension. Errors in the early stages of the procedure may negatively affect the learning process and even cause *semantic drift* (Riloff and Shepherd, 1999; McIntosh and Curran, 2009). We therefore impose the constraint which requires translation pairs to be *symmetric* in order to qualify as potential new dimensions of the space. In other words, given the current set of dimensions $\mathcal{Z}_s$, a translation pair (w_i^S, w_j^T) has a possibility to be chosen as a new dimension from the pool of candidate dimensions if and only if it holds: $TC(w_i^S) = w_j^T$ and $TC(w_j^T) = w_i^S$. This *symmetry constraint* should ensure a relative reliability of translation pairs.

In each iteration of the bootstrapping process, we may add all symmetric pairs from the pool of candidates as new dimensions, or we could impose additional selection criteria that quantify the degree of confidence in translation pairs. We are then able to rank the symmetric candidate translation pairs in the pool of candidates according to their confidence scores (step 3 of alg. 1), and choose only the best B candidates from the pool in each iteration (step 4) as done in (Thelen and Riloff, 2002; McIntosh and Curran, 2009; Huang and Riloff, 2012). By picking only a subset of the B most confident candidates in each iteration, we hope to further prevent a possibility of semantic drift, i.e., "poisoning" the bootstrapping process that might happen if we include incorrect translation pairs as dimensions of the space.

In this paper, we investigate 3 different confidence estimation functions:[3]

(1) **Absolute similarity score.** Confidence of a translation pair $CF(w_i^S, TC(w_i^S))$ is simply the absolute similarity value $sim(w_i^S, TC(w_i^S))$

(2) **M-Best confidence function.** It contrasts the score of the translation candidate with the average score over the first M most similar words in the ranked list. The larger the difference, the more confidence we have in the translation candidate. Given a word $w_i^S \in V^S$ and a ranked list $RL_M(w_i^S)$, the

[2] One can also use other models that are similar to MuPTM such as (Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011) to produce the initial seed lexicon, but that analysis is beyond the scope of this work.

[3] A symmetrized version of the confidence functions is computed as the geometric mean of source-to-target and target-to-source confidence scores.

average score of the best M words is computed as:

$$sim_M(w_i^S) = \frac{1}{M} \sum_{w_j^T \in RL_M(w_i^S)} sim(w_i^S, w_j^T)$$

The final confidence score is then:

$$CF(w_i^S, TC(w_i^S)) = sim(w_i^S, TC(w_i^S)) - sim_M(w_i^S)$$

(3) **Entropy-based confidence function.** We adapt the well-known entropy-based confidence (Smith and Eisner, 2007; Tu and Honavar, 2012) to this particular task. First, we need to define a distribution:

$$p(w_j^T|w_i^S) = \frac{e^{sim(w_i^S, w_j^T)}}{\sum_{w_l^T \in V^T} e^{sim(w_i^S, w_l^T)}}$$

The confidence function is then minus the entropy of the probability distribution p:

$$CF(w_i^S, TC(w_i^S)) = \sum_{w_l^T \in V^T} p(w_l^T|w_i^S) \log p(w_l^T|w_i^S)$$

3 Experimental Setup

Data collections. We investigate our bootstrapping approach on the BLE task for 2 language pairs: Spanish-English (ES-EN) and Italian-English (IT-EN), and work with the following corpora previously used by Vulić and Moens (2013): (i) a collection of 13,696 Spanish-English Wikipedia article pairs (**Wiki-ES-EN**), (ii) 18,898 Italian-English Wikipedia article pairs (**Wiki-IT-EN**).[4]

Following (Koehn and Knight, 2002; Haghighi et al., 2008; Prochasson and Fung, 2011; Vulić and Moens, 2013), we use TreeTagger (Schmid, 1994) for POS-tagging and lemmatization of the corpora, and then retain only nouns that occur at least 5 times in the corpus. We record the lemmatized form when available, and the original form otherwise. Our final vocabularies consist of 9,439 Spanish nouns and 12,945 nouns for ES-EN, and 7,160 Italian nouns and 9,116 English nouns for IT-EN.

Ground truth. The goal of the BLE task is to extract a bilingual lexicon of one-to-one translations. In order to test the quality of bilingual vector spaces induced by our bootstrapping approach, we evaluate it on standard 1000 ground truth one-to-one translation pairs built for the Wiki-ES-EN and Wiki-IT-EN datasets (Vulić and Moens, 2013). Note that we do not explicitly test the bilingual vector space as a bilingual lexicon, but rather its ability to find semantically similar words and translations also for words that are not used as dimensions of the space (see sect. 2.1).

Evaluation metrics. We measure the performance on the BLE task using a standard *Top M* accuracy (Acc_M) metric. It denotes the number of source words w_i^S from ground truth translation pairs whose list $RL_M(w_i^S)$ contains the correct translation according to our ground truth over the total number of ground truth translation pairs (=*1000*) (Gaussier et al., 2004; Tamura et al., 2012).[5] Additionally, we report the *mean reciprocal rank (MRR)* scores (Voorhees, 1999) for some experimental runs.

Multilingual topic model. We utilize a straightforward multilingual extension of the standard Blei et al.'s LDA model (Blei et al., 2003) called *bilingual LDA* (Mimno et al., 2009; Ni et al., 2009; De Smet and Moens, 2009). BiLDA training follows the procedure from (Vulić and Moens, 2013), that is, the training method is Gibbs sampling with the number of topics set to $K = 2000$. Hyperparameters of the model are set to standard values (Steyvers and Griffiths, 2007): $\alpha = 50/K$ and $\beta = 0.01$.

Building initial seed lexicons. To produce the lists of one-to-one translation pairs that are used as seeds for the bootstrapping approach (see sect. 2.2), we experiment with the *TopicBC* and the *ResponseBC* methods from (Vulić and Moens, 2013), which are the MuPTM-based models of cross-lingual semantic similarity that obtain the best results in the BLE task on these datasets. In short, the *TopicBC* method computes the similarity of two words according to the similarity of their conditional topic distributions (Griffiths et al., 2007; Vulić et al., 2011) using

[4] Vulić and Moens (2013) also worked with Dutch-English (NL-EN), but we have decided to leave out the results obtained for that language pair due to space constraints, high similarity between the two languages, and the fact that the results obtained for that language pair are qualitatively similar to the results we report for ES-EN and IT-EN. Hence including the results for NL-EN would not contribute to the paper with any new important insight and conclusion.

[5] We can build a one-to-one bilingual lexicon by harvesting one-to-one translation pairs $(w_i^S, TC(w_i^S))$, and the quality of that lexicon is best reflected in the Acc_1 score.

the Bhattacharyya coefficient (BC) (Kazama et al., 2010) as the similarity function. *ResponseBC* is a second-order similarity method. It first computes initial similarity scores between all words cross-lingually and monolingually using the cross-lingual topical space and, in the second step, it computes the similarity between 2 words as the similarity between their word vectors that now contain the initial word-to-word similarity scores with all source and target words. The similarity function is again BC.

We use these models of similarity as a black box to acquire seeds for the bootstrapping approach, but we encourage the interested reader to find more details about the methods in the relevant literature. These two models also serve as our *baseline models*, and our goal is to test whether we are able to obtain bilingual lexicons of higher quality using bootstrapping that starts from the output of these models.

Weighting and similarity functions. We have experimented with different families of weighting (e.g., PMI, LLR, TF-IDF, chi-square) and similarity functions (e.g., cosine, Dice, Kullback-Leibler, Jensen-Shannon) (Lee, 1999; Turney and Pantel, 2010). In this paper, we present results obtained by *positive pointwise mutual information (PPMI)* (Niwa and Nitta, 1994) as a weighting function, which is a standard choice in vector space semantics (Turney and Pantel, 2010), and (combined with cosine) yields the best results over a group of semantic tasks according to (Bullinaria and Levy, 2007). We use a smoothed version of PPMI as presented in (Pantel and Lin, 2002; Turney and Pantel, 2010). Again, based on the results reported in the relevant literature (Bullinaria and Levy, 2007; Laroche and Langlais, 2010; Turney and Pantel, 2010), we opt for the cosine similarity as a standard choice for SF. We have also experimented with different window sizes ranging from 3 to 15 in both directions around the pivot word, but we have not detected any major qualitative difference in the results and their interpretation. Therefore, all results reported in the paper are obtained by setting the window size to 6.

4 Results and Discussion

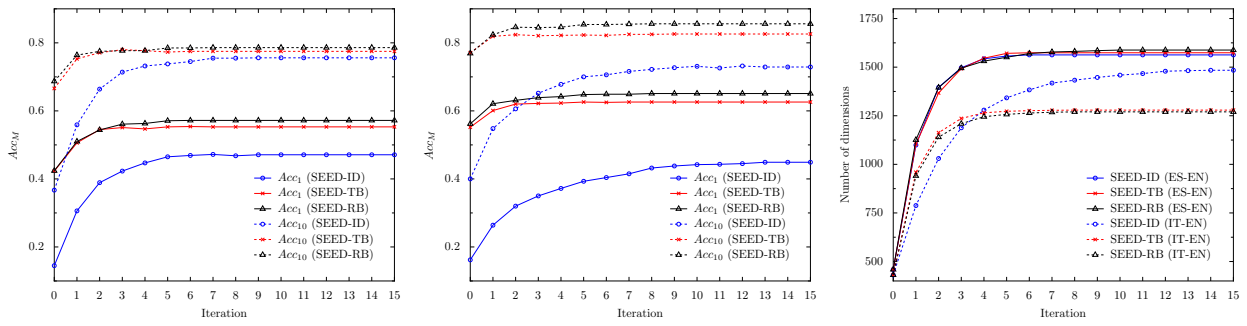
4.1 Are Seeds Important?

In recent work, Peirsman and Padó (2010; 2011) report that "the size and quality of the (seed) lexicon are not of primary importance given that the bootstrapping procedure effectively helped filter out incorrect translation pairs and added more newly identified mutual nearest neighbors." According to their findings, (1) noisy translation pairs are corrected in later stages of the bootstrapping process, since the quality of bilingual vector spaces gradually increases, (2) the size of the seed lexicon does not matter since the bootstrapping approach is able to learn translation pairs that were previously not present in the seed lexicon. Additionally, they do not provide any insight whether the frequency of seeds in the corpus influences the quality of induced bilingual vector spaces. In this paper, we question these claims with a series of BLE experiments.

All experiments conducted in this section do not rely on any extra confidence estimation except for the symmetry constraint, that is, in each step we enrich the bilingual vector space with all new symmetric translation pairs (see alg. 1 and sect. 2.3).

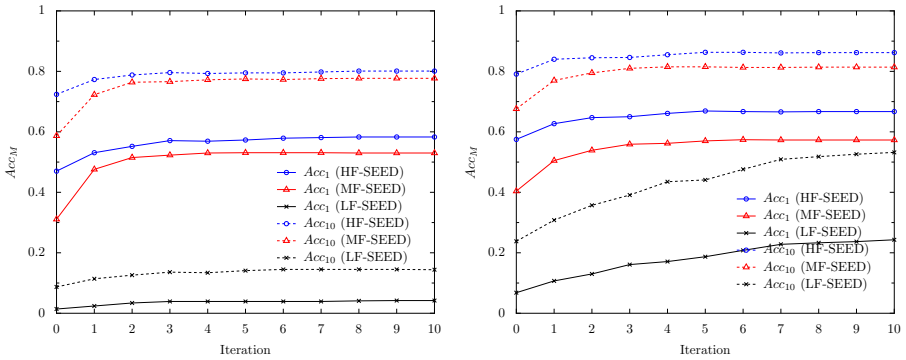
Exp. I: Same size, different seedings? The goal of this experiment is to test whether the quality of seeds plays an important role in the bootstrapping approach. We experiment with 3 different seed lexicons: (1) Following (Peirsman and Padó, 2010; Fišer and Ljubešić, 2011), we harvest identically spelled words across 2 languages and treat them as one-to-one translations. This procedure results in 459 seed translation pairs for ES-EN, and 431 pairs for IT-EN (SEED-ID), (2) We obtain symmetric translation pairs using the *TopicBC* method (see sect. 3) and use 459 pairs that have the highest frequency in the Wiki-ES-EN corpus as seeds for ES-EN (similarly 431 pairs for IT-EN) (SEED-TB), (3) As in (2), but we now use the *ResponseBC* method to acquire seeds (SEED-RB). The frequency of a one-to-one translation pair is simply computed as the geometric mean of the frequencies of words that constitute the translation pair.

Fig. 1(a) and 1(b) display the progress of the same bootstrapping procedure using the 3 different seed lexicons. We derive several interesting conclusions: (i) *Regardless of the actual choice of the seeding method, the bootstrapping process proves its validity and utility* since we observe that the quality of induced bilingual vector spaces increases over time for all 3 seeding methods. The bootstrapping procedure converges quickly. The increase is especially



(a) Spanish to English (b) Italian to English (c) # Dimensions over iterations

Figure 1: Results with 3 different seeding methods as starting points of the bootstrapping process: (i) identical words only (SEED-ID), (ii) the *TopicBC* method (SEED-TB), (iii) the *ResponseBC* method (SEED-RB). (a) Acc_M scores for ES-EN; (b) Acc_M scores for IT-EN; (c) the number of dimensions in the space with the 3 different seeding methods in each iteration for ES-EN and IT-EN. The bootstrapping procedure typically converges after a few iterations.



(a) Spanish to English (b) Italian to English

Figure 2: Results on the BLE task with SEED-RB when using seed translation pairs of different frequency: (i) high-frequency (HF-SEED), (ii) medium-frequency (MF-SEED), (iii) low-frequency (LF-SEED).

prominent in the first few iterations, when the approach learns more new dimensions (see fig. 1(c)). (ii) *The seeding method is important.* A bootstrapping approach that starts with a better seed lexicon is able to extract bilingual lexicons of higher quality as reflected in Acc_1 scores. Although the bootstrapping approach seems more beneficial when dealing with noisier seed lexicons (226% increase in terms of Acc_1 for ES-EN and 177% increase for IT-EN when starting with SEED-ID, compared to 35% increase for ES-EN, and 15% for IT-EN with SEED-RB), when starting from a noisy seed lexicon such as SEED-ID the method is unable to reach the same level of performance. Starting with SEED-ID, the approach is able to recover noisy dimensions from an initial bilingual vector space, but it is still unable to match the results that are obtained when starting from a better initial space (e.g., SEED-RB).

(iii) SEED-RB produces slightly better results than SEED-TB (e.g., the final Acc_1 of 0.649 for SEED-RB compared to 0.626 for SEED-TB for IT-EN, and 0.572 compared to 0.553 for ES-EN). This finding is in line with the results reported in (Vulić and Moens, 2013) where *ResponseBC* proved to be a more robust and a more effective method when applied to the BLE task directly. In all further experiments we use *ResponseBC* to acquire seed pairs, i.e., the seeding method is SEED-RB.

Exp. II: Does the frequency of seeds matter? In the next experiment, we test whether the frequency of seeds in the corpus plays an important role in the bootstrapping process. The intuition is that by using highly frequent and highly confident translation pairs the bootstrapping method has more reliable clues that help extract new dimensions in subsequent iterations. On the other hand, low-frequency

pairs (although potentially correct one-to-one translations) do not occur in the corpus and in the contexts of other words frequently enough, and are therefore not sufficient to extract reliable new dimensions of the space.

To test the hypothesis, we again obtain all symmetric translation pairs using *ResponseBC* and then sort them in descending order based on their frequency in the corpus. In total, we retrieve a sorted list of 2031 symmetric translation pairs for ES-EN, and 1689 pairs for IT-EN. Following that, we split the list in 3 parts of equal size: (i) the top third comprises translation pairs with the highest frequency in the corpus (HF-SEED), (ii) the middle third comprises pairs of "medium" frequency (MF-SEED), (iii) the bottom third are low-frequency pairs (LF-SEED). We then use these 3 different seed lexicons of equal size to seed the bootstrapping approach. Fig. 2(a) and 2(b) show the progress of the bootstrapping process using these 3 seed lexicons. We again observe several interesting phenomena:
(i) *High-frequency seed translation pairs are better seeds*, and that finding is in line with our hypothesis. Although the bootstrapping approach again displays a positive trend regardless of the actual choice of seeds (we observe an increase even when using LF-SEED), high-frequency seeds lead to better overall results in the BLE task. Besides its high presence in contexts of other words, another advantage of high-frequency seed pairs is the fact that an initial similarity method will typically acquire more reliable translation candidates for such words (Pekar et al., 2006). For instance, 89.5% of ES-EN pairs in HF-SEED are correct one-to-one translations, compared to 65.1% in MF-SEED, and 44.3% in LF-SEED.
(ii) The difference in results between HF-SEED and MF-SEED is more visible in Acc_1 scores. Although both seed lexicons for all test words provide ranked lists which contain words that exhibit some semantic relation to the given word, the reliability and the frequency of translation pairs are especially important for detecting the relation of cross-lingual word synonymy, that is, the translational equivalence that is exploited in building one-to-one bilingual lexicons.

Exp. III: Does size matter? The following experiment investigates whether bilingual vector spaces may be effectively bootstrapped from small high-quality seed lexicons, and if larger seed lexicons necessarily lead to bilingual vector spaces of higher quality as reflected in BLE results. We again retrieve a sorted list of symmetric translation pairs as in Exp. II. Following that, we build seed lexicons of various sizes by retaining only the first N pairs from the list, where we vary N from 200 to 1400 in steps of 200. We also use the entire sorted list as a seed lexicon (*All*), and compare the results on the BLE task with the results obtained by applying the *ResponseBC* and *TopicBC* methods directly (Vulić and Moens, 2013). The results are summarized in tables 1 and 2. We observe the following:
(i) If we provide a seed lexicon with sufficient entries, the bootstrapping procedure provides comparable results regardless of the seed lexicon size, although results tend to be higher for larger seed lexicons (e.g., compare results when starting with 600 and 1200 lexicon entries). When starting with the size of 600, the bootstrapping approach is able to find dimensions that were already in the seed lexicon of size 1200. The consequence is that, although bootstrapping with a smaller seed lexicon displays a slower start (see the difference in results at iteration 0), the performances level after convergence.
(ii) Regardless of the seed lexicon size, the bootstrapping approach is valuable. It consistently improves the quality of the induced bilingual vector space, and consequently, the quality of bilingual lexicons extracted using that vector space. The positive impact is more prominent for smaller seed lexicons, i.e., we observe an increase of 78% for ES-EN when starting with only 200 seed pairs, compared to an increase of 15% when starting with 800 seed pairs, and 10% when starting with 1400 seed pairs.
(iii) The bootstrapping approach outperforms *ResponseBC* and *TopicBC* in terms of Acc_1 and MRR scores for both language pairs when the seed lexicon provides a sufficient number of entries. However, in terms of Acc_{10}, *TopicBC* and *ResponseBC* still exhibit comparable (for IT-EN) or even better (ES-EN) results. Both *TopicBC* and *ResponseBC* are MuPTM-based methods that, due to MuPTM properties, model the similarity of two words at the level of documents as contexts, while the bootstrapping approach is a window-based approach that narrows down the context to a local neighborhood of a word. The MuPTM-based models are better suited to detect a general *topical* similarity of words, and

are therefore not always able to push the real cross-lingual synonyms higher in the ranked list of semantically similar words, while the window-based bootstrapping approach is better tailored to model the relation of cross-lingual synonymy, i.e., to extract one-to-one translation pairs (as reflected in Acc_1 scores). A similar conclusion for monolingual settings is drawn by Baroni and Lenci (2010).

(iv) Since our bootstrapping approach utilizes *ResponseBC* or *TopicBC* as a preprocessing step, it is obvious that the approach leads to an increased complexity. On top of the initial complexity of *ResponseBC* and *TopicBC*, the bootstrapping method requires $|V^S||V^T|$ comparisons at each iteration, but given the fact that each $w_i^S \in V^S$ may be processed independently of any other $w_j^S \in V^S$ in each iteration, the bootstrapping method is trivially parallelizable. That makes the method computationally feasible even for vocabularies larger than the ones reported in the paper.

4.2 Is Confidence Estimation Important?

According to the results from tables 1 and 2, regardless of the seed lexicon size, the bootstrapping approach does not suffer from semantic drift, i.e., if we seed the process with high-quality symmetric translation pairs, it is able to recover more pairs and add them as new dimensions of the bilingual vector space. However, we also study the influence of applying different confidence estimation functions on top of the symmetry constraint (see sect 2.3), but we do not observe any improvement in the BLE results, regardless of the actual choice of a confidence estimation function. The only observed phenomenon, as illustrated by fig. 3, is the *slower convergence rate* when setting the parameter B to lower values.

The symmetry constraint alone seems to be sufficient to prevent semantic drift, but it might also be a too strong and a too conservative assumption, since only a small portion of all possible translation pairs is used to span the bilingual vector space (for instance,

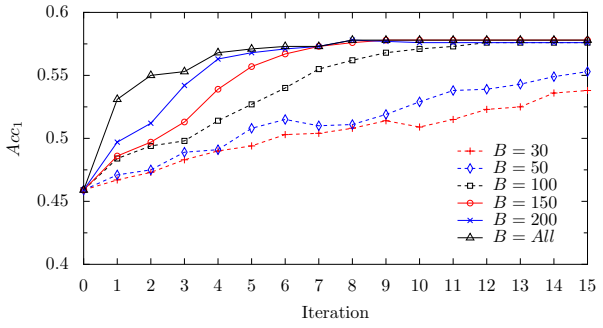

Figure 3: The effect of learning rate B on bootstrapping. Language pair: ES-EN, seed lexicon: SEED-RB with 600 pairs, confidence function: symmetrized M-Best.

when starting with 600 entries for ES-EN, the final bilingual vector space consists of only 1554 pairs, while the total number of ES nouns is 9439). One line of future work will address the construction of bootstrapping algorithms that also enable the usage of highly reliable asymmetric pairs as dimensions, and the confidence estimation functions might have a more important role in that setting.

5 Conclusion

We have presented a new bootstrapping approach to inducing bilingual vector spaces from non-parallel data, and have shown the utility of the induced space in the BLE task. The approach is fully corpus-based and, unlike previous work, it does not rely on the availability of machine-readable translation dictionaries or predefined concept categories. We have systematically described, analyzed and evaluated all key components of the bootstrapping approach. Results reveal that, contrary to conclusions from prior work, the initialization of the bilingual vector space is especially important. We have presented a novel approach to initializing the bootstrapping procedure, and have shown that better results in the BLE task are obtained by starting from seed lexicons that comprise highly reliable high-frequent translation pairs. The bootstrapping framework presented in the paper is completely language pair independent, which makes it effectively applicable to any language pair.

In future work, we will investigate other models of similarity besides *TopicBC* and *ResponseBC* (e.g, the method from (Haghighi et al., 2008)) that could be used as preliminary models for constructing an initial bilingual vector space. Furthermore, we plan to study other confidence functions and explore if asymmetric translation candidates could also contribute to the bootstrapping method. Finally, we also plan to test the robustness of our fully corpus-based bootstrapping approach by porting it to more language pairs.

Acknowledgments

We would like to thank the anonymous reviewers for their useful suggestions. This research has been carried out in the framework of the TermWise Knowledge Platform (IOF-KP/09/001) funded by the Industrial Research Fund, KU Leuven, Belgium.

Abstract

Continuous space word representations extracted from neural network language models have been used effectively for natural language processing, but until recently it was not clear whether the spatial relationships of such representations were interpretable. Mikolov et al. (2013) show that these representations do capture syntactic and semantic regularities. Here, we push the interpretation of continuous space word representations further by demonstrating that vector offsets can be used to derive adjectival scales (e.g., *okay* $<$ *good* $<$ *excellent*). We evaluate the scales on the indirect answers to *yes/no* questions corpus (de Marneffe et al., 2010). We obtain 72.8% accuracy, which outperforms previous results ($\sim$60%) on this corpus and highlights the quality of the scales extracted, providing further support that the continuous space word representations are meaningful.

1 Introduction

There has recently been a surge of interest for deep learning in natural language processing. In particular, neural network language models (NNLMs) have been used to learn distributional word vectors (Bengio et al., 2003; Schwenk, 2007; Mikolov et al., 2010): the models jointly learn an embedding of words into an n-dimensional feature space. One of the advantages put forth for such distributed representations compared to traditional n-gram models is that similar words are likely to have similar vector representations in a continuous space model, whereas the discrete units of an n-gram model do not exhibit any inherent relation with one another. It has been shown that the continuous space representations improve performance in a variety of NLP tasks, such as POS tagging, semantic role labeling, named entity resolution, parsing (Collobert and Weston, 2008; Turian et al., 2010; Huang et al., 2012).

Mikolov et al. (2013) show that there are some syntactic and semantic regularities in the word representations learned, such as the singular/plural relation (the difference of singular and plural word vectors are equivalent: *apple* $-$ *apples* $\approx$ *car* $-$ *cars* $\approx$ *family* $-$ *families*) or the gender relation (a masculine noun can be transformed into the feminine form: *king* $-$ *man* $+$ *woman* $\approx$ *queen*).

We extend Mikolov et al. (2013)'s approach and explore further the interpretation of the vector space. We show that the word vectors learned by NNLMs are meaningful: we can extract scalar relationships between adjectives (e.g., *bad* $<$ *okay* $<$ *good* $<$ *excellent*), which can not only serve to build a sentiment lexicon but also be used for inference. To evaluate the quality of the scalar relationships learned by NNLMs, we use the indirect *yes/no* question answer pairs (IQAP) from (de Marneffe et al., 2010), where scales between adjectives are needed to infer a *yes/no* answer from a reply without explicit *yes* or *no* such as *Was the movie good? It was excellent.* Our method reaches 72.8% accuracy, which is the best result reported so far when scales are used.

2 Previous work

We use the continuous word representations from (Mikolov et al., 2011), extracted from a recurrent neural network language model (RNNLM), whose

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1625–1630,
Seattle, Washington, USA, 18-21 October 2013.

three-layer architecture is represented in Figure 1.

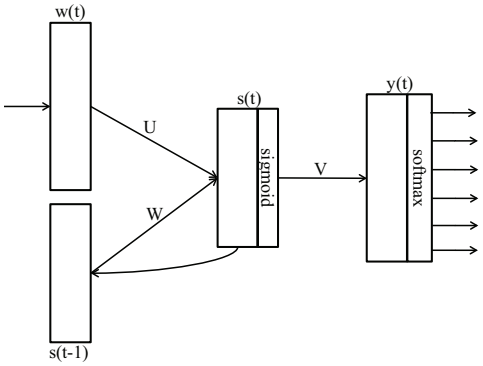

Figure 1: The architecture of the RNNLM.

In the input layer, $w(t)$ is the input word represented by 1-of-N coding at time t when the vocabulary size is N. When there are M nodes in the hidden layer, the number of connections between the input layer and the hidden layer is NM and the connections can be represented by a matrix U.

The hidden layer is also connected recurrently to the context $s(t-1)$ at time $t-1$ ($s(0)$ is initialized with small values like 0.1). The connections between the previous context and the hidden layer are represented by a matrix W. The dimensionality of the word representations is controlled by the size of W. The output of the hidden layer is $s(t) = f(Uw(t) + Ws(t-1))$, where f is a sigmoid function.

Because the inputs of the hidden layer consist of the word $w(t)$ and the previous hidden layer output $s(t-1)$, the current context of the RNN is influenced by the current word and the previous context. Therefore, we can regard that the continuous representations from the RNNLM exploit the context implicitly considering the word sequence information (Mikolov et al., 2010).

V is a N by M matrix representing the connections between the hidden layer and the output layer. The final output is $y(t) = g(Vs(t))$, where g is a softmax function to represent the probability distribution over all the words in the vocabulary.

When the RNN is trained by the back propagation algorithm, we can regard the ith column vector of U as the continuous representation of the ith word in the vocabulary since the column was adjusted correspondingly to the ith element of $w(t)$. Because the $s(t)$ outputs of two input words will be similar when they have similar $s(t-1)$ values, the corresponding column vectors of the words will also be similar.

Mikolov et al. (2013) showed that constant vector offsets of word pairs can represent linguistic regularities. Let w_a and w_b denote the vectors for the words a and b, respectively. Then the vector offset of the word pair is $w_a - w_b$. If a and b are syntactically or semantically related, the vector offset can be interpreted as a transformation of the syntactic form or the meaning. The offset can also be added to another word vector c. The word vector nearest to $w_a - w_b + w_c$ would be related to word c with the syntactic or semantic difference as the difference between a and b, as it is the case for the *king*, *man*, and *woman* example, where *king* $-$ *man* $+$ *woman* would approximately represent *king* with feminine gender (i.e., *queen*). They also tried to use the continuous representations generated by Latent Semantic Analysis (LSA) (Landauer et al., 1998). However, the results using LSA were worse because LSA is a bag-of-words model, in which it is difficult to exploit word sequence information as the context.

For all the experiments in this paper, we use the precomputed word representations generated by the RNNLM from (Mikolov et al., 2013). Their RNN is trained with 320M words from the Broadcast News data (the vocabulary size is 82,390 words), and we used word vectors with a dimensionality of 1,600 (the highest dimensionality provided).[1] We standardized the dataset so that the mean and the variance of the representations are 0 and 1, respectively.[2]

3 Deriving adjectival scales

Here we explore further the interpretation of word vectors. Assuming that the transformation of form or meaning represented by the vector offset is linear, an intermediate vector between two word vectors would represent some "middle" form or meaning. For example, given the positive and superlative forms of an adjective (e.g., *good* and *best*), we expect that the word representation in the middle of

[1] We also experimented with smaller dimensions, but consistent with the analyses in (Mikolov et al., 2013), the highest dimensionality gave better results.

Input words	Words with highest cosine similarities to the mean vector			
good:best	**better: 0.738**	strong: 0.644	normal: 0.619	less: 0.609
bad:worst	terrible: 0.726	great: 0.678	horrible: 0.674	**worse: 0.665**
slow:slowest	**slower: 0.637**	sluggish: 0.614	steady: 0.558	brisk: 0.543
fast:fastest	**faster: 0.645**	slower: 0.602	quicker: 0.542	harder: 0.518

Table 1: Words with corresponding vectors closest to the mean of positive:superlative word vectors.

First word (-)		1st quarter		Half		3rd quarter		Second word (+)	
furious	1	angry	0.632	unhappy	0.640	pleased	0.516	**happy**	1
furious	1	angry	0.615	tense	0.465	quiet	0.560	**calm**	1
terrible	1	horrible	0.783	incredible	0.714	wonderful	0.772	**terrific**	1
cold	1	mild	0.348	warm	0.517	sticky	0.424	**hot**	1
ugly	1	nasty	0.672	wacky	0.645	lovely	0.715	**gorgeous**	1

Table 2: Adjectival scales extracted from the RNN: each row represent a scale, and for each intermediate point the closest word in term of cosine similarity is given.

them will correspond to the comparative form (i.e., *better*). To extract the "middle" word between two word vectors w_a and w_b, we take the vector offset $w_a - w_b$ divided by 2, and add w_b: $w_b + (w_a - w_b)/2$. The result corresponds to the midpoint between the two words. Then, we find the word whose cosine similarity to the midpoint is the highest.

Table 1 gives some positive:superlative pairs and the top four closest words to the mean vectors, where the distance metric is the cosine similarity. The correct comparative forms (in bold) are quite close to the mean vector of the positive and superlative form vectors, highlighting the fact that there is some meaningful interpretation of the vector space: the word vectors are constituting a scale.

We can extend this idea of extracting an ordering between two words. For any two semantically related adjectives, intermediate vectors extracted along the line connecting the first and second word vectors should exhibit scalar properties, as seen above for the positive-comparative-superlative triplets. If we take two antonyms (*furious* and *happy*), words extracted at the intermediate points x_1, x_2 and x_3 should correspond to words lying on a scale of happiness (from "less furious" to "more happy"), as illustrated in Figure 2. Table 2 gives some adjectival scales that we extracted from the continuous word space, using antonym pairs. We picked three points with equal intervals on the line from the first to the second word (1st quarter, half and 3rd quarter). The extracted scales look quite reasonable: the words form a continuum from more negative to more positive meanings.

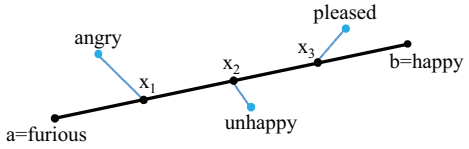

Figure 2: An example of vectors with the highest cosine similarity to intermediate points on the line between *furious* and *happy*.

Tables 1 and 2 demonstrate that the word vector space is interpretable: intermediate vectors between two word vectors represent a semantic continuum.

4 Evaluation: Indirect answers to *yes/no* questions

To evaluate the quality of the adjective scales learned by the neural network approach, we use the corpus of indirect answers to *yes/no* questions created by (de Marneffe et al., 2010), which consists of question-answer pairs involving gradable modifiers to test scalar implicatures. We focus on the 125 pairs in the corpus where both the question and answer contain an adjective: e.g., *Is Obama qualified? I think he's young.*[3] Each question-answer pair has

[3]These 125 pairs correspond to the 'Other adjective' category in (de Marneffe et al., 2010).

been annotated via Mechanical Turk for whether the answer conveys *yes*, *no* or *uncertain*.

4.1 Method

The previous section showed that we can draw a line passing through an adjective and its antonym and that the words extracted along the line are roughly semantically ordered. To infer a *yes* or *no* answer in the case of the IQAP corpus, we use the following approach illustrated with the *Obama* example above (Figure 3). Using WordNet 3.1 (Fellbaum, 1998), we look for an antonym of the adjective in the question *qualified*: *unqualified* is retrieved. Since the scales extracted are only roughly ordered, to infer *yes* when the question and answer words are very close, we set the decision boundary perpendicular to the line connecting the two words and passing through the midpoint of the line.

Since the answer word is *young*, we check whether *young* is in the area including *qualified* or in the other area. We infer a *yes* answer in the former case, and a *no* answer in the latter case. If *young* is on the boundary, we infer *uncertain*. If a sentence contains a negation (e.g., *Are you stressed? I am not peaceful.*), we compute the scale for *stressed-peaceful* and then reverse the answer obtained, similarly to what is done in (de Marneffe et al., 2010).

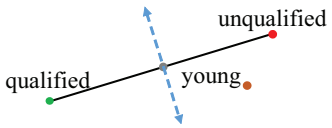

Figure 3: An example of the decision boundary given *qualified* as the question and *young* as the answer.

Since a word can have multiple senses and different antonyms for the senses, it is important to select the most appropriate antonym to build a more accurate decision boundary. We consider all antonyms across senses[4] and select the antonym that is most collinear with the question and the answer. For the word vectors of the question w_q, the ith antonym w_{ant_i}, and the answer w_a, we select ant_i where $argmax_{ant_i}|cos(w_q - w_a, w_q - w_{ant_i})|$. Figure 4 schematically shows antonym selection when the question is *good* and the answer is *excellent*: *bad* and *evil* are the antonym candidates of *good*. Because the absolute cosine similarity of *good-excellent* to *good-bad* is higher than to *good-evil*, we choose *bad* as the antonym in this case.

[4]Antonyms in WordNet can be directly opposed to a given word or indirectly opposed via other words. When there are direct antonyms for the question word, we only consider those.

	Acc	Macro P	Macro R	Macro F1
de Marneffe (2010)	60.00	59.72	59.40	59.56
Mohtarami (2011)	–	62.23	60.88	61.55
RNN model	**72.80**	**69.78**	**71.39**	**70.58**

Table 3: Score (%) comparison on the 125 scalar adjective pairs in the IQAP corpus.

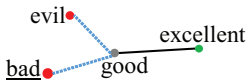

Figure 4: An example of antonym selection.

4.2 Results and discussion

Table 3 compares our results with previous ones where adjectival scales are considered: de Marneffe et al. (2010) propose an unsupervised approach where scales are learned from distributional information in a Web corpus; Mohtarami et al. (2011)'s model is similar to ours but uses word representations obtained by LSA and a word sense disambiguation system (Zhong and Ng, 2010) to choose antonyms. To compare with Mohtarami et al. (2011), we use macro-averaged precision and recall for *yes* and *no*. For the given metrics, our model significantly outperforms the previous ones ($p < 0.05$, McNemar's test).

Mohtarami et al. (2011) present higher numbers obtained by replacing the answer words with their synonyms in WordNet. However, that approach fails to capture orderings. Two words of different degree are often regarded as synonyms: even though *furious* means extremely angry, *furious* and *angry* are synonyms in WordNet. Therefore using synonyms, the system will output the same answer irrespective of the order in the pair. Mohtarami et al. (2012) also presented results on the interpretation of indirect questions on the IQAP corpus, but their method

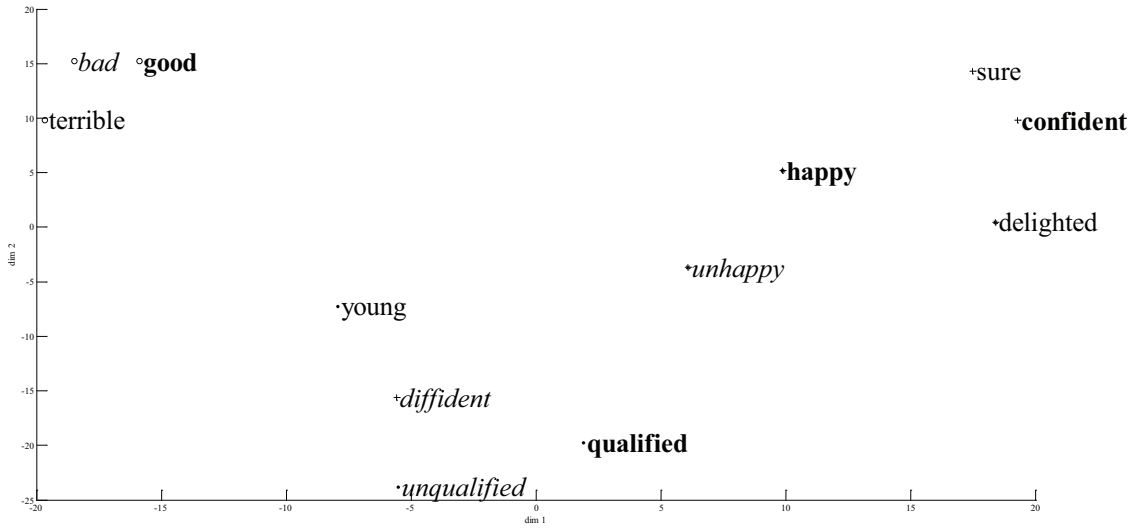

Figure 5: Question words (bold), their antonyms (italic), and answer words (normal) of four pairs from the IQAP dataset. The words are visualized by MDS.

did not involve learning or using scalar implicatures.

Figure 5 gives a qualitative picture: the question words, antonyms and answer words for four of the IQAP pairs are visualized in 2D space by multi-dimensional scaling (MDS). Note that MDS introduces some distortion in the lower dimensions. Bullet markers correspond to words in the same pair. Question words, antonyms, and answer words are displayed by bold, italic, and normal fonts, respectively. In the *Obama* example previously mentioned (*Is Obama qualified? I think he's young.*), the question word is *qualified* and the answer word is *young*. In Figure 5, *qualified* is around (2,-20) while its antonym *unqualified* is around (-6,-24). Since *young* is around (-7,-8), we infer that *young* is semantically closer to *unqualified* which corroborates with the Turkers' intuitions in this case. (1), (2) and (3) give the other examples displayed in Figure 5.

(1) A: Do you think she'd be *happy* with this book?
B: I think she'd be *delighted* by it.

(2) A: Do you think that's a *good* idea?
B: It's a *terrible* idea.

(3) A: The president is promising support for Americans who have suffered from this hurricane. Are you *confident* you are going to be getting that?
B: I'm not so *sure* about my insurance company.

In (1), *delighted* is stronger than *happy*, leading to a *yes* answer, whereas in (2), *terrible* is weaker than *good* leading to a *no* answer. In (3), the presence of a negation will reverse the answer inferred, leading to *no*.

5 Conclusion

In this paper we give further evidence that the relationships in the continuous vector space learned by recurrent neural network models are interpretable. We show that using vector offsets, we can successfully learn adjectival scales, which are useful for scalar implicatures, as demonstrated by the high results we obtain on the IQAP corpus.

Abstract

Semantic word spaces have been very useful but cannot express the meaning of longer phrases in a principled way. Further progress towards understanding compositionality in tasks such as sentiment detection requires richer supervised training and evaluation resources and more powerful models of composition. To remedy this, we introduce a Sentiment Treebank. It includes fine grained sentiment labels for 215,154 phrases in the parse trees of 11,855 sentences and presents new challenges for sentiment compositionality. To address them, we introduce the Recursive Neural Tensor Network. When trained on the new treebank, this model outperforms all previous methods on several metrics. It pushes the state of the art in single sentence positive/negative classification from 80% up to 85.4%. The accuracy of predicting fine-grained sentiment labels for all phrases reaches 80.7%, an improvement of 9.7% over bag of features baselines. Lastly, it is the only model that can accurately capture the effects of negation and its scope at various tree levels for both positive and negative phrases.

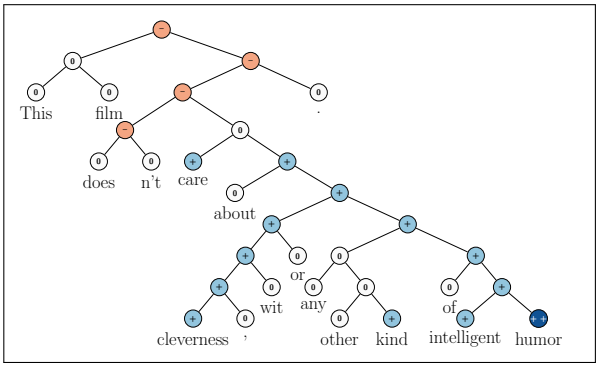

Figure 1: Example of the Recursive Neural Tensor Network accurately predicting 5 sentiment classes, very negative to very positive (– –, –, 0, +, + +), at every node of a parse tree and capturing the negation and its scope in this sentence.

1 Introduction

Semantic vector spaces for single words have been widely used as features (Turney and Pantel, 2010). Because they cannot capture the meaning of longer phrases properly, compositionality in semantic vector spaces has recently received a lot of attention (Mitchell and Lapata, 2010; Socher et al., 2010; Zanzotto et al., 2010; Yessenalina and Cardie, 2011; Socher et al., 2012; Grefenstette et al., 2013). However, progress is held back by the current lack of large and labeled compositionality resources and models to accurately capture the underlying phenomena presented in such data. To address this need, we introduce the Stanford Sentiment Treebank and a powerful Recursive Neural Tensor Network that can accurately predict the compositional semantic effects present in this new corpus.

The *Stanford Sentiment Treebank* is the first corpus with fully labeled parse trees that allows for a complete analysis of the compositional effects of sentiment in language. The corpus is based on the dataset introduced by Pang and Lee (2005) and consists of 11,855 single sentences extracted from movie reviews. It was parsed with the Stanford parser (Klein and Manning, 2003) and includes a total of 215,154 unique phrases from those parse trees, each annotated by 3 human judges. This new dataset allows us to analyze the intricacies of sentiment and to capture complex linguistic phenomena. Fig. 1 shows one of the many examples with clear compositional structure. The granularity and size of

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1631–1642,
Seattle, Washington, USA, 18-21 October 2013.

this dataset will enable the community to train compositional models that are based on supervised and structured machine learning techniques. While there are several datasets with document and chunk labels available, there is a need to better capture sentiment from short comments, such as Twitter data, which provide less overall signal per document.

In order to capture the compositional effects with higher accuracy, we propose a new model called the Recursive Neural Tensor Network (RNTN). Recursive Neural Tensor Networks take as input phrases of any length. They represent a phrase through word vectors and a parse tree and then compute vectors for higher nodes in the tree using the same tensor-based composition function. We compare to several supervised, compositional models such as standard recursive neural networks (RNN) (Socher et al., 2011b), matrix-vector RNNs (Socher et al., 2012), and baselines such as neural networks that ignore word order, Naive Bayes (NB), bi-gram NB and SVM. All models get a significant boost when trained with the new dataset but the RNTN obtains the highest performance with 80.7% accuracy when predicting fine-grained sentiment for all nodes. Lastly, we use a test set of positive and negative sentences and their respective negations to show that, unlike bag of words models, the RNTN accurately captures the sentiment change and scope of negation. RNTNs also learn that sentiment of phrases following the contrastive conjunction 'but' dominates.

The complete training and testing code, a live demo and the Stanford Sentiment Treebank dataset are available at `http://nlp.stanford.edu/sentiment`.

2 Related Work

This work is connected to five different areas of NLP research, each with their own large amount of related work to which we cannot do full justice given space constraints.

Semantic Vector Spaces. The dominant approach in semantic vector spaces uses distributional similarities of single words. Often, co-occurrence statistics of a word and its context are used to describe each word (Turney and Pantel, 2010; Baroni and Lenci, 2010), such as tf-idf. Variants of this idea use more complex frequencies such as how often a word appears in a certain syntactic context (Pado and Lapata, 2007; Erk and Padó, 2008). However, distributional vectors often do not properly capture the differences in antonyms since those often have similar contexts. One possibility to remedy this is to use neural word vectors (Bengio et al., 2003). These vectors can be trained in an unsupervised fashion to capture distributional similarities (Collobert and Weston, 2008; Huang et al., 2012) but then also be fine-tuned and trained to specific tasks such as sentiment detection (Socher et al., 2011b). The models in this paper can use purely supervised word representations learned entirely on the new corpus.

Compositionality in Vector Spaces. Most of the compositionality algorithms and related datasets capture two word compositions. Mitchell and Lapata (2010) use e.g. two-word phrases and analyze similarities computed by vector addition, multiplication and others. Some related models such as holographic reduced representations (Plate, 1995), quantum logic (Widdows, 2008), discrete-continuous models (Clark and Pulman, 2007) and the recent compositional matrix space model (Rudolph and Giesbrecht, 2010) have not been experimentally validated on larger corpora. Yessenalina and Cardie (2011) compute matrix representations for longer phrases and define composition as matrix multiplication, and also evaluate on sentiment. Grefenstette and Sadrzadeh (2011) analyze subject-verb-object triplets and find a matrix-based categorical model to correlate well with human judgments. We compare to the recent line of work on supervised compositional models. In particular we will describe and experimentally compare our new RNTN model to recursive neural networks (RNN) (Socher et al., 2011b) and matrix-vector RNNs (Socher et al., 2012) both of which have been applied to bag of words sentiment corpora.

Logical Form. A related field that tackles compositionality from a very different angle is that of trying to map sentences to logical form (Zettlemoyer and Collins, 2005). While these models are highly interesting and work well in closed domains and on discrete sets, they could only capture sentiment distributions using separate mechanisms beyond the currently used logical forms.

Deep Learning. Apart from the above mentioned

work on RNNs, several compositionality ideas related to neural networks have been discussed by Bottou (2011) and Hinton (1990) and first models such as Recursive Auto-associative memories been experimented with by Pollack (1990). The idea to relate inputs through three way interactions, parameterized by a tensor have been proposed for relation classification (Sutskever et al., 2009; Jenatton et al., 2012), extending Restricted Boltzmann machines (Ranzato and Hinton, 2010) and as a special layer for speech recognition (Yu et al., 2012).

Sentiment Analysis. Apart from the above-mentioned work, most approaches in sentiment analysis use bag of words representations (Pang and Lee, 2008). Snyder and Barzilay (2007) analyzed larger reviews in more detail by analyzing the sentiment of multiple aspects of restaurants, such as food or atmosphere. Several works have explored sentiment compositionality through careful engineering of features or polarity shifting rules on syntactic structures (Polanyi and Zaenen, 2006; Moilanen and Pulman, 2007; Rentoumi et al., 2010; Nakagawa et al., 2010).

3 Stanford Sentiment Treebank

Bag of words classifiers can work well in longer documents by relying on a few words with strong sentiment like 'awesome' or 'exhilarating.' However, sentiment accuracies even for binary positive/negative classification for single sentences has not exceeded 80% for several years. For the more difficult multiclass case including a neutral class, accuracy is often below 60% for short messages on Twitter (Wang et al., 2012). From a linguistic or cognitive standpoint, ignoring word order in the treatment of a semantic task is not plausible, and, as we will show, it cannot accurately classify hard examples of negation. Correctly predicting these hard cases is necessary to further improve performance.

In this section we will introduce and provide some analyses for the new *Sentiment Treebank* which includes labels for every syntactically plausible phrase in thousands of sentences, allowing us to train and evaluate compositional models.

We consider the corpus of movie review excerpts from the `rottentomatoes.com` website originally collected and published by Pang and Lee (2005). The original dataset includes 10,662 sentences, half of which were considered positive and the other half negative. Each label is extracted from a longer movie review and reflects the writer's overall intention for this review. The normalized, lowercased text is first used to recover, from the original website, the text with capitalization. Remaining HTML tags and sentences that are not in English are deleted. The Stanford Parser (Klein and Manning, 2003) is used to parses all 10,662 sentences. In approximately 1,100 cases it splits the snippet into multiple sentences. We then used Amazon Mechanical Turk to label the resulting 215,154 phrases. Fig. 3 shows the interface annotators saw. The slider has 25 different values and is initially set to neutral. The phrases in each hit are randomly sampled from the set of all phrases in order to prevent labels being influenced by what follows. For more details on the dataset collection, see supplementary material.

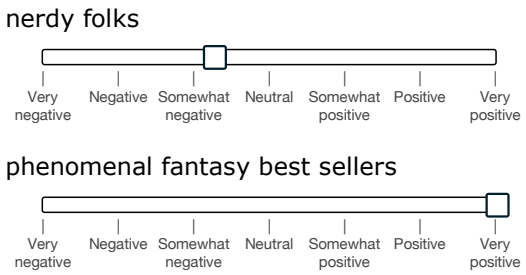

Figure 3: The labeling interface. Random phrases were shown and annotators had a slider for selecting the sentiment and its degree.

Fig. 2 shows the normalized label distributions at each n-gram length. Starting at length 20, the majority are full sentences. One of the findings from labeling sentences based on *reader's perception* is that many of them could be considered neutral. We also notice that stronger sentiment often builds up in longer phrases and the majority of the shorter phrases are neutral. Another observation is that most annotators moved the slider to one of the five positions: negative, somewhat negative, neutral, positive or somewhat positive. The extreme values were rarely used and the slider was not often left in between the ticks. Hence, *even a 5-class classification into these categories captures the main variability of the labels*. We will name this *fine-grained sentiment* classification and our main experiment will be to recover these five labels for phrases of all lengths.

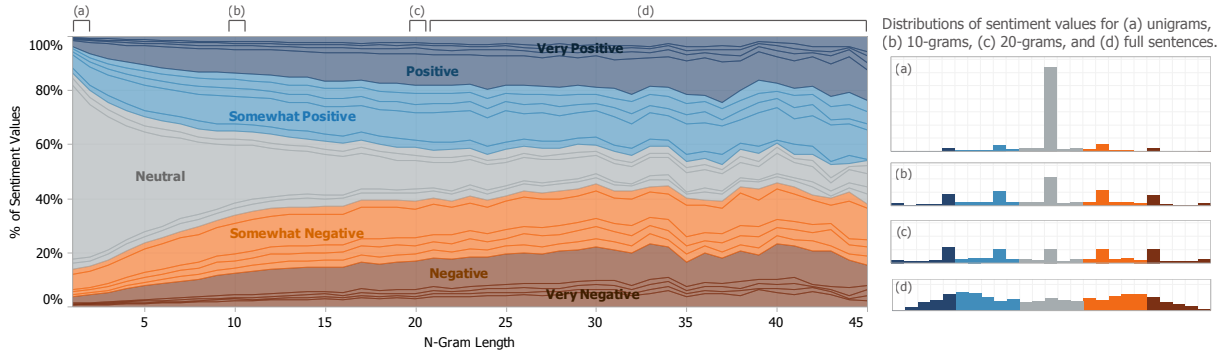

Figure 2: Normalized histogram of sentiment annotations at each n-gram length. Many shorter n-grams are neutral; longer phrases are well distributed. Few annotators used slider positions between ticks or the extreme values. Hence the two strongest labels and intermediate tick positions are merged into 5 classes.

4 Recursive Neural Models

The models in this section compute compositional vector representations for phrases of variable length and syntactic type. These representations will then be used as features to classify each phrase. Fig. 4 displays this approach. When an n-gram is given to the compositional models, it is parsed into a binary tree and each leaf node, corresponding to a word, is represented as a vector. Recursive neural models will then compute parent vectors in a bottom up fashion using different types of compositionality functions g. The parent vectors are again given as features to a classifier. For ease of exposition, we will use the tri-gram in this figure to explain all models.

We first describe the operations that the below recursive neural models have in common: word vector representations and classification. This is followed by descriptions of two previous RNN models and our RNTN.

Each word is represented as a d-dimensional vector. We initialize all word vectors by randomly sampling each value from a uniform distribution: $\mathcal{U}(-r, r)$, where $r = 0.0001$. All the word vectors are stacked in the word embedding matrix $L \in \mathbb{R}^{d \times |V|}$, where $|V|$ is the size of the vocabulary. Initially the word vectors will be random but the L matrix is seen as a parameter that is trained jointly with the compositionality models.

We can use the word vectors immediately as parameters to optimize and as feature inputs to a softmax classifier. For classification into five classes, we compute the posterior probability over

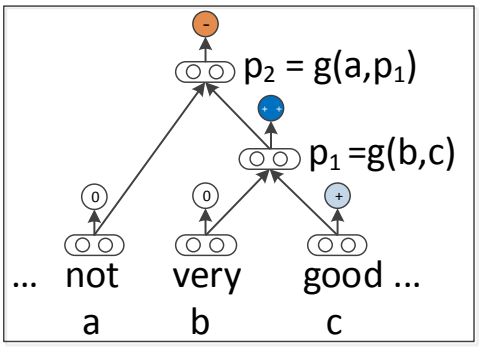

Figure 4: Approach of Recursive Neural Network models for sentiment: Compute parent vectors in a bottom up fashion using a compositionality function g and use node vectors as features for a classifier at that node. This function varies for the different models.

labels given the word vector via:

$$y^a = \text{softmax}(W_s a), \tag{1}$$

where $W_s \in \mathbb{R}^{5 \times d}$ is the sentiment classification matrix. For the given tri-gram, this is repeated for vectors b and c. The main task of and difference between the models will be to compute the hidden vectors $p_i \in \mathbb{R}^d$ in a bottom up fashion.

4.1 RNN: Recursive Neural Network

The simplest member of this family of neural network models is the standard recursive neural network (Goller and Küchler, 1996; Socher et al., 2011a). First, it is determined which parent already has all its children computed. In the above tree example, p_1 has its two children's vectors since both are words. RNNs use the following equations to compute the parent vectors:

$$p_1 = f\left(W \begin{bmatrix} b \\ c \end{bmatrix}\right), p_2 = f\left(W \begin{bmatrix} a \\ p_1 \end{bmatrix}\right),$$

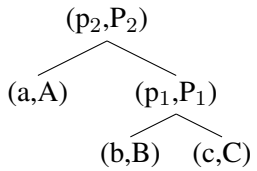
where $f = \tanh$ is a standard element-wise nonlinearity, $W \in \mathbb{R}^{d \times 2d}$ is the main parameter to learn and we omit the bias for simplicity. The bias can be added as an extra column to W if an additional 1 is added to the concatenation of the input vectors. The parent vectors must be of the same dimensionality to be recursively compatible and be used as input to the next composition. Each parent vector p_i, is given to the same $\mathrm{softmax}$ classifier of Eq. 1 to compute its label probabilities.

This model uses the same compositionality function as the recursive autoencoder (Socher et al., 2011b) and recursive auto-associate memories (Pollack, 1990). The only difference to the former model is that we fix the tree structures and ignore the reconstruction loss. In initial experiments, we found that with the additional amount of training data, the reconstruction loss at each node is not necessary to obtain high performance.

4.2 MV-RNN: Matrix-Vector RNN

The MV-RNN is linguistically motivated in that most of the parameters are associated with words and each composition function that computes vectors for longer phrases depends on the actual words being combined. The main idea of the MV-RNN (Socher et al., 2012) is to represent every word and longer phrase in a parse tree as both a vector and a matrix. When two constituents are combined the matrix of one is multiplied with the vector of the other and vice versa. Hence, the compositional function is parameterized by the words that participate in it.

Each word's matrix is initialized as a $d \times d$ identity matrix, plus a small amount of Gaussian noise. Similar to the random word vectors, the parameters of these matrices will be trained to minimize the classification error at each node. For this model, each n-gram is represented as a list of (vector,matrix) pairs, together with the parse tree. For the tree with (vector,matrix) nodes:



the MV-RNN computes the first parent vector and its matrix via two equations:

$$p_1 = f\left(W \begin{bmatrix} Cb \\ Bc \end{bmatrix}\right), P_1 = f\left(W_M \begin{bmatrix} B \\ C \end{bmatrix}\right),$$

where $W_M \in \mathbb{R}^{d \times 2d}$ and the result is again a $d \times d$ matrix. Similarly, the second parent node is computed using the previously computed (vector,matrix) pair (p_1, P_1) as well as (a, A). The vectors are used for classifying each phrase using the same $\mathrm{softmax}$ classifier as in Eq. 1.

4.3 RNTN:Recursive Neural Tensor Network

One problem with the MV-RNN is that the number of parameters becomes very large and depends on the size of the vocabulary. It would be cognitively more plausible if there was a single powerful composition function with a fixed number of parameters. The standard RNN is a good candidate for such a function. However, in the standard RNN, the input vectors only implicitly interact through the nonlinearity (squashing) function. A more direct, possibly multiplicative, interaction would allow the model to have greater interactions between the input vectors.

Motivated by these ideas we ask the question: Can a single, more powerful composition function perform better and compose aggregate meaning from smaller constituents more accurately than many input specific ones? In order to answer this question, we propose a new model called the Recursive Neural Tensor Network (RNTN). The main idea is to use the same, tensor-based composition function for all nodes.

Fig. 5 shows a single tensor layer. We define the output of a tensor product $h \in \mathbb{R}^d$ via the following vectorized notation and the equivalent but more detailed notation for each slice $V^{[i]} \in \mathbb{R}^{d \times d}$:

$$h = \begin{bmatrix} b \\ c \end{bmatrix}^T V^{[1:d]} \begin{bmatrix} b \\ c \end{bmatrix}; h_i = \begin{bmatrix} b \\ c \end{bmatrix}^T V^{[i]} \begin{bmatrix} b \\ c \end{bmatrix}.$$

where $V^{[1:d]} \in \mathbb{R}^{2d \times 2d \times d}$ is the tensor that defines multiple bilinear forms.

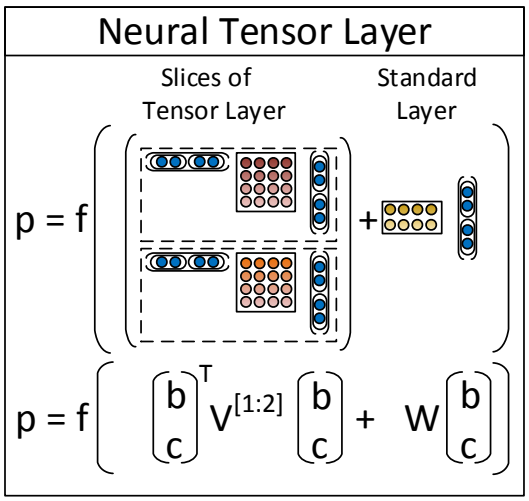


Figure 5: A single layer of the Recursive Neural Tensor Network. Each dashed box represents one of d-many slices and can capture a type of influence a child can have on its parent.

The RNTN uses this definition for computing p_1:

$$p_1 = f\left(\begin{bmatrix} b \\ c \end{bmatrix}^T V^{[1:d]} \begin{bmatrix} b \\ c \end{bmatrix} + W \begin{bmatrix} b \\ c \end{bmatrix}\right),$$

where W is as defined in the previous models. The next parent vector p_2 in the tri-gram will be computed with the same weights:

$$p_2 = f\left(\begin{bmatrix} a \\ p_1 \end{bmatrix}^T V^{[1:d]} \begin{bmatrix} a \\ p_1 \end{bmatrix} + W \begin{bmatrix} a \\ p_1 \end{bmatrix}\right).$$

The main advantage over the previous RNN model, which is a special case of the RNTN when V is set to 0, is that the tensor can directly relate input vectors. Intuitively, we can interpret each slice of the tensor as capturing a specific type of composition.

An alternative to RNTNs would be to make the compositional function more powerful by adding a second neural network layer. However, initial experiments showed that it is hard to optimize this model and vector interactions are still more implicit than in the RNTN.

4.4 Tensor Backprop through Structure

We describe in this section how to train the RNTN model. As mentioned above, each node has a $\mathrm{softmax}$ classifier trained on its vector representation to predict a given ground truth or target vector t. We assume the target distribution vector at each node has a 0-1 encoding. If there are C classes, then it has length C and a 1 at the correct label. All other entries are 0.

We want to maximize the probability of the correct prediction, or minimize the cross-entropy error between the predicted distribution $y^i \in \mathbb{R}^{C\times 1}$ at node i and the target distribution $t^i \in \mathbb{R}^{C\times 1}$ at that node. This is equivalent (up to a constant) to minimizing the KL-divergence between the two distributions. The error as a function of the RNTN parameters $\theta = (V, W, W_s, L)$ for a sentence is:

$$E(\theta) = \sum_i \sum_j t_j^i \log y_j^i + \lambda \|\theta\|^2 \qquad (2)$$

The derivative for the weights of the $\mathrm{softmax}$ classifier are standard and simply sum up from each node's error. We define x^i to be the vector at node i (in the example trigram, the $x^i \in \mathbb{R}^{d\times 1}$'s are (a, b, c, p_1, p_2)). We skip the standard derivative for W_s. Each node backpropagates its error through to the recursively used weights V, W. Let $\delta^{i,s} \in \mathbb{R}^{d\times 1}$ be the $\mathrm{softmax}$ error vector at node i:

$$\delta^{i,s} = \left(W_s^T (y^i - t^i)\right) \otimes f'(x^i),$$

where $\otimes$ is the Hadamard product between the two vectors and f' is the element-wise derivative of f which in the standard case of using $f = \tanh$ can be computed using only $f(x^i)$.

The remaining derivatives can only be computed in a top-down fashion from the top node through the tree and into the leaf nodes. The full derivative for V and W is the sum of the derivatives at each of the nodes. We define the complete incoming error messages for a node i as $\delta^{i,com}$. The top node, in our case p_2, only received errors from the top node's $\mathrm{softmax}$. Hence, $\delta^{p_2,com} = \delta^{p_2,s}$ which we can use to obtain the standard backprop derivative for W (Goller and Küchler, 1996; Socher et al., 2010). For the derivative of each slice $k = 1, \ldots, d$, we get:

$$\frac{\partial E^{p_2}}{\partial V^{[k]}} = \delta_k^{p_2,com} \begin{bmatrix} a \\ p_1 \end{bmatrix} \begin{bmatrix} a \\ p_1 \end{bmatrix}^T,$$

where $\delta_k^{p_2,com}$ is just the k'th element of this vector. Now, we can compute the error message for the two

children of p_2:

$$\delta^{p_2,down} = \left(W^T\delta^{p_2,com} + S\right) \otimes f'\left(\begin{bmatrix} a \\ p_1 \end{bmatrix}\right),$$

where we define

$$S = \sum_{k=1}^{d} \delta_k^{p_2,com}\left(V^{[k]} + \left(V^{[k]}\right)^T\right)\begin{bmatrix} a \\ p_1 \end{bmatrix}$$

The children of p_2, will then each take half of this vector and add their own $\mathrm{softmax}$ error message for the complete δ. In particular, we have

$$\delta^{p_1,com} = \delta^{p_1,s} + \delta^{p_2,down}[d+1:2d],$$

where $\delta^{p_2,down}[d+1:2d]$ indicates that p_1 is the right child of p_2 and hence takes the 2nd half of the error, for the final word vector derivative for a, it will be $\delta^{p_2,down}[1:d]$.

The full derivative for slice $V^{[k]}$ for this trigram tree then is the sum at each node:

$$\frac{\partial E}{\partial V^{[k]}} = \frac{E^{p_2}}{\partial V^{[k]}} + \delta_k^{p_1,com}\begin{bmatrix} b \\ c \end{bmatrix}\begin{bmatrix} b \\ c \end{bmatrix}^T,$$

and similarly for W. For this nonconvex optimization we use AdaGrad (Duchi et al., 2011) which converges in less than 3 hours to a local optimum.

5 Experiments

We include two types of analyses. The first type includes several large quantitative evaluations on the test set. The second type focuses on two linguistic phenomena that are important in sentiment.

For all models, we use the dev set and cross-validate over regularization of the weights, word vector size as well as learning rate and minibatch size for AdaGrad. Optimal performance for all models was achieved at word vector sizes between 25 and 35 dimensions and batch sizes between 20 and 30. Performance decreased at larger or smaller vector and batch sizes. This indicates that the RNTN does not outperform the standard RNN due to simply having more parameters. The MV-RNN has orders of magnitudes more parameters than any other model due to the word matrices. The RNTN would usually achieve its best performance on the dev set after training for 3 - 5 hours. Initial experiments showed that the recursive models worked significantly worse (over 5% drop in accuracy) when no nonlinearity was used. We use $f = \tanh$ in all experiments.

Model	Fine-grained		Positive/Negative	
	All	Root	All	Root
NB	67.2	41.0	82.6	81.8
SVM	64.3	40.7	84.6	79.4
BiNB	71.0	41.9	82.7	83.1
VecAvg	73.3	32.7	85.1	80.1
RNN	79.0	43.2	86.1	82.4
MV-RNN	78.7	44.4	86.8	82.9
RNTN	**80.7**	**45.7**	**87.6**	**85.4**

Table 1: Accuracy for fine grained (5-class) and binary predictions at the sentence level (root) and for all nodes.

We compare to commonly used methods that use bag of words features with Naive Bayes and SVMs, as well as Naive Bayes with bag of bigram features. We abbreviate these with NB, SVM and biNB. We also compare to a model that averages neural word vectors and ignores word order (VecAvg).

The sentences in the treebank were split into a train (8544), dev (1101) and test splits (2210) and these splits are made available with the data release. We also analyze performance on only positive and negative sentences, ignoring the neutral class. This filters about 20% of the data with the three sets having 6920/872/1821 sentences.

5.1 Fine-grained Sentiment For All Phrases

The main novel experiment and evaluation metric analyze the accuracy of fine-grained sentiment classification for all phrases. Fig. 2 showed that a fine grained classification into 5 classes is a reasonable approximation to capture most of the data variation.

Fig. 6 shows the result on this new corpus. The RNTN gets the highest performance, followed by the MV-RNN and RNN. The recursive models work very well on shorter phrases, where negation and composition are important, while bag of features baselines perform well only with longer sentences. The RNTN accuracy upper bounds other models at most n-gram lengths.

Table 1 (left) shows the overall accuracy numbers for fine grained prediction at all phrase lengths and full sentences.

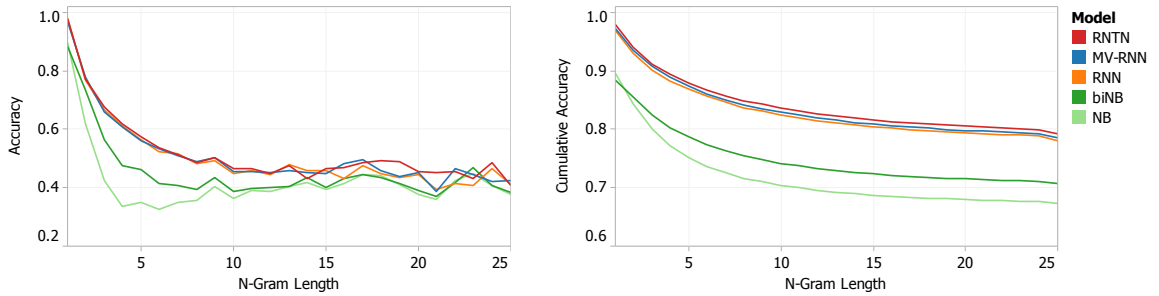

Figure 6: Accuracy curves for fine grained sentiment classification at each n-gram lengths. Left: Accuracy separately for each set of n-grams. Right: Cumulative accuracy of all $\leq n$-grams.

5.2 Full Sentence Binary Sentiment

This setup is comparable to previous work on the original rotten tomatoes dataset which only used full sentence labels and binary classification of positive/negative. Hence, these experiments show the improvement even baseline methods can achieve with the sentiment treebank. Table 1 shows results of this binary classification for both all phrases and for only full sentences. The previous state of the art was below 80% (Socher et al., 2012). With the coarse bag of words annotation for training, many of the more complex phenomena could not be captured, even by more powerful models. The combination of the new sentiment treebank and the RNTN pushes the state of the art on short phrases up to 85.4%.

5.3 Model Analysis: Contrastive Conjunction

In this section, we use a subset of the test set which includes only sentences with an 'X *but* Y' structure: A phrase X being followed by *but* which is followed by a phrase Y. The conjunction is interpreted as an argument for the second conjunct, with the first functioning concessively (Lakoff, 1971; Blakemore, 1989; Merin, 1999). Fig. 7 contains an example. We analyze a strict setting, where X and Y are phrases of different sentiment (including neutral). The example is counted as correct, if the classifications for both phrases X and Y are correct. Furthermore, the lowest node that dominates both of the word *but* and the node that spans Y also have to have the same correct sentiment. For the resulting 131 cases, the RNTN obtains an accuracy of 41% compared to MV-RNN (37), RNN (36) and biNB (27).

5.4 Model Analysis: High Level Negation

We investigate two types of negation. For each type, we use a separate dataset for evaluation.

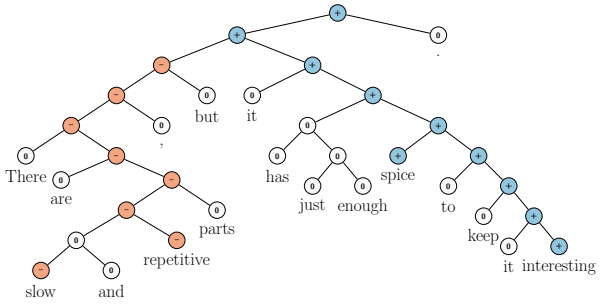

Figure 7: Example of correct prediction for contrastive conjunction X *but* Y.

Set 1: Negating Positive Sentences. The first set contains positive sentences and their negation. In this set, the negation changes the overall sentiment of a sentence from positive to negative. Hence, we compute accuracy in terms of correct sentiment reversal from positive to negative. Fig. 9 shows two examples of positive negation the RNTN correctly classified, even if negation is less obvious in the case of 'least'. Table 2 (left) gives the accuracies over 21 positive sentences and their negation for all models. The RNTN has the highest reversal accuracy, showing its ability to structurally learn negation of positive sentences. But what if the model simply makes phrases very negative when negation is in the sentence? The next experiments show that the model captures more than such a simplistic negation rule.

Set 2: Negating Negative Sentences. The second set contains negative sentences and their negation. When negative sentences are negated, the sentiment treebank shows that overall sentiment should become *less negative*, but not necessarily positive. For instance, 'The movie was terrible' is negative but the 'The movie was not terrible' says only that it was less bad than a terrible one, not that it was good (Horn, 1989; Israel, 2001). Hence, we evaluate ac-

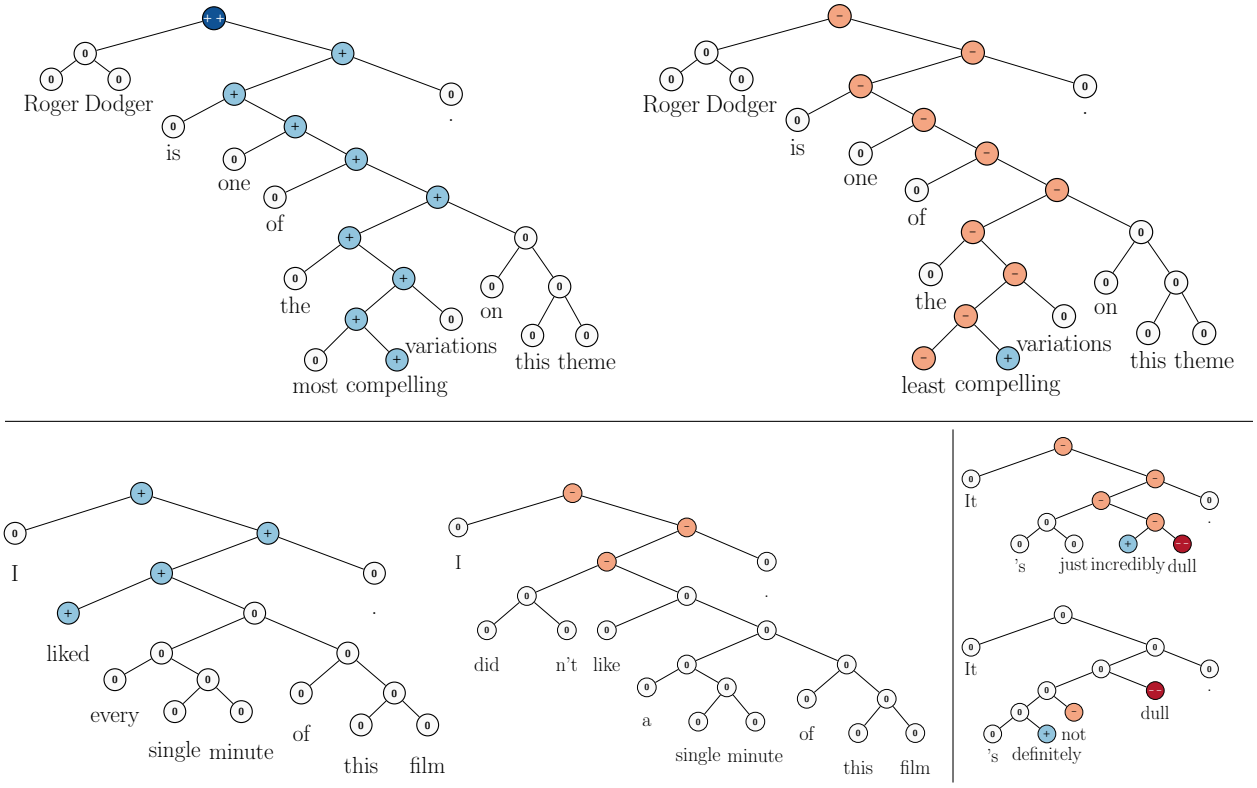

Figure 9: RNTN prediction of positive and negative (bottom right) sentences and their negation.

Model	Accuracy	
	Negated Positive	Negated Negative
biNB	19.0	27.3
RNN	33.3	45.5
MV-RNN	52.4	54.6
RNTN	**71.4**	**81.8**

Table 2: Accuracy of negation detection. Negated positive is measured as correct sentiment inversions. Negated negative is measured as increases in positive activations.

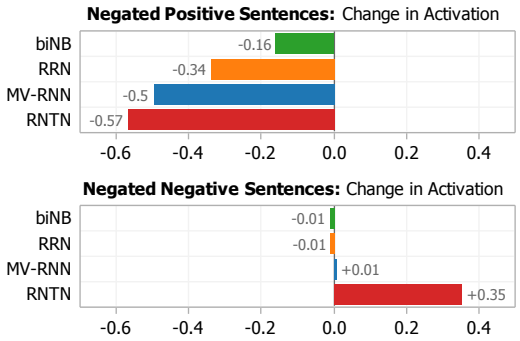

Figure 8: Change in activations for negations. Only the RNTN correctly captures both types. It decreases positive sentiment more when it is negated and learns that negating negative phrases (such as *not terrible*) should increase neutral and positive activations.

curacy in terms of how often each model was able to increase non-negative activation in the sentiment of the sentence. Table 2 (right) shows the accuracy. In over 81% of cases, the RNTN correctly increases the positive activations. Fig. 9 (bottom right) shows a typical case in which sentiment was made more positive by switching the main class from negative to neutral even though both *not* and *dull* were negative. Fig. 8 shows the changes in activation for both sets. Negative values indicate a decrease in average positive activation (for set 1) and positive values mean an increase in average positive activation (set 2). The RNTN has the largest shifts in the correct directions. Therefore we can conclude that the RNTN is best able to identify the effect of negations upon both positive and negative sentiment sentences.

n	Most positive n-grams	Most negative n-grams
1	engaging; best; powerful; love; beautiful	bad; dull; boring; fails; worst; stupid; painfully
2	excellent performances; A masterpiece; masterful film; wonderful movie; marvelous performances	worst movie; very bad; shapeless mess; worst thing; instantly forgettable; complete failure
3	an amazing performance; wonderful all-ages triumph; a wonderful movie; most visually stunning	for worst movie; A lousy movie; a complete failure; most painfully marginal; very bad sign
5	nicely acted and beautifully shot; gorgeous imagery, effective performances; the best of the year; a terrific American sports movie; refreshingly honest and ultimately touching	silliest and most incoherent movie; completely crass and forgettable movie; just another bad movie. A cumbersome and cliche-ridden movie; a humorless, disjointed mess
8	one of the best films of the year; A love for films shines through each frame; created a masterful piece of artistry right here; A masterful film from a master filmmaker,	A trashy, exploitative, thoroughly unpleasant experience ; this sloppy drama is an empty vessel.; quickly drags on becoming boring and predictable.; be the worst special-effects creation of the year

Table 3: Examples of n-grams for which the RNTN predicted the most positive and most negative responses.

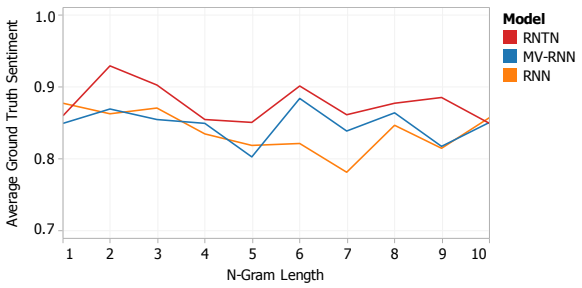

Figure 10: Average ground truth sentiment of top 10 most positive n-grams at various n. The RNTN correctly picks the more negative and positive examples.

5.5 Model Analysis: Most Positive and Negative Phrases

We queried the model for its predictions on what the most positive or negative n-grams are, measured as the highest activation of the most negative and most positive classes. Table 3 shows some phrases from the dev set which the RNTN selected for their strongest sentiment.

Due to lack of space we cannot compare top phrases of the other models but Fig. 10 shows that the RNTN selects more strongly positive phrases at most n-gram lengths compared to other models.

For this and the previous experiment, please find additional examples and descriptions in the supplementary material.

6 Conclusion

We introduced Recursive Neural Tensor Networks and the Stanford Sentiment Treebank. The combination of new model and data results in a system for single sentence sentiment detection that pushes state of the art by 5.4% for positive/negative sentence classification. Apart from this standard setting, the dataset also poses important new challenges and allows for new evaluation metrics. For instance, the RNTN obtains 80.7% accuracy on fine-grained sentiment prediction across all phrases and captures negation of different sentiments and scope more accurately than previous models.

Abstract

We propose a novel approach to sentiment analysis for a low resource setting. The intuition behind this work is that sentiment expressed towards an entity, *targeted sentiment*, may be viewed as a span of sentiment expressed across the entity. This representation allows us to model sentiment detection as a sequence tagging problem, jointly discovering people and organizations along with whether there is sentiment directed towards them. We compare performance in both Spanish and English on microblog data, using only a sentiment lexicon as an external resource. By leveraging linguistically-informed features within conditional random fields (CRFs) trained to minimize empirical risk, our best models in Spanish significantly outperform a strong baseline, and reach around 90% accuracy on the combined task of named entity recognition and sentiment prediction. Our models in English, trained on a much smaller dataset, are not yet statistically significant against their baselines.

1 Introduction

Sentiment analysis is a multi-faceted problem. Determining when a positive or negative sentiment is being expressed is a large part of the challenge, but identifying other attributes, such as the target of the sentiment, is also crucial if the ultimate goal is to pinpoint and extract opinions. Consider the examples below, all of which contain a positive sentiment:

(1) So happy that Kentucky lost to Tennessee!

(2) Kentucky versus Kansas I can hardly wait...

(3) Kentucky is the best alley-oop throwing team since Sherman Douglas' Syracuse squads!!

The entities in these examples are college basketball teams, and the events referred to are games. In (1), although there is a positive sentiment, the target of the sentiment is an event (Kentucky losing to Tennessee). However, from the positive sentiment toward this event, we can infer that the speaker has a negative sentiment toward Kentucky and a positive sentiment toward Tennessee. In (2), the positive sentiment is toward a future event, but we are not given enough information to infer a sentiment toward the mentioned entities. In (3), Kentucky is the direct target of the positive sentiment. We can also infer a positive sentiment toward Douglas's Syracuse teams, and even toward Douglas himself.

These examples illustrate the importance of the target when interpreting sentiment in context. If we are looking for sentiments toward Kentucky, for example, we would want to identify (1) as negative, (2) as neutral (no sentiment) and (3) as positive. However, if we are looking for sentiment toward Tennessee, we would want to identify (1) as positive, and (2) and (3) as neutral.

The expression of these and other kinds of sentiment can be understood as involving three items:

(1) An experiencer

(2) An attitude

(3) A target (optionally)

Research in sentiment analysis often focuses on (2), predicting overall sentiment polarity (Agarwal et al., 2011; Bora, 2012). Recent work has begun to combine (2) with (3), examining how to automatically predict the sentiment polarity expressed towards a target entity (Jiang et al., 2011; Chen et al., 2012) for a fixed set of targets. This topic-dependent sentiment classification requires that the target entity be

Seattle, Washington, USA, 18-21 October 2013.

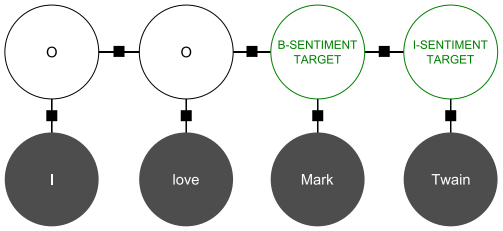

Figure 1: Sentiment expressed across an entity.

given, and returns statements expressing sentiment towards the given entity.

In this paper, we take a step towards open-domain, *targeted sentiment analysis* by investigating how to detect both the named entity and the sentiment expressed toward it. We observe that sentiment expressed towards a target entity may be possible to learn in a graphical model along the span of the entity itself: Similar to how named entity recognition (NER) learns labels along the span of each word in an entity name, sentiment may be expressed along the entity as well. A small example is shown in Figure 1. We focus on people and organizations (*volitional named entities*), which are the primary targets of sentiment in our microblog data (see Table 1).

Both NER and opinion expression extraction have achieved impressive results using conditional random fields (CRFs) (Lafferty et al., 2001) to define the conditional probability of entity categories (McCallum and Li, 2003; Choi et al., 2006; Yang and Cardie, 2013). We develop such models to jointly predict the NE and the sentiment expressed towards it using minimum risk training (Stoyanov and Eisner, 2012). We learn our models on informal Spanish and English language taken from the social network Twitter,[1] where the language variety makes NLP particularly challenging (see Figure 2).

Our ultimate goal is to develop models that will be useful for low resource languages, where a sentiment lexicon may be known or bootstrapped, but more sophisticated linguistic tools may not be readily available. We therefore do not rely on an external part-of-speech tagger or parser, which are often used for features in fine-grained sentiment analysis; such tools are not available in many languages, and if they are, are not usually adapted for noisy social media.

Instead, we use information from sentiment lexicons and some simple hand-written features, and otherwise use only features of the word that can be

@[user] le dijo erralo muy por lo bajo jaja un grande juancito grandes amigos mios
@[*user*] *he told him it was very on the dl haha a great juancito great friends of mine*

@[user] buenos días Profe!! Nos quedamos accidentados otra vez en la carretera vieja guarenas echando gasoil, estamos a la interperie
@[*user*] *good morning, Prof!! We were wrecked again on the old guarenas highway while getting diesel, we're out in the open*

Sin ánimo de ofender a los Militares, que realmente se merecen ese aumento y más. Pero, dónde queda la misma recompensa para Médicos.
I do not intend to offend the military in the slightest, they truly deserve the raise and more. However, I'm wondering whether doctors will ever receive a similar compensation.

Figure 2: Messages on Twitter use a wide range of formality, style, and errors, which makes extracting information particularly difficult. Examples from Spanish (screen names anonymized), with approximate translations in English.

extracted without supervision. These include features based on unsupervised word tags (Brown clusters) and a method that automatically syllabifies a word based on the orthography of the language. All tools and code used for this research are released with this paper.[2]

2 Related Work

As the scale of social media has grown, using sources such as Twitter to mine public sentiment has become increasingly promising. Commercial systems include Sentiment140[3] (products and brands) and tweetfeel[4] (suggests searching for popular movies, celebrities and companies).

The majority of academic research has focused on supervised classification of message sentiment irrespective of target (Barbosa and Feng, 2010; Pak and Paroubek, 2010; Bifet and Frank, 2010; Davidov et al., 2010; Kouloumpis et al., 2011; Agarwal et al., 2011). Large datasets are collected for this work by leveraging the sentiment inherent in emoticons (e.g., smilies and frownies) and/or select Twitter hashtags (e.g., #bestdayever, #fail), resulting in noisy collec-

[3] www.sentiment140.com

[4] www.tweetfeel.com

tions appropriate for initial exploration. Prior work includes: the use of a social network (Speriosu et al., 2011; Tan et al., 2011; Calais Guerra et al., 2011; Jiang et al., 2011; Li et al., 2012; Hu et al., 2013); user-adapted models based on collaborative online-learning (Li et al., 2010b); unsupervised, joint sentiment-topic modeling (Saif et al., 2012); tracking changing sentiment during debates (Diakopoulos and Shamma, 2010); and how orthographic conventions such as word-lengthening can be used to adapt a Twitter-specific sentiment lexicon (Brody and Diakopoulos, 2011).

Efforts in targeted sentiment (Bermingham and Smeaton, 2010; Jin and Ho, 2009; Li et al., 2010a; Jiang et al., 2011; Tan et al., 2011; Wang et al., 2011; Li et al., 2012; Chen et al., 2012), have mostly focused on topic-dependent analysis. In these approaches, messages are collected on a fixed set of topics/targets, such as products or sports teams, and sentiment is learned for the given set. In contrast, we aim to predict sentiment in tweets for any named person or organization. We refer to this task as *open domain targeted sentiment analysis*.

Within topic-dependent sentiment analysis, several approaches have explored applying CRFs or HMMs to extract sentiment and target words from text (Jin and Ho, 2009; Li et al., 2010a). In these approaches, opinion expressions are extracted, and polarity is annotated across the opinion expression. However, as noted by many researchers in sentiment, opinion orientation towards a specific target is often not equal to the orientation of a neighboring opinion expression; and opinion expressions in one context may not be opinion expressions in another (Kim and Hovy, 2006), making open domain approaches particularly challenging.

The above work by Jiang et al. (2011) is most similar to our own. They do not use joint learning, but they do incorporate a number of parse-based features designed to capture relationships between sentiment terms and topic references. In our work these relationships are captured by the CRF model, and we compare against their approach in Section 6.

Recent work by Yang and Cardie (2013) is similar in spirit to our own, where the identification of opinion holders, opinion targets, and opinion expressions is modeled as a sequence tagging problem using a CRF. However, similar to previous work applying CRFs to extract sentiment, Yang and Cardie use syntactic relations to connect an opinion target to an opinion expression. In contrast, we model the expression of sentiment polarity across the sentiment target itself, extracting both the sentiment target and the sentiment expressed towards it within the same span of words. This allows us to use surrounding context to determine sentiment polarity without identifying explicit opinion expressions or relying on a parser to help link expression to target.

Most work in targeted sentiment outside the microblogging domain has been in relation to product review mining (e.g., Yi et al. (2003), Hu and Liu (2004), Popescu and Etzioni (2005), Qiu et al. (2011)). Rather than identify named entities (NEs), this work seeks to identify products and their features mentioned in reviews, and classify these for sentiment. Recent work by Qui et al. jointly learns targets and opinion words, and Jakob and Gurevych (2010) use CRFs to extract the targets of opinions, but do not attempt to classify the sentiment toward these targets. To the best of our knowledge, this is the first work to approach targeted sentiment in a low resource setting and to jointly predict NEs and targeted sentiment.

3 Data

Twitter Collection We use the Spanish/English Twitter dataset of Etter et al. (2013) to train and test our models. Approximately 30,000 Spanish tweets and 10,000 English were labeled for named entities in BIO encoding: The start of an NE is labeled B-{NE} and the rest of the NE is labeled I-{NE}. The

NE	COUNT	NEUTRAL	POS	NEG

LOCATION	1405	100%	0%	0%
URL	1030	100%	0%	0%
TIME	535	70%	10%	20%
DATE	222	100%	0%	0%
MONEY	95	90%	0%	10%
PERCENT	81	80%	20%	0%
TELEPHONE	23	100%	0%	0%
EMAIL	8	100%	0%	0%

Table 1: Distribution of named entities in our Spanish Twitter corpus. Targeted sentiment percentages are based on expert annotations from a random sample of 10 (or all) of of each entity. Most entities are not sentiment targets (NEUTRAL). PERSON and ORGANIZATION are most frequent, and among the top recipients of sentiment.

full set of NE categories are shown in Table 1. For example, the sequence "Mark Twain" would be labeled B-PERSON, I-PERSON. We are interested in both PERSON and ORGANIZATION entities, which make up the majority of named entities in this data, and we evaluate these using the more general entity category VOLITIONAL. Removing retweets, 7,105 Spanish tweets contained a total of 9,870 volitional entities and 2,350 English tweets contained a total of 3,577 volitional entities.

Sentiment Lexicons We use two sentiment lexicon sources in each language. For English, we use the MPQA lexicon (Wilson et al., 2005), which identifies 12,296 manually and semi-automatically produced subjective terms along with their polarity. For the second lexicon, we use SentiWordNet 3.0 (Baccianella et al., 2010), which assigns positive and negative polarity scores to WordNet synsets. We use the majority polarity of all words with a subjectivity score above 0.5.

For Spanish, the first lexicon is obtained from Volkova et al. (2013), who automatically translated strongly subjective terms from the MPQA lexicon (Wilson et al., 2005) into Spanish. The resulting Spanish lexicon contains about 65K words. The second lexicon is available from Perez-Rosas et al. (2012). This contains approximately 1000 sentiment-bearing words collected leveraging manual resources and 2000 collected leveraging automatic resources.

Annotation To collect sentiment labels, we use crowdsourcing through Amazon's Mechanical Turk.[5] Annotators ("Turkers") were shown six tweets at a time, each with a single highlighted named entity. Turkers were instructed to (1) select the sentiment being expressed towards the entity (*positive*, *negative*, or *no sentiment*); and (2) rate their level of confidence in their selection. Following best practices on collecting language data with Mechanical Turk (Callison-Burch and Dredze, 2010), two controls were placed among each set of six tweets to screen out unreliable judgments. An example prompt is shown in Figure 3.

Each ⟨tweet, NE⟩ pair was shown to three Turkers, and those with majority consensus on sentiment polarity were extracted. Tweets without sentiment consensus on all NEs were removed. In Spanish, this yielded 6,658 unique ⟨tweet, NE⟩ pairs. In English, which is a smaller data set, this yielded 3,288 unique pairs. We split the data into folds for 10-fold cross-validation, developing on the data from one fold and reporting results for the remaining nine.

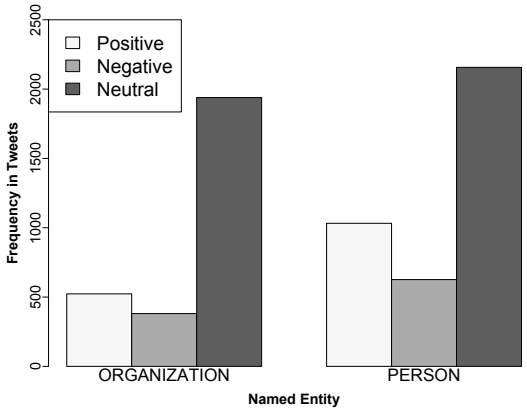

Figure 4: Targeted sentiment annotated for Spanish.

		Majority		
		POS	NEUTRAL	NEG
Minority	POS	757	1249	130
	NEUTRAL	707	2151	473
	NEG	129	726	452

Table 2: Number of targeted sentiment instances where at least two of the three annotators (Majority) agreed. Common disagreements with a third annotator (Minority) were over whether no sentiment or positive sentiment was expressed, and whether no sentiment or negative sentiment was expressed.

The distribution of sentiment for the named entities annotated by Turkers is shown in Figure 4. Neutral (no targeted sentiment) dominates, followed by positive sentiment for both organizations and people. As shown in Table 2, common disagreements were over whether or not there was targeted positive sentiment, and whether or not there was targeted negative sentiment. This is in line with previous research showing that distinguishing positive sentiment from no sentiment (and distinguishing negative sentiment from no sentiment) is often more challenging than distinguishing between positive and negative sentiment (Wilson et al., 2009). Indeed, we see that it was more common for annotators to disagree than to agree on targeted sentiment, particularly for negative targeted sentiment, where more instances had NEUTRAL/NEGATIVE disagreement than NEGATIVE three-way agreement.

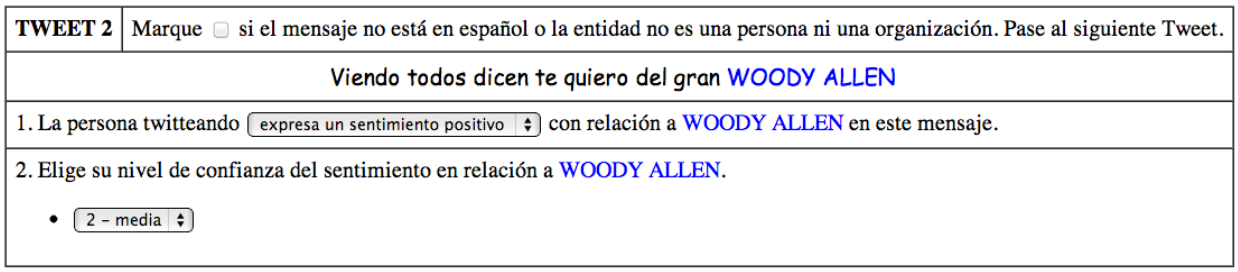

Figure 3: Example Tweet shown to Turkers.

Variable	Possible values
Sentiment (s) (PIPE & JOINT models)	NOT-TARG, SENT-TARG
Named Entity (l) (PIPE & JOINT models)	O, B-VOLITIONAL, I-VOLITIONAL

4 Targeted Subjectivity and Sentiment

Formally, we define the problem as follows: Given an observed message $\mathbf{w} = (w_1 \dots w_n)$, where n is the number of words in the message and $w_j (1 \leq j \leq n)$ is a word, we learn the probability of a label sequence $\mathbf{l} = (l_1 \dots l_n)$, where $l_i \in$ the set of named entity values; and a sentiment sequence $\mathbf{s} = (s_1 \dots s_n)$, where $s_i \in$ the set of sentiment values. We additionally explore simpler linear-chain models that learn the probability of a single label sequence $\mathbf{y} = (y_1 \dots y_n)$, where $y_i \in$ the set of conjoined entity+sentiment values (Tables 3 and 4).

Our basic model is a linear conditional random field, an undirected graph that represents the conditional distribution $p(\mathbf{l}, \mathbf{s}|\mathbf{w})$.[6] Sentiment towards a named entity may be modeled in a CRF as a sequence of random variables for sentiment $\mathbf{s}$ connected to named entities $\mathbf{l}$. In all models, entity variables are connected by a factor to their neighbors in sequence, and we include skip-chains (Finkel and Manning, 2010) connecting identical words where at least one is capitalized. Our model strategies include: a pipeline that first learns volitional entities then sentiment directed towards them (PIPE); one that jointly learns volitional entities along with sentiment directed towards them (JOINT); and one that learns volitional entities and targeted sentiment with combined labels (COLL) (Figure 5).

Using these models, we explore two primary tasks: (1) the task of detecting whether sentiment is targeted at an entity, which we refer to as *targeted subjectivity*; and (2) the task of detecting whether positive, negative, or neutral sentiment (no sentiment) is targeted at an entity, which we refer to as *targeted sentiment*. Moving from targeted subjectivity prediction to targeted sentiment prediction is possible by changing the sentiment target (SENT-TARG) variable into two variables, one for positive targeted sentiment (POS) and one for negative (NEG). Possible values for targeted subjectivity are shown in Table 3, and possible values for targeted sentiment are shown in Table 4.

In the pipeline models (PIPE), we first build a CRF where each word is connected by a factor to an entity label $l_i \in \mathbf{l}$. In a second model, every observed volitional entity node is connected by a factor to a sentiment label $s_i \in \mathbf{s}$. An example is shown in Figure 5 (1).

In the joint models (JOINT), each $s_i \in \mathbf{s}$ is connected by a factor to the corresponding entity label in the sequence, $l_i \in \mathbf{l}$. Sentiment in this model is partially observed: All sentiment variables are treated as latent except for the sentiment connected to the volitional entity. An example is shown in Figure 5 (2).

[6] For the COLL models, this is instead the conditional distribution $p(\mathbf{y}|\mathbf{w})$, where entity and sentiment labels are conjoined in one sequence assignment $\mathbf{y}$.

In the collapsed models (COLL), we combine sentiment and named entity into one label sequence (e.g., O, B+SENT-TARG, I+SENT-TARG). An example is shown in Figure 5 (3). The JOINT and PIPE models therefore predict named entity sequences, their category labels, and the sentiment expressed towards volitional named entities.[7] The collapsed models predict volitional labels and targeted sentiment as combined categories. The COLL and PIPE models are considerably faster than JOINT models, where exact inference is intractable.

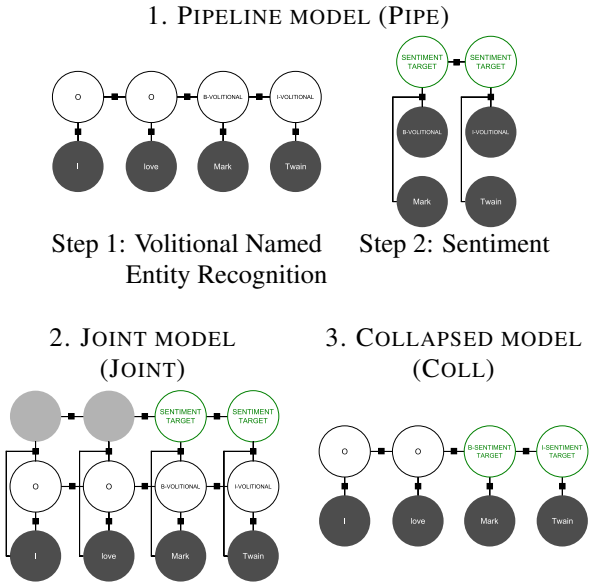

Figure 5: Example CRFs for targeted subjectivity with observed variables (dark nodes), predicted variables (white nodes) and hidden variables (light grey nodes).

5 Training

Minimum-Risk CRF Training We use the ERMA system (Stoyanov et al., 2011) to learn our models.[8] ERMA (Empirical Risk Minimization under Approximations) learns parameters to minimize loss on the training data. Predicting NE labels using a linear-chain CRF trained with empirical risk minimization has been shown to result in a statistically significant improvement over the common approach of maximum likelihood estimation (Stoyanov and Eisner, 2012). All models are trained to optimize log likelihood using 20 iterations of stochastic gradient descent, and a maximum of 100 iterations of belief propagation to compute the marginals for each example.

Features Features of the models are shown in Table 5. For an observed word, features are extracted for the word itself as well as within a context window of three words in either direction. Words seen only once are treated as out-of-vocabulary. Surface features and linguistic features are concatenated in groups of two and three to create further features. All algorithms and code that we have developed for feature extraction are available online.[9]

Because we aim to develop models that do not heavily rely on language-specific resources, we are interested in exploring unsupervised and lightly supervised methods for learning relevant features. Rather than use part-of-speech tags, we therefore use Brown cluster labels as unsupervised word tags (Brown et al., 1992; Koo et al., 2008). Brown clustering is a distributional similarity method that merges pairs of word clusters in the training data[10] to create the smallest decrease in corpus likelihood, using a bigram language model on the clusters. For our task, we cut clusters at length 3 and length 5, and these serve as rough part-of-speech tags without the need to train additional models. For example, the word *hello* is tagged as belonging to cluster 011 (length 3) and 01111 (length 5).

During development, we found that being able to syllabify the word (break the word into syllables) was a positive indicator of people names, but a negative indicator of organization names. This observation can be approximated automatically using constraints from the sonority sequencing principle (Hooper, 1976; Clements, 1990; Blevins, 1996; Morelli, 2003) on a language's orthography. This is a phonotactic principle that states that syllables will tend to have a sonority peak, usually a vowel, in the center of the syllable, followed on either side by consonants with decreasing sonority. Although languages may violate this principle, the core idea that a vowel forms the nucleus of a syllable with op-

[7] We found that learning the VOLITIONAL categories during training rather than maintaining beliefs about separate named entities during inference (ORGANIZATION, PERSON) and then post-processing to VOLITIONAL leads to slightly better accuracy.

[8] sites.google.com/site/ermasoftware

[9] www.m-mitchell.com/code

[10] For Spanish, we train on a sample of ~7 million Spanish tweets. For English, we train on the essays (Pennebaker et al., 2007) and Facebook data (Kosinskia et al., 2013) available from ICWSM 2013.

tional consonants before (the onset) and after (the coda) can be used to begin to automatically learn syllable structure.[11] We learn this in an unsupervised way, using the most frequent (seen more than 1,000 times) word-initial non-vowel sequences from the Brown cluster data as allowable syllable onset consonants. Similarly, the most frequent word-final non-vowel sequences are learned as possible syllable codas. For each word, we then attempt to segment syllables using the learned onsets and codas around each vowel. If a word cannot be syllabified, it is often an initialism (e.g., *CND*, *lsat*).

We follow the approach from the out-of-vocabulary assignment in the Berkeley parser (Petrov et al., 2006) to encode common surface patterns such as capitalization and lexical patterns such as verb endings as a single feature for words we have seen once or less. We also use the Jerboa toolkit (Van Durme, 2012) to extract further language-independent features from the data, such as features for emoticons and binning for repeated characters (like !!!). In addition, we include features for whether the word is three or four letters, which is often used for acronyms and initialisms in several languages (including Spanish and English); whether the word is neighbored by a punctuation mark; word identity; word length; message length; and position in the sentence.

We utilize a speaker of each language to simply list word forms for sentiment features that may be indicative of sentiment, totaling less than two hours of annotation time. This set includes intensifiers (e.g., *hella*, *freakin'* in English; e.g., *muy*, *sumamente* in Spanish), positive/negative abbreviations (*WTF*, *pso*), positive/negative slang words, and positive/negative prefix and suffixes (e.g., *anti-* in English and Spanish, *-ito* in Spanish).

6 Experiments

We are interested in both PERSON and ORGANIZATION entities, and evaluate these in the collapsed category VOLITIONAL. This suggests that the data may be pre-processed to label all volitional entities as VOLITIONAL NEs, or the models may be learned with the traditional named entities in place, and post-processed to identify those that are VOLITIONAL. We explored results using both methods, and found that training models on VOLITIONAL tags yielded the best performance overall; we report numbers for this approach below.

[11] Further development is necessary to extend a similar idea to languages that do not ordinarily mark all vowels in their orthography, such as Hebrew and Arabic.

SURFACE FEATURES
binned word length, message length, and sentence position; Jerboa features; word identity; word lengthening; punctuation characters, has digit; has dash; is lower case; is 3 or 4 letters; first letter capitalized; more than one letter capitalized, etc.
LINGUISTIC FEATURES
function words; can syllabify; curse words; laugh words; words for *good*, *bad*, *no*, *my*; slang words; abbreviations; intensifiers; subjective suffixes and prefixes (such as diminutive forms); common verb endings; common noun endings
BROWN CLUSTERING FEATURES
cluster at length 3; cluster at length 5
SENTIMENT FEATURES
is sentiment-bearing word; prior sentiment polarity

Table 5: Features used in model.

We compare against a baseline (BASE-NS) where we use our volitional entity labels and assign no sentiment directed towards the entity (the majority case). This is a strong baseline to isolate how our methods perform specifically for the task of identifying sentiment targeted at an entity.

We report on precision, recall, and sensitivity for the tasks of NER and targeted subjectivity/sentiment prediction in isolation; and we report on accuracy for the targeted subjectivity and targeted sentiment models. For sentiment, a true positive is an instance where the label has sentiment, and a true negative is an instance where the label has no sentiment (neutral). For NER, a true positive is an instance where the label is a B- or I- label; a true negative is an instance where the label is O. The three systems are evaluated against one another for NER, subjectivity (entity has/does not have sentiment expressed towards it), and sentiment (positive/negative/no sentiment) using paired t-tests across folds, with a Bonferroni correction to set α to 0.02.

NER We include results for the isolated task of volitional named entity recognition in Table 6. In both Spanish and English, all three models are roughly comparable for precision, recall, and specificity. The task of finding O tags – spans that are *not* named entities – works especially well (**NE spec**). Common

Model	Spanish			English		
	Joint	Pipe	Coll	Joint	Pipe	Coll
NE prec	**65.2**	64.3	65.1	59.8	**62.3**	60.5
NE rec	**65.8**	64.7	61.2	**60.2**	57.2	56.5
NE spec	95.4	95.2	**95.6**	94.3	**95.1**	94.7

Table 6: Average precision, recall, and specificity for volitional entity NER (in %).

mistakes include confusing B- labels with I- labels.

Subjectivity and Sentiment Table 7 shows results for the isolated task of predicting the presence of sentiment about a volitional entity. In Spanish, the pipeline models (PIPE) perform optimally for subjectivity recall (**Subj rec**), and significantly above the COLL models ($p<.001$). Precision and specificity are comparable across models. In English as in Spanish, the collapsed model is particularly poor at subjectivity recall.

As discussed in Section 2, the subtask of predicting whether subjectivity is expressed towards an entity is comparable to the main task of Jiang et al. (2011), and so we compare our approach here. The Jiang et al. study is similar to the current study in that they aim to detect targeted sentiment, but it differs from the current study in that they focus exclusively on subjectivity towards five manually selected entities: {*Obama*, *Google*, *iPad*, *Lakers*, *Lady Gaga*}. They also evaluate on artificially balanced evaluation data, and evaluate sentiment polarity (positive/negative) separately from subjectivity (has/does not have sentiment).

Our dataset includes any entity labeled as PERSON or ORGANIZATION, and is not balanced (most targets have no sentiment expressed towards them; see Table 1), thus we can only roughly compare against their approach. *Lakers* and *Lady Gaga* are rare in our collection (appearing less than 3 times), and so we updated the comparison set prior to evaluation to: {*Obama*, *Google*, *iPad*, *BBC*, *Tebow*}. On this set, a baseline that always guesses no sentiment reaches an accuracy of 66.9%, compared to Jiang et al.'s 65.5% accuracy on a balanced set (not strictly comparable, but provided for reference). The JOINT models reach an accuracy of 71.04% on this set, demonstrating this approach as potentially useful for topic-dependent targeted sentiment.

Table 8 shows results for the task of predicting the polarity of the sentiment expressed about an entity. In Spanish, the PIPE models significantly outperform the COLL models on sentiment recall, and the JOINT models on sentiment precision ($p<.01$). In English, PIPE significantly outperforms JOINT on precision ($p<.001$).

Model	Spanish			English		
	Joint	Pipe	Coll	Joint	Pipe	Coll
Subj prec	58.3	58.8	**58.9**	46.6	**52.2**	45.9
Subj rec	40.1	**50.9**	19.1	44.5	**48.5**	16.4
Subj spec	**79.6**	77.5	77.8	77.6	**80.8**	74.0

Table 7: Average precision, recall, and specificity (in %) for subjectivity prediction (has/does not have sentiment) along the target entity.

Model	Spanish			English		
	Joint	Pipe	Coll	Joint	Pipe	Coll
Sent prec	36.6	**45.8**	42.5	31.6	**42.9**	38.5
Sent rec	38.0	**40.6**	15.5	**36.6**	34.8	9.7
Sent spec	67.1	**75.2**	73.3	72.3	**82.0**	78.1

Table 8: Average precision, recall, and specificity (in %) for sentiment prediction (positive/negative/no sentiment) along the target entity.

Targeted Subjectivity and Targeted Sentiment The JOINT and PIPE models work reasonably well for the isolated tasks of NER and subjectivity/sentiment prediction. We now examine results for *targeted subjectivity* – labeling an entity and predicting whether there is sentiment directed towards it – in Table 9; and *targeted sentiment* – labeling an entity and predicting what the sentiment directed towards it is – in Table 10.

We evaluate using two accuracy metrics: **Acc-all**, which measures the accuracy of the entire named entity span along with the sentiment span; and **Acc-Bsent**, which measures the accuracy of identifying the start of a named entity (B- labels) along with the sentiment expressed towards it. Acc-all primarily measures the correctness of O labels, while Acc-Bsent focuses on the beginning of named entities.

For the targeted subjectivity task, our JOINT models perform optimally in Spanish, and significantly above their baselines. For the Acc-Bsent task, JOINT models perform best, significantly outperforming their baseline for subjectivity prediction. In English, where our data is half the size, we do not see a statistically significant difference between the predictive models and the no sentiment baselines.

For the targeted sentiment task, the JOINT models again perform relatively well in Spanish (Table 10), labeling volitional entities, predicting whether or not there is sentiment targeted towards them, and

	Model	Joint	Joint Base	Pipe	Pipe Base	Coll	Coll Base
Spa	**Acc-all**	89.5*	89.3	89.3**	89.1	89.5*	89.3
	Acc-Bsent	32.1***	29.5	30.9***	28.3	30.1**	28.1
Eng	**Acc-all**	88.0	88.1	88.6	88.6	87.9	88.1
	Acc-Bsent	30.4	30.8	30.7	30.3	28.1	29.2

***p<.001 **p<.01 *p<.05

Table 9: Average accuracy on Targeted Subjectivity Prediction: Identifying volitional entities and whether they are a sentiment target. In the core task, **Acc-Bsent**, the best model in Spanish is JOINT, significantly outperforming the baseline. In English, the best model (PIPE) does not significantly improve over its baseline.

	Model	Joint	Joint Base	Pipe	Pipe Base	Coll	Coll Base
Spa	**Acc-all**	89.4	89.4	89.0	89.0	89.2	89.3
	Acc-Bsent	29.7*	29.0	30.0	29.2	28.9	29.0
Eng	**Acc-all**	88.0	88.1	88.2	88.4	87.7	88.1
	Acc-Bsent	30.4	30.6	30.5	30.8	27.9	29.8

*p<.05

Table 10: Average accuracy on Targeted Sentiment Prediction: Identifying volitional entities and the polarity of the sentiment expressed towards them. The Spanish JOINT models significantly improve over their baseline for the core task. In English, no models outperform their baseline.

the sentiment polarity above their no sentiment baselines. We find this to be the most difficult task: It may be clear that sentiment is being expressed towards an entity, but it is not always clear what the polarity of that sentiment is. Error analysis is given below in this section. In the smaller English set, the models do not outperform the no sentiment baseline.

7 Discussion

Feature Analysis Examples of some of the top-weighted features in the Spanish models are shown in Table 11. In addition to lexical identity and Brown cluster, we find that positive indicators include positive suffixes such as diminutive forms, whether the word can be syllabized (Section 5), and whether it is three or four letters.

Error Analysis Because it is relatively common for there *not* to be sentiment targeted at a named entity, it is difficult to tease out the polarity in instances where there is targeted sentiment. Similarly, our predictions are most reliable for detecting the absence of a named entity (O labels).

Label confusions are shown in Table 12. Mistakes are often made by confusing B- labels (the start of an entity) with I- labels (inside an entity); and by predicting sentiment polarity when the gold annotations say there is not sentiment targeted at the entity. Some example errors are shown in Figure 13. In (1), "CANSADO" (*"TIRED"*) was predicted to be volitional, while "Matthew" was not. In (2), "Matias del río" was not predicted to be an entity, likely due to the fact that the capitalization patterns we see in this sentence are indicative of the start of a sentence rather than a proper name (similar to 1). In (3),

B-VOLITIONAL FEATURES	
Negative	is a function word; jerboa tags; followed by a word with 3 or 4 letters that cannot be syllabified
Positive	ends in -a, -o, or -s; is capitalized; has one non-initial capital letter; is 3 or 4 letters
B-VOLITIONAL, POS FEATURES	
Negative	preceded by a curse word; followed by a word with a positive suffix; immediately preceded by a word with a negative prefix
Positive	not in a sentiment lexicon; preceded by a happy emoticon; followed by an exclamation or a 'my' word; immediately preceded by a laugh; has two or more sentiment-bearing words in the sentence
B-VOLITIONAL, NEG FEATURES	
Negative	is immediately followed by a question mark or positive abbreviation word
Positive	preceded by a 'bad' word or curse word; has four or more sentiment lexicon items
B-VOLITIONAL, NOT-TARG FEATURES	
Negative	immediately followed by a 'no' word or word with a negative prefix; is preceded by a question mark; is immediately preceded by a curse word or laugh; is followed by an exclamation mark
Positive	not followed by sentiment lexicon word

Table 11: Example strongly weighted features for a Spanish joint sentiment model. In addition to lexical identity, we find that curse words and positive and negative prefixes are used to detect volitional entities and the sentiment directed towards them.

a.

Predicted \ Observed	B	I	O
B	423	21	186
I	36	236	135
O	197	90	7168

b.

Predicted \ Observed	POS	NEG	NEUT
POS	68	24	42
NEG	58	65	102
NEUT	115	61	468

Table 12: Predicted vs. observed values for a joint model. (**a**) For named entities, most common confusions were between B-VOLITIONAL and O labels. (**b**) For sentiment, most common mistakes were to predict that a positive sentiment was neutral (no sentiment), and that a neutral sentiment was negative.

Table 13: Example errors made by joint models.

sentiment may not be clear without spelling correction: "dio" should be "dios", meaning "God"; otherwise, "dio" is the word for "gave". Humans can easily fix the spelling error, which changes the overall reading of the expression. In (4), the positive polarity item "verdad" (*"believe"*) and the exclamation marks (!!!) were likely used as indicators of positive sentiment; however, in this case the annotators marked the targeted sentiment as neutral. In (5), the "Humala" entity was predicted to be longer than it is ("Hamala dos" or *"Hamala two"*). It was also predicted that both "Giesecke" and "Eiguiguren" had no sentiment expressed towards them; annotators disagreed, with the majority of those who annotated "Giesecke" marking negative sentiment, and the majority of those who annotated "Eiguiguren" marking no sentiment. This highlights some of the difficulty in predicting sentiment discussed in Section 3, where annotators will often disagree as to whether there is no sentiment or positive/negative sentiment.

During development, we found that the collapsed model (COLL) performed best on small amounts of data. However, as we scaled up the amount of data we trained on, the PIPE and JOINT models significantly improved, while the COLL models did not have significant performance gains.

8 Conclusion

We have introduced the task of open domain targeted sentiment: predicting sentiment directed towards an entity along with discovering the entity itself. Our approach is developed to find targeted sentiment towards both person and organization named entities by modeling sentiment as a span along the entity.

We find that by modeling targeted sentiment in this way, we can reliably detect entities and whether or not they are sentiment targets above a no sentiment baseline. How best to determine the *polarity* of the sentiment expressed towards the entity, however, is still an open issue. Our data suggests that it is usually not clear-cut whether sentiment is being expressed or not; the strong disagreement between annotators suggests that detecting sentiment polarity in microblogs is difficult even for humans.

In future work, we hope to explore further methods for teasing apart sentiment polarity expressed towards a target. This research has achieved promising results for detecting sentiment targets without relying on external supervised models, and we hope that the features and approaches developed here can aid in sentiment analysis in noisy text and languages without rich linguistic resources.

Abstract

Aspect extraction is one of the key tasks in sentiment analysis. In recent years, statistical models have been used for the task. However, such models without any domain knowledge often produce aspects that are not interpretable in applications. To tackle the issue, some knowledge-based topic models have been proposed, which allow the user to input some prior domain knowledge to generate coherent aspects. However, existing knowledge-based topic models have several major shortcomings, e.g., little work has been done to incorporate the cannot-link type of knowledge or to automatically adjust the number of topics based on domain knowledge. This paper proposes a more advanced topic model, called *MC-LDA* (LDA with m-set and c-set), to address these problems, which is based on an *Extended generalized Pólya urn* (*E-GPU*) model (which is also proposed in this paper). Experiments on real-life product reviews from a variety of domains show that MC-LDA outperforms the existing state-of-the-art models markedly.

1 Introduction

In sentiment analysis and opinion mining, aspect extraction aims to extract entity aspects or features on which opinions have been expressed (Hu and Liu, 2004; Liu, 2012). For example, in a sentence "The picture looks great," the aspect is "picture." Aspect extraction consists of two sub-tasks: (1) extracting all *aspect terms* (e.g., "picture") from the corpus, and (2) clustering aspect terms with similar meanings (e.g., cluster "picture" and "photo" into one *aspect category* as they mean the same in the domain "Camera"). In this work, we adopt the topic modeling approach as it can perform both sub-tasks simultaneously (see § 2).

Topic models, such as LDA (Blei et al., 2003), provide an unsupervised framework for extracting latent topics in text documents. Topics are aspect categories (or simply aspects) in our context. However, in recent years, researchers have found that fully unsupervised topic models may not produce topics that are very coherent for a particular application. This is because the objective functions of topic models do not always correlate well with human judgments and needs (Chang et al., 2009).

To address the issue, several *knowledge-based topic models* have been proposed. The DF-LDA model (Andrzejewski et al., 2009) incorporates two forms of prior knowledge, also called two types of constraints: *must-links* and *cannot-links*. A must-link states that two words (or terms) should belong to the same topic whereas a cannot-link indicates that two words should not be in the same topic. In (Andrzejewski et al., 2011), more general knowledge can be specified using first-order logic. In (Burns et al., 2012; Jagarlamudi et al., 2012; Lu et al., 2011; Mukherjee and Liu, 2012), seeded models were proposed. They enable the user to specify prior knowledge as seed words/terms for some topics. Petterson et al. (2010) also used word similarity as priors for guidance.

However, none of the existing models is capable of incorporating the cannot-link type of knowledge except DF-LDA (Andrzejewski et al., 2009). Furthermore, none of the existing models, including DF-LDA, is able to automatically adjust the number of topics based on domain knowledge. The domain knowledge, such as cannot-links, may change the number of topics. There are two types of cannot-links: consistent and inconsistent with the domain corpus. For example, in the reviews of

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1655–1667,
Seattle, Washington, USA, 18-21 October 2013.

domain "Computer", a topic model may generate two topics *Battery* and *Screen* that represent two different aspects. A cannot-link {battery, screen} as the domain knowledge is thus consistent with the corpus. However, words *Amazon* and *Price* may appear in the same topic due to their high co-occurrences in the Amazon.com review corpus. To separate them, a cannot-link {amazon, price} can be added as the domain knowledge, which is inconsistent with the corpus as these two words have high co-occurrences in the corpus. In this case, the number of topics needs to be *increased* by 1 since the mixed topic has to be separated into two individual topics *Amazon* and *Price*. Apart from the above shortcoming, earlier knowledge-based topic models also have some major shortcomings:

Incapability of handling multiple senses: A word typically has multiple meanings or senses. For example, *light* can mean "of little weight" or "something that makes things visible." DF-LDA cannot handle multiple senses because its definition of must-link is transitive. That is, if A and B form a must-link, and B and C form a must-link, it implies a must-link between A and C, indicating A, B, and C should be in the same topic. This case also applies to the models in (Andrzejewski et al., 2011), (Petterson et al., 2010), and (Mukherjee and Liu, 2012). Although the model in (Jagarlamudi et al., 2012) allows multiple senses, it requires that each topic has at most one set of seed words (seed set), which is restrictive as the amount of knowledge should not be limited.

Sensitivity to the adverse effect of knowledge: When using must-links or seeds, existing models basically try to ensure that the words in a must-link or a seed set have similar probabilities under a topic. This causes a problem: if a must-link comprises of a frequent word and an infrequent word, due to the redistribution of probability mass, the probability of the frequent word will decrease while the probability of the infrequent word will increase. This can harm the final topics because the attenuation of the frequent (often domain important) words can result in some irrelevant words being ranked higher (with higher probabilities).

To address the above shortcomings, we define *m-set* (for *must-set*) as a set of words that should belong to the same topic and *c-set* (*cannot-set*) as a set of words that should not be in the same topic. They are similar to must-link and cannot-link but m-sets do not enforce transitivity. Transitivity is the main cause of the inability to handle multiple senses. Our m-sets and c-sets are also more concise providing knowledge in the context of a set. As in (Andrzejewski et al., 2009), we assume that there is no conflict between m-sets and c-sets, i.e., if w_1 is a cannot-word of w_2 (i.e., shares a c-set with w_2), any word that shares an m-set with w_1 is also a cannot-word of w_2. Note that knowledge as m-sets has also been used in (Chen et al., 2013a) and (Chen et al., 2013b).

We then propose a new topic model, called *MC-LDA* (LDA with m-set and c-set), which is not only able to deal with c-sets and automatically adjust the number of topics, but also deal with the multiple senses and adverse effect of knowledge problems at the same time. For the issue of multiple senses, a new latent variable s is added to LDA to distinguish multiple senses (§ 3). Then, we employ the *generalized Pólya urn* (GPU) model (Mahmoud, 2008) to address the issue of adverse effect of knowledge (§ 4). Deviating from the standard topic modeling approaches, we propose the *Extended generalized Pólya urn* (E-GPU) model (§ 5). E-GPU extends the GPU model to enable multi-urn interactions. This is necessary for handling c-sets and for adjusting the number of topics. E-GPU is the heart of MC-LDA. Due to the extension, a new inference mechanism is designed for MC-LDA (§ 6). Note that E-GPU is generic and can be used in any appropriate application.

In summary, this paper makes the following three contributions:

1. It proposed a new knowledge-based topic model called MC-LDA, which is able to use both m-sets and c-sets, as well as automatically adjust the number of topics based on domain knowledge. At the same time, it can deal with some other major shortcomings of early existing models. To our knowledge, none of the existing knowledge-based models is as comprehensive as MC-LDA in terms of capabilities.
2. It proposed the E-GPU model to enable multi-urn interactions, which enables c-sets to be naturally integrated into a topic model. To the best of our knowledge, E-GPU has not been proposed and used before.
3. A comprehensive evaluation has been conducted to compare MC-LDA with several state-of-the-art models. Experimental results based on both qualitative and quantitative measures demonstrate the superiority of MC-LDA.

2 Related Work

Sentiment analysis has been studied extensively in recent years (Hu and Liu, 2004; Pang and Lee, 2008; Wiebe and Riloff, 2005; Wiebe et al., 2004). According to (Liu, 2012), there are three main approaches to aspect extraction: 1) Using word frequency and syntactic dependency of aspects and sentiment words for extraction (e.g., Blair-goldensohn et al., 2008; Hu and Liu, 2004; Ku et al., 2006; Popescu and Etzioni, 2005; Qiu et al., 2011; Somasundaran and Wiebe, 2009; Wu et al., 2009; Yu et al., 2011; Zhang and Liu, 2011; Zhuang et al., 2006); 2) Using supervised sequence labeling/classification (e.g., Choi and Cardie, 2010; Jakob and Gurevych, 2010; Kobayashi et al., 2007; Li et al., 2010); 3) Topic models (Branavan et al., 2008; Brody and Elhadad, 2010; Fang and Huang, 2012; Jo and Oh, 2011; Kim et al., 2013; Lazaridou et al., 2013; Li et al., 2011; Lin and He, 2009; Lu et al., 2009, 2012, 2011; Lu and Zhai, 2008; Mei et al., 2007; Moghaddam and Ester, 2011; Mukherjee and Liu, 2012; Sauper et al., 2011; Titov and McDonald, 2008; Wang et al., 2010, 2011; Zhao et al., 2010). Other approaches include shallow semantic parsing (Li et al., 2012b), bootstrapping (Xia et al., 2009), Non-English techniques (Abu-Jbara et al., 2013; Zhou et al., 2012), graph-based representation (Wu et al., 2011), convolution kernels (Wiegand and Klakow, 2010) and domain adaption (Li et al., 2012). Stoyanov and Cardie (2011), Wang and Liu (2011), and Meng et al. (2012) studied opinion summarization outside the reviews. Some other works related with sentiment analysis include (Agarwal and Sabharwal, 2012; Kennedy and Inkpen, 2006; Kim et al., 2009; Mohammad et al., 2009).

In this work, we focus on topic models owing to their advantage of performing both aspect extraction and clustering simultaneously. All other approaches only perform extraction. Although there are several related works on clustering aspect terms (e.g., Carenini et al., 2005; Guo et al., 2009; Zhai et al., 2011), they all assume that the aspect terms have been extracted beforehand. We also notice that some aspect extraction models in sentiment analysis separately discover aspect words and aspect specific sentiment words (e.g., Sauper and Barzilay, 2013; Zhao et al., 2010). Our proposed model does not separate them as most sentiment words also imply aspects and most adjectives modify specific attributes of objects. For example, sentiment words *expensive* and *beautiful* imply aspects *price* and *appearance* respectively.

Regarding the knowledge-based models, besides those discussed in § 1, the model (Hu et al., 2011) enables the user to provide guidance interactively. Blei and McAuliffe (2007) and Ramage et al. (2009) used document labels in supervised setting. In (Chen et al., 2013a), we proposed MDK-LDA to leverage multi-domain knowledge, which serves as the basic mechanism to exploit m-sets in MC-LDA. In (Chen et al., 2013b), we proposed a framework (called GK-LDA) to explicitly deal with the wrong knowledge when exploring the lexical semantic relations as the general (domain independent) knowledge in topic models. But these models above did not consider the knowledge in the form of c-sets (or cannot-links).

The *generalized Pólya urn* (GPU) model (Mahmoud, 2008) was first introduced in LDA by Mimno et al. (2011). However, Mimno et al. (2011) did not use domain knowledge. Our results in § 7 show that using domain knowledge can significantly improve aspect extraction. The GPU model was also employed in topic models in our work of (Chen et al., 2013a, 2013b). In this paper, we propose the Extended GPU (E-GPU) model. The E-GPU model is more powerful in handling complex situations in dealing with c-sets.

3 Dealing with M-sets and Multiple Senses

Since the proposed MC-LDA model is a major extension to our earlier work in (Chen et al., 2013a), which can deal with m-sets, we include this earlier work here as the background.

To incorporate m-sets and deal with multiple senses of a word, the MDK-LDA(b) model was proposed in (Chen et al., 2013a), which adds a new latent variable s into LDA. The rationale here is that this new latent variable s guides the model to choose the right sense represented by an m-set. The generative process of MDK-LDA(b) is (the notations are explained in Table 1):

$$\theta \sim Dirichlet(\alpha)$$
$$z_i|\theta_m \sim Multinomial(\theta_m)$$
$$\varphi \sim Dirichlet(\beta)$$
$$s_i|z_i, \varphi \sim Multinomial(\varphi_{z_i})$$
$$\eta \sim Dirichlet(\gamma)$$
$$w_i|z_i, s_i, \eta \sim Multinomial(\eta_{z_i,s_i})$$

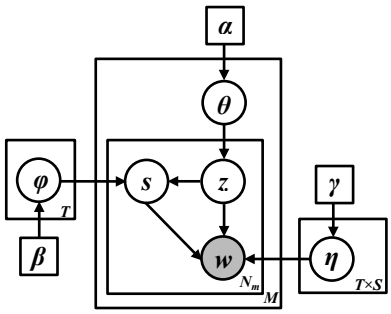

Figure 1. Plate notation for MDK-LDA(b) and MC-LDA.

The corresponding plate is shown in Figure 1. Under MDK-LDA(b), the probability of word w given topic t, i.e., $\pi_t(w)$, is given by:

$$\pi_t(w) = \sum_{s=1}^{S} \varphi_t(s) \cdot \eta_{t,s}(w) \quad (1)$$

where $\varphi_t(s)$ denotes the probability of m-set s occurring under topic t and $\eta_{t,s}(w)$ is the probability of word w appearing in m-set s under topic t.

According to (Chen et al., 2013a), the conditional probability of Gibbs sampler for MDK-LDA(b) is given by (see notations in Table 1):

$$P(z_i = t, s_i = s \,|\, \boldsymbol{z}^{-i}, \boldsymbol{s}^{-i}, \boldsymbol{w}, \alpha, \beta, \gamma) \propto \frac{n_{m,t}^{-i} + \alpha}{\sum_{t'=1}^{T}(n_{m,t'}^{-i} + \alpha)} \times \frac{n_{t,s}^{-i} + \beta}{\sum_{s'=1}^{S}(n_{t,s'}^{-i} + \beta)} \times \frac{n_{t,s,w_i}^{-i} + \gamma_s}{\sum_{v'=1}^{V}(n_{t,s,v'}^{-i} + \gamma_s)} \quad (2)$$

The superscript $-i$ denotes the counts excluding the current assignments (z_i and s_i) for word w_i.

4 Handling Adverse Effect of Knowledge

4.1 Generalized Pólya urn (GPU) Model

The Pólya urn model involves an urn containing balls of different colors. At discrete time intervals, balls are added or removed from the urn according to their color distributions.

In the simple Pólya urn (SPU) model, a ball is first drawn randomly from the urn and its color is recorded, then that ball is put back along with a new ball of the same color. This selection process is repeated and the contents of the urn change over time, with a self-reinforcing property sometimes expressed as "the rich get richer." SPU is actually exhibited in the Gibbs sampling for LDA.

The *generalized Pólya urn* (GPU) model differs from the SPU model in the replacement scheme during sampling. Specifically, when a ball is randomly drawn, certain numbers of additional balls of each color are returned to the urn, rather than just two balls of the same color as in SPU.

Hyperparameters	
α, β, γ	Dirichlet priors for $\theta,\ \varphi,\ \eta$
Latent & Visible Variables	
z	Topic (Aspect)
s	M-set
w	Word
θ	Document-Topic distribution
θ_m	Topic distribution of document m
φ	Topic-M-set distribution
φ_t	M-set distribution of topic t
η	Topic-M-set-Word distribution
$\eta_{t,s}$	Word distribution of topic t, m-set s
Cardinalities	
M	Number of documents
N_m	Number of words in document m
T	Number of topics
S	Number of m-sets
V	The vocabulary size
Sampling & Count Notations	
z_i	Topic assignment for word w_i
s_i	M-set assignment for word w_i
$\boldsymbol{z}^{-i}$	Topic assignments for all words except w_i
$\boldsymbol{s}^{-i}$	M-set assignments for all words except w_i
$n_{m,t}$	Number of times that topic t is assigned to word tokens in document m
$n_{t,s}$	Number of times that m-set s occurs under topic t
$n_{t,s,w}$	Number of times that word w appears in m-set s under topic t

Table 1. Meanings of symbols.

4.2 Promoting M-sets using GPU

To deal with the issue of sensitivity to the adverse effect of knowledge, MDK-LDA(b) is extended to MDK-LDA which employs the generalized Pólya urn (GPU) sampling scheme**.**

As discussed in § 1, due to the problem of the adverse effect of knowledge, important words may suffer from the presence of rare words in the same m-set. This problem can be dealt with the very sampling scheme of the GPU model (Chen et al., 2013a). Specifically, by adding additional $\mathbb{A}_{s,w',w}$ balls of color s into U_t^S while keeping the drawn ball, we increase the proportion (probability) of seeing the m-set s under topic t and thus promote m-set s as a whole. Consequently, each word in s is more likely to be emitted. We define $\mathbb{A}_{s,w',w}$ as:

$$\mathbb{A}_{s,w',w} = \begin{cases} 1 & w = w' \\ \sigma & w \in s, w' \in s, w \neq w' \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

The corresponding Gibbs sampler for MDK-LDA will be introduced in § 6.

5 Incorporating C-sets

5.1 Extended Generalized Pólya urn Model

To handle the complex situation resulted from incorporating c-sets, we propose an *Extended generalized Pólya urn* (E-GPU) model. Instead of involving only one urn as in SPU and GPU, E-GPU model considers a set of urns in the sampling process. The E-GPU model allows a ball to be transferred from one urn to another, enabling multi-urn interactions. Thus, during sampling, the populations of several urns will evolve even if only one ball is drawn from one urn. This capability makes the E-GPU model more powerful as it models relationships among multiple urns.

We define three sets of urns which will be used in the new sampling scheme in the proposed MC-LDA model. The first set of urns is the topic urns $U^T_{m\in\{1\dots M\}}$, where each topic urn contains T colors (topics) and each ball inside has a color $t \in \{1 \dots T\}$. It corresponds to the document-topic distribution θ in Table 1. The second set of urns (m-set urn $U^S_{t\in\{1\dots T\}}$) corresponds to the topic-m-set distribution φ, with balls of colors (m-sets) $s \in \{1 \dots S\}$ in each m-set urn. The third set of urns is the word urns $U^W_{t,s}$,where $t \in \{1 \dots T\}$ and $s \in \{1 \dots S\}$. Each ball inside a word urn has a color (word) $w \in \{1 \dots V\}$. The distribution η can be reflected in this set of urns.

5.2 Handling C-sets using E-GPU

As MDK-LDA can only use m-sets but not c-sets, we now extend MDK-LDA to the MC-LDA model in order to exploit c-sets. As pointed out in § 1, c-sets may be inconsistent with the corpus domain, which makes them considerably harder to deal with. To tackle the issue, we utilize the proposed E-GPU model and incorporate c-sets handling inside the E-GPU sampling scheme, which is also designed to enable automated adjustment of the number of topics based on domain knowledge.

Based on the definition of c-set, each pair of words in a c-set cannot both have large probabilities under the same topic. As the E-GPU model allows multi-urn interactions, when sampling a ball represents word w from a word urn $U^W_{t,s}$, we want to transfer the balls representing cannot-words of w (sharing a c-set with w) to other urns (see Step 3 a below). That is, decrease the probabilities of those cannot-words under this topic while increasing their corresponding probabilities under some other topics. In order to correctly transfer a ball that represents word w, it should be transferred to an urn which has a higher proportion of w and its related words (i.e., words sharing m-sets with w). That is, we randomly sample an urn that has a higher proportion of any m-set of w to transfer w to (Step 3 b below). However, the situation becomes more involved when a c-set is not consistent with the corpus. For example, aspects *price* and *amazon* may be mixed under one topic (say t) in LDA. The user may want to separate them by providing a c-set {price, amazon}. In this case, according to LDA, word *price* has no topic with a higher proportion of it (and its related words) than topic t. To transfer it, we need to increment the number of topics by 1 and then transfer the word to this new topic urn (step 3 c below). Based on these ideas, we propose the E-GPU sampling scheme for the MC-LDA model below:

1. Sample a topic t from U^T_m, an m-set s from U^S_t, and a word w from $U^W_{t,s}$ sequentially, where m is the mth document.
2. Record t, s and w, put back two balls of color t into urn U^T_m, one ball of color s into urn U^S_t, and two balls of color w into urn $U^W_{t,s}$. Given the matrix $\mathbb{A}$ (in Equation 3), for each word $w' \in s$, we put back $\mathbb{A}_{s,w',w}$ number of balls of color s into urn U^S_t.
3. For each word w_c that shares a c-set with w:
   a) Sample an m-set s_c from U^S_t which satisfies $w_c \in s_c$. Draw a ball b of color w_c (to be transferred) from U^W_{t,s_c} and remove it from U^W_{t,s_c}. The document of ball b is denoted by m_c. If no ball of color w_c can be drawn (i.e., there is no ball of color w_c in U^W_{t,s_c}), skip steps b) to d).
   b) Produce an urn set $\{U^W_{t',s'}\}$ such that each urn in it satisfies the following conditions:
      i) $t' \neq t, w_c \in s'$
      ii) The proportion of balls of color s' in $U^S_{t'}$ is higher than that of balls of color s_c in U^S_t.
   c) If $\{U^W_{t',s'}\}$ is not empty, randomly select one urn $U^W_{t',s'}$ from it. If $\{U^W_{t',s'}\}$ is empty, set $T = T + 1, t' = T$, draw an m-set s' from $U^S_{t'}$ which satisfies $w_c \in s'$. Record s' for step d).
   d) Put the ball b drawn from Step a) into $U^W_{t',s'}$, as well as a ball of color s' into $U^S_{t'}$ and a ball of color t' into $U^T_{m_c}$.

Note that the E-GPU model cannot be reflected in the graphical model in Figure 1 as it is essentially

Algorithm 1. GibbsSampling(m, w_i, $\mathbb{A}$, μ, Ω)

Input: Document m, Word w_i, Matrix $\mathbb{A}$,
Transfer cannot-word flag μ,
A set of valid topics Ω to be assigned to w_i

1: $n_{m,z_i} \leftarrow n_{m,z_i} - 1$;
2: **for** each word w' in s_i **do**
3: $n_{z_i,s_i} \leftarrow n_{z_i,s_i} - \mathbb{A}_{s_i,w',w_i}$;
4: **end for**
5: $n_{z_i,s_i,w_i} \leftarrow n_{z_i,s_i,w_i} - 1$;
6: Jointly sample $z_i \in \Omega$ and $s_i \ni w_i$ using Equation 2;
7: $n_{m,z_i} \leftarrow n_{m,z_i} + 1$;
8: **for** each word w' in s_i **do**
9: $n_{z_i,s_i} \leftarrow n_{z_i,s_i} + \mathbb{A}_{s_i,w',w_i}$;
10: **end for**
11: $n_{z_i,s_i,w_i} \leftarrow n_{z_i,s_i,w_i} + 1$;
12: **if** μ is true **then**
13: TransferCannotWords(w_i, z_i);
14: **end if**

Figure 2. Gibbs sampling for MC-LDA.

sampling scheme, and hence MC-LDA shares the same plate as MDK-LDA(b).

6 Collapsed Gibbs Sampling

We now describe the collapsed Gibbs sampler (Griffiths and Steyvers, 2004) with the detailed conditional distributions and algorithms for MC-LDA. Inference of z and s can be computationally expensive due to the non-exchangeability of words under the E-GPU models. We take the approach of (Mimno et al., 2011) which approximates the true Gibbs sampling distribution by treating each word as if it were the last.

For each word w_i, we perform hierarchical sampling consisting of the following three steps (the detailed algorithms are given in Figures 2 and 3):

Step 1 (Lines 1-11 in Figure 2): We jointly sample a topic z_i and an m-set s_i (containing w_i) for w_i, which gives us a blocked Gibbs sampler (Ishwaran and James, 2001), with the conditional probability given by:

$$P(z_i = t, s_i = s | \boldsymbol{z}^{-i}, \boldsymbol{s}^{-i}, \boldsymbol{w}, \alpha, \beta, \gamma, \mathbb{A}) \propto \frac{n_{m,t}^{-i} + \alpha}{\sum_{t'=1}^{T}\left(n_{m,t'}^{-i} + \alpha\right)} \times \frac{\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{s,v',w'} \cdot n_{t,s,v'}^{-i} + \beta}{\sum_{s'=1}^{S}\left(\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{s',v',w'} \cdot n_{t,s',v'}^{-i} + \beta\right)} \times \frac{n_{t,s,w_i}^{-i} + \gamma_s}{\sum_{v'=1}^{V}\left(n_{t,s,v'}^{-i} + \gamma_s\right)} \quad (4)$$

This step is the same as the Gibbs sampling for the MDK-LDA model.

Algorithm 2.TransferCannotWords(w_i, z_i)

Input: Word w_i, Topic z_i,

1: **for** each cannot-word w_c of w_i **do**
2: Randomly select an m-set s_c from all m-sets of w_c;
3: Build a set Ψ containing all the instances of w_c from the corpus with topic and m-set assignments being z_i and s_c;
4: **if** Ψ is not empty **then**
5: Draw an instance of w_c from Ψ (denoting the document of this instance by m_c) using Equation 5;
6: Generate a topic set Ω' that each topic t' inside satisfies $max_{s' \ni w_c}(\varphi_{t'}(s')) > \varphi_{z_i}(s_c)$.
7: **if** Ω' is not empty **then**
8: GibbsSampling(m_c, w_c, $\mathbb{A}$, false, Ω');
9: **else**
10: $Dummy = T + 1$; // T is #Topics.
11: GibbsSampling(m_c, w_c, $\mathbb{A}$, false, $\{Dummy\}$);
12: **end if**
13: **end if**
14: **end for**

Figure 3. Transfer cannot-words in Gibbs sampling.

Step 2 (lines 1-5 in Figure 3): For every cannot-word (say w_c) of w_i, randomly pick an urn U_{z_i,s_c}^{W} from the urn set $\{U_{z_i,\bar{s}}^{W}\}$ where $\bar{s} \ni w_c$. If there exists at least one ball of color w_c in urn U_{z_i,s_c}^{W}, we sample one ball (say b_c) of color w_c from urn U_{z_i,s_c}^{W}, based on the following conditional distribution:

$$P(b = b_c | \boldsymbol{z}, \boldsymbol{s}, \boldsymbol{w}, \alpha, \beta, \gamma, \mathbb{A}) \propto \frac{n_{m_c,t} + \alpha}{\sum_{t'=1}^{T}\left(n_{m_c,t'} + \alpha\right)} \quad (5)$$

where m_c denotes the document of the ball b_c of color w_c.

Step 3 (lines 6-12 in Figure 3): For each drawn ball b from Step 2, resample a topic t and an m-set s (containing w_c) based on the following conditional distribution:

$$\begin{aligned} & P(z_b = t, s_b = s | \boldsymbol{z}^{-b}, \boldsymbol{s}^{-b}, \boldsymbol{w}, \alpha, \beta, \gamma, \mathbb{A}, b = b_c) \\ & \propto \mathbf{I}_{\left[0, \max\limits_{s' \ni w_c}(\varphi_t(s'))\right]}\left(\varphi_{z_c}(s_c)\right) \times \frac{n_{m,t}^{-b} + \alpha}{\sum_{t'=1}^{T}\left(n_{m,t'}^{-b} + \alpha\right)} \\ & \times \frac{\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{s,v',w'} \cdot n_{t,s,v'}^{-b} + \beta}{\sum_{s'=1}^{S}\left(\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{s',v',w'} \cdot n_{t,s',v'}^{-b} + \beta\right)} \\ & \times \frac{n_{t,s,w_b}^{-b} + \gamma_s}{\sum_{v'=1}^{V}\left(n_{t,s,v'}^{-b} + \gamma_s\right)} \end{aligned} \quad (6)$$

where z_c (same as z_i in Figure 3) and s_c are the original topic and m-set assignments. The superscript $-b$ denotes the counts excluding the original

assignments. **I**() is an indicator function, which restricts the ball to be transferred only to an urn that contains a higher proportion of its m-set. When no topic t can be successfully sampled and the current sweep (iteration) of Gibbs sampling has the same number of topic (T) as the previous sweep, we increment T by 1. And then assign T to z_b. The counts and parameters are also updated accordingly.

7 Experiments

We now evaluate the proposed MC-LDA model and compare it with state-of-the-art existing models. Two unsupervised baseline models that we compare with are:

- **LDA**: LDA is the basic unsupervised topic model (Blei et al., 2003).
- **LDA-GPU**: LDA with GPU (Mimno et al., 2011). Specifically, LDA-GPU applies GPU in LDA using co-document frequency.

As for knowledge-based models, we focus on comparing with DF-LDA model (Andrzejewski et al., 2009), which is perhaps the best known knowledge-based model and it allows both must-links and cannot-links.

For a comprehensive evaluation, we consider the following variations of MC-LDA and DF-LDA:

- **MC-LDA:** MC-LDA with both m-sets and c-sets. This is the newly proposed model.
- **M-LDA**: MC-LDA with m-sets only. This is the MDK-LDA model in (Chen et al., 2013a).
- **DF-M**: DF-LDA with must-links only.
- **DF-MC**: DF-LDA with both must-links and cannot-links. This is the full DF-LDA model in (Andrzejewski et al., 2009).

We do not compare with seeded models in (Burns et al., 2012; Jagarlamudi et al., 2012; Lu et al., 2011; Mukherjee and Liu, 2012) as seed sets are special cases of must-links and they also do not allow c-sets (or cannot-links).

7.1 Datasets and Settings

Datasets: We use product reviews from four domains (types of products) from Amazon.com for evaluation. The corpus statistics are shown in Table 2 (columns 2 and 3). The domains are "Camera," "Food," "Computer," and "Care" (short for "Personal Care"). We have made the datasets publically available at the website of the first author.

Domain	#Reviews	#Sentences	#M-sets	#C-sets
Camera	500	5171	173	18
Food	500	2416	85	10
Computer	500	2864	92	6
Care	500	3008	119	13
Average	500	3116	103	9

Table 2. Corpus statistics with #m-sets and #c-sets having at least two words.

Pre-processing: We ran the Stanford Core NLP Tools[1] to perform sentence detection and lemmatization. Punctuations, stopwords[2], numbers and words appearing less than 5 times in each corpus were removed. The domain name was also removed, e.g., word *camera* in the domain "Camera", since it co-occurs with most words in the corpus, leading to high similarity among topics/aspects.

Sentences as documents: As noted in (Titov and McDonald, 2008), when standard topic models are applied to reviews as documents, they tend to produce topics that correspond to global properties of products (e.g., brand name), which make topics overlapping with each other. The reason is that all reviews of the same type of products discuss about the same aspects of these products. Only the brand names and product names are different. Thus, using individual reviews for modeling is not very effective. Although there are approaches which model sentences (Jo and Oh, 2011; Titov and McDonald, 2008), we take the approach of (Brody and Elhadad, 2010), dividing each review into sentences and treating each sentence as an independent document. Sentences can be used by all three baselines without any change to their models. Although the relationships between sentences are lost, the data is fair to all models.

Parameter settings: For all models, posterior inference was drawn using 1000 Gibbs iterations with an initial burn-in of 100 iterations. For all models, we set $\alpha = 1$ and $\beta = 0.1$. We found that small changes of α and β did not affect the results much, which was also reported in (Jo and Oh, 2011) who also used online reviews. For the number of topics T, we tried different values (see §7.2) as it is hard to know the exact number of topics. While non-parametric Bayesian approaches (Teh et al., 2006) aim to estimate T from the corpus, they are often sensitive to the hyper-parameters (Heinrich, 2009).

[1] http://nlp.stanford.edu/software/corenlp.shtml
[2] http://jmlr.org/papers/volume5/lewis04a/a11-smart-stop-list

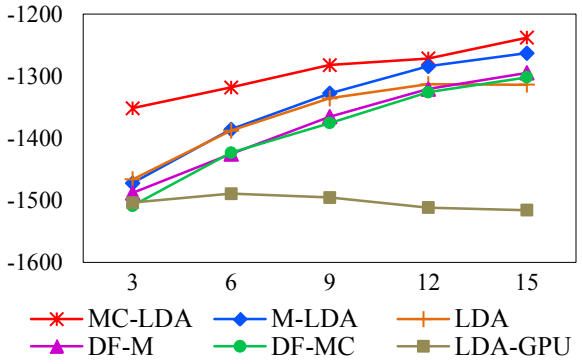

Figure 4. Avg. Topic Coherence score of each model across different number of topics.

For DF-LDA, we followed (Andrzejewski et al., 2009) to generate must-links and cannot-links from our domain knowledge. We then ran DF-LDA[3] while keeping its parameters as proposed in (Andrzejewski et al., 2009) (we also experimented with different parameter settings but they did not produce better results). For our proposed model, we estimated the thresholds using cross validation in our pilot experiments. Estimated value $\sigma = 0.2$ in equation 3 yielded good results. The second stage (steps 2 and 3) of the Gibbs sampler for MC-LDA (for dealing with c-sets) is applied after burn-in phrase.

Domain knowledge: User knowledge about a domain can vary a great deal. Different users may have very different knowledge. To reduce this variance for a more reliable evaluation, instead of asking a human user to provide m-sets, we obtain the synonym sets and the antonym sets of each word that is a noun or adjective (as words of other parts-of-speech usually do not indicate aspects) from WordNet (Miller, 1995) and manually verify the words in those sets for the domain. Note that if a word w is not provided with any m-set, it is treated as a singleton m-set $\{w\}$. For c-sets, we ran LDA in each domain and provide c-sets based on the wrong results of LDA as in (Andrzejewski et al., 2009). Then, the knowledge is provided to each model in the format required by each model. The numbers of m-sets and c-sets are listed in columns 4 and 5 of Table 2. Duplicate sets have been removed.

7.2 Objective Evaluation

In this section, we evaluate our proposed MC-LDA model objectively. Topic models are often evaluated using perplexity on held-out test data. However, the perplexity metric does not reflect the semantic coherence of individual topics learned by a topic model (Newman et al., 2010). Recent research has shown potential issues with perplexity as a measure: (Chang et al., 2009) suggested that the perplexity can sometimes be contrary to human judgments. Also, perplexity does not really reflect our goal of finding coherent aspects with accurate semantic clustering. It only provides a measure of how well the model fits the data.

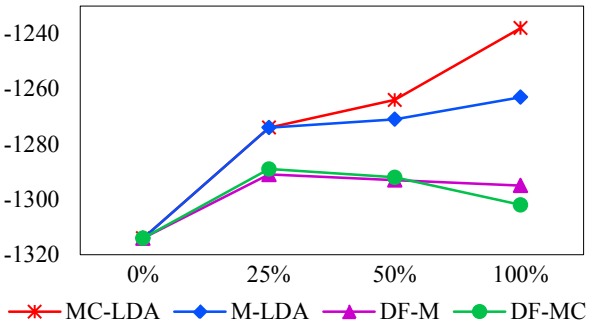

Figure 5. Avg. Topic Coherence score for different proportions of knowledge.

The *Topic Coherence* metric (Mimno et al., 2011) (also called the "UMass" measure (Stevens and Buttler, 2012)) was proposed as a better alternative for assessing topic quality. This metric relies upon word co-occurrence statistics within the documents, and does not depend on external resources or human labeling. It was shown that topic coherence is highly consistent with human expert labeling by Mimno et al. (2011). Higher topic coherence score indicates higher quality of topics, i.e., better topic interpretability.

Effects of Number of Topics

Since our proposed models and the baseline models are all parametric models, we first compare each model given different numbers of topics. Figure 4 shows the average Topic Coherence score of each model given different numbers of topics. From Figure 4, we note the following:

1. MC-LDA consistently achieves the highest Topic Coherence scores given different numbers of topics. M-LDA also works better than the other baseline models, but not as well as MC-LDA. This shows that both m-sets and c-sets are beneficial in producing coherent aspects.
2. DF-LDA variants, DF-M and DF-MC, do not perform well due to the shortcomings discussed

[3] http://pages.cs.wisc.edu/~andrzeje/research/df_lda.html

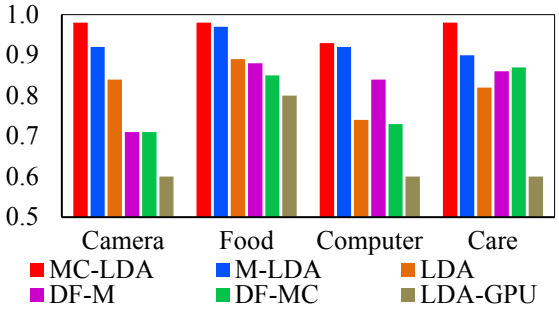

Figure 6. Avg. *p@5* of good topics for each model across different domains.

The models of each bar from left to rights are MC-LDA, M-LDA, LDA, DF-M, DF-MC, LDA-GPU. (Same for Figure 7)

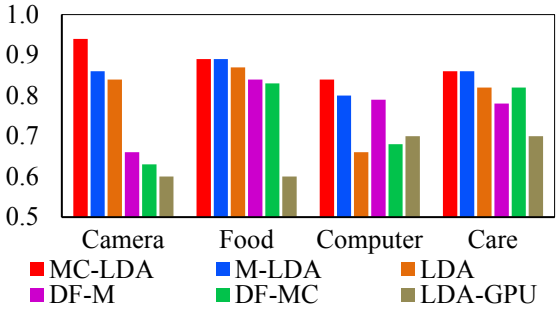

Figure 7. Avg. *p@10* of good topics for each model across different domains.

in § 1. It is slightly better than LDA when $T = 15$, but worse than LDA in other cases. We will further analyze the effects of knowledge on MC-LDA and DF-LDA shortly.

3. LDA-GPU does not perform well due to its use of co-document frequency. As frequent words usually have high co-document frequency with many other words, the frequent words are ranked top in many topics. This shows that the guidance using domain knowledge is more effective than using co-document frequency.

In terms of improvements, MC-LDA outperforms M-LDA significantly ($p < 0.03$) and all other baseline models significantly ($p < 0.01$) based on a paired *t*-test. It is important to note that by no means do we say that LDA-GPU and DF-LDA are not effective. We only say that for the task of aspect extraction and leveraging domain knowledge, these models do not generate as coherent aspects as ours because of their shortcomings discussed in § 1. In general, with more topics, the Topic Coherence scores increase. We found that when T is larger than 15, aspects found by each model became more and more overlapping, with several aspects expressing the same features of products. So we fix $T = 15$ in the subsequent experiments.

Effects of Knowledge

To further analyze the effects of knowledge on models, in each domain, we randomly sampled different proportions of knowledge (i.e., different numbers of m-sets/must-links and c-sets/cannot-links) as shown in Figure 5, where 0% means no knowledge (same as LDA and LDA-GPU, which do not incorporate knowledge) and 100% means all knowledge. From Figure 5, we see that MC-LDA and M-LDA both perform consistently better than DF-MC and DF-M across different proportions of knowledge. With the increasing number of knowledge sets, MC-LDA and M-LDA achieve higher Topic Coherence scores (i.e., produce more coherent aspects). In general, MC-LDA performs the best. For both DF-MC and DF-M, the Topic Coherence score increases from 0% to 25% knowledge, but decreases with more knowledge (50% and 100%). This shows that with limited amount of knowledge, the shortcomings of DF-LDA are not very obvious, but with more knowledge, these issues become more serious and thus degrade the performance of DF-LDA.

7.3 Human Evaluation

Since our aim is to make topics more interpretable and conformable to human judgments, we worked with two judges who are familiar with Amazon products and reviews to evaluate the models subjectively. Since topics from topic models are rankings based on word probability and we do not know the number of correct topical words, a natural way to evaluate these rankings is to use *Precision@n* (or *p@n*) which was also used in (Mukherjee and Liu, 2012; Zhao et al., 2010), where *n* is the rank position. We give *p@n* for $n = 5$ and 10. There are two steps in human evaluation: topic labeling and word labeling.

Topic Labeling: We followed the instructions in (Mimno et al., 2011) and asked the judges to label each topic as *good* or *bad*. Each topic was presented as a list of 10 most probable words in descending order of their probabilities under that topic. The models which generated the topics for labeling were obscure to the judges. In general, each topic was annotated as *good* if it had more than half of its words coherently related to each other representing a semantic concept together; otherwise *bad*. Agreement of human judges on topic

labeling using Cohen's Kappa yielded a score of 0.92 indicating almost perfect agreements according to the scale in (Landis and Koch, 1977). This is reasonable as topic labeling is an easy task and semantic coherence can be judged well by humans.

Word Labeling: After topic labeling, we chose the topics, which were labeled as good by both judges, as good topics. Then, we asked the two judges to label each word of the top 10 words in these good topics. Each word was annotated as *correct* if it was coherently related to the concept represented by the topic; otherwise *incorrect*. Since judges already had the conception of each topic in mind when they were labeling topics, labeling each word was not difficult which explains the high Kappa score for this labeling task (score = 0.892).

Quantitative Results

Figures 6 and 7 give the average *p@5* and *p@10* of all good topics over all four domains. The numbers of good topics generated by each model are shown in Table 3. We can see that the human evaluation results are highly consistent with Topic Coherence results in §7.2. MC-LDA improves over M-LDA significantly ($p < 0.01$) and both MC-LDA and M-LDA outperforms the other baseline models significantly ($p < 0.005$) using a paired *t*-test. We also found that when the domain knowledge is simple with one word usually expressing only one meaning/sense (e.g., in the domain "Computer"), DF-LDA performs better than LDA. In other domains, it performs similarly or worse than LDA. Again, it shows that DF-LDA is not effective to handle complex knowledge, which is consistent with the results of effects of knowledge on DF-LDA in §7.2.

Qualitative Results

We now show some qualitative results to give an intuitive feeling of the outputs from different models. There are a large number of aspects that are dramatically improved by MC-LDA. Due to space constraints, we only show some examples. To further focus, we just show some results of MC-LDA, M-LDA and LDA. The results from LDA-GPU and DF-LDA were inferior and hard for the human judges to match them with aspects found by the other models for qualitative comparison.

Table 4 shows three aspects Amazon, Price, Battery generated by each model in the domain

#Good Topics	MC-LDA	M-LDA	LDA	DF-M	DF-MC	LDA-GPU
Camera	**15/18**	12	11	9	7	3
Food	**8/16**	7	7	5	4	5
Computer	**12/16**	10	7	9	6	4
Care	**11/16**	10	9	10	9	3
Average	**11.5/16.5**	9.75/15	8.5/15	8.25/15	6.5/15	3.75/15

Table 3. Number of good topics of each model.

In x/y, x is the number of discovered good topics, and y is the total number of topics generated.

MC-LDA			M-LDA		LDA	
Amazon	**Price**	**Battery**	**Price**	**Battery**	**Amazon**	**Battery**
review	price	battery	price	battery	*card*	battery
amazon	*perform*	life	*lot*	*review*	*day*	*screen*
software	money	*day*	money	*amazon*	amazon	life
customer	expensive	extra	*big*	life	*memory*	*lcd*
month	cost	charger	expensive	extra	product	*water*
support	*week*	*water*	*point*	*day*	*sd*	usb

hardware	product	aa	purchase	*customer*	*class*	hour

Table 4. Example aspects in the domain "Camera"; errors are marked in red/italic.

"Camera". Both LDA and M-LDA can only discover two aspects but M-LDA has a higher average precision. Given the c-set {amazon, price, battery}, MC-LDA can discover all three aspects with the highest average precision.

8 Conclusion

This paper proposed a new model to exploit domain knowledge in the form of m-sets and c-sets to generate coherent aspects (topics) from online reviews. The paper first identified and characterized some shortcomings of the existing knowledge-based models. A new model called MC-LDA was then proposed, whose sampling scheme was based on the proposed Extended GPU (E-GPU) model enabling multi-urn interactions. A comprehensive evaluation using real-life online reviews from multiple domains shows that MC-LDA outperforms the state-of-the-art models significantly and discovers aspects with high semantic coherence. In our future work, we plan to incorporate aspect specific sentiments in the MC-LDA model.

Dependency-Based Decipherment for Resource-Limited Machine Translation

Qing Dou and Kevin Knight
Information Sciences Institute
Department of Computer Science
University of Southern California
{qdou,knight}@isi.edu

Abstract

We introduce dependency relations into deciphering foreign languages and show that dependency relations help improve the state-of-the-art deciphering accuracy by over 500%. We learn a translation lexicon from large amounts of genuinely non parallel data with decipherment to improve a phrase-based machine translation system trained with limited parallel data. In experiments, we observe BLEU gains of 1.2 to 1.8 across three different test sets.

1 Introduction

State-of-the-art machine translation (MT) systems apply statistical techniques to learn translation rules from large amounts of parallel data. However, parallel data is limited for many language pairs and domains.

In general, it is easier to obtain non parallel data. The ability to build a machine translation system using monolingual data could alleviate problems caused by insufficient parallel data. Towards building a machine translation system without a parallel corpus, Klementiev et al. (2012) use non parallel data to estimate parameters for a large scale MT system. Other work tries to learn full MT systems using only non parallel data through decipherment (Ravi and Knight, 2011; Ravi, 2013). However, the performance of such systems is poor compared with those trained with parallel data.

Given that we often have some parallel data, it is more practical to improve a translation system trained on parallel corpora with non parallel data. Dou and Knight (2012) successfully apply decipherment to learn a domain specific translation lexicon from monolingual data to improve out-of-domain machine translation. Although their approach works well for Spanish/French, they do not show whether their approach works for other language pairs. Moreover, the non parallel data used in their experiments is created from a parallel corpus. Such highly comparable data is difficult to obtain in reality.

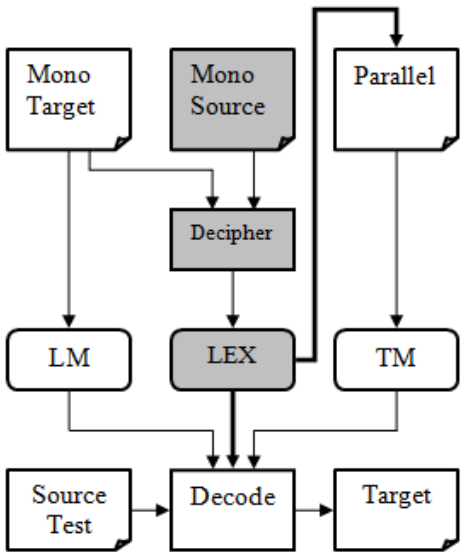

Figure 1: Improving machine translation with decipherment (Grey boxes represent new data and process). Mono: monolingual; LM: language model; LEX: translation lexicon; TM: translation model.

In this work, we improve previous work by Dou and Knight (2012) using genuinely non parallel data,

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1668–1676,
Seattle, Washington, USA, 18-21 October 2013.

and propose a framework to improve a machine translation system trained with a small amount of parallel data. As shown in Figure 1, we use a lexicon learned from decipherment to improve translations of both observed and out-of-vocabulary (OOV) words. The main contributions of this work are:

- We extract bigrams based on dependency relations for decipherment, which improves the state-of-the-art deciphering accuracy by over 500%.
- We demonstrate how to improve translations of words observed in parallel data by using a translation lexicon obtained from large amounts of non parallel data.
- We show that decipherment is able to find correct translations for OOV words.
- We use a translation lexicon learned by deciphering large amounts of non parallel data to improve a phrase-based MT system trained with limited amounts of parallel data. In experiments, we observe 1.2 to 1.8 BLEU gains across three different test sets.

2 Previous Work

Motivated by the idea that a translation lexicon induced from non parallel data can be applied to MT, a variety of prior research has tried to build a translation lexicon from non parallel or comparable data (Rapp, 1995; Fung and Yee, 1998; Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009; Bergsma and Van Durme, 2011; Daumé and Jagarlamudi, 2011; Irvine and Callison-Burch, 2013b; Irvine and Callison-Burch, 2013a). Although previous work is able to build a translation lexicon without parallel data, little has used the lexicon to improve machine translation.

There has been increasing interest in learning translation lexicons from non parallel data with decipherment techniques (Ravi and Knight, 2011; Dou and Knight, 2012; Nuhn et al., 2012). Decipherment views one language as a cipher for another and learns a translation lexicon that produces a good decipherment.

In an effort to build a MT system without a parallel corpus, Ravi and Knight (2011) view Spanish as a cipher for English and apply Bayesian learning to directly decipher Spanish into English. Unfortunately, their approach can only work on small data with limited vocabulary. Dou and Knight (2012) propose two techniques to make Bayesian decipherment scalable.

First, unlike Ravi and Knight (2011), who decipher whole sentences, Dou and Knight (2012) decipher bigrams. Reducing a ciphertext to a set of bigrams with counts significantly reduces the amount of cipher data. According to Dou and Knight (2012), a ciphertext bigram F is generated through the following generative story:

- Generate a sequence of two plaintext tokens e_1e_2 with probability $P(e_1e_2)$ given by a language model built from large numbers of plaintext bigrams.
- Substitute e_1 with f_1 and e_2 with f_2 with probability $P(f_1|e_1) \cdot P(f_2|e_2)$.

The probability of any cipher bigram F is:

$$P(F) = \sum_{e_1e_2} P(e_1e_2) \prod_{i=1}^{2} P(f_i|e_i)$$

Given a corpus of N cipher bigrams $F_1...F_N$, the probability of the corpus is:

$$P(corpus) = \prod_{j=1}^{N} P(F_j)$$

Given a plaintext bigram language model, the goal is to manipulate $P(f|e)$ to maximize $P(corpus)$. Theoretically, one can directly apply EM to solve the problem (Knight et al., 2006). However, EM has time complexity $O(N \cdot V_e^2)$ and space complexity $O(V_f \cdot V_e)$, where V_f, V_e are the sizes of ciphertext and plaintext vocabularies respectively, and N is the number of cipher bigrams.

Ravi and Knight (2011) apply Bayesian learning to reduce the space complexity. Instead of estimating probabilities $P(f|e)$, Bayesian learning tries to draw samples from plaintext sequences given ciphertext bigrams. During sampling, the probability of any possible plaintext sample e_1e_2 is given as:

$$P_{sample}(e_1e_2) = P(e_1e_2) \prod_{i=1}^{2} P_{bayes}(f_i|e_i)$$

misión de naciones unidas en oriente medio

Table 1: Comparison of adjacent bigrams (left) and dependency bigrams (right) extracted from the same Spanish text

with $P_{bayes}(f_i|e_i)$ defined as:

$$P_{bayes}(f_i|e_i) = \frac{\alpha P_0(f_i|e_i) + count(f_i, e_i)}{\alpha + count(e_i)}$$

where P_0 is a base distribution, and α is a parameter that controls how much we trust P_0. $count(f_i, e_i)$ and $count(e_i)$ record the number of times f_i, e_i and e_i appear in previously generated samples respectively.

At the end of sampling, $P(f_i|e_i)$ is estimated by:

$$P(f_i|e_i) = \frac{count(f_i, e_i)}{count(e_i)}$$

However, Bayesian decipherment is still very slow with Gibbs sampling (Geman and Geman, 1987), as each sampling step requires considering V_e possibilities. Dou and Knight (2012) solve the problem by introducing slice sampling (Neal, 2000) to Bayesian decipherment.

3 From Adjacent Bigrams to Dependency Bigrams

A major limitation of work by Dou and Knight (2012) is their monotonic generative story for deciphering adjacent bigrams. While the generation process works well for deciphering similar languages (e.g. Spanish and French) without considering reordering, it does not work well for languages that are more different in grammar and word order (e.g. Spanish and English). In this section, we first look at why adjacent bigrams are bad for decipherment. Then we describe how to use syntax to solve the problem.

The left column in Table 1 contains adjacent bigrams extracted from the Spanish phrase "misión de naciones unidas en oriente medio". The correct decipherment for the bigram "naciones unidas" should be "united nations". Since the deciphering model described by Dou and Knight (2012) does not consider word reordering, it needs to decipher the bigram into "nations united" in order to get the right word translations "naciones"→"nations" and "unidas"→"united". However, the English language model used for decipherment is built from English adjacent bigrams, so it strongly disprefers "nations united" and is not likely to produce a sensible decipherment for "naciones unidas". The Spanish bigram "oriente medio" poses the same problem. Thus, without considering word reordering, the model described by Dou and Knight (2012) is not a good fit for deciphering Spanish into English.

However, if we extract bigrams based on dependency relations for both languages, the model fits better. To extract such bigrams, we first use dependency parsers to parse both languages, and extract bigrams by putting head word first, followed by the modifier.[1] We call these dependency bigrams. The right column in Table 1 lists examples of Spanish dependency bigrams extracted from the same Spanish phrase. With a language model built with English dependency bigrams, the same model used for deciphering adjacent bigrams is able to decipher Spanish dependency bigram "naciones(head) unidas(modifier)" into "nations(head) united(modifier)".

We might instead propose to consider word reordering when deciphering adjacent bigrams (e.g. add an operation to swap tokens in a bigram). However, using dependency bigrams has the following advantages:

- First, using dependency bigrams avoids complicating the model, keeping deciphering efficient and scalable.
- Second, it addresses the problem of long distance reordering, which can not be modeled by swapping tokens in bigrams.

Furthermore, using dependency bigrams allows us to use dependency types to further

[1] As use of "del" and "de" in Spanish is much more frequent than the use of "of" in English, we skip those words by using their head words as new heads if any of them serves as a head.

improve decipherment. Suppose we have a Spanish dependency bigram "aceptó(verb) solicitud(object)". Then all of the following English dependency bigrams are possible decipherments: "accepted(verb) UN(subject)", "accepted(verb) government(subject)", "accepted(verb) request(object)". However, if we know the type of the Spanish dependency bigram and use a language model built with the same type in English, the only possible decipherment is "accepted(verb) request(object)". If we limit the search space, a system is more likely to find a better decipherment.

4 Deciphering Spanish Gigaword

In this section, we compare dependency bigrams with adjacent bigrams for deciphering Spanish into English.

4.1 Data

We use the Gigaword corpus for our decipherment experiments. The corpus contains news articles from different news agencies and is available in Spanish and English. We use only the AFP (Agence France-Presse) section of the corpus in decipherment experiments. We tokenize the corpus using tools that come with the Europarl corpus (Koehn, 2005). To shorten the time required for running different systems on large amounts of data, we keep only the top 5000 most frequent word types in both languages and replace all other word types with UNK. We also throw away lines with more than 40 tokens, as the Spanish parser (Bohnet, 2010) we use is slow when processing long sentences. After preprocessing, the corpus contains approximately 440 million tokens in Spanish and 350 million tokens in English. To obtain dependency bigrams, we use the Bohnet parsers (Bohnet, 2010) to parse both the Spanish and English version of the corpus.

4.2 Systems

Three systems are evaluated in the experiments. We implement a baseline system, **Adjacent**, based on Dou and Knight (2012). The baseline system collects adjacent bigrams and their counts from Spanish and English texts. It then builds an English bigram language model using the English adjacent bigrams and uses it to decipher the Spanish adjacent bigrams.

	Dependency Types
Group 1	Verb/Subject
Group 2	Preposition/Preposition-Object, Noun/Noun-Modifier
Group 3	Verb/Noun-Object

Table 2: Dependency relations divided into three groups

We build the second system, **Dependency**, using dependency bigrams for decipherment. As the two parsers do not output the same set of dependency relations, we cannot extract all types of dependency bigrams. Instead, we select a subset of dependency bigrams whose dependency relations are shared by the two parser outputs. The selected dependency relations are: Verb/Subject, Verb/Noun-Object, Preposition/Object, Noun/Modifier. Decipherment runs the same way as in the baseline system.

The third system, **DepType**, is built using both dependent bigrams and their dependency types. We first extract dependency bigrams for both languages, then group them based on their dependency types. As both parsers treat noun phrases dependent on "del", "de", and "of" as prepositional phrases, we choose to divide the dependency bigrams into 3 groups and list them in Table 2. A separate language model is built for each group of English dependency bigrams and used to decipher the group of Spanish dependency bigrams with same dependency type.

For all the systems, language models are built using the SRILM toolkit (Stolcke, 2002). For the Adjacent system, we use Good-Turing smoothing. For the other systems, we use a mix of Witten-Bell and Good-Turing smoothing.

4.3 Sampling Procedure

In experiments, we find that the iterative sampling method described by Dou and Knight (2012) helps improve deciphering accuracy. We also find that combining results from different decipherments helps find more correct translations at each iteration. Thus, instead of using a single sampling process, we use 10 different sampling processes at each iteration. The details of the new sampling procedure are provided here:

- Extract dependency bigrams from parsing outputs and collect their counts.

- Keep bigrams whose counts are greater than a threshold α. Then start 10 different randomly seeded and initialized sampling processes. Perform sampling.
- At the end of sampling, extract word translation pairs (f, e) from the final sample. Estimate translation probabilities $P(e|f)$ for each pair. Then construct a translation table by keeping translation pairs (f, e) seen in more than one decipherment and use the average $P(e|f)$ as the new translation probability.
- Lower the threshold α to include more bigrams into the sampling process. Start 10 different sampling processes again and initialize the first sample using the translation pairs obtained from the previous step (for each Spanish token f, choose an English token e whose $P(e|f)$ is the highest). Perform sampling again.
- Repeat until $\alpha = 1$.

4.4 Deciphering Accuracy

We choose the first 1000 lines of the monolingual Spanish texts as our test data. The data contains 37,505 tokens and 6556 word types. We use type accuracy as our evaluation metric: Given a word type f in Spanish, we find a translation pair (f, e) with the highest average $P(e|f)$ from the translation table learned through decipherment. If the translation pair (f, e) can also be found in a gold translation lexicon T_{gold}, we treat the word type f as correctly deciphered. Let $|C|$ be the number of word types correctly deciphered, and $|V|$ be the total number of word types evaluated. We define type accuracy as $\frac{|C|}{|V|}$.

To create T_{gold}, we use GIZA (Och and Ney, 2003) to align a small amount of Spanish-English parallel text (1 million tokens for each language), and use the lexicon derived from the alignment as our gold translation lexicon. T_{gold} contains a subset of 4408 types seen in the test data, among which, 2878 are also top 5000 frequent word types.

4.5 Results

During decipherment, we gradually increase the size of Spanish texts and compare the learning curves of three deciphering systems in Figure 2.

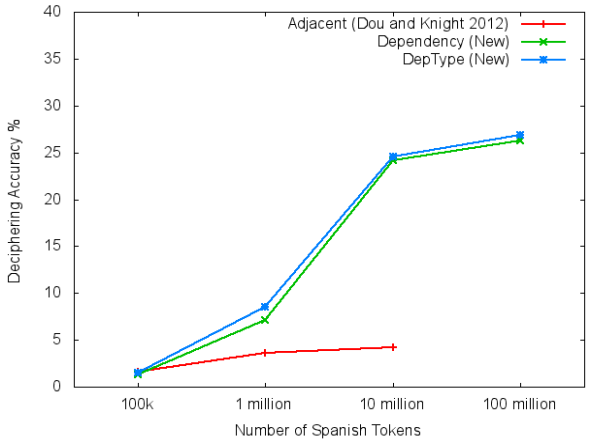

Figure 2: Learning curves for three decipherment systems. Compared with Adjacent (previous state of the art), systems that use dependency bigrams improve deciphering accuracy by over 500%.

With 100k tokens of Spanish text, the performance of the three systems are similar. However, the learning curve of Adjacent plateaus quickly, while those of the dependency based systems soar up as more data becomes available and still rise sharply when the size of Spanish texts increases to 10 million tokens, where the DepType system improves deciphering accuracy of the Adjacent system from 4.2% to 24.6%. In the end, with 100 million tokens, the accuracy of the DepType system rises to 27.0%. The accuracy is even higher (41%), when evaluated against the top 5000 frequent word types only.

5 Improving Machine Translation with Decipherment

In this section, we demonstrate how to use a translation lexicon learned by deciphering large amounts of in-domain (news) monolingual data to improve a phrase-based machine translation system trained with limited out-of-domain (politics) parallel data.

5.1 Data

We use approximately one million tokens of the Europarl corpus (Koehn, 2005) as our small out-of-domain parallel training data and Gigaword as our large in-domain monolingual training data to build language models and a new translation lexicon to improve a phrase-based MT baseline system. For tuning and testing, we use the development data

Parallel		
	Spanish	English
Europarl	1.1 million	1.0 million
Tune-2008	52.6k	49.8k
Test-2009	68.1k	65.6k
Test-2010	65.5k	61.9k
Test-2011	79.4k	74.7k
Non Parallel		
	Spanish	English
Gigaword	894 million	940 million

Table 3: Size of training, tuning, and testing data in number of tokens

from the NAACL 2012 workshop on statistical machine translation. The data contains test data in the news domain from the 2008, 2009, 2010, and 2011 workshops. We use the 2008 test data for tuning and the rest for testing. The sizes of the training, tuning, and testing sets are listed in Table 3.

5.2 Systems

5.2.1 Baseline Machine Translation System

We build a state-of-the-art phrase-based MT system, PBMT, using Moses (Koehn et al., 2007). PBMT has 3 models: a translation model, a distortion model, and a language model. We build a 5-gram language model using the AFP section of the English Gigaword. We train the other models using the Europarl corpus. By default, Moses uses the following 8 features to score a candidate translation:

- direct and inverse translation probabilities
- direct and inverse lexical weighting
- a language model score
- a distortion score
- phrase penalty
- word penalty

The 8 features have weights adjusted on the tuning data using minimum error rate training (MERT) (Och, 2003). PBMT has a phrase table T_{phrase}. During decoding, Moses copies out-of-vocabulary (OOV) words, which can not be found in T_{phrase}, directly to output. In the following sections, we describe how to use a translation lexicon learned from large amounts of non parallel data to improve translation of OOV words, as well as words observed in T_{phrase}.

5.2.2 Decipherment for Machine Translation

To achieve better decipherment, we:

- Increase the size of Spanish ciphertext from 100 million tokens to 894 million tokens.
- Keep top 50k instead of top 5k most frequent word types of the ciphertext.
- Instead of seeding the sampling process randomly, we use a translation lexicon learned from a limited amount of parallel data as seed: For each Spanish dependency bigram f_1, f_2, where both f_1 and f_2 are found in the seed lexicon, we find the English sequence e_1, e_2 that maximizes $P(e_1, e_2)P(e_1|f_1)P(e_2|f_2)$. Otherwise, for any Spanish token f that can be found in the seed lexicon, we choose English word e, where $P(e|f)$ is the highest as the initial sample; for any f that are not seen in the seed lexicon, we do random initialization.

We perform 20 random restarts with 10k iterations on each and build a word-to-word translation lexicon $T_{decipher}$ by collecting translation pairs seen in at least 3 final decipherments with either $P(f|e) \geq 0.2$ or $P(e|f) \geq 0.2$.

5.2.3 Improving Translation of Observed Words with Decipherment

To improve translation of words observed in our parallel corpus, we simply use $T_{decipher}$ as an additional parallel corpus. First, we filter $T_{decipher}$ by keeping only translation pairs (f, e), where f is observed in the Spanish part and e is observed in the English part of the parallel corpus. Then we append all the Spanish and English words in the filtered $T_{decipher}$ to the end of Spanish part and English part of the parallel corpus respectively. The training and tuning process is the same as the baseline machine translation system PBMT. We denote this system as **Decipher-OBSV**.

5.2.4 Improving OOV translation with Decipherment

As $T_{decipher}$ is learned from large amounts of in-domain monolingual data, we expect that $T_{decipher}$ contains a number of useful translations for words not seen in the limited amount of parallel data (OOV words). Instead of copying OOV words directly to output, which is what Moses does by default, we try to find translations from $T_{decipher}$ to improve translation.

During decoding, if a source word f is in T_{phrase}, its translation options are collected from T_{phrase} exclusively. If f is not in T_{phrase} but in $T_{decipher}$, the decoder will find translations from $T_{decipher}$. If f is not in either translation table, the decoder just copies it directly to the output. We call this system **Decipher-OOV**.

However, when an OOV's correct translation is same as its surface form and all its possible translations in $T_{decipher}$ are wrong, it is better to just copy OOV words directly to output. This scenario happens frequently, as Spanish and English share many common words. To avoid over trusting $T_{decipher}$, we add a new translation pair (f, f) for each source word f in $T_{decipher}$ if the translation pair (f, f) is not originally in $T_{decipher}$. For each newly added translation pair, both of its log translation probabilities are set to 0. To distinguish the added translation pairs from the others learned through decipherment, we add a binary feature θ to each translation pair in $T_{decipher}$. The final version of $T_{decipher}$ has three feature scores: $P(e|f)$, $P(f|e)$, and θ. Finally, we tune weights of the features in $T_{decipher}$ using MERT (Och, 2003) on the tuning set.

5.2.5 A Combined Approach

In the end, we build a system **Decipher-COMB**, which uses $T_{decipher}$ to improve translation of both observed and OOV words with methods described in sections 5.2.3 and 5.2.4.

5.3 Results

We tune each system three times with MERT and choose the best weights based on BLEU scores on tuning set.

Table 4 shows that the translation lexicon learned from decipherment helps achieve higher BLEU scores across tuning and testing sets. **Decipher-OBSV** improves BLEU scores by as much as 1.2 points. We analyze the results and find the gain mainly comes from two parts. First, adding $T_{decipher}$ to small amounts of parallel corpus improves word level translation probabilities, which lead to better lexical weighting; second, $T_{decipher}$ contains new alternative translations for words observed in the parallel corpus.

Moreover, **Decipher-OOV** also achieves better BLEU scores compared with PBMT across all tuning and test sets. We also observe that systems using $T_{decipher}$ learned by deciphering dependency bigrams leads to larger gains in BLEU scores. When decipherment is used to improve translation of both observed and OOV words, we see improvement in BLEU score as high as 1.8 points on the 2010 news test set.

The consistent improvement on the tuning and different testing data suggests that decipherment is capable of learning good translations for a number of OOV words. To further demonstrate that our decipherment approach finds useful translations for OOV words, we list the top 10 most frequent OOV words from both the tuning set and testing set as well as their translations (up to three most likely translations) in Table 5. $P(e|f)$ and $P(f|e)$ are average scores over different decipherment runs.

From the table, we can see that decipherment finds correct translations (bolded) for 7 out of the 10 most frequent OOV words. Moreover, many OOVs and their correct translations are homographs , which makes copying OOVs directly to the output a strong baseline to beat. Nonetheless, decipherment still finds enough correct translations to improve the baseline.

6 Conclusion

We introduce syntax for deciphering Spanish into English. Experiment results show that using dependency bigrams improves decipherment accuracy by over 500% compared with the state-of-the-art approach. Moreover, we learn a domain specific translation lexicon by deciphering large amounts of monolingual data and show that the lexicon can improve a baseline machine translation system trained with limited parallel data.

Decipherment	System	$Tune_{2008}$	$Test_{2009}$	$Test_{2010}$	$Test_{2011}$
None	PBMT (Baseline)	19.1	19.6	21.3	22.1
Adjacent	Decipher-OBSV	19.5	20.1	22.2	22.6
	Decipher-OOV	19.4	19.9	21.7	22.5
	Decipher-COMB	19.5	20.2	22.3	22.5
Dependency	Decipher-OBSV	19.7	20.5	22.5	23.0
	Decipher-OOV	19.9	20.4	22.4	22.9
	Decipher-COMB	20.0	20.8	23.1	23.4

Table 4: Systems that use translation lexicons learned from decipherment show consistent improvement over the baseline system across tuning and testing sets. The best system, Decipher-COMB, achieves as much as 1.8 BLEU point gain on the 2010 news test set.

Translating into Morphologically Rich Languages with Synthetic Phrases

Abstract

Translation into morphologically rich languages is an important but recalcitrant problem in MT. We present a simple and effective approach that deals with the problem in two phases. First, a discriminative model is learned to predict inflections of target words from rich source-side annotations. Then, this model is used to create additional sentence-specific word- and phrase-level translations that are added to a standard translation model as "synthetic" phrases. Our approach relies on morphological analysis of the target language, but we show that an unsupervised Bayesian model of morphology can successfully be used in place of a supervised analyzer. We report significant improvements in translation quality when translating from English to Russian, Hebrew and Swahili.

1 Introduction

Machine translation into morphologically rich languages is challenging, due to lexical sparsity and the large variety of grammatical features expressed with morphology. In this paper, we introduce a method that uses target language morphological grammars (either hand-crafted or learned unsupervisedly) to address this challenge and demonstrate its effectiveness at improving translation from English into several morphologically rich target languages.

Our approach decomposes the process of producing a translation for a word (or phrase) into two steps. First, a meaning-bearing **stem** is chosen and then an appropriate **inflection** is selected using a feature-rich discriminative model that conditions on the source context of the word being translated.

Rather than attempting to directly produce full-sentence translations using such an elementary process, we use our model to generate translations of individual words and short phrases that *augment*—on a sentence-by-sentence basis—the inventory of translation rules obtained using standard translation rule extraction techniques (Chiang, 2007). We call these **synthetic phrases**.

The major advantages of our approach are: (i) synthesized forms are targeted to a specific translation context; (ii) multiple, alternative phrases may be generated with the final choice among rules left to the global translation model; (iii) virtually no language-specific engineering is necessary; (iv) any phrase- or syntax-based decoder can be used without modification; and (v) we can generate forms that were not attested in the bilingual training data.

The paper is structured as follows. We first present our "translate-and-inflect" model for predicting lexical translations into morphologically rich languages given a source word and its context (§2). Our approach requires a morphological grammar to relate surface forms to underlying $\langle \text{stem}, \text{inflection} \rangle$ pairs; we discuss how either a standard morphological analyzer or a simple Bayesian unsupervised analyzer can be used (§3). After describing an efficient parameter estimation procedure for the inflection model (§4), we employ the translate-and-inflect model in an MT system. We describe how we use our model to synthesize translation options (§5) and then evaluate translation quality on English–Russian, English–Hebrew, and English–

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1677–1687,
Seattle, Washington, USA, 18-21 October 2013.

Swahili translation tasks, finding significant improvements in all language pairs (§6). We finally review related work (§7) and conclude (§8).

2 Translate-and-Inflect Model

The task of the translate-and-inflect model is illustrated in Fig. 1 for an English–Russian sentence pair. The input will be a sentence $\boldsymbol{e}$ in the source language (in this paper, always English) and any available linguistic analysis of $\boldsymbol{e}$. The output $\boldsymbol{f}$ will be composed of (i) a sequence of stems, each denoted σ and (ii) one morphological inflection pattern for each stem, denoted μ. When the information is available, a stem σ is composed of a lemma and an inflectional class. Throughout, we use Ω_σ to denote the set of possible morphological inflection patterns for a given stem σ. Ω_σ might be defined by a grammar; our models restrict Ω_σ to be the set of inflections observed anywhere in our monolingual or bilingual training data as a realization of σ.[1]

We assume the availability of a deterministic function that maps a stem σ and morphological inflection μ to a target language surface form f. In some cases, such as our unsupervised approach in §3.2, this will be a concatenation operation, though finite-state transducers are traditionally used to define such relations (§3.1). We abstractly denote this operation by $\star$: $f = \sigma \star \mu$.

Our approach consists in defining a probabilistic model over target words $\boldsymbol{f}$. The model assumes independence between each target word f conditioned on the source sentence $\boldsymbol{e}$ and its aligned position i in this sentence.[2] This assumption is further relaxed in §5 when the model is integrated in the translation system.

We decompose the probability of generating each target word f in the following way:

$$p(f \mid \boldsymbol{e}, i) = \sum_{\sigma \star \mu = f} \underbrace{p(\sigma \mid e_i)}_{\text{gen. stem}} \times \underbrace{p(\mu \mid \sigma, \boldsymbol{e}, i)}_{\text{gen. inflection}}$$

Here, each stem is generated independently from a single aligned source word e_i, but in practice we use a standard phrase-based model to generate sequences of stems and only the inflection model operates word-by-word. We turn next to the inflection model.

2.1 Modeling Inflection

In morphologically rich languages, each stem may be combined with one or more inflectional morphemes to express many different grammatical features (e.g., case, definiteness, mood, tense, etc.).

Since the inflectional morphology of a word generally expresses multiple grammatical features, we would like a model that naturally incorporates rich, possibly overlapping features in its representation of both the input (i.e., conditioning context) and output (i.e., the inflection pattern). We therefore use the following parametric form to model inflectional probabilities:

$$u(\mu, \boldsymbol{e}, i) = \exp\Big[\boldsymbol{\varphi}(\boldsymbol{e}, i)^\top \mathbf{W} \boldsymbol{\psi}(\mu) + \boldsymbol{\psi}(\mu)^\top \mathbf{V} \boldsymbol{\psi}(\mu)\Big],$$

$$p(\mu \mid \sigma, \boldsymbol{e}, i) = \frac{u(\mu, \boldsymbol{e}, i)}{\sum_{\mu' \in \Omega_\sigma} u(\mu', \boldsymbol{e}, i)}. \quad (1)$$

Here, $\boldsymbol{\varphi}$ is an m-dimensional *source context* feature vector function, $\boldsymbol{\psi}$ is an n-dimensional *morphology* feature vector function, $\mathbf{W} \in \mathbb{R}^{m \times n}$ and $\mathbf{V} \in \mathbb{R}^{n \times n}$ are parameter matrices. As with the more familiar log-linear parametrization that is written with a single feature vector, single weight vector and single bias vector, this model is linear in its parameters (it can be understood as working with a feature space that is the outer product of the two feature spaces). However, using two feature vectors allows to define overlapping features of both the input *and* the output, which is important for modeling morphology in which output variables are naturally expressed as bundles of features. The second term in the sum in u enables correlations among output features to be modeled independently of input, and as such can be understood as a generalization of the bias terms in multi-class logistic regression (on the diagonal $\mathbf{V}_{ii}$) and interaction terms between output variables in a conditional random field (off the diagonal $\mathbf{V}_{ij}$).

[1] This prevents the model from generating words that would be difficult for the language model to reliably score.

[2] This is the same assumption that Brown et al. (1993) make in, for example, IBM Model 1.

Figure 1: The inflection model predicts a form for the target verb lemma σ =пытаться (*pytat'sya*) based on its source *attempted* and the linear and syntactic source context. The correct inflection string for the observed Russian form in this particular training instance is μ = mis-sfm-e (equivalent to the more traditional morphological string: +MAIN+IND+PAST+SING+FEM+MEDIAL+PERF).

$$\left\{\begin{array}{c}\text{source aligned word } e_i \\ \text{parent word } e_{\pi_i} \text{ with its dependency } \pi_i \rightarrow i \\ \text{all children } e_j \mid \pi_j = i \text{ with their dependency } i \rightarrow j \\ \text{source words } e_{i-1} \text{ and } e_{i+1}\end{array}\right\} \left\{\begin{array}{c}\text{token} \\ \text{part-of-speech tag} \\ \text{word cluster}\end{array}\right\}$$
$$\text{– are } e_i, e_{\pi_i} \text{ at the root of the dependency tree?}$$
$$\text{– number of children, siblings of } e_i$$

Figure 2: Source features $\boldsymbol{\varphi}(\boldsymbol{e}, i)$ extracted from $\boldsymbol{e}$ and its linguistic analysis. π_i denotes the parent of the token in position i in the dependency tree and $\pi_i \rightarrow i$ the typed dependency link.

2.2 Source Context Features: $\boldsymbol{\varphi}(\boldsymbol{e}, i)$

In order to select the best inflection of a target-language word, given the source word it translates and the context of that source word, we seek to exploit as many features of the context as are available. Consider the example shown in Fig. 1, where most of the inflection features of the Russian word (past tense, singular number, and feminine gender) can be inferred from the context of the English word it is aligned to. Indeed, many grammatical functions expressed morphologically in Russian are expressed syntactically in English. Fortunately, high-quality parsers and other linguistic analyzers are available for English.

On the source side, we apply the following processing steps:

- Part-of-speech tagging with a CRF tagger trained on sections 02–21 of the Penn Treebank.
- Dependency parsing with TurboParser (Martins et al., 2010), a non-projective dependency parser trained on the Penn Treebank to produce basic Stanford dependencies.
- Assignment of tokens to one of 600 Brown clusters, trained on 8G words of English text.[3]

We then extract binary features from $\boldsymbol{e}$ using this information, by considering the aligned source word e_i, its preceding and following words, and its syntactic neighbors. These are detailed in Figure 2.

3 Morphological Grammars and Features

We now describe how to obtain morphological analyses and convert them into feature vectors ($\boldsymbol{\psi}$) for our target languages, Russian, Hebrew, and Swahili, using supervised and unsupervised methods.

3.1 Supervised Morphology

The state-of-the-art in morphological analysis uses unweighted morphological transduction rules (usu-

[3]The entire monolingual data available for the translation task of the 8th ACL Workshop on Statistical Machine Translation was used.

ally in the form of an FST) to produce candidate analyses for each word in a sentence and then statistical models to disambiguate among the analyses in context (Hakkani-Tür et al., 2000; Hajič et al., 2001; Smith et al., 2005; Habash and Rambow, 2005, *inter alia*). While this technique is capable of producing high quality linguistic analyses, it is expensive to develop, requiring hand-crafted rule-based analyzers and annotated corpora to train the disambiguation models. As a result, such analyzers are only available for a small number of languages, and, as a practical matter, each analyzer (which resulted from different development efforts) operates differently from the others.

We therefore focus on using supervised analysis for a single target language, Russian. We use the analysis tool of Sharoff et al. (2008) which produces for each word in context a lemma and a fixed-length morphological tag encoding the grammatical features. We process the target side of the parallel data with this tool to obtain the information necessary to extract $\langle \text{lemma}, \text{inflection} \rangle$ pairs, from which we compute σ and morphological feature vectors $\boldsymbol{\psi}(\mu)$.

Supervised morphology features: $\boldsymbol{\psi}(\mu)$. Since a positional tag set is used, it is straightforward to convert each fixed-length tag μ into a feature vector by defining a binary feature for each key-value pair (e.g., Tense=past) composing the tag.

3.2 Unsupervised Morphology

Since many languages into which we might want to translate do not have supervised morphological analyzers, we now turn to the question of how to generate morphological analyses and features using an unsupervised analyzer. We hypothesize that perfect decomposition into rich linguistic structures may not be required for accurate generation of new inflected forms. We will test this hypothesis by experimenting with a simple, *unsupervised* model of morphology that segments words into sequences of morphemes, assuming a (naïve) concatenative generation process and a single analysis per type.

Unsupervised morphological segmentation. We assume that each word can be decomposed into any number of prefixes, a stem, and any number of suffixes. Formally, we let M represent the set of all possible morphemes and define a regular grammar M^*MM^* (i.e., zero or more prefixes, a stem, and zero or more suffixes). To infer the decomposition structure for the words in the target language, we assume that the vocabulary was generated by the following process:

1. Sample morpheme distributions from symmetric Dirichlet distributions: $\theta_p \sim \text{Dir}_{|M|}(\alpha_p)$ for prefixes, $\theta_\sigma \sim \text{Dir}_{|M|}(\alpha_\sigma)$ for stems, and $\theta_s \sim \text{Dir}_{|M|}(\alpha_s)$ for suffixes.

2. Sample length distribution parameters $\lambda_p \sim \text{Beta}(\beta_p, \gamma_p)$ for prefix sequences and $\lambda_s \sim \text{Beta}(\beta_s, \gamma_s)$ for suffix sequences.

3. Sample a vocabulary by creating each word type w using the following steps:
   (a) Sample affix sequence lengths: $l_p \sim \text{Geometric}(\lambda_p)$; $l_s \sim \text{Geometric}(\lambda_s)$.
   (b) Sample l_p prefixes $p_1, \ldots, p_{l_p}$ independently from θ_p; l_s suffixes $s_1, \ldots, s_{l_s}$ independently from θ_s; and a stem $\sigma \sim \theta_\sigma$.
   (c) Concatenate prefixes, the stem, and suffixes: $w = p_1 + \cdots + p_{l_p} + \sigma + s_1 + \cdots + s_{l_s}$.

We use blocked Gibbs sampling to sample segmentations for each word in the training vocabulary. Because of our particular choice of priors, it possible to approximately decompose the posterior over the arcs of a compact finite-state machine. Sampling a segmentation or obtaining the most likely segmentation *a posteriori* then reduces to familiar FST operations. This model is reminiscent of work on learning morphology using adaptor grammars (Johnson et al., 2006; Johnson, 2008).

The inferred morphological grammar is very sensitive to the Dirichlet hyperparameters $(\alpha_p, \alpha_s, \alpha_\sigma)$ and these are, in turn, sensitive to the number of types in the vocabulary. Using $\alpha_p, \alpha_s \ll \alpha_\sigma \ll 1$ tended to recover useful segmentations, but we have not yet been able to find reliable generic priors for these values. Therefore, we selected them empirically to obtain a stem vocabulary size on the parallel data that is one-to-one with English.[4] Future work

[4] Our default starting point was to use $\alpha_p = \alpha_s = 10^{-6}, \alpha_\sigma = 10^{-4}$ and then to adjust all parameters by factors of 10.

Table 1: Corpus statistics.

	Parallel					Parallel+Monolingual		
	Sentences	EN-tokens	TRG-tokens	EN-types	TRG-types	Sentences	TRG-tokens	TRG-types
Russian	150k	3.5M	3.3M	131k	254k	20M	360M	1,971k
Hebrew	134k	2.7M	2.0M	48k	120k	806k	15M	316k
Swahili	15k	0.3M	0.3M	23k	35k	596k	13M	334k

will involve a more direct method for specifying or inferring these values.

Unsupervised morphology features: $\psi(\mu)$. For the unsupervised analyzer, we do not have a mapping from morphemes to structured morphological attributes; however, we can create features from the affix sequences obtained after morphological segmentation. We produce binary features corresponding to the content of each potential affixation position relative to the stem:

For example, the unsupervised analysis μ = wa+ki+wa+STEM of the Swahili word *wakiwapiga* will produce the following features:

$$\psi_{\text{prefix}[-3][\text{wa}]}(\mu) = 1,$$
$$\psi_{\text{prefix}[-2][\text{ki}]}(\mu) = 1,$$
$$\psi_{\text{prefix}[-1][\text{wa}]}(\mu) = 1.$$

4 Inflection Model Parameter Estimation

To set the parameters $\mathbf{W}$ and $\mathbf{V}$ of the inflection prediction model (Eq. 1), we use stochastic gradient descent to maximize the conditional log-likelihood of a training set consisting of pairs of source (English) sentence contextual features ($\boldsymbol{\varphi}$) and target word inflectional features ($\boldsymbol{\psi}$). The training instances are extracted from the word-aligned parallel corpus with the English side preprocessed as discussed in §2.2 and the target side disambiguated as discussed in §3. When morphological category information is available, we train an independent model for each open-class category (in Russian, nouns, verbs, adjectives, numerals, adverbs); otherwise a single model is used for all words (excluding words less than four characters long, which are ignored).

Statistics of the parallel corpora used to train the inflection model are summarized in Table 1. It is important to note here that our richly parameterized model is trained on the full parallel training corpus, not just on a handful of development sentences (which are typically used to tune MT system parameters). Despite this scale, training is simple: the inflection model is trained to discriminate among different inflectional paradigms, not over all possible target language sentences (Blunsom et al., 2008) or learning from all observable rules (Subotin, 2011). This makes the training problem relatively tractable: all experiments in this paper were trained on a single processor using a Cython implementation of the SGD optimizer. For our largest model, trained on 3.3M Russian words, $n = 231K \times m = 336$ features were produced, and 10 SGD iterations were performed in less than 16 hours.

4.1 Intrinsic Evaluation

Before considering the broader problem of integrating the inflection model in a machine translation system, we perform an artificial evaluation to verify that the model learns sensible source sentence-target inflection patterns. To do so, we create an inflection test set as follows. We preprocess the source (English) sentences exactly as during training (§2.2), and using the target language morphological analyzer, we convert each aligned target word to $\langle$stem, inflection$\rangle$ pairs. We perform word alignment on the held-out MT development data for each language pair (cf. Table 1), exactly as if it were going to produce training instances, but instead we use them for testing.

Although the resulting dataset is noisy (e.g., due to alignment errors), this becomes our intrinsic evaluation test set. Using this data, we measure inflection quality using two measurements:[5]

[5]Note that we are not evaluating the stem translation model,

			acc.	ppl.	$\lvert\Omega_\sigma\rvert$
Supervised	Russian	N	64.1%	3.46	9.16
		V	63.7%	3.41	20.12
		A	51.5%	6.24	19.56
		M	73.0%	2.81	9.14
		average	63.1%	3.98	14.49
Unsup.	Russian	all	71.2%	2.15	4.73
	Hebrew	all	85.5%	1.49	2.55
	Swahili	all	78.2%	2.09	11.46

Table 2: Intrinsic evaluation of inflection model (N: nouns, V: verbs, A: adjectives, M: numerals).

- the accuracy of predicting the inflection given the source, source context and target stem, and
- the inflection model perplexity on the same set of test instances.

Additionally, we report the average number of possible inflections for each stem, an upper bound to the perplexity that indicates the inherent difficulty of the task. The results of this evaluation are presented in Table 2 for the three language pairs considered. We remark on two patterns in these results. First, perplexity is substantially lower than the perplexity of a uniform model, indicating our model is overall quite effective at predicting inflections using source context only. Second, in the supervised Russian results, we see that predicting the inflections of adjectives is relatively more difficult than for other parts-of-speech. Since adjectives agree with the nouns they modify in gender and case, and gender is an idiosyncratic feature of Russian nouns (and therefore not directly predictable from the English source), this difficulty is unsurprising.

We can also inspect the weights learned by the model to assess the effectiveness of the features in relating source-context structure with target-side morphology. Such an analysis is presented in Fig. 3.

4.2 Feature Ablation

Our inflection model makes use of numerous feature types. Table 3 explores the effect of removing different kinds of (source) features from the model, evaluated on predicting Russian inflections using supervised morphological grammars.[6] Rows 2–3 show the effect of removing either linear or dependency context. We see that both are necessary for good performance; however removing dependency context substantially degrades performance of the model (we interpret this result as evidence that Russian morphological inflection captures grammatical relationships that would be expressed structurally in English). The bottom four rows explore the effect of source language word representation. The results indicate that lexical features are important for accurate prediction of inflection, and that POS tags and Brown clusters are likewise important, but they seem to capture similar information (removing one has little impact, but removing both substantially degrades performance).

Table 3: Feature ablation experiments using supervised Russian classification experiments.

Features ($\boldsymbol{\varphi}(\boldsymbol{e}, i)$)	acc.
all	54.7%
−linear context	52.7%
−dependency context	44.4%
−POS tags	54.5%
−Brown clusters	54.5%
−POS tags, −Brown cl.	50.9%
−lexical items	51.2%

5 Synthetic Phrases

We turn now to translation; recall that our translate-and-inflect model is used to augment the set of rules available to a conventional statistical machine translation decoder. We refer to the phrases it produces as *synthetic* phrases.

Our baseline system is a standard hierarchical phrase-based translation model (Chiang, 2007). Following Lopez (2007), the training data is compiled into an efficient binary representation which allows extraction of sentence-specific grammars just before decoding. In our case, this also allows the creation of synthetic inflected phrases that are produced conditioning on the sentence to translate.

To generate these synthetic phrases with new inflections possibly unseen in the parallel training

just the inflection prediction model.

[6]The models used in the feature ablation experiment were trained on fewer examples, resulting in overall lower accuracies than seen in Table 2, but the pattern of results is the relevant datapoint here.

Russian supervised

Verb: 1st Person
`child(nsubj)=I child(nsubj)=we`
Verb: Future tense
`child(aux)=MD child(aux)=will`
Noun: Animate
`source=animals/victims/...`
Noun: Feminine gender
`source=obama/economy/...`
Noun: Dative case
`parent(iobj)`
Adjective: Genitive case
`grandparent(poss)`

Hebrew

Suffix ים (masculine plural)
`parent=NNS after=NNS`
Prefix א (first person sing. + future)
`child(nsubj)=I child(aux)='ll`
Prefix כ (preposition like/as)
`child(prep)=IN parent=as`
Suffix י (possesive mark)
`before=my child(poss)=my`
Suffix ה (feminine mark)
`child(nsubj)=she before=she`
Prefix כש (when)
`before=when before=WRB`

Swahili

Prefix *li* (past)
`source=VBD source=VBN`
Prefix *nita* (1st person sing. + future)
`child(aux) child(nsubj)=I`
Prefix *ana* (3rd person sing. + present)
`source=VBZ`
Prefix *wa* (3rd person plural)
`before=they child(nsubj)=NNS`
Suffix *tu* (1st person plural)
`child(nsubj)=she before=she`
Prefix *ha* (negative tense)
`source=no after=not`

Figure 3: Examples of highly weighted features learned by the inflection model. We selected a few frequent morphological features and show their top corresponding source context features.

data, we first construct an additional phrase-based translation model on the parallel corpus preprocessed to replace inflected surface words with their stems. We then extract a set of non-gappy phrases for each sentence (e.g., X → <attempted, пытаться_V>). The target side of each such phrase is re-inflected, conditioned on the source sentence, using the inflection model from §2. Each stem is given its most likely inflection.[7]

The original features extracted for the stemmed phrase are conserved, and the following features are added to help the decoder select good synthetic phrases:

- a binary feature indicating that the phrase is synthetic,
- the log-probability of the inflected forms according to our model,
- the count of words that have been inflected, with a separate feature for each morphological category in the supervised case.

Finally, these synthetic phrases are combined with the original translation rules obtained for the baseline system to produce an extended sentence-specific grammar which is used as input to the decoder. If a phrase already existing in the standard phrase table happens to be recreated, both phrases are kept and will compete with each other with different features in the decoder.

For example, for the large EN→RU system, 6% of all the rules used for translation are synthetic phrases, with 65% of these phrases being entirely new rules.

6 Translation Experiments

We evaluate our approach in the standard discriminative MT framework. We use cdec (Dyer et al., 2010) as our decoder and perform MIRA training to learn feature weights of the sentence translation model (Chiang, 2012). We compare the following configurations:

- A baseline system, using a 4-gram language model trained on the entire monolingual and bilingual data available.
- An enriched system with a class-based n-gram language model[8] trained on the monolingual data mapped to 600 Brown clusters. Class-based language modeling is a strong baseline for scenarios with high out-of-vocabulary rates but in which large amounts of monolingual target-language data are available.
- The enriched system further augmented with our inflected synthetic phrases. We expect the class-based language model to be especially

[7] Several reviewers asked about what happens when k-best inflections are added. The results for $k \in \{2, 4, 8\}$ range from no effect to an improvement over $k = 1$ of about 0.2 BLEU (absolute). We hypothesize that larger values of k could have a greater impact, perhaps in a more "global" model of the target string; however, exploration of this question is beyond the scope of this paper.

[8] For Swahili and Hebrew, $n = 6$; for Russian, $n = 7$.

helpful here and capture some basic agreement patterns that can be learned more easily on dense clusters than from plain word sequences.

Detailed corpus statistics are given in Table 1:

- The Russian data consist of the News Commentary parallel corpus and additional monolingual data crawled from news websites.[9]
- The Hebrew parallel corpus is composed of transcribed TED talks (Cettolo et al., 2012). Additional monolingual news data is also used.
- The Swahili parallel corpus was obtained by crawling the Global Voices project website[10] for parallel articles. Additional monolingual data was taken from the Helsinki Corpus of Swahili.[11]

We evaluate translation quality by translating and measuring the BLEU score of a 2000–3000 sentence-long evaluation corpus, averaging the results over 3 MIRA runs to control for optimizer instability (Clark et al., 2011). Table 4 reports the results. For all languages, using class language models improves over the baseline. When synthetic phrases are added, significant additional improvements are obtained. For the English–Russian language pair, where both supervised and unsupervised analyses can be obtained, we notice that expert-crafted morphological analyzers are more efficient at improving translation quality. Globally, the amount of improvement observed varies depending on the language; this is most likely indicative of the quality of unsupervised morphological segmentations produced and the kinds of grammatical relations expressed morphologically.

Finally, to confirm the effectiveness of our approach as corpus size increases, we use our technique on top of a state-of-the art English–Russian system trained on data from the 8th ACL Workshop on Machine Translation (30M words of bilingual text and 410M words of monolingual text). The setup is identical except for the addition of sparse rule shape indicator features and bigram cluster features. In these large scale conditions, the BLEU score improves from 18.8 to 19.6 with the addition of word clusters and reaches 20.0 with synthetic phrases. Details regarding this system are reported in Ammar et al. (2013).

Table 4: Translation quality (measured by BLEU) averaged over 3 MIRA runs.

	EN→RU	EN→HE	EN→SW
Baseline	14.7±0.1	15.8±0.3	18.3±0.1
+Class LM	15.7±0.1	16.8±0.4	18.7±0.2
+Synthetic			
unsupervised	16.2±0.1	17.6±0.1	19.0±0.1
supervised	16.7±0.1	—	—

7 Related Work

Translation into morphologically rich languages is a widely studied problem and there is a tremendous amount of related work. Our technique of synthesizing translation options to improve generation of inflected forms is closely related to the factored translation approach proposed by Koehn and Hoang (2007); however, an important difference to that work is that we use a discriminative model that conditions on source context to make "local" decisions about what inflections may be used before combining the phrases into a complete sentence translation.

Combination pre-/post-processing solutions are also frequently proposed. In these, the target language is generally transformed from multi-morphemic surface words into smaller units more amenable to direct translation, and then a post-processing step is applied independent of the translation model. For example, Oflazer and El-Kahlout (2007) experiment with partial morpheme groupings to produce novel inflected forms when translating into Turkish; Al-Haj and Lavie (2010) compare different processing schemes for Arabic. A related but different approach is to *enrich* the source language items with grammatical features (e.g., a source sentence like *John saw Mary* is preprocessed into, e.g., John+subj saw+msubj+fobj Mary+obj) so as to make the source and target lexicons have similar morphological contrasts (Avramidis and Koehn, 2008; Yeniterzi and Oflazer, 2010; Chang et al.,

[9] http://www.statmt.org/wmt13/translation-task.html

[10] http://sw.globalvoicesonline.org

[11] http://www.aakkl.helsinki.fi/cameel/corpus/intro.htm

2009). In general, this work suffers from the problem that it is extremely difficult to know *a priori* what the right preprocessing is for a given language pair, data size, and domain.

Several post-processing approaches have relied on supervised classifiers to predict the optimal complete inflection for an incomplete or lemmatized translation. Minkov et al. (2007) present a method for predicting the inflection of Russian and Arabic sentences aligned to English sentences. They train a sequence model to predict target morphological features from the lemmas and the syntactic structures of both aligned sentences and demonstrate its ability to recover accurately inflections on reference translations. Toutanova et al. (2008) apply this method to generate inflections after translation in two different ways: by rescoring inflected n-best outputs or by translating lemmas and re-inflecting them *a posteriori*. El Kholy and Habash (2012) follow a similar method and compare different approaches for generating rich morphology in Arabic after a translation step. Fraser et al. (2012) observe improvements for translation into German with a similar method. As in that work, we model morphological features rather than directly inflected forms. However, that work may be criticized for providing no mechanism to translate surface forms directly, even when evidence for a direct translation is available in the parallel data.

Unsupervised morphology has begun to play a role in translation between morphologically complex languages. Stallard et al. (2012) show that an unsupervised approach to Arabic segmentation performs as well as a supervised segmenter for source-side preprocessing (in terms of English translation quality). For translation *into* morphological rich languages, Clifton and Sarkar (2011) use an unsupervised morphological analyzer to produce morphological affixes in Finnish, injecting some linguistic knowledge in the generation process.

Several authors have proposed using conditional models to predict the probability of phrase translation in context (Gimpel and Smith, 2008; Chan et al., 2007; Carpuat and Wu, 2007; Jeong et al., 2010). Of particular note is the work of Subotin (2011), who use a conditional model to predict morphological features conditioned on rich linguistic features; however, this latter work also conditions on target context, which substantially complicates decoding.

Finally, synthetic phrases have been used for different purposes than generating morphology. Callison-Burch et al. (2006) expanded the coverage of a phrase table by adding synthesized phrases by paraphrasing source language phrases, Chen et al. (2011) produced "fabricated" phrases by paraphrasing both source and target phrases, and Habash (2009) created new rules to handle out-of-vocabulary words. In related work, Tsvetkov et al. (2013) used synthetic phrases to improve generation of (in)definite articles when translating into English from Russian and Czech, two languages which do not lexically mark definiteness.

8 Conclusion

We have presented an efficient technique that exploits morphologically analyzed corpora to produce new inflections possibly unseen in the bilingual training data. Our method decomposes into two simple independent steps involving well-understood discriminative models.

By relying on source-side context to generate additional local translation options and by leaving the choice of the full sentence translation to the decoder, we sidestep the difficulty of computing features on target translations hypotheses. However, many morphological processes (most notably, agreement) are most best modeled using target language context. To capture target context effects, we depend on strong target language models. Therefore, an important extension of our work is to explore the interaction of our approach with more sophisticated language models that more directly model morphology, e.g., the models of Bilmes and Kirchhoff (2003), or, alternatively, ways to incorporate target language context in the inflection model.

We also achieve language independence by exploiting unsupervised morphological segmentations in the absence of linguistically informed morphological analyses.

Code for replicating the experiments is available from `https://github.com/eschling/morphogen`; further details are available in (Schlinger et al., 2013).

Abstract

We present an approach to learning bilingual n-gram correspondences from relevance rankings of English documents for Japanese queries. We show that directly optimizing cross-lingual rankings rivals and complements machine translation-based cross-language information retrieval (CLIR). We propose an efficient boosting algorithm that deals with very large cross-product spaces of word correspondences. We show in an experimental evaluation on patent prior art search that our approach, and in particular a consensus-based combination of boosting and translation-based approaches, yields substantial improvements in CLIR performance. Our training and test data are made publicly available.

1 Introduction

The central problem addressed in Cross-Language Information Retrieval (CLIR) is that of translating or projecting a query into the language of the document repository across which retrieval is performed. There are two main approaches to tackle this problem: The first approach leverages the standard Statistical Machine Translation (SMT) machinery to produce a single best translation that is used as search query in the target language. We will henceforth call this the *direct translation* approach. This technique is particularly useful if large amounts of data are available in domain-specific form.

Alternative approaches avoid to solve the hard problem of word reordering, and instead rely on token-to-token translations that are used to project the query terms into the target language with a probabilistic weighting of the standard term tf-idf scheme. Darwish and Oard (2003) termed this method the *probabilistic structured query* approach. The advantage of this technique is an implicit query expansion effect due to the use of probability distributions over term translations (Xu et al., 2001). Recent research has shown that leveraging query context by extracting term translation probabilities from n-best direct translations of queries instead of using context-free translation tables outperforms both direct translation and context-free projection (Ture et al., 2012b; Ture et al., 2012a).

While direct translation as well as probabilistic structured query approaches use machine learning to optimize the SMT module, retrieval is done by standard search algorithms in both approaches. For example, Google's CLIR approach uses their standard proprietary search engine (Chin et al., 2008). Ture et al. (2012b; 2012a) use standard retrieval algorithms such as BM25 (Robertson et al., 1998). That means, machine learning in SMT-based approaches concentrates on the cross-language aspect of CLIR and is agnostic of the ultimate ranking task.

In this paper, we present a method to project search queries into the target language that is complementary to SMT-based CLIR approaches. Our method learns a table of n-gram correspondences by direct optimization of a ranking objective on relevance rankings of English documents for Japanese queries. Our model is similar to the approach of Bai et al. (2010) who characterize their technique as "Learning to rank with (a Lot of) Word Features". Given a set of search queries $\mathbf{q} \in \mathbb{R}^Q$ and docu-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1688–1699,
Seattle, Washington, USA, 18-21 October 2013.

ments $\mathbf{d} \in \mathbb{R}^D$, where the j^{th} dimension of a vector indicates the occurrence of the j^{th} word for dictionaries of size Q and D, we want to learn a score $f(\mathbf{q}, \mathbf{d})$ between a query and a given document using the model[1]

$$f(\mathbf{q}, \mathbf{d}) = \mathbf{q}^\top W \mathbf{d} = \sum_{i=1}^{Q} \sum_{j=1}^{D} q_i W_{ij} d_j.$$

We take a pairwise ranking approach to optimization. That is, given labeled data in the form of a set $\mathcal{R}$ of tuples $(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-)$, where $\mathbf{d}^+$ is a relevant (or higher ranked) document and $\mathbf{d}^-$ an irrelevant (or lower ranked) document for query $\mathbf{q}$, the goal is to find a weight matrix $W \in \mathbb{R}^{Q \times D}$ such that $f(\mathbf{q}, \mathbf{d}^+) > f(\mathbf{q}, \mathbf{d}^-)$ for all data tuples from $\mathcal{R}$. The scoring model learns weights for all possible correspondences of query terms and document terms by directly optimizing the ranking objective at hand. Such a phrase table contains domain-specific word associations that are useful to discern relevant from irrelevant documents, something that is orthogonal and complementary to standard SMT models.

The challenge of our approach can be explained by constructing a joint feature map ϕ from the outer product of the vectors $\mathbf{q}$ and $\mathbf{d}$ where

$$\phi_{((i-1)D+j)}(\mathbf{q}, \mathbf{d}) = (\mathbf{q} \otimes \mathbf{d})_{ij} = (\mathbf{q}\mathbf{d}^\top)_{ij}. \quad (1)$$

Using this feature map, we see that the score function f can be written in the standard form of a linear model that computes the inner product between a weight vector w and a feature vector ϕ where $w, \phi \in \mathbb{R}^{Q \times D}$ and

$$f(\mathbf{q}, \mathbf{d}) = \langle w, \phi(\mathbf{q}, \mathbf{d}) \rangle. \quad (2)$$

While various standard algorithms exist to optimize linear models, the difficulty lies in the memory footprint and capacity of the word-based model. A full-sized model includes $Q \times D$ parameters which is easily in the billions even for moderately sized dictionaries. Clearly, an efficient implementation and remedies against overfitting are essential.

The main contribution of our paper is the presentation of algorithms that make learning a phrase table by direct rank optimization feasible, and an experimental verification of the benefits of this approach, especially with regard to a combination of the orthogonal information sources of ranking-based and SMT-based CLIR approaches. Our approach builds upon a boosting framework for pairwise ranking (Freund et al., 2003) that allows the model to grow incrementally, thus avoiding having to deal with the full matrix W. Furthermore, we present an implementation of boosting that utilizes parallel estimation on bootstrap samples from the training set for increased efficiency and reduced error (Breiman, 1996). Our "bagged boosting" approach allows to combine incremental feature selection, parallel training, and efficient management of large data structures.

We show in an experimental evaluation on large-scale retrieval on patent abstracts that our boosting approach is comparable in MAP and improves significantly by 13-15 PRES points over very competitive translation-based CLIR systems that are trained on 1.8 million parallel sentence pairs from Japanese-English patent documents. Moreover, a combination of the orthogonal information learned in ranking-based and translation-based approaches improves over 7 MAP points and over 15 PRES points over the respective translation-based system in a consensus-based voting approach following the Borda Count technique (Aslam and Montague, 2001).

2 Related Work

Recent research in CLIR follows the two main paradigms of direct translation and probabilistic structured query approaches. An example for the first approach is the work of Magdy and Jones (2011) who presented an efficient technique to adapt off-the-shelf SMT systems for CLIR by training them on data pre-processed for retrieval (case folding, stopword removal, stemming). Nikoulina et al. (2012) presented an approach to direct translation-based CLIR where the n-best list of an SMT system is re-ranked according to the MAP performance of the translated queries. The probabilistic structured query approach has seen a lot of work on context-aware query expansion across languages, based on various similarity statistics (Ballesteros and Croft, 1998; Gao et al., 2001; Lavrenko et al., 2002; Gao

[1] With bold letters we denote vectors for query $\mathbf{q}$ and document $\mathbf{d}$. Vector components are denoted with normal font letters and indices (e.g., q_i).

et al., 2007). At the time of writing this paper, the most recent extension to this paradigm is Ture et al. (2012a). In addition to projecting terms from n-best translations, they propose a projection extracted from the hierarchical phrase- based grammar models, and a scoring method based on multi-token terms. Since the latter techniques achieved only marginal improvements over the context-sensitive query translation from n-best lists, we did not pursue them in our work.

CLIR in the context of patent prior art search was done as extrinsic evaluation at the NTCIR PatentMT[2] workshops until 2010, and has been ongoing in the CLEF-IP[3] benchmarking workshops since 2009. However, most workshop participants did either not make use of automatic translation at all, or they used an off-the-shelf translation tool. This is due to the CLEF-IP data collection where parts of patent documents are provided as manual translations into three languages. In order to evaluate CLIR in a truly cross-lingual scenario, we created a large patent CLIR dataset where queries and documents are Japanese and English patent abstracts, respectively.

Ranking approaches to CLIR have been presented by Guo and Gomes (2009) who use pairwise ranking for patent retrieval. Their method is a classical learning-to-rank setup where retrieval scores such as tf-idf or BM25 are combined with domain knowledge on patent class, inventor, date, location, etc. into a dense feature vector of a few hundred features. Methods to learn word-based translation correspondences from supervised ranking signals have been presented by Bai et al. (2010) and Chen et al. (2010). These approaches tackle the problem of complexity and capacity of the cross product matrix of word correspondences from different directions. The first proposes to learn a low rank representation of the matrix; the second deploys sparse online learning under ℓ_1 regularization to keep the matrix small. Both approaches are mainly evaluated in a monolingual setting. The cross-lingual evaluation presented in Bai et al. (2010) uses weak translation-based baselines and non-public data such that a direct comparison is not possible.

A combination of bagging and boosting in the context of retrieval has been presented by Pavlov et al. (2010) and Ganjisaffar et al. (2011). This work is done in a standard learning-to-rank setup using a few hundred dense features trained on hundreds of thousands of pairs. Our setup deals with billions of sparse features (from the cross-product of the unrestricted dictionaries) trained on millions of pairs (sampled from a much larger space). Parallel boosting where all feature weights are updated simultaneously has been presented by Collins et al. (2002) and Canini et al. (2010). The first method distributes the gradient calculation for different features among different compute nodes. This is not possible in our approach because we construct the cross-product matrix on-the-fly. The second approach requires substantial efforts in changing the data representation to use the MapReduce framework. Overall, one of the goals of our work is sequential updating for implicit feature selection, something that runs contrary to parallel boosting.

3 CLIR Approaches

3.1 Direct translation approach

For direct translation, we use the SCFG decoder cdec (Dyer et al., 2010)[4] and build grammars using its implementation of the suffix array extraction method described in Lopez (2007). Word alignments are built from all parallel data using mgiza[5] and the Moses scripts[6]. SCFG models use the same settings as described in Chiang (2007). Training and querying of a modified Kneser-Ney smoothed 5-gram language model are done on the English side of the training data using KenLM (Heafield, 2011)[7]. Model parameters were optimized using cdec's implementation of MERT (Och (2003)).

At retrieval time, all queries are translated sentence-wise and subsequently re-joined to form one query per patent. Our baseline retrieval system uses the Okapi BM25 scores for document ranking.

3.2 Probabilistic structured query approach

Early Probabilistic Structured Query approaches (Xu et al., 2001; Darwish and Oard, 2003) represent translation options by lexical, i.e., token-to-token translation tables that are estimated using standard word alignment techniques (Och and Ney, 2000). Later approaches (Ture et al., 2012b; Ture et al., 2012a) extract translation options from the decoder's n-best list for translating a particular query. The central idea is to let the language model choose fluent, context-aware translations for each query term during decoding. This retains the desired query-expansion effect of probabilistic structured models, but it reduces query drift by filtering translations with respect to the context of the full query.

A projection of source language query terms $f \in F$ into the target language is achieved by representing each source token f by its probabilistically weighted translations. The score of target document E, given source language query F, is computed by calculating the BM25 rank over projected term frequency and document frequency weights as follows:

$$score(E|F) = \sum_{f \in F} BM25(tf(f,E), df(f)) \quad (3)$$

$$tf(f,E) = \sum_{e \in E_f} tf(e,E)p(e|f)$$

$$df(f) = \sum_{e \in E_f} df(e)p(e|f)$$

where $E_f = \{e \in E | p(e|f) > p_L\}$ is the set of translation options for query term f with probability greater than p_L. We also use a cumulative threshold p_C so that only the most probable options are added until p_C is reached.

Ture et al. (2012b; 2012a) achieved best retrieval performance by interpolating between (context-free) lexical translation probabilities p_{lex} estimated on symmetrized word alignments, and (context-aware) translation probabilities p_{nbest} estimated on the n-best list of an SMT decoder:

$$p(e|f) = \lambda p_{nbest}(e|f) + (1-\lambda)p_{lex}(e|f) \quad (4)$$

$p_{nbest}(e|f)$ is estimated by calculating expectations of term translations from k-best translations:

$$p_{nbest}(e|f) = \frac{\sum_{k=1}^{n} a_k(e,f)\mathcal{D}(k,F)}{\sum_{k=1}^{n}\sum_{e'} a_k(e',f)\mathcal{D}(k,F)}$$

where $a_k(e,f)$ is a function indicating an alignment of target term e to source term f in the k^{th} derivation of query F, and $\mathcal{D}(k,F)$ is the model score of the k^{th} derivation in the n-best list for query F.

We use the same hierarchical phrase-based system that was used for direct translation to calculate n-best translations for the probabilistic structured query approach. This allows us to extract word alignments between source and target text for F from the SCFG rules used in the derivation. The concept of self-translation is covered by the decoder's ability to use pass-through rules if words or phrases cannot be translated.

Probabilistic structured queries that include context-aware estimates of translation probabilities require a preservation of sentence-wise context-sensitivity also in retrieval. Thus, unlike the direct translation approach, we compute weighted term and document frequencies for each sentence s in query F separately. The scoring (3) of a target document for a multiple sentence query then becomes:

$$score(E|F) = \sum_{s \text{ in } F} \sum_{f \in s} BM25(tf(f,E), df(f))$$

3.3 Direct Phrase Table Learning from Relevance Rankings

Pairwise Ranking using Boosting The general form of the RankBoost algorithm (Freund et al., 2003; Collins and Koo, 2005) defines a scoring function $f(\mathbf{q},\mathbf{d})$ on query $\mathbf{q}$ and document $\mathbf{d}$ as a weighted linear combination of T *weak learners* h_t such that $f(\mathbf{q},\mathbf{d}) = \sum_{t=1}^{T} w_t h_t(\mathbf{q},\mathbf{d})$. Weak learners can belong to an arbitrary family of functions, but in our case they are restricted to the simplest case of unparameterized indicator functions selecting components of the feature vector $\phi(\mathbf{q},\mathbf{d})$ in (1) such that f is of the standard linear form (2). In our experiments, these features indicate the presence of pairs of uni- and bi-grams from the source-side vocabulary of query terms and the target-side vocabulary of document-terms, respectively. Furthermore, in order to simulate the pass-through behavior of SMT, we introduce additional features to the model that indicate the identity of terms in source and target. All identity features have the same fixed weight β, which is found on the development set.

For training, we are given labeled data in the form

of a set $\mathcal{R}$ of tuples $(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-)$, where $\mathbf{d}^+$ is a relevant (or higher ranked) document and $\mathbf{d}^-$ an irrelevant (or lower ranked) document for query $\mathbf{q}$. RankBoost's objective is to correctly rank query-document pairs such that $f(\mathbf{q}, \mathbf{d}^+) > f(\mathbf{q}, \mathbf{d}^-)$ for all data tuples from $\mathcal{R}$. RankBoost achieves this by optimizing the following convex exponential loss:

$$\mathcal{L}_{exp} = \sum_{(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-)\in\mathcal{R}} D(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-) e^{f(\mathbf{q},\mathbf{d}^-)-f(\mathbf{q},\mathbf{d}^+)},$$

where $D(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-)$ is a non-negative importance function on pairs of documents for a given $\mathbf{q}$.

We optimize $\mathcal{L}_{exp}$ in a greedy iterative fashion, which closely follows an efficient algorithm of Collins and Koo (2005) for the case of binary-valued h. In each step, the single feature h is selected that provides the largest decrease of $\mathcal{L}_{exp}$, i.e., that has the largest projection on the direction of the gradient $\nabla_h \mathcal{L}_{exp}$. Because of the sequential nature of the algorithm, RankBoost implicitly performs automatic feature selection and regularization (Rosset et al., 2004), which is crucial to reduce complexity and capacity for our application.

Parallelization and Bagging To achieve parallelization we use a variant of bagging (Breiman, 1996) on top of boosting, which has been observed to improve performance, reduce variance and is trivial to parallelize. The procedure is described as part of Algorithm 1: From the set of preference pairs $\mathcal{R}$, draw S equal-sized samples with replacement and distribute to nodes. Then, using each of the samples as a training set, separate boosting models $\{w_t^s, h_t^s\}, s = 1 \dots S$ are trained that contain the same number of features $t = 1 \dots T$. Finally the models are averaged: $f(\mathbf{q}, \mathbf{d}) = \frac{1}{S} \sum_t \sum_s w_t^s h_t^s(\mathbf{q}, \mathbf{d})$.

Algorithm The entire training procedure is outlined in Algorithm 1. For each possible feature h we maintain auxiliary variables W_h^+ and W_h^-:

$$W_h^{\pm} = \sum_{(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-):h(\mathbf{q},\mathbf{d}^+)-h(\mathbf{q},\mathbf{d}^-)=\pm 1} D(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-),$$

which are the cumulative weights of correctly and incorrectly ranked instances by a candidate feature h. The absolute value of $\partial \mathcal{L}_{exp} / \partial h$ can be expressed as $\left|\sqrt{W_h^+} - \sqrt{W_h^-}\right|$ which is used as feature selection criterion (Collins and Koo, 2005). The optimum of minimizing $\mathcal{L}_{exp}$ over w (with fixed h) can be shown to be $w = \frac{1}{2} \ln \frac{W_h^+ + \epsilon Z}{W_h^- + \epsilon Z}$, where ϵ is a smoothing parameter to avoid problems with small $W_h^{\pm}$ (Schapire and Singer, 1999), and $Z = \sum_{(\mathbf{q},\mathbf{d}^+,\mathbf{d}^-)\in\mathcal{R}} D(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-)$. Furthermore, for each step t of the learning process, values of D are updated to concentrate on pairs that have not been correctly ranked so far:

$$D_{t+1} = D_t \cdot e^{w_t \left(h_t(\mathbf{q},\mathbf{d}^-) - h_t(\mathbf{q},\mathbf{d}^+)\right)}. \qquad (5)$$

Finally, to speed up learning, on iteration t we recalculate $W_h^{\pm}$ only for those h that cooccur with previously selected h_t and keep the rest unchanged (Collins and Koo, 2005).

Algorithm 1: Bagged Boosting

Input: training tuples $\mathcal{R}$, max number of features T, initial D_0, smoothing param. $\epsilon \simeq 10^{-5}$
Initialize:
from $\mathcal{R}$ draw S samples with replacement and distribute to nodes
Learn:
for *all samples* $s = 1 \dots S$ *in parallel* **do**
  calculate W_h^+,W_h^-, Z on sample's data
  for *all* $t = 1 \dots T$ **do**
    choose $h_t = \arg\max_h \left|\sqrt{W_h^+} - \sqrt{W_h^-}\right|$
    and $w_t = \frac{1}{2} \ln \frac{W_h^+ + \epsilon Z}{W_h^- + \epsilon Z}$
    update D_t according to (5)
    update $W_h^{\pm}$ for all h that cooccur with h_t
  end
  return to master $\{h_t^s, w_t^s\}, t = 1 \dots T$
end
Bagging:
return scoring function
$f(\mathbf{q}, \mathbf{d}) = \frac{1}{S} \sum_t \sum_s w_t^s h_t^s(\mathbf{q}, \mathbf{d})$

Implementation Because of the total number of features (billions) there are several obstacles for the straight-forward implementation of Algorithm 1.

First, we cannot directly access all pairs $(\mathbf{q}, \mathbf{d})$ containing a particular feature h needed for calculating $W_h^{\pm}$. Building an inverted index is complicated as it needs to fit into memory for fast fre-

quent access[8]. We resort to the on-the-fly creation of the cross-product space of features, following prior work by Grangier and Bengio (2008) and Goel et al. (2008). That is, while processing a pair $(\mathbf{q}, \mathbf{d})$, we update $W_h^{\pm}$ for all h found for the pair.

Second, even if the explicit representation of all features is avoided by on-the-fly feature construction, we still need to keep all $W_h^{\pm}$ in addressable RAM. To achieve that we use hash kernels (Shi et al., 2009) and map original features into b-bit integer hashes. The values $W_{h'}^{\pm}$ for new, "hashed", features h' become $W_{h'}^{\pm} = \sum_{h:HASH(h)=h'} W_h^{\pm}$. We used the MurmurHash3 function on the UTF-8 representations of features and $b = 30$ (resulting in more than 1 billion distinct hashes).

4 Model Combination by Borda Counts

SMT-based approaches to CLIR and our boosting approach have different strengths. The SMT-based approaches produce fluent translations that are useful for matching general passages written in natural language. Both baseline SMT-based approaches presented above are agnostic of the ultimate retrieval task and are not specifically adapted for it. The boosting method, on the other hand, learns domain-specific word associations that are useful to discern relevant from irrelevant documents. In order to combine these orthogonal sources of information in a way that democratically respects each approach we use Borda Counts, i.e., a consensus-based voting procedure that has been successfully employed to aggregate ranked lists of documents for metasearch (Aslam and Montague, 2001).

We implemented a weighted version of the Borda Count method where each voter has a fixed amount of voting points which she is free to distribute among the candidates to indicate the amount of preference she is giving to each of them. In the case of retrieval, for each $\mathbf{q}$, the candidates are the scored documents in the retrieved subset of the whole document set. The aggregate score f_{agg} for two rankings $f_1(\mathbf{q}, \mathbf{d})$ and $f_2(\mathbf{q}, \mathbf{d})$ for all $(\mathbf{q}, \mathbf{d})$ in the test set is then:

$$f_{agg}(\mathbf{q}, \mathbf{d}) = \kappa \frac{f_1(\mathbf{q}, \mathbf{d})}{\sum_{\mathbf{d}} f_1(\mathbf{q}, \mathbf{d})} + (1-\kappa) \frac{f_2(\mathbf{q}, \mathbf{d})}{\sum_{\mathbf{d}} f_2(\mathbf{q}, \mathbf{d})}.$$

In practice, the normalizations sum over the top K retrieved documents. If a document is present only in the top-K list of one system, its score is considered zero for the other system. The aggregated scores $f_{agg}(\mathbf{q}, \mathbf{d})$ are sorted in descending order and top K scores are kept for evaluation.

Using the terminology proposed by Belkin et al. (1995), combining several systems' scores with Borda Counts can be viewed as the "data fusion" approach to IR, that merges outputs of the systems, while the PSQ baseline is an example of the "query combination" approach that extends the query at the input. Both techniques were earlier found to have similar performance in CLIR tasks based on direct translation, with a preference for the data fusion approach (Jones and Lam-Adesina, 2002).

5 Translation and Ranking Data

5.1 Parallel Translation Data

For Japanese-to-English patent translation we used data provided by the organizers of the NTCIR[9] workshop for the JP-EN PatentMT subtask. In particular, we used the data provided for NTCIR-7 (Fujii et al., 2008), consisting of 1.8 million parallel sentence pairs from the years 1993-2002 for training. For parameter tuning we used the development set of the NTCIR-8 test collection, consisting of 2,000 sentence pairs. The data were extracted from the description section of patents published by the Japanese Patent Office (JPO) and the United States Patent and Trademark Office (USPTO) by the method described in Utiyama and Isahara (2007).

Japanese text was segmented using the MeCab[10] toolkit. Following Feng et al. (2011), we applied a modified version of the compound splitter described in Koehn and Knight (2003) to katakana terms, which are often transliterations of English compound words. As these are usually not split by MeCab, they can cause a large number of out-of-vocabulary terms.

[8] It is possible to construct separate query and document inverted indices and intersect them on the fly to determine the set of documents that contains some pair of words. In practice, however, we found the overhead of set intersection during each feature access prohibitive.

[10] https://code.google.com/p/mecab/

	#queries	#relevant	#unique docs
train	107,061	1,422,253	888,127
dev	2,000	26,478	25,669
test	2,000	25,173	24,668

Table 1: Statistics of ranking data.

For the English side of the training data, we applied a modified version of the tokenizer included in the Moses scripts. This tokenizer relies on a list of non-breaking prefixes which mark expressions that are usually followed by a "." (period). We customized the list of prefixes by adding some abbreviations like "Chem", "FIG" or "Pat", which are specific to patent documents.

5.2 Ranking Data from Patent Citations

Graf and Azzopardi (2008) describe a method to extract relevance judgements for patent retrieval from patent citations. The key idea is to regard patent documents that are cited in a query patent, either by the patent applicant, or by the patent examiner or in a patent office's search report, as relevant for the query patent. Furthermore, patent documents that are related to the query patent via a patent family relationship, i.e., patents granted by different patent authorities but related to the same invention, are regarded as relevant. We assign three integer relevance levels to these three categories of relationships, with highest relevance (3) for family patents, lower relevance for patents cited in search reports by patent examiners (2), and lowest relevance level (1) for applicants' citations. We also include all patents which are in the same patent family as an applicant or examiner citation to avoid false negatives. This methodology has been used to create patent retrieval data at CLEF-IP[11] and proved very useful to automatically create a patent retrieval dataset for our experiments.

For the creation of our dataset, we used the MAREC[12] citation graph to extract patents in citation or family relation. Since the Japanese portion of the MAREC corpus only contains English abstracts, but not the Japanese full texts, we merged the patent documents in the NTCIR-10 test collection described above with the Japanese (JP) section of MAREC. Title, abstract, description and claims were added to the MAREC-JP data if the document was available in NTCIR. In order to keep parallel data for SMT training separate from ranking data, we used only data from the years 2003-2005 to extract training data for ranking, and two small datasets of 2,000 queries each from the years 2006-2007 for development and testing. Table 1 gives an overview over the data used for ranking. For development and test data, we randomly added irrelevant documents from the NTCIR-10 collection until we obtained two pools of 100,000 documents. The necessary information to reproduce the exact train, development and test data samples is downloadable from authors' webpage[13].

The experiments reported here use only the abstract of the Japanese and English patents in our training, development and test collection.

6 Experiments

6.1 System Development

System development and evaluation in our experiments was done on the ranking data described in the previous section (see Table 1). We report Mean Average Precision (MAP) scores, using the `trec_eval` (ver. 8.1) script from the TREC evaluation campaign[14], with a limit of top $K = 1,000$ retrieved documents for each query. Furthermore, we use the Patent Retrieval Evaluation Score (PRES)[15] introduced by Magdy and Jones (2010). This metric accounts for both precision and recall. In the study by Magdy and Jones (2010), PRES agreed with MAP in almost 80% of cases, and both agreed on the ranks of the best and the worst IR system. Both MAP and PRES scores are reported in the same range $[0, 1]$, and 0.01 stands for 1 MAP (PRES) point. Statistical significance of pairwise system comparisons was assessed using the paired randomization test (Noreen, 1989; Smucker et al., 2007).

For each system, optimal meta-parameter settings were found by choosing the configuration with highest MAP score on the development set. These results

[15] http://www.computing.dcu.ie/~wmagdy/Scripts/PRESeval.htm

method	MAP		PRES	
	dev	test	dev	test
1 DT	0.2636	0.2555	0.5669	0.5681
2 PSQ lexical table	0.2520	0.2444	0.5445	0.5498
3 PSQ n-best table	0.2698	0.2659	0.5789	0.5851
Boost-1g	0.2064	^{123}0.1982	0.5850	^{12}0.6122
Boost-2g	0.2526	^{3}0.2474	0.6900	^{123}0.7196

Table 2: MAP and PRES scores for CLIR methods (best configurations) on the development and test sets. Prefixed numbers denote statistical significance of a pairwise comparison with the baseline indicated by the superscript. For example, the bottom right result shows that Boost-2g is significantly better than DT (method 1), PSQ lexical table (method 2) and PSQ n-best table (method 3).

(together with PRES results) are shown in the second and fourth column of Table 2.

The direct translation approach (DT) was developed in three configurations: no stopword filtering, small stopword list (52 words) and a large stopword list (543 words). The last configuration achieved the highest score (MAP 0.2636).

The probabilistic structured query (PSQ) approach was developed using the lexical translation table and the translation table estimated on the decoder's n-best list, both optionally pruned with a variable lower p_L and cumulative p_C threshold on the word pair probability in the table (Section 3.2). A further meta-parameter of PSQ was whether to use standard or unique n-best lists. Finally, all variants were coupled with the same stopword filters as in the DT approach. The configurations that achieved the highest scores were: MAP 0.2520 for PSQ with a lexical table ($p_L = 0.01, p_C = 0.95$, no stopword filtering), and MAP 0.2698 for PSQ with a translation table estimated on the n-best list ($p_L = 0.005, p_C = 0.95$, large stopword list). Interpolating between lexical and n-best tables did not improve results in our experiments, thus we set $\lambda = 1$ in equation (4).

Each SMT-based system was run with 4 different MERT optimizations, leading to variations of less than 1 MAP point for each system. The best configurations for DT and PSQ on the development set were fixed and used for evaluation on the test set.

Training of the boosting approach (Boost) was done in parallel on bootstrap samples from the training data. First, a query $\mathbf{q}$ (i.e., a Japanese abstract) was sampled uniformly from all training queries.

method	MAP		PRES	
	dev	test	dev	test
DT + PSQ n-best	0.2778	*0.2726	0.5884	*0.5942
DT + Boost-1g	0.2778	*0.2728	0.6157	*0.6225
DT + Boost-2g	0.3309	***0.3300**	0.7132	***0.7279**
PSQ lexical + Boost-1g	0.2695	*0.2653	0.6068	*0.6131
PSQ lexical + Boost-2g	0.3215	***0.3187**	0.7071	***0.7240**
PSQ n-best + Boost-1g	0.2863	*0.2850	0.6309	*0.6402
PSQ n-best + Boost-2g	0.3439	***0.3416**	0.7212	***0.7376**

Table 3: MAP and PRES scores of the aggregated models on the development and test sets. Development scores correspond to peaks in Figures 1 and 3, respectively, for MAP and PRES; test scores are given for the κ's delivering these peaks on the development set. Prefixed $*$ indicates statistical significance of the result difference between aggregated system and the respective translation-based system used in the aggregation.

Then we sampled independently and uniformly a relevant document $\mathbf{d}^+$ (i.e., an English abstract) from the English patents marked relevant for the Japanese patent, and a random document $\mathbf{d}^-$ from the whole pool of English patent abstracts. If $\mathbf{d}^-$ had a relevance score greater or equal to the relevance score of $\mathbf{d}^+$, it was resampled. The initial importance weight D_0 for a triplet $(\mathbf{q}, \mathbf{d}^+, \mathbf{d}^-)$ was set to the positive difference in relevance scores for $\mathbf{d}^+$ and $\mathbf{d}^-$. Each bootstrap sample consisted of 10 pairs of documents for each of $10,000$ queries, resulting in $100,000$ training instances per sample.

The Boost approach was developed for uni-gram and combined uni- and bi-gram versions. We observed that the performance of the Boost method continuously improved with the number of iterations T and with the number of samples S, but saturated at about 15-20 samples without visible over-fitting in the tested range of T. Therefore we arbitrarily stopped training after obtaining $5,000$ features per sample, and used 35 samples for uni-gram version and 65 samples for the combined bi-gram version, resulting in models with 104K and 172K unique features, respectively. The optimal values for the pass-through weight β were found to be 0.3 and 0.2 for the uni-gram and bi-gram models on the development set. The best configuration of uni-gram and bi-gram model achieved MAP scores of 0.2064 and 0.2526 the development set. Using stopword filters during training did not improve the results here.

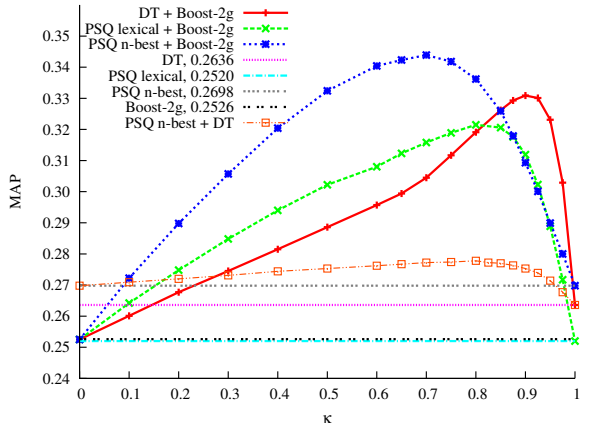

Figure 1: MAP rank aggregation for combinations of the bi-gram boosting and the baselines on the dev set.

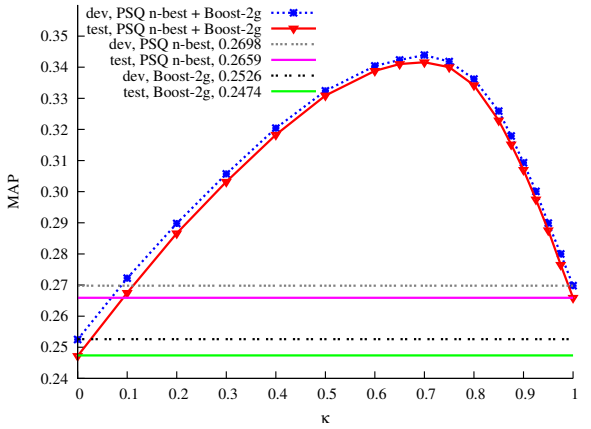

Figure 2: MAP rank aggregation for the bi-gram boosting and the "PSQ n-best table" approach on dev and test sets.

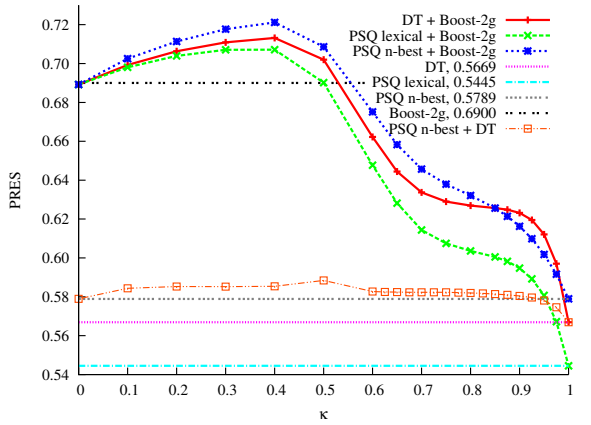

Figure 3: PRES rank aggregation for combinations of the bi-gram boosting and the baselines on the dev set.

6.2 Testing and Model Combination

The third and the fifth columns of Table 2 give a comparison of the MAP scores of the baseline approaches and the Boost model evaluated individually on the test set. Each score corresponds to the best configuration found on the development set. We see that the PSQ approach using n-best lists for projection outperforms all other methods in terms of MAP, but loses to both Boost approaches when evaluated with PRES. Direct translation is about 1 MAP point lower than PSQ n-best; Boost with combined uni- and bi-grams is another 0.8 MAP points worse, but is better in terms of PRES, especially for the bi-gram version. Given the fact that the complex SMT system behind the direct translation and PSQ approach is trained and tuned on very large in-domain datasets, the performance of the bare phrase table induced by the Boost method is respectable.

Our best results are obtained by a combination of the orthogonal information sources of the SMT and the Boost approaches. We evaluated the Borda Count aggregation scheme on the development data in order to find the optimal value for $\kappa \in [0, 1]$. The interpolation was done for the best combined uni- and bi-gram boosting model with the best variants of the DT and PSQ approaches. As can be seen from Figures 1 and 3, rank aggregation by Borda Count outperforms both individual approaches by a large margin. Figure 2 verifies that the results are transferable from the development set to the test set. The best performing system combination on the development data is also optimal on the test data.

Table 3 shows the retrieval performance of the best baseline model (PSQ n-best) combined with the best Boost model (bi-gram), with an impressive gain of over 7 MAP points (15 PRES points) over the best individual baseline result from Table 2. Even when, according to the PRES measure (Figure 3), the Boost-2g system is better on its own, injecting complementary information from the PSQ or DT approach still contributes several points. Similar gains are obtained by model combination of the DT approach with the best Boost model. However, a combination of the SMT-based CLIR approaches DT and PSQ barely improved results over the best input model. In summary, aggregating rankings is helpful for orthogonal systems, but not for systems including similar information.

6.3 Analysis

Table 4 lists some of the top-200 selected features for the boosting approach (the most common translation of the Japanese term is put in subscript).

We see that the direct ranking approach is able to penalize uni- and bi-gram cooccurrences that are harmful for retrieval by assigning them a negative weight, e.g., the pairing of 解決$_{\text{resolution}}$ with *image*. Pairs of uni- and bi-grams that are useful for retrieval are boosted by positive weights, e.g., the pair 圧縮$_{\text{compression}}$,機$_{\text{machine}}$ and *compressor* captures an important compound. Further examples, not shown in the table, are matches of the same source (target) n-gram with several different target (source) n-grams, e.g., the Japanese term 画像$_{\text{image}}$ is paired not only with its main translation, but also with dozens of related notions: *video*, *picture*, *scanning*, *printing*, *photosensitive*, *pixel*, *background* etc. This has a query expansion effect that is not possible in systems that use one translation or a small list of n-best translations. In addition, associations of source n-grams with overlapping target n-grams help boost the final score: e.g., the same term 画像$_{\text{image}}$ is positively paired with target bi-grams as {*an,original*}, {*original,image*} and {*image,for*}. This has the effect of compensating for the lack of handling phrase overlaps in an SMT decoder.

t	h_t **(uni- & bi-grams)**	w_t
1	層$_{\text{layer}}$ - layer	1.29

7 Conclusion

We presented a boosting approach to induce a table of bilingual n-gram correspondences by direct preference learning on relevance rankings. This table can be seen as a phrase table that encodes word-based information that is orthogonal and complementary to the information in standard translation-based CLIR approaches. We compared our boosting approach to very competitive CLIR baselines that use a complex SMT system trained and tuned on large in-domain datasets. Furthermore, our patent retrieval setup gives SMT-based approaches an advantage in that queries consist of several normal-length sentences, as opposed to the short queries common to web search. Despite this and despite the tiny size (about 170K parameters) of the boosting phrase table, compared to standard SMT phrase tables, this approach reached performance similar to direct translation using a full SMT model in terms of MAP, and was significantly better in terms of PRES. Overall, we obtained the best results by a model combination using consensus- based voting where the best SMT-based approach was combined with the boosting phrase table (gaining more than 7 MAP or 15 PRES points). We attribute this to the fact that the boosting approach augments SMT approaches with valuable information that is hard to get in approaches that are agnostic about the ranking data and the ranking task at hand.

The experimental setup presented in this paper uses relevance links between patent abstracts as ranking data. While this technique is useful to develop patent retrieval systems, it would be interesting to see if our results transfer to patent retrieval scenarios where full patent documents are used instead of only abstracts, or to standard CLIR scenarios that use short search queries in retrieval.

Acknowledgements

The research presented in this paper was supported in part by DFG grant "Cross-language Learning-to-Rank for Patent Retrieval". We would like to thank Eugen Ruppert for his contribution to the ranking data construction.

Recurrent Continuous Translation Models

Nal Kalchbrenner **Phil Blunsom**
Department of Computer Science
University of Oxford
{nal.kalchbrenner,phil.blunsom}@cs.ox.ac.uk

Abstract

We introduce a class of probabilistic continuous translation models called Recurrent Continuous Translation Models that are purely based on continuous representations for words, phrases and sentences and do not rely on alignments or phrasal translation units. The models have a generation and a conditioning aspect. The generation of the translation is modelled with a target Recurrent Language Model, whereas the conditioning on the source sentence is modelled with a Convolutional Sentence Model. Through various experiments, we show first that our models obtain a perplexity with respect to gold translations that is $> 43\%$ lower than that of state-of-the-art alignment-based translation models. Secondly, we show that they are remarkably sensitive to the word order, syntax, and meaning of the source sentence despite lacking alignments. Finally we show that they match a state-of-the-art system when rescoring n-best lists of translations.

1 Introduction

In most statistical approaches to machine translation the basic units of translation are phrases that are composed of one or more words. A crucial component of translation systems are models that estimate translation probabilities for pairs of phrases, one phrase being from the source language and the other from the target language. Such models count phrase pairs and their occurrences as distinct if the surface forms of the phrases are distinct. Although distinct phrase pairs often share significant similarities, linguistic or otherwise, they do not share statistical weight in the models' estimation of their translation probabilities. Besides ignoring the similarity of phrase pairs, this leads to general sparsity issues. The estimation is sparse or skewed for the large number of rare or unseen phrase pairs, which grows exponentially in the length of the phrases, and the generalisation to other domains is often limited.

Continuous representations have shown promise at tackling these issues. Continuous representations for words are able to capture their morphological, syntactic and semantic similarity (Collobert and Weston, 2008). They have been applied in continuous language models demonstrating the ability to overcome sparsity issues and to achieve state-of-the-art performance (Bengio et al., 2003; Mikolov et al., 2010). Word representations have also shown a marked sensitivity to conditioning information (Mikolov and Zweig, 2012). Continuous representations for characters have been deployed in character-level language models demonstrating notable language generation capabilities (Sutskever et al., 2011). Continuous representations have also been constructed for phrases and sentences. The representations are able to carry similarity and task dependent information, e.g. sentiment, paraphrase or dialogue labels, significantly beyond the word level and to accurately predict labels for a highly diverse range of unseen phrases and sentences (Grefenstette et al., 2011; Socher et al., 2011; Socher et al., 2012; Hermann and Blunsom, 2013; Kalchbrenner and Blunsom, 2013).

Phrase-based continuous translation models were first proposed in (Schwenk et al., 2006) and re-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1700–1709,
Seattle, Washington, USA, 18-21 October 2013.

cently further developed in (Schwenk, 2012; Le et al., 2012). The models incorporate a principled way of estimating translation probabilities that robustly extends to rare and unseen phrases. They achieve significant Bleu score improvements and yield semantically more suggestive translations. Although wide-reaching in their scope, these models are limited to fixed-size source and target phrases and simplify the dependencies between the target words taking into account restricted target language modelling information.

We describe a class of continuous translation models called Recurrent Continuous Translation Models (RCTM) that map without loss of generality a sentence from the source language to a probability distribution over the sentences in the target language. We define two specific RCTM architectures. Both models adopt a recurrent language model for the generation of the target translation (Mikolov et al., 2010). In contrast to other n-gram approaches, the recurrent language model makes no Markov assumptions about the dependencies of the words in the target sentence.

The two RCTMs differ in the way they condition the target language model on the source sentence. The first RCTM uses the convolutional sentence model (Kalchbrenner and Blunsom, 2013) to transform the source word representations into a representation for the source sentence. The source sentence representation in turn constraints the generation of each target word. The second RCTM introduces an intermediate representation. It uses a truncated variant of the convolutional sentence model to first transform the source word representations into representations for the target words; the latter then constrain the generation of the target sentence. In both cases, the convolutional layers are used to generate combined representations for the phrases in a sentence from the representations of the words in the sentence.

An advantage of RCTMs is the lack of latent alignment segmentations and the sparsity associated with them. Connections between source and target words, phrases and sentences are learnt only implicitly as mappings between their continuous representations. As we see in Sect. 5, these mappings often carry remarkably precise morphological, syntactic and semantic information. Another advantage is that the probability of a translation under the models is efficiently computable requiring a small number of matrix-vector products that is linear in the length of the source and the target sentence. Further, translations can be generated directly from the probability distribution of the RCTM without any external resources.

We evaluate the performance of the models in four experiments. Since the translation probabilities of the RCTMs are tractable, we can measure the perplexity of the models with respect to the reference translations. The perplexity of the models is significantly lower than that of IBM Model 1 and is $> 43\%$ lower than the perplexity of a state-of-the-art variant of the IBM Model 2 (Brown et al., 1993; Dyer et al., 2013). The second and third experiments aim to show the sensitivity of the output of the RCTM II to the linguistic information in the source sentence. The second experiment shows that under a random permutation of the words in the source sentences, the perplexity of the model with respect to the reference translations becomes significantly worse, suggesting that the model is highly sensitive to word position and order. The third experiment inspects the translations generated by the RCTM II. The generated translations demonstrate remarkable morphological, syntactic and semantic agreement with the source sentence. Finally, we test the RCTMs on the task of rescoring n-best lists of translations. The performance of the RCTM probabilities joined with a single word penalty feature matches the performance of the state-of-the-art translation system `cdec` that makes use of twelve features including five alignment-based translation models (Dyer et al., 2010).

We proceed as follows. We begin in Sect. 2 by describing the general modelling framework underlying the RCTMs. In Sect. 3 we describe the RCTM I and in Sect. 4 the RCTM II. Section 5 is dedicated to the four experiments and we conclude in Sect. 6.[1]

2 Framework

We begin by describing the modelling framework underlying RCTMs. An RCTM estimates the probability $P(\mathsf{f}|\mathsf{e})$ of a target sentence $\mathsf{f} = \mathsf{f}_1, ..., \mathsf{f}_m$ being a translation of a source sentence $\mathsf{e} = \mathsf{e}_1, ..., \mathsf{e}_k$. Let

[1] Code and models available at `nal.co`

us denote by $\mathsf{f}_{i:j}$ the substring of words $\mathsf{f}_i, ..., \mathsf{f}_j$. Using the following identity,

$$P(\mathsf{f}|\mathsf{e}) = \prod_{i=1}^{m} P(\mathsf{f}_i|\mathsf{f}_{1:i-1}, \mathsf{e}) \quad (1)$$

an RCTM estimates $P(\mathsf{f}|\mathsf{e})$ by directly computing for each target position i the conditional probability $P(\mathsf{f}_i|\mathsf{f}_{1:i-1}, \mathsf{e})$ of the target word f_i occurring in the translation at position i, given the preceding target words $\mathsf{f}_{1:i-1}$ and the source sentence e. We see that an RCTM is sensitive not just to the source sentence e but also to the preceding words $\mathsf{f}_{1:i-1}$ in the target sentence; by doing so it incorporates a model of the target language itself.

To model the conditional probability $P(\mathsf{f}|\mathsf{e})$, an RCTM comprises both a generative architecture for the target sentence and an architecture for conditioning the latter on the source sentence. To fully capture Eq. 1, we model the generative architecture with a recurrent language model (RLM) based on a recurrent neural network (Mikolov et al., 2010). The prediction of the i-th word f_i in a RLM depends on all the preceding words $\mathsf{f}_{1:i-1}$ in the target sentence ensuring that conditional independence assumptions are not introduced in Eq. 1. Although the prediction is most strongly influenced by words closely preceding f_i, long-range dependencies from across the whole sentence can also be exhibited. The conditioning architectures are model specific and are treated in Sect. 3-4. Both the generative and conditioning aspects of the models deploy continuous representations for the constituents and are trained as a single joint architecture. Given the modelling framework underlying RCTMs, we now proceed to describe in detail the recurrent language model underlying the generative aspect.

2.1 Recurrent Language Model

A RLM models the probability $P(\mathsf{f})$ that the sequence of words f occurs in a given language. Let $\mathsf{f} = \mathsf{f}_1, ..., \mathsf{f}_m$ be a sequence of m words, e.g. a sentence in the target language. Analogously to Eq. 1, using the identity,

$$P(\mathsf{f}) = \prod_{i=1}^{m} P(\mathsf{f}_i|\mathsf{f}_{1:i-1}) \quad (2)$$

the model explicitly computes without simplifying assumptions the conditional distributions

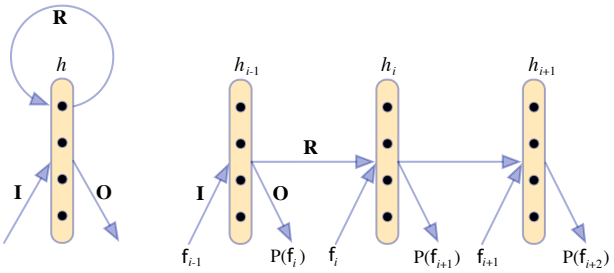

Figure 1: A RLM (left) and its unravelling to depth 3 (right). The recurrent transformation is applied to the hidden layer h_{i-1} and the result is summed to the representation for the current word f_i. After a non-linear transformation, a probability distribution over the next word f_{i+1} is predicted.

$P(\mathsf{f}_i|\mathsf{f}_{1:i-1})$. The architecture of a RLM comprises a vocabulary V that contains the words f_i of the language as well as three transformations: an input vocabulary transformation $\mathbf{I} \in \mathbb{R}^{q \times |V|}$, a recurrent transformation $\mathbf{R} \in \mathbb{R}^{q \times q}$ and an output vocabulary transformation $\mathbf{O} \in \mathbb{R}^{|V| \times q}$. For each word $\mathsf{f}_k \in V$, we indicate by $\mathsf{i}(\mathsf{f}_k)$ its index in V and by $\mathsf{v}(\mathsf{f}_k) \in \mathbb{R}^{|V| \times 1}$ an all zero vector with only $\mathsf{v}(\mathsf{f}_k)_{\mathsf{i}(\mathsf{f}_k)} = 1$.

For a word f_i, the result of $\mathbf{I} \cdot \mathsf{v}(\mathsf{f}_i) \in \mathbb{R}^{q \times 1}$ is the input continuous representation of f_i. The parameter q governs the size of the word representation. The prediction proceeds by successively applying the recurrent transformation $\mathbf{R}$ to the word representations and predicting the next word at each step. In detail, the computation of each $P(\mathsf{f}_i|\mathsf{f}_{1:i-1})$ proceeds recursively. For $1 < i < m$,

$$h_1 = \sigma(\mathbf{I} \cdot \mathsf{v}(\mathsf{f}_1)) \quad (3a)$$
$$h_{i+1} = \sigma(\mathbf{R} \cdot h_i + \mathbf{I} \cdot \mathsf{v}(\mathsf{f}_{i+1})) \quad (3b)$$
$$o_{i+1} = \mathbf{O} \cdot h_i \quad (3c)$$

and the conditional distribution is given by,

$$P(\mathsf{f}_i = v|\mathsf{f}_{1:i-1}) = \frac{\exp(o_{i,v})}{\sum_{v=1}^{V} \exp(o_{i,v})} \quad (4)$$

In Eq. 3, σ is a nonlinear function such as $\tanh$. Bias values b_h and b_o are included in the computation. An illustration of the RLM is given in Fig. 1.

The RLM is trained by backpropagation through time (Mikolov et al., 2010). The error in the predicted distribution calculated at the output layer is

backpropagated through the recurrent layers and cumulatively added to the errors of the previous predictions for a given number d of steps. The procedure is equivalent to standard backpropagation over a RLM that is unravelled to depth d as in Fig. 1.

RCTMs may be thought of as RLMs, in which the predicted distributions for each word f_i are conditioned on the source sentence e. We next define two conditioning architectures each giving rise to a specific RCTM.

3 Recurrent Continuous Translation Model I

The RCTM I uses a convolutional sentence model (CSM) in the conditioning architecture. The CSM creates a representation for a sentence that is progressively built up from representations of the n-grams in the sentence. The CSM embodies a hierarchical structure. Although it does not make use of an explicit parse tree, the operations that generate the representations act locally on small n-grams in the lower layers of the model and act increasingly more globally on the whole sentence in the upper layers of the model. The lack of the need for a parse tree yields two central advantages over sentence models that require it (Grefenstette et al., 2011; Socher et al., 2012). First, it makes the model robustly applicable to a large number of languages for which accurate parsers are not available. Secondly, the translation probability distribution over the target sentences does not depend on the chosen parse tree.

The RCTM I conditions the probability of each target word f_i on the continuous representation of the source sentence e generated through the CSM. This is accomplished by adding the sentence representation to each hidden layer h_i in the target recurrent language model. We next describe the procedure in more detail, starting with the CSM itself.

3.1 Convolutional Sentence Model

The CSM models the continuous representation of a sentence based on the continuous representations of the words in the sentence. Let $\mathsf{e} = \mathsf{e}_1 ... \mathsf{e}_k$ be a sentence in a language and let $\mathsf{v}(\mathsf{e}_i) \in \mathbb{R}^{q \times 1}$ be the continuous representation of the word e_i. Let $\mathbf{E}^{\mathsf{e}} \in \mathbb{R}^{q \times k}$ be the *sentence matrix* for e defined by,

$$\mathbf{E}^{\mathsf{e}}_{:,i} = \mathsf{v}(\mathsf{e}_i) \quad (5)$$

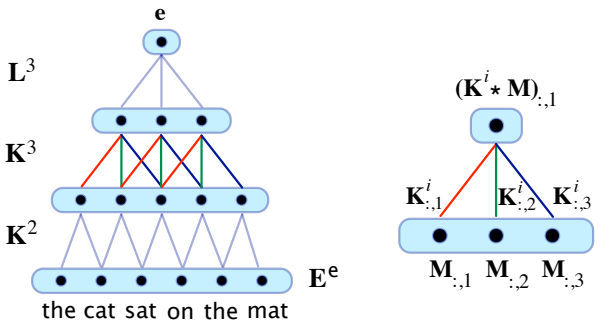

Figure 2: A CSM for a six word source sentence e and the computed sentence representation $\mathbf{e}$. $\mathbf{K}^2, \mathbf{K}^3$ are weight matrices and $\mathbf{L}^3$ is a top weight matrix. To the right, an instance of a one-dimensional convolution between some weight matrix $\mathbf{K}^i$ and a generic matrix $\mathbf{M}$ that could for instance correspond to $\mathbf{E}^{\mathsf{e}}_2$. The color coding of weights indicates weight sharing.

The main component of the architecture of the CSM is a sequence of *weight* matrices $(\mathbf{K}^i)_{2 \leq i \leq r}$ that correspond to the kernels or filters of the convolution and can be thought of as learnt feature detectors. From the sentence matrix $\mathbf{E}^{\mathsf{e}}$ the CSM computes a continuous vector representation $\mathbf{e} \in \mathbb{R}^{q \times 1}$ for the sentence e by applying a sequence of convolutions to $\mathbf{E}^{\mathsf{e}}$ whose weights are given by the weight matrices. The weight matrices and the sequence of convolutions are defined next.

We denote by $(\mathbf{K}^i)_{2 \leq i \leq r}$ a sequence of weight matrices where each $\mathbf{K}^i \in \mathbb{R}^{q \times i}$ is a matrix of i columns and $r = \lceil \sqrt{2N} \rceil$, where N is the length of the longest source sentence in the training set. Each row of $\mathbf{K}^i$ is a vector of i weights that is treated as the kernel or filter of a *one-dimensional* convolution. Given for instance a matrix $\mathbf{M} \in \mathbb{R}^{q \times j}$ where the number of columns $j \geq i$, each row of $\mathbf{K}^i$ can be convolved with the corresponding row in $\mathbf{M}$, resulting in a matrix $\mathbf{K}^i * \mathbf{M}$, where $*$ indicates the convolution operation and $(\mathbf{K}^i * \mathbf{M}) \in \mathbb{R}^{q \times (j-i+1)}$. For $i = 3$, the value $(\mathbf{K}^i * \mathbf{M})_{:,a}$ is computed by:

$$\mathbf{K}^i_{:,1} \odot \mathbf{M}_{:,a} + \mathbf{K}^i_{:,2} \odot \mathbf{M}_{:,a+1} + \mathbf{K}^i_{:,3} \odot \mathbf{M}_{:,a+2} \quad (6)$$

where $\odot$ is component-wise vector product. Applying the convolution kernel $\mathbf{K}^i$ yields a matrix $(\mathbf{K}^i * \mathbf{M})$ that has $i-1$ columns less than the original matrix $\mathbf{M}$.

Given a source sentence of length k, the CSM convolves successively with the sentence matrix $\mathbf{E}^{\mathsf{e}}$

the sequence of weight matrices $(\mathbf{K}^i)_{2\leq i\leq r}$, one after the other starting with $\mathbf{K}^2$ as follows:

$$\mathbf{E}^{\mathsf{e}}_1 = \mathbf{E}^{\mathsf{e}} \tag{7a}$$

$$\mathbf{E}^{\mathsf{e}}_{i+1} = \sigma(\mathbf{K}^{i+1} * \mathbf{E}^{\mathsf{e}}_i) \tag{7b}$$

After a few convolution operations, $\mathbf{E}^{\mathsf{e}}_i$ is either a vector in $\mathbb{R}^{q\times 1}$, in which case we obtained the desired representation, or the number of columns in $\mathbf{E}^{\mathsf{e}}_i$ is smaller than the number $i+1$ of columns in the next weight matrix $\mathbf{K}^{i+1}$. In the latter case, we equally obtain a vector in $\mathbb{R}^{q\times 1}$ by simply applying a top weight matrix $\mathbf{L}^j$ that has the same number of columns as $\mathbf{E}^{\mathsf{e}}_i$. We thus obtain a sentence representation $\mathbf{e} \in \mathbb{R}^{q\times 1}$ for the source sentence e. Note that the convolution operations in Eq. 7b are interleaved with non-linear functions σ. Note also that, given the different levels at which the weight matrices $\mathbf{K}^i$ and $\mathbf{L}^i$ are applied, the top weight matrix $\mathbf{L}^j$ comes from an additional sequence of weight matrices $(\mathbf{L}^i)_{2\leq i\leq r}$ distinct from $(\mathbf{K}^i)_{2\leq i\leq r}$. Fig. 2 depicts an instance of the CSM and of a one-dimensional convolution.[2]

3.2 RCTM I

As defined in Sect. 2, the RCTM I models the conditional probability $P(\mathsf{f}|\mathsf{e})$ of a sentence $\mathsf{f} = \mathsf{f}_1, ..., \mathsf{f}_m$ in a target language F being the translation of a sentence $\mathsf{e} = \mathsf{e}_1, ..., \mathsf{e}_k$ in a source language E. According to Eq. 1, the RCTM I explicitly computes the conditional distributions $P(\mathsf{f}_i|\mathsf{f}_{1:i-1}, \mathsf{e})$. The architecture of the RCTM I comprises a source vocabulary V^{E} and a target vocabulary V^{F}, two sequences of weight matrices $(\mathbf{K}^i)_{2\leq i\leq r}$ and $(\mathbf{L}^i)_{2\leq i\leq r}$ that are part of the constituent CSM, transformations $\mathbf{I} \in \mathbb{R}^{q\times|V^{\mathsf{F}}|}$, $\mathbf{R} \in \mathbb{R}^{q\times q}$ and $\mathbf{O} \in \mathbb{R}^{|V^{\mathsf{F}}|\times q}$ that are part of the constituent RLM and a sentence transformation $\mathbf{S} \in \mathbb{R}^{q\times q}$. We write $\mathbf{e} = \mathsf{csm}(\mathsf{e})$ for the output of the CSM with e as the input sentence.

The computation of the RCTM I is a simple modification to the computation of the RLM described in Eq. 3. It proceeds recursively as follows:

$$\mathbf{s} = \mathbf{S} \cdot \mathsf{csm}(\mathsf{e}) \tag{8a}$$

$$h_1 = \sigma(\mathbf{I} \cdot \mathsf{v}(\mathsf{f}_1) + \mathbf{s}) \tag{8b}$$

$$h_{i+1} = \sigma(\mathbf{R} \cdot h_i + \mathbf{I} \cdot \mathsf{v}(\mathsf{f}_{i+1}) + \mathbf{s}) \tag{8c}$$

$$o_{i+1} = \mathbf{O} \cdot h_i \tag{8d}$$

[2]For a formal treatment of the construction, see (Kalchbrenner and Blunsom, 2013).

and the conditional distributions $P(\mathsf{f}_{i+1}|\mathsf{f}_{1:i}, \mathsf{e})$ are obtained from o_i as in Eq. 4. σ is a nonlinear function and bias values are included throughout the computation. Fig. 3 illustrates an RCTM I.

Two aspects of the RCTM I are to be remarked. First, the length of the target sentence is predicted by the target RLM itself that by its architecture has a bias towards shorter sentences. Secondly, the representation of the source sentence e constraints uniformly all the target words, contrary to the fact that the target words depend more strongly on certain parts of the source sentence and less on other parts. The next model proposes an alternative formulation of these aspects.

4 Recurrent Continuous Translation Model II

The central idea behind the RCTM II is to first estimate the length m of the target sentence independently of the main architecture. Given m and the source sentence e, the model constructs a representation for the n-grams in e, where n is set to 4. Note that each level of the CSM yields n-gram representations of e for a specific value of n. The 4-gram representation of e is thus constructed by truncating the CSM at the level that corresponds to $n = 4$. The procedure is then inverted. From the 4-gram representation of the source sentence e, the model builds a representation of a sentence that has the predicted length m of the target. This is similarly accomplished by truncating the *inverted* CSM for a sentence of length m.

We next describe in detail the Convolutional n-gram Model (CGM). Then we return to specify the RCTM II.

4.1 Convolutional n-gram model

The CGM is obtained by truncating the CSM at the level where n-grams are represented for the chosen value of n. A column $\mathbf{g}$ of a matrix $\mathbf{E}^{\mathsf{e}}_i$ obtained according to Eq. 7 represents an n-gram from the source sentence e. The value of n corresponds to the number of word vectors from which the n-gram representation $\mathbf{g}$ is constructed; equivalently, n is the span of the weights in the CSM underneath $\mathbf{g}$ (see Fig. 2-3). Note that any column in a matrix $\mathbf{E}^{\mathsf{e}}_i$ represents an n-gram with the same span value n. We denote by $\mathsf{gram}(\mathbf{E}^{\mathsf{e}}_i)$ the size of the n-grams

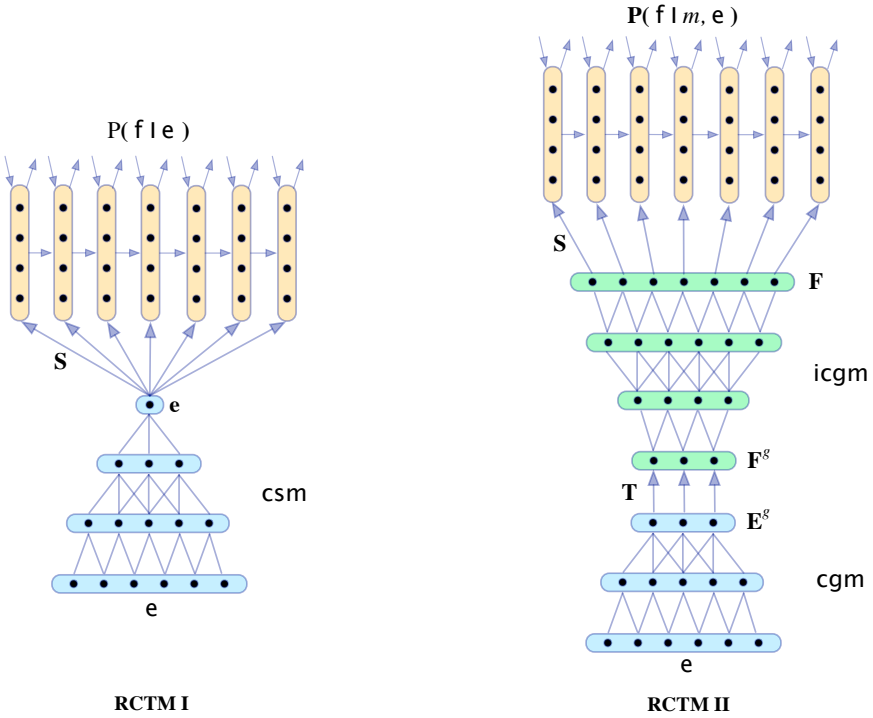

Figure 3: A graphical depiction of the two RCTMs. Arrows represent full matrix transformations while lines are vector transformations corresponding to columns of weight matrices.

represented by $\mathbf{E}^{\mathsf{e}}_i$. For example, for a sufficiently long sentence e, $\mathsf{gram}(\mathbf{E}^{\mathsf{e}}_2) = 2$, $\mathsf{gram}(\mathbf{E}^{\mathsf{e}}_3) = 4$, $\mathsf{gram}(\mathbf{E}^{\mathsf{e}}_4) = 7$. We denote by $\mathsf{cgm}(\mathsf{e}, n)$ that matrix $\mathbf{E}^{\mathsf{e}}_i$ from the CSM that represents the n-grams of the source sentence e.

The CGM can also be inverted to obtain a representation for a sentence from the representation of its n-grams. We denote by icgm the inverse CGM, which depends on the size of the n-gram representation $\mathsf{cgm}(\mathsf{e}, n)$ and on the target sentence length m. The transformation icgm unfolds the n-gram representation onto a representation of a target sentence with m words. The architecture corresponds to an inverted CGM or, equivalently, to an inverted truncated CSM (Fig. 3). Given the transformations cgm and icgm, we now detail the computation of the RCTM II.

4.2 RCTM II

The RCTM II models the conditional probability $P(\mathsf{f}|\mathsf{e})$ by factoring it as follows:

$$P(\mathsf{f}|\mathsf{e}) = P(\mathsf{f}|m, \mathsf{e}) \cdot P(m|\mathsf{e}) \tag{9a}$$

$$= \prod_{i=1}^{m} P(\mathsf{f}_{i+1}|\mathsf{f}_{1:i}, m, \mathsf{e}) \cdot P(m|\mathsf{e}) \tag{9b}$$

and computing the distributions $P(\mathsf{f}_{i+1}|\mathsf{f}_{1:i}, m, \mathsf{e})$ and $P(m|\mathsf{e})$. The architecture of the RCTM II comprises all the elements of the RCTM I together with the following additional elements: a translation transformation $\mathbf{T}^{q\times q}$ and two sequences of weight matrices $(\mathbf{J}^i)_{2\le i\le s}$ and $(\mathbf{H}^i)_{2\le i\le s}$ that are part of the icgm[3].

The computation of the RCTM II proceeds recursively as follows:

$$\mathbf{E}^g = \mathsf{cgm}(\mathsf{e}, 4) \tag{10a}$$

$$\mathbf{F}^g_{:,j} = \sigma(\mathbf{T} \cdot \mathbf{E}^g_{:,j}) \tag{10b}$$

$$\mathbf{F} = \mathsf{icgm}(\mathbf{F}^g, m) \tag{10c}$$

$$h_1 = \sigma(\mathbf{I} \cdot \mathsf{v}(\mathsf{f}_1) + \mathbf{S} \cdot \mathbf{F}_{:,1}) \tag{10d}$$

$$h_{i+1} = \sigma(\mathbf{R} \cdot h_i + \mathbf{I} \cdot \mathsf{v}(\mathsf{f}_{i+1}) + \mathbf{S} \cdot \mathbf{F}_{:,i+1}) \tag{10e}$$

$$o_{i+1} = \mathbf{O} \cdot h_i \tag{10f}$$

and the conditional distributions $P(\mathsf{f}_{i+1}|\mathsf{f}_{1:i}, \mathsf{e})$ are obtained from o_i as in Eq. 4. Note how each reconstructed vector $\mathbf{F}_{:,i}$ is added successively to the corresponding layer h_i that predicts the target word f_i. The RCTM II is illustrated in Fig. 3.

[3]Just like r the value s is small and depends on the length of the source and target sentences in the training set. See Sect. 5.1.2.

For the separate estimation of the length of the translation, we estimate the conditional probability $P(m|\mathsf{e})$ by letting,

$$P(m|\mathsf{e}) = P(m|k) = \mathsf{Poisson}(\lambda_k) \qquad (11)$$

where k is the length of the source sentence e and $\mathsf{Poisson}(\lambda)$ is a Poisson distribution with mean λ. This concludes the description of the RCTM II. We now turn to the experiments.

5 Experiments

We report on four experiments. The first experiment considers the perplexities of the models with respect to reference translations. The second and third experiments test the sensitivity of the RCTM II to the linguistic aspects of the source sentences. The final experiment tests the rescoring performance of the two models.

5.1 Training

Before turning to the experiments, we describe the data sets, hyper parameters and optimisation algorithms used for the training of the RCTMs.

5.1.1 Data sets

The training set used for all the experiments comprises a bilingual corpus of 144953 pairs of sentences less than 80 words in length from the news commentary section of the Eighth Workshop on Machine Translation (WMT) 2013 training data. The source language is English and the target language is French. The English sentences contain about 4.1M words and the French ones about 4.5M words. Words in both the English and French sentences that occur twice or less are substituted with the $\langle unknown \rangle$ token. The resulting vocabularies V^{E} and V^{F} contain, respectively, 25403 English words and 34831 French words.

For the experiments we use four different test sets comprised of the Workshop on Machine Translation News Test (WMT-NT) sets for the years 2009, 2010, 2011 and 2012. They contain, respectively, 2525, 2489, 3003 and 3003 pairs of English-French sentences. For the perplexity experiments unknown words occurring in these data sets are replaced with the $\langle unknown \rangle$ token. The respective 2008 WMT-NT set containing 2051 pairs of English-French sentences is used as the validation set throughout.

5.1.2 Model hyperparameters

The parameter q that defines the size of the English vectors $\mathsf{v}(\mathsf{e}_i)$ for $\mathsf{e}_i \in V^{\mathsf{E}}$, the size of the hidden layer h_i and the size of the French vectors $\mathsf{v}(\mathsf{f}_i)$ for $\mathsf{v}(\mathsf{f}_i) \in V^{\mathsf{F}}$ is set to $q = 256$. This yields a relatively small recurrent matrix and corresponding models. To speed up training, we factorize the target vocabulary V^{F} into 256 classes following the procedure in (Mikolov et al., 2011).

The RCTM II uses a convolutional n-gram model CGM where n is set to 4. For the RCTM I, the number of weight matrices r for the CSM is 15, whereas in the RCTM II the number r of weight matrices for the CGM is 7 and the number s of weight matrices for the inverse CGM is 9. If a test sentence is longer than all training sentences and a larger weight matrix is required by the model, the larger weight matrix is easily factorized into two smaller weight matrices whose weights have been trained. For instance, if a weight matrix of 10 weights is required, but weight matrices have been trained only up to weight 9, then one can factorize the matrix of 10 weights with one of 9 and one of 2. Across all test sets the proportion of sentence pairs that require larger weight matrices to be factorized into smaller ones is $< 0.1\%$.

5.1.3 Objective and optimisation

The objective function is the average of the sum of the cross-entropy errors of the predicted words and the true words in the French sentences. The English sentences are taken as input in the prediction of the French sentences, but they are not themselves ever predicted. An l_2 regularisation term is added to the objective. The training of the model proceeds by back-propagation through time. The cross-entropy error calculated at the output layer at each step is back-propagated through the recurrent structure for a number d of steps; for all models we let $d = 6$. The error accumulated at the hidden layers is then further back-propagated through the transformation $\mathbf{S}$ and the CSM/CGM to the input vectors $\mathsf{v}(\mathsf{e}_i)$ of the English input sentence e. All weights, including the English vectors, are randomly initialised and inferred during training.

The objective is minimised using mini-batch adaptive gradient descent (Adagrad) (Duchi et al., 2011). The training of an RCTM takes about 15 hours on 3 multicore CPUs. While our experiments

Table 1: Perplexity results on the WMT-NT sets.

are relatively small, we note that in principle our models should scale similarly to RLMs which have been applied to hundreds of millions of words.

5.2 Perplexity of gold translations

Since the computation of the probability of a translation under one of the RCTMs is efficient, we can compute the perplexities of the RCTMs with respect to the reference translations in the test sets. The perplexity measure is an indication of the quality that a model assigns to a translation. We compare the perplexities of the RCTMs with the perplexity of the IBM Model 1 (Brown et al., 1993) and of the Fast-Aligner (FA-IBM 2) model that is a state-of-the-art variant of IBM Model 2 (Dyer et al., 2013). We add as baselines the unconditional target RLM and a 5-gram target language model with modified Kneser-Nay smoothing (KN-5). The results are reported in Tab. 1. The RCTM II obtains a perplexity that is $> 43\%$ lower than that of the alignment based models and that is 40% lower than the perplexity of the RCTM I. The low perplexity of the RCTMs suggests that continuous representations and the transformations between them make up well for the lack of explicit alignments. Further, the difference in perplexity between the RCTMs themselves demonstrates the importance of the conditioning architecture and suggests that the localised 4-gram conditioning in the RCTM II is superior to the conditioning with the whole source sentence of the RCTM I.

5.3 Sensitivity to source sentence structure

The second experiment aims at showing the sensitivity of the RCTM II to the order and position of words in the English source sentence. To this end, we randomly permute in the training and testing sets

WMT-NT PERM	*2009*	*2010*	*2011*	*2012*
RCTM II	174	168	175	178

Table 2: Perplexity results of the RCTM II on the WMT-NT sets where the words in the English source sentences are randomly permuted.

the words in the English source sentence. The results on the permuted data are reported in Tab. 2. If the RCTM II were roughly comparable to a bag-of-words approach, there would be no difference under the permutation of the words. By contrast, the difference of the results reported in Tab. 2 with those reported in Tab. 1 is very significant, clearly indicating the sensitivity to word order and position of the translation model.

5.3.1 Generating from the RCTM II

To show that the RCTM II is sensitive not only to word order, but also to other syntactic and semantic traits of the sentence, we generate and inspect candidate translations for various English source sentences. The generation proceeds by sampling from the probability distribution of the RCTM II itself and does not depend on any other external resources. Given an English source sentence e, we let m be the length of the gold translation and we search the distribution computed by the RCTM II over all sentences of length m. The number of possible target sentences of length m amounts to $|V|^m = 34831^m$ where $V = V^{\mathsf{F}}$ is the French vocabulary; directly considering all possible translations is intractable. We proceed as follows: we sample with replacement 2000 sentences from the distribution of the RCTM II, each obtained by predicting one word at a time. We start by predicting a distribution for the first target word, restricting that distribution to the top 5 most probable words and sampling the first word of a candidate translation from the restricted distribution of 5 words. We proceed similarly for the remaining words. Each sampled sentence has a well-defined probability assigned by the model and can thus be ranked. Table 3 gives various English source sentences and some candidate French translations generated by the RCTM II together with their ranks.

The results in Tab. 3 show the remarkable syntactic agreements of the candidate translations; the

WMT-NT	*2009*	*2010*	*2011*	*2012*
RCTM I + WP	19.7	21.1	22.5	21.5
RCTM II + WP	19.8	21.1	22.5	21.7
`cdec` (12 features)	19.9	21.2	22.6	21.8

Table 4: Bleu scores on the WMT-NT sets of each RCTM linearly interpolated with a word penalty WP. The `cdec` system includes WP as well as five translation models and two language modelling features, among others.

large majority of the candidate translations are fully well-formed French sentences. Further, subtle syntactic features such as the singular or plural ending of nouns and the present and past tense of verbs are well correlated between the English source and the French candidate targets. Finally, the meaning of the English source is well transferred on the French candidate targets; where a correlation is unlikely or the target word is not in the French vocabulary, a semantically related word or synonym is selected by the model. All of these traits suggest that the RCTM II is able to capture a significant amount of both syntactic and semantic information from the English source sentence and successfully transfer it onto the French translation.

5.4 Rescoring and BLEU Evaluation

The fourth experiment tests the ability of the RCTM I and the RCTM II to choose the best translation among a large number of candidate translations produced by another system. We use the `cdec` system to generate a list of 1000 best candidate translations for each English sentence in the four WMT-NT sets. We compare the rescoring performance of the RCTM I and the RCTM II with that of the `cdec` itself. `cdec` employs 12 engineered features including, among others, 5 translation models, 2 language model features and a word penalty feature (WP). For the RCTMs we simply interpolate the log probability assigned by the models to the candidate translations with the word penalty feature WP, tuned on the validation data. The results of the experiment are reported in Tab. 4.

While there is little variance in the resulting Bleu scores, the performance of the RCTMs shows that their probabilities correlate with translation quality. Combining a monolingual RLM feature with the RCTMs does not improve the scores, while reducing `cdec` to just one core translation probability and language model features drops its score by two to five tenths. These results indicate that the RCTMs have been able to learn both translation and language modelling distributions.

6 Conclusion

We have introduced Recurrent Continuous Translation Models that comprise a class of purely continuous sentence-level translation models. We have shown the translation capabilities of these models and the low perplexities that they obtain with respect to reference translations. We have shown the ability of these models at capturing syntactic and semantic information and at estimating during reranking the quality of candidate translations.

The RCTMs offer great modelling flexibility due to the sensitivity of the continuous representations to conditioning information. The models also suggest a wide range of potential advantages and extensions, from being able to include discourse representations beyond the single sentence and multilingual source representations, to being able to model morphologically rich languages through character-level recurrences.

Abstract

Biological processes are complex phenomena involving a series of events that are related to one another through various relationships. Systems that can understand and reason over biological processes would dramatically improve the performance of semantic applications involving inference such as question answering (QA) – specifically *"How?"* and *"Why?"* questions. In this paper, we present the task of *process extraction*, in which events within a process and the relations between the events are automatically extracted from text. We represent processes by graphs whose edges describe a set of temporal, causal and co-reference event-event relations, and characterize the structural properties of these graphs (e.g., the graphs are *connected*). Then, we present a method for extracting relations between the events, which exploits these structural properties by performing joint inference over the set of extracted relations. On a novel dataset containing 148 descriptions of biological processes (released with this paper), we show significant improvement comparing to baselines that disregard process structure.

1 Introduction

A *process* is defined as a series of inter-related events that involve multiple entities and lead to an end result. Product manufacturing, economical developments, and various phenomena in life and social sciences can all be viewed as types of processes. Processes are complicated objects; consider for example the biological process of ATP synthesis described in Figure 1. This process involves 12 entities and 8 events. Additionally, it describes relations between events and entities, and the relationship between events (e.g., the second occurrence of the event *'enter'*, causes the event *'changing'*).

Automatically extracting the structure of processes from text is crucial for applications that require reasoning, such as non-factoid QA. For instance, answering a question on ATP synthesis, such as *"How do H+ ions contribute to the production of ATP?"* requires a structure that links *H+ ions* (Figure 1, sentence 1) to *ATP* (Figure 1, sentence 4) through a sequence of intermediate events. Such *"How?"* questions are common on FAQ websites (Surdeanu et al., 2011), which further supports the importance of process extraction.

Process extraction is related to two recent lines of work in Information Extraction – event extraction and timeline construction. Traditional event extraction focuses on identifying a closed set of events within a single sentence. For example, the BioNLP 2009 and 2011 shared tasks (Kim et al., 2009; Kim et al., 2011) consider nine events types related to proteins. In practice, events are currently almost always extracted from a single sentence. Process extraction, on the other hand, is centered around discovering *relations* between events that span *multiple* sentences. The set of possible event types in process extraction is also much larger.

Timeline construction involves identifying temporal relations between events (Do et al., 2012; McClosky and Manning, 2012; D'Souza and Ng, 2013), and is thus related to process extraction as both focus on event-event relations spanning multiple sentences. However, events in processes are tightly coupled in ways that go beyond simple temporal ordering, and these dependencies are central for the process extraction task. Hence, capturing process structure requires modeling a larger set of relations that includes temporal, causal and co-reference relations.

In this paper, we formally define the task of process extraction and present automatic extraction methods. Our approach handles an open set of event types and works over multiple sentences, extracting a rich set of event-event relations. Furthermore,

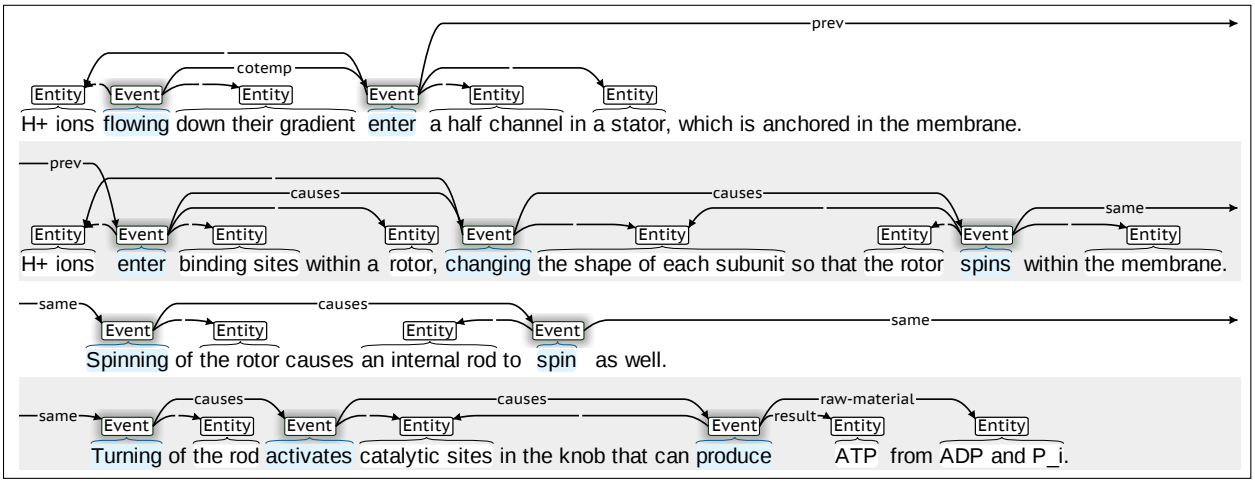

Figure 1: Partial annotation of the ATP synthesis process. Most of the semantic roles have been removed for simplicity.

we characterize a set of global properties of process structure that can be utilized during process extraction. For example, all events in a process are somehow connected to one another. Also, processes usually exhibit a "chain-like" structure reflecting process progression over time. We show that incorporating such global properties into our model and performing joint inference over the extracted relations significantly improves the quality of process structures predicted. We conduct experiments on a novel dataset of process descriptions from the textbook "Biology" (Campbell and Reece, 2005) that were annotated by trained biologists. Our method does not require any domain-specific knowledge and can be easily adapted to non-biology domains.

The main contributions of this paper are:

1. We define process extraction and characterize processes' structural properties.
2. We model global structural properties in processes and demonstrate significant improvement in extraction accuracy.
3. We publicly release a novel data set of 148 fully annotated biological process descriptions along with the source code for our system. The dataset and code can be downloaded from `http://nlp.stanford.edu/software/bioprocess/`.

2 Process Definition and Dataset

We define a process description as a paragraph or sequence of tokens $\mathbf{x} = \{x_1, \ldots x_{|\mathbf{x}|}\}$ that describes a series of events related by temporal and/or causal relations. For example, in ATP synthesis (Figure 1), the event of rotor spinning *causes* the event where an internal rod spins.

We model the events within a process and their relations by a directed graph $\mathcal{P} = (V, E)$, where the nodes $V = \{1, \ldots, |V|\}$ represent event mentions and labeled edges E correspond to event-event relations. An event mention $v \in V$ is defined by a trigger t_v, which is a span of words $x_i, x_{i+1}, \ldots, x_j$; and by a set of argument mentions A_v, where each argument mention $a_v \in A_v$ is also a span of words labeled by a semantic role l taken from a set $\mathcal{L}$. For example, in the last event mention of ATP synthesis, $t_v =$ *produce*, and one of the argument mentions is $a_v =$ *(ATP,* RESULT*)*. A labeled edge (u, v, r) in the graph describes a relation $r \in \mathcal{R}$ between the event mentions u and v. The task of process extraction is to extract the graph $\mathcal{P}$ from the text $\mathbf{x}$.[1]

A natural way to break down process extraction into sub-parts is to first perform semantic role labeling (SRL), that is, identify triggers and predict argument mentions with their semantic role, and then extract event-event relations between pairs of event mentions. In this paper, we focus on the second step, where given a set of event triggers $\mathcal{T}$, we find all event-event relations, where a trigger represents the entire event. For completeness, we now describe the semantic roles $\mathcal{L}$ used in our dataset, and then

[1] Argument mentions are also related by coreference relations, but we neglect that since it is not central in this paper.

present the set of event-event relations $\mathcal{R}$.

The set $\mathcal{L}$ contains standard semantic roles such as AGENT, THEME, ORIGIN, DESTINATION and LOCATION. Two additional semantic roles were employed that are relevant for biological text: RESULT corresponds to an entity that is the result of an event, and RAW-MATERIAL describes an entity that is used or consumed during an event. For example, the last event *'produce'* in Figure 1, has *'ATP'* as the RESULT, and *'ADP'* as the RAW-MATERIAL.

The event-event relation set $\mathcal{R}$ contains the following (assuming a labeled edge (u, v, r)):

1. PREV denotes that u is an event immediately before v. Thus, the edges (u, v, PREV) and (v, w, PREV), preclude the edge (u, w, PREV). For example, in "When a photon *strikes* ...energy is *passed* ...until it *reaches* ...", there is no edge (*strikes*, *reaches*, PREV) due to the intervening event *'passed'*.
2. COTEMP denotes that events u and v overlap in time (e.g., the first two event mentions *flowing* and *enter* in Figure 1).
3. SUPER denotes that event u includes event v. For instance, in "During *DNA replication*, DNA polymerases *proofread* each nucleotide..." there is an edge (*DNA replication*, *proofread*, SUPER).
4. CAUSES denotes that event u causes event v (e.g., the relation between *changing* and *spins* in sentence 2 of Figure 1).
5. ENABLES denotes that event u creates preconditions that allow event v to take place. For example, the description "...cause cancer cells to *lose* attachments to neighboring cells..., allowing them to *spread* into nearby tissues" has the edge (*lose*, *spread*, ENABLES). An intuitive way to think about the difference between *Causes* and *Enables* is the following: if u causes v this means that if u happens, then v happens. If u enables v, then if u does not happen, then v does not happen.
6. SAME denotes that u and v both refer to the same event (*spins* and *Spinning* in Figure 1).

Early work on temporal logic (Allen, 1983) contained more temporal relations than are used in our relation set $\mathcal{R}$. We chose a relation set $\mathcal{R}$ that captures the essential aspects of temporal relations between events in a process, while keeping the annotation as simple as possible. For instance, we include the SUPER relation that appears in temporal annotations such as the Timebank corpus (Pustejovsky et al., 2003) and Allen's work, but in practice was not considered by many temporal ordering systems (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Do et al., 2012). Importantly, our relation set also includes the relations CAUSES and ENABLES, which are fundamental to modeling processes and go beyond simple temporal ordering.

	Avg	**Min**	**Max**
# of sentences	3.80	1	15
# of tokens	89.98	19	319
# of events	6.20	2	15
# of non-NONE relations	5.64	1	24

Table 1: Process statistics over 148 process descriptions. NONE is used to indicate no relation.

We also added event coreference (SAME) to $\mathcal{R}$. Do et al. (2012) used event coreference information in a temporal ordering task to modify probabilities provided by pairwise classifiers prior to joint inference. In this paper, we simply treat SAME as another event-event relation, which allows us to easily perform joint inference and employ structural constraints that combine both coreference and temporal relations simultaneously. For example, if u and v are the same event, then there can exist no w, such that u is before w, but v is after w (see Section 3.3)

We annotated 148 process descriptions based on the aforementioned definitions. Further details on annotation and data set statistics are provided in Section 4 and Table 1.

Structural properties of processes Coherent processes exhibit many structural properties. For example, two argument mentions related to the same event cannot overlap – a constraint that has been used in the past in SRL (Toutanova et al., 2008). In this paper we focus on three main structural properties of the graph $\mathcal{P}$. First, in a coherent process, all events mentioned are related to one another, and hence the graph $\mathcal{P}$ must be connected. Second, processes tend to have a "chain-like" structure where one event follows another, and thus we expect

Deg.	Gold	Local	Global
0	0	29	0
1	219	274	224
2	369	337	408
3	46	14	17
≥ 4	22	2	7

Table 2: Node degree distribution for event mentions on the training set. Predictions for the *Local* and *Global* models were obtained using 10-fold cross validation.

nodes' degree to generally be ≤ 2. Indeed, 90% of event mentions have degree ≤ 2, as demonstrated by the *Gold* column of Table 2. Last, if we consider relations between all possible triples of events in a process, clearly some configurations are impossible, while others are common (illustrated in Figure 2). In Section 3.3, we show that modeling these properties using a joint inference framework improves the quality of process extraction significantly.

3 Joint Model for Process Extraction

Given a paragraph $\mathbf{x}$ and a trigger set $\mathcal{T}$, we wish to extract all event-event relations E. Similar to Do et al. (2012), our model consists of a local pairwise classifier and global constraints. We first introduce a classifier that is based on features from previous work. Next, we describe novel features specific for process extraction. Last, we incorporate global constraints into our model using an ILP formulation.

3.1 Local pairwise classifier

The local pairwise classifier predicts relations between all event mention pairs. In order to model the direction of relations, we expand the set $\mathcal{R}$ to include the reverse of four directed relations: PREV-NEXT, SUPER- SUB, CAUSES-CAUSED, ENABLES-ENABLED. After adding NONE to indicate no relation, and including the undirected relations COTEMP and SAME, $\mathcal{R}$ contains 11 relations. The classifier is hence a function $f : \mathcal{T} \times \mathcal{T} \rightarrow \mathcal{R}$. As an example, $f(t_i, t_j) = \text{PREV}$ iff $f(t_j, t_i) = \text{NEXT}$. Let n be the number of triggers in a process, and t_i be the i-th trigger in its description. Since $f(t_i, t_j)$ completely determines $f(t_j, t_i)$, it suffices to consider only pairs with $i < j$. Note that the process graph $\mathcal{P}$ is undirected under the new definition of $\mathcal{R}$.

Table 3 describes features from previous work (Chambers and Jurafsky, 2008; Do et al., 2012) extracted for a trigger pair (t_i, t_j). Some features were omitted since they did not yield improvement in performance on a development set (e.g., lemmas and part-of-speech tags of context words surrounding t_i and t_j), or they require gold annotations provided in TimeBank, which we do not have (e.g., *tense* and *aspect* of triggers). To reduce sparseness, we convert nominalizations into their verbal forms when computing word lemmas, using WordNet's (Fellbaum, 1998) derivation links.

Feature	Description
POS	Pair of POS tags
Lemma	Pair of lemmas
Prep*	Preposition lexeme, if in a prepositional phrase
Sent. count	Quantized number of sentences between triggers
Word count	Quantized number of words between triggers
LCA	Least common ancestor on constituency tree, if exists
Dominates*	Whether one trigger dominates other
Share	Whether triggers share a child on dependency tree
Adjacency	Whether two triggers are adjacent
Words btw.	For adjacent triggers, content words between triggers
Temp. btw.	For adjacent triggers, temporal connectives (from a small list) between triggers

Table 3: Features extracted for a trigger pair (t_i, t_j). Asteriks (*) indicate features that are duplicated, once for each trigger.

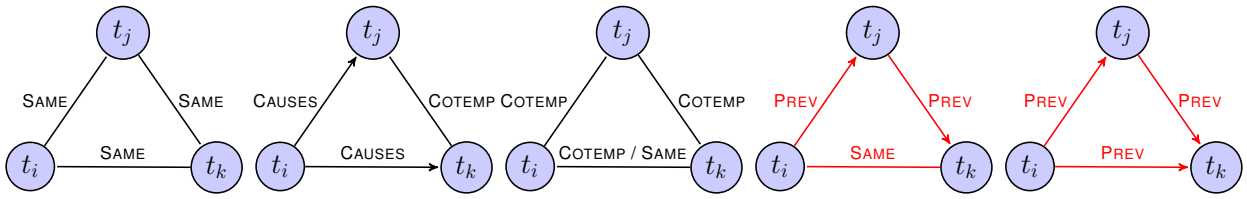
3.2 Classifier extensions

A central source of information to extract event-event relations from text are *connectives* such as *after*, *during*, etc. However, there is variability in the occurrence of these connectives as demonstrated by the following two sentences (connectives in boldface, triggers in italics):

1. **Because** alleles are *exchanged* during *gene flow*, genetic differences are *reduced*.

2. During *gene flow*, alleles are *exchanged*, and genetic differences are **hence** *reduced*.

Even though both sentences express the same relation $(\textit{exchanged}, \textit{reduced}, \text{CAUSES})$, the connectives used and their linear position with respect to the triggers are different. Also, in sentence 1, *gene flow* intervenes between *exchanged* and *reduced*. Since our dataset is small, we wish to identify the triggers related to each connective, and share features between such sentences. We do this using the syntactic structure and by clustering the connectives.



(a) SAME transitivity (b) CAUSE-COTEMP (c) COTEMP transitivity (d) SAME contradiction (e) PREV contradiction

Figure 2: Relation triangles (a)-(c) are common in the gold standard while (d)-(e) are impossible.

Sentence 1 presents a typical case where by walking up the dependency tree from the marker *because*, we can find the triggers related by this marker: *because* $\xleftarrow{mark}$ *exchanged* $\xleftarrow{advcl}$ *reduced*. Whenever a trigger is the head of an adverbial clause and marked by a *mark* dependency label, we walk on the dependency tree and look for a trigger in the main clause that is closest to the root (or the root itself in this example). By utilizing the syntactic structure, we can correctly spot that the trigger *gene flow* is not related to the trigger *exchanged* through the connective *because*, even though they are linearly closer. In order to reduce sparseness of connectives, we created a hand-made clustering of 30 connectives that maps words into clusters[2] (e.g., *because*, *since* and *hence* to a "causality" cluster). After locating the relevant pair of triggers, we use these clusters to fire the same feature for connectives belonging to the same cluster. We perform a similar procedure whenever a trigger is part of a prepositional phrase (imagine sentence 1 starting with *"due to allele exchange during gene flow ..."*) by walking up the constituency tree, but details are omitted for brevity. In sentence 2, the connective *hence* is an adverbial modifier of the trigger *reduced*. We look up the cluster for the connective *hence* and fire the same feature for the adjacent triggers *exchanged* and *reduced*.

We further extend our features to handle the rich relation set necessary for process extraction. The first event of a process is often expressed as a nominalization and includes subsequent events (SUPER relation), e.g., "The *Calvin cycle* begins by *incorporating*...". To capture this, we add a feature that fires when the first event of the process description is a noun. We also add two features targeted at the SAME relation: one indicating if the lemmas of t_i and t_j are the same, and another specifying the determiner of t_j, if it exists. Certain determiners indicate that an event trigger has already been mentioned, e.g., the determiner *this* hints a SAME relation in "The next steps *decompose* citrate back to oxaloacetate. This *regeneration* makes ...". Last, we add as a feature the dependency path between t_i and t_j, if it exists, e.g., in "meiosis produces cells that divide ...", the feature $\xrightarrow{dobj}\xrightarrow{rcmod}$ is fired for the trigger pair *produces* and *divide*. In Section 4.1 we empirically show that our extensions to the local classifier substantially improve performance.

For our pairwise classifier, we train a maximum entropy classifier that computes a probability p_{ijr} for every trigger pair (t_i, t_j) and relation r. Hence, $f(t_i, t_j) = \arg\max_r p_{ijr}$.

3.3 Global Constraints

Naturally, pairwise classifiers are local models that can violate global properties in the process structure. Figure 3 (left) presents an example for predictions made by the pairwise classifier, which result in two triggers (*deleted* and *dupcliated*) that are isolated from the rest of the triggers. In this section, we discuss how we incorporate constraints into our model to generate coherent global process structures.

Let θ_{ijr} be the score for a relation r between the trigger pair (t_i, t_j) (e.g., $\theta_{ijr} = \log p_{ijr}$), and y_{ijr} be the corresponding indicator variable. Our goal is to find an assignment for the indicators $\mathbf{y} = \{y_{ijr} \mid 1 \leq i < j \leq n, r \in \mathcal{R}\}$. With no global constraints this can be formulated as the following ILP:

[2]The full set of connectives and their clustering are provided as part of our publicly released package.

$$\arg\max_{\mathbf{y}} \sum_{ijr} \theta_{ijr} y_{ijr} \quad (1)$$
$$\text{s.t.} \forall_{i,j} \sum_{r} y_{ijr} = 1$$

where the constraint ensures exactly one relation between each event pair. We now describe constraints that result in a coherent global process structure.

Connectivity Our ILP formulation for enforcing connectivity is a minor variation of the one suggested by Martins et al. (2009) for dependency parsing. In our setup, we want $\mathcal{P}$ to be a connected undirected graph, and not a directed tree. However, an undirected graph $\mathcal{P}$ is connected iff there exists a directed tree that is a subgraph of $\mathcal{P}$ when edge directions are ignored. Thus the resulting formulation is almost identical and is based on flow constraints which ensure that there is a path from a designated root in the graph to all other nodes.

Let $\bar{\mathcal{R}}$ be the set $\mathcal{R} \setminus$ NONE. An edge (t_i, t_j) is in E iff there is some non-NONE relation between t_i and t_j, i.e. iff $y_{ij} := \sum_{r \in \bar{\mathcal{R}}} y_{ijr}$ is equal to 1. For each variable y_{ij} we define two auxiliary binary variables z_{ij} and z_{ji} that correspond to edges of the directed tree that is a subgraph of $\mathcal{P}$. We ensure that the edges in the tree exist also in $\mathcal{P}$ by tying each auxiliary variable to its corresponding ILP variable:

$$\forall_{i<j}\ z_{ij} \leq y_{ij}, z_{ji} \leq y_{ij} \quad (2)$$

Next, we add constraints that ensure that the graph structure induced by the auxiliary variables is a tree rooted in an arbitrary node 1 (The choice of root does not affect connectivity). We add for every $i \neq j$ a flow variable ϕ_{ij} which specifies the amount of flow on the directed edge z_{ij}.

$$\sum_{i} z_{i1} = 0, \forall_{j \neq 1} \sum_{i} z_{ij} = 1 \quad (3)$$

$$\sum_{i} \phi_{1i} = n - 1 \quad (4)$$

$$\forall_{j \neq 1} \sum_{i} \phi_{ij} - \sum_{k} \phi_{jk} = 1 \quad (5)$$

$$\forall_{i \neq j}\ \phi_{ij} \leq n \cdot z_{ij} \quad (6)$$

Equation 3 says that all nodes in the graph have exactly one parent, except for the root that has no parents. Equation 4 ensures that the outgoing flow from the root is $n-1$, and Equation 5 states that each of the other $n-1$ nodes consume exactly one unit of flow. Last, Equation 6 ties the auxiliary variables to the flow variables, making sure that flow occurs only on edges. The combination of these constraints guarantees that the graph induced by the variables z_{ij} is a directed tree and consequently the graph induced by the objective variables $\mathbf{y}$ is connected.

Chain structure A chain is a connected graph where the degree of all nodes is ≤ 2. Table 2 presents nodes' degree and demonstrates that indeed process graphs are close to being chains. The following constraint bounds nodes' degree by 2:

$$\forall_j (\sum_{i<j} y_{ij} + \sum_{j<k} y_{jk} \leq 2) \quad (7)$$

Since graph structures are not always chains, we add this as a soft constraint, that is, we penalize the objective for each node with degree > 2. The chain structure is one of the several soft constraints we enforce. Thus, our modified objective function is $\sum_{ijr} \theta_{ijr} y_{ijr} + \sum_{k \in \mathcal{K}} \alpha_k C_k$, where $\mathcal{K}$ is the set of soft constraints, α_k is the penalty (or reward for desirable structures), and C_k indicates whether a constraint is violated (or satisfied). Note that under this formulation our model is simply a constrained conditional model (wei Chang et al., 2012). The parameters α_k are tuned on a development set (see Section 4).

Relation triads A relation triad (or a relation triangle) for any three triggers t_i, t_j and t_k in a process is a 3-tuple of relations $(f(t_i, t_j), f(t_j, t_k), f(t_i, t_k))$. Clearly, some triads are impossible while others are quite common. To find triads that could improve process extraction, the frequency of all possible triads in both the training set and the output of the pairwise classifier were found, and we focused on those for which the classifier and the gold standard disagree. We are interested in triads that never occur in training data but are predicted by the classifier, and vice versa. Figure 2 illustrates some of the triads found and Equa-

tions 8-12 provide the corresponding ILP formulations. Equations 8-10 were formulated as soft constraints (expanding the set $\mathcal{K}$) and were incorporated by defining a reward α_k for each triad type.[3] On the other hand, Equations 11-12 were formulated as hard constraints to prevent certain structures.

1. SAME transitivity (Figure 2a, Eqn. 8): Coreference transitivity has been used in past work (Finkel and Manning, 2008) and we incorporate it by a constraint that encourages triads that respect transitivity.
2. CAUSE-COTEMP (Figure 2b, Eqn. 9): If t_i causes both t_j and t_k, then often t_j and t_k are co-temporal. E.g, in "*genetic drift* has led to a *loss* of genetic variation and an *increase* in the frequency of . . .", a single event causes two subsequent events that occur simultaneously.
3. COTEMP transitivity (Figure 2c, Eqn. 10): If t_i is co-temporal with t_j and t_j is co-temporal with t_k, then usually t_i and t_k are either co-temporal or denote the same event.
4. SAME contradiction (Figure 2d, Eqn. 11): If t_i is the same event as t_k, then their temporal ordering with respect to a third trigger t_j may result in a contradiction, e.g., if t_j is after t_i, but before t_k. We define 5 temporal categories that generate $\binom{5}{2}$ possible contradictions, but for brevity present just one representative hard constraint. This constraint depends on prediction of temporal and co-reference relations jointly.
5. PREV contradiction (Figure 2e, Eqn. 12): As mentioned (Section 3.3), if t_i is immediately before t_j, and t_j is immediately before t_k, then t_i cannot be immediately before t_k.

$$y_{ij\text{SAME}} + y_{jk\text{SAME}} + y_{ik\text{SAME}} \geq 3 \quad (8)$$

$$y_{ij\text{CAUSES}} + y_{ik\text{CAUSES}} + y_{jk\text{COTEMP}} \geq 3 \quad (9)$$

$$y_{ij\text{COTEMP}} + y_{jk\text{COTEMP}} + y_{ik\text{COTEMP}} + y_{ik\text{SAME}} \geq 3 \quad (10)$$

$$y_{ij\text{PREV}} + y_{jk\text{PREV}} + y_{ik\text{SAME}} \leq 2 \quad (11)$$

$$y_{ij\text{PREV}} + y_{jk\text{PREV}} - y_{ik\text{NONE}} \leq 1 \quad (12)$$

[3]We experimented with a reward for certain triads or a penalty for others and empirically found that using rewards results in better performance on the development set.

We used the Gurobi optimization package[4] to find an exact solution for our ILP, which contains $O(n^2|\mathcal{R}|)$ variables and $O(n^3)$ constraints. We also developed an equivalent formulation amenable to dual decomposition (Sontag et al., 2011), which is a faster approximation method. But practically, solving the ILP exactly with Gurobi was quite fast (average/median time per process: 0.294 sec/0.152 sec on a standard laptop).

4 Experimental Evaluation

We extracted 148 process descriptions by going through chapters from the textbook "Biology" and marking any contiguous sequence of sentences that describes a process, i.e., a series of events that lead towards some objective. Then, each process description was annotated by a biologist. The annotator was first presented with annotation guidelines and annotated 20 descriptions. The annotations were then discussed with the authors, after which all process descriptions were annotated. After training a second biologist, we measured inter-annotator agreement $\kappa = 0.69$, on 30 random process descriptions.

Process descriptions were parsed with Stanford constituency and dependency parsers (Klein and Manning, 2003; de Marneffe et al., 2006), and 35 process descriptions were set aside as a test set (number of training set trigger pairs: 1932, number of test set trigger pairs: 906). We performed 10-fold cross validation over the training set for feature selection and tuning of constraint parameters. For each constraint type (connectivity, chain-structure, and five triad constraints) we introduced a parameter and tuned the seven parameters by coordinate-wise ascent, where for hard constraints a binary parameter controls whether the constraint is used, and for soft constraints we attempted 10 different reward/penalty values. For our global model we defined $\theta_{ijr} = \log p_{ijr}$, where p_{ijr} is the probability at edge (t_i, t_j) for label r, given by the pairwise classifier.

We test the following systems: (a) *All-Prev*: Since the most common process structure was chain-like, we simply predict PREV for every two adjacent triggers in text. (b) $Local_{base}$: A pairwise classifier with features from previous work (Section 3.1) (c) *Local*:

[4]www.gurobi.com

	Temporal			Full		
	P	R	F_1	P	R	F_1
All-Prev	58.4	54.8	56.6	34.1	32.0	33.0
$Local_{base}$	61.5	51.8	56.2	52.1	43.9	47.6
Local	63.2	55.7†	59.2	54.7	48.3†	51.3
Chain	**64.5**	60.5†‡	62.4†	56.1	52.6†‡	54.3†
Global	63.9	**61.4**†‡	**62.6**†‡	**56.2**	**54.0**†‡	**55.0**†‡

Table 4: Test set results on all experiments. Best number in each column is bolded. † and ‡ denote statistical significance ($p < 0.01$) against $Local_{base}$ and *Local* baselines, respectively.

A pairwise classifier with all features (Section 3.2) (d) *Chain*: For every two adjacent triggers, choose the non-NONE relation with highest probability according to *Local*. This baseline heuristically combines our structural assumptions with the pairwise classifier. We deterministically choose a connected chain structure, and then use the classifier to label the edges. (e) *Global*: Our full model that uses ILP inference.

To evaluate system performance we compare the set of predictions on all trigger pairs to the gold standard annotations and compute micro-averaged precision, recall and F_1. We perform two types of evaluations: (a) *Full*: evaluation on our full set of 11 relations (b) *Temporal:* Evaluation on temporal relations only, by collapsing PREV, CAUSES, and ENABLES to a single category and similarly for NEXT, CAUSED, and ENABLED (inter-annotator agreement $\kappa = 0.75$). We computed statistical significance of our results with the paired bootstrap resampling method of 2000 iterations (Efron and Tibshirani, 1993), where the units resampled are trigger-trigger-relation triples.

4.1 Results

Table 4 presents performance of all systems. We see that using global constraints improves performance almost invariably on all measures in both full and temporal evaluations. Particularly, in the full evaluation *Global* improves recall by 12% and overall F_1 improves significantly by 3.7 points against *Local* ($p < 0.01$). Recall improvement suggests that modeling connectivity allowed *Global* to add correct relations in cases where some events were not connected to one another.

The *Local* classifier substantially outperforms $Local_{base}$. This indicates that our novel features (Section 3.2) are important for discriminating between process relations. Specifically, in the full evaluation *Local* improves precision more than in the temporal evaluation, suggesting that designing syntactic and semantic features for connectives is useful for distinguishing PREV, CAUSES, and ENABLES when the amount of training data is small.

The *Chain* baseline performs only slightly worse than our global model. This demonstrates the strong tendency of processes to proceed linearly from one event to the other, which is a known property of discourse structure (Schegloff and Sacks, 1973). However, since the structure is deterministically fixed, *Chain* is highly inflexible and does not allow any extensions or incorporation of other structural constraints or domain knowledge. Thus, it can be used as a simple and efficient approximation but is not a good candidate for a real system. Further support for the linear nature of process structure is provided by the *All-Prev* baseline, which performs poorly in the full evaluation, but in temporal evaluation works reasonably well.

Table 2 presents the degree distribution of *Local* and *Global* on the development set comparing to the gold standard. The degree distribution of *Global* is more similar to the gold standard than *Local*. In particular, the connectivity constraint ensures that there are no isolated nodes and shifts mass from nodes with degree 0 and 1 to nodes with degree 2.

Table 5 presents the order in which constraints were introduced into the global model using coordinate ascent on the development set. Connectivity is the first constraint to be introduced, and improves performance considerably. The chain constraint, on the other hand, is included third and the improvement in F_1 score is relatively smaller. This can be explained by the distribution of degrees in Table 2 which shows that the predictions of *Local* does not have many nodes with degree > 2. As for triad constraints, we see that four constraints are important and are included in the model, but one is discarded.

Last, we examined the results of *Global* when macro-averaging over processes, i.e., assigning each process the same weight by computing recall, precision and F_1 for each process and averaging those scores. We found that results are quite similar (with a slight improvement): in the full evalua-

Order	Parameter name	Value (α)	F_1 score
–	*Local model*	–	49.9
1	Connectivity constraint	∞	51.2
2	SAME transitivity	0.5	52.9
3	Chain constraint	-0.5	53.3
4	CAUSE-COTEMP	1.0	53.7
6	PREV contradiction	∞	53.8
7	SAME contradiction	∞	53.9

Table 5: Order by which constraint parameters were set using coordinate ascent on the development set. For each parameter, the value chosen and F_1 score after including the constraint are provided. Negative values correspond to penalties, positive values to rewards, and a value of ∞ indicates a hard constraint.

tion *Global* obtains R/P/F_1 of 56.4/55.0/55.7, and in the temporal evaluation *Global* obtains R/P/F_1 of 63.8/62.3/63.1.

4.2 Qualitative Analysis

Figure 3 shows two examples where global constraints corrected the predictions of *Local*. In Figure 3, left, *Local* failed to predict the causal relations *skipped-deleted* and *used-duplicated*, possibly because they are not in the same sentence and are not adjacent to one another. By enforcing the connectivity constraint, *Global* correctly adds the correct relations and connects *deleted* and *duplicated* to the other triggers in the process.

In Figure 3, right, *Local* predicts a structure that results in a "SAME contradiction" structure. The triggers *bind* and *binds* cannot denote the same event if a third trigger *secrete* is temporally between them. However, *Local* predicts they are the same event, as they share a lemma. *Global* prohibits this structure and correctly predicts the relation as NONE.

To better understand the performance of *Local*, we analyzed the confusion matrix generated based on its predictions. Although this is a challenging 11-class classification task, most of the mass is concentrated on the matrix diagonal, as desired. Error analysis reveals that 17.5% of all errors are confusions between NONE and PREV, 11.1% between PREV and CAUSES, and 8.6% between PREV and COTEMP. This demonstrates that distinguishing the classes PREV, CAUSES and COTEMP is challenging for *Local*. Our current global constraints do not address this type of error, and thus an important direction for future work is to improve the local model.

The global model depends on the predictions of the local classifier, and so enforcing global constraints does not guarantee improvement in performance. For instance, if *Local* produces a graph that is disconnected (e.g., *deleted* in Figure 3, left), then *Global* will add an edge. However, the label of the edge is determined by scores computed based on the local classifier, and if this prediction is wrong, we will now be penalized for both the false negative of the correct class (just as before), and also for the false positive of the predicted class. Despite that we see that *Global* improves overall performance by 3.7 F_1 points on the test set.

5 Related Work

A related line of work is biomedical event extraction in recent BioNLP shared tasks (Kim et al., 2009; Kim et al., 2011). Earlier work employed a pipeline architecture where first events are found, and then their arguments are identified (Miwa et al., 2010; Björne et al., 2011). Subsequent methods predicted events and arguments jointly using Markov logic (Poon and Vanderwende, 2010) and dependency parsing algorithms (McClosky et al., 2011). Riedel and McCallum (2011) further improved performance by capturing correlations between events and enforcing consistency across arguments.

Temporal event-event relations have been extensively studied (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Denis and Muller, 2011; Do et al., 2012; McClosky and Manning, 2012; D'Souza and Ng, 2013), and we leverage such techniques in our work (Section 3.1). However, we extend beyond temporal relations alone, and strongly rely on dependencies between process events. Chambers and Jurafsky (2011) learned event templates (or frames), where events that are related to one another and their semantic roles are extracted. Recently, Cheung et al. (2013) proposed an unsupervised generative model for inducing such templates. A major difference in our work is that we do not learn typical event relations from a large and redundant corpus, but are given a paragraph and have a "one-shot" chance to extract the process structure.

We showed in this paper that global structural properties lead to significant improvements in extraction accuracy, and ILP is an effective framework

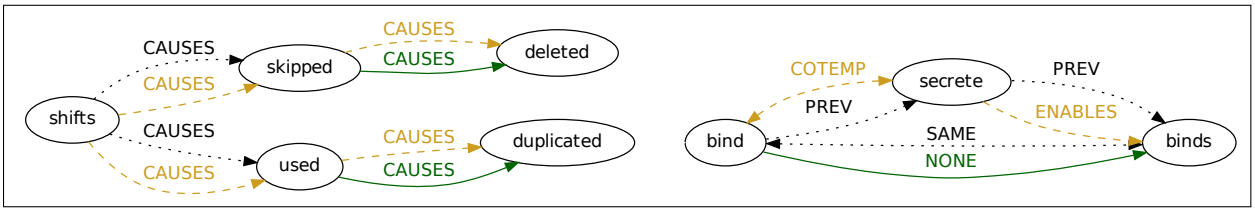


Figure 3: Process graph fragments. Black edges (dotted) are predictions of *Local*, green (solid) are predictions of *Global*, and gold (dashed) are gold standard edges. To reduce clutter, we present the predictions of *Global* only when it disagrees with *Local*. In all other cases, the predictions of *Global* and *Local* are identical. Original text, Left: "... the template *shifts* ..., and a part of the template strand is either *skipped* by the replication machinery or *used* twice as a template. As a result, a segment of DNA is *deleted* or *duplicated*." Right: "Cells of mating type A secrete a signaling molecule, which can *bind* to specific receptor proteins on nearby cells. At the same time, cells *secrete* factor, which *binds* to receptors on A cells."

for modeling global constraints. Similar observations and techniques have been proposed in other information extraction tasks. Reichart and Barzilay (2012) tied information from multiple sequence models that describe the same event by using global higher-order potentials. Berant et al. (2011) proposed a global inference algorithm to identify entailment relations. There is an abundance of examples of enforcing global constraints in other NLP tasks, such as in coreference resolution (Finkel and Manning, 2008), parsing (Rush et al., 2012) and named entity recognition (Wang et al., 2013).

6 Conclusion

Developing systems that understand process descriptions is an important step towards building applications that require deeper reasoning, such as biological process models from text, intelligent tutoring systems, and non-factoid QA systems. In this paper we have presented the task of process extraction, and developed methods for extracting relations between process events. Processes contain events that are tightly coupled through strong dependencies. We have shown that exploiting these structural dependencies and performing joint inference over all event mentions can significantly improve accuracy over several baselines. We have also released a new dataset containing 148 fully annotated descriptions of biological processes. Though the models we built were trained on biological processes, they do not encode domain specific information, and hence should be extensible to other domains.

In this paper we assumed that event triggers are given as input. In future work, we want to perform trigger identification jointly with extraction of event-event relations. As explained in Section 4.2, the performance of our system is confined by the performance of the local classifier, which is trained on relatively small amounts of data. Since data annotation is expensive, it is important to improve the local classifier without increasing the annotation burden. For example, one can use unsupervised methods that learn narrative chains (Chambers and Jurafsky, 2011) to provide some prior on the typical order of events. Alternatively, we can search on the web for redundant descriptions of the same process and use this redundancy to improve classification. Last, we would like to integrate our method into QA systems and allow non-factoid questions that require deeper reasoning to be answered by matching the questions against the learned process structures.

Generating Coherent Event Schemas at Scale

Niranjan Balasubramanian, Stephen Soderland, Mausam, Oren Etzioni

Abstract

Chambers and Jurafsky (2009) demonstrated that event schemas can be automatically induced from text corpora. However, our analysis of their schemas identifies several weaknesses, e.g., some schemas lack a common topic and distinct roles are incorrectly mixed into a single actor. It is due in part to their pair-wise representation that treats subject-verb independently from verb-object. This often leads to subject-verb-object triples that are not meaningful in the real-world.

We present a novel approach to inducing open-domain event schemas that overcomes these limitations. Our approach uses co-occurrence statistics of semantically typed relational triples, which we call Rel-grams (relational n-grams). In a human evaluation, our schemas outperform Chambers's schemas by wide margins on several evaluation criteria. Both Rel-grams and event schemas are freely available to the research community.

1 Introduction

Event schemas (also known as templates or frames) have been widely used in information extraction. An event schema is a set of actors (also known as slots) that play different roles in an event, such as the perpetrator, victim, and instrument in a bombing event. They provide essential guidance in extracting information related to events from free text (Patwardhan and Riloff, 2009), and can also aid in other NLP tasks, such as coreference (Irwin et al., 2011), summarization (Owczarzak and Dang, 2010), and inference about temporal ordering and causality.

Actor	Rel	Actor
A1:<person>	failed	A2:test
A1:<person>	was suspended for	A3:<time period>
A1:<person>	used	A4:<substance, drug>
A1:<person>	was suspended for	A5:<game, activity>
A1:<person>	was in	A6:<location>
A1:<person>	was suspended by	A7:<org, person>
Actor Instances:		
A1: {Murray, Morgan, Governor Bush, Martin, Nelson}		
A2: {test}		
A3: {season, year, week, month, night}		
A4: {cocaine, drug, gasoline, vodka, sedative}		
A5: {violation, game, abuse, misfeasance, riding}		
A6: {desert, Simsbury, Albany, Damascus, Akron}		
A7: {Fitch, NBA, Bud Selig, NFL, Gov Jeb Bush}		

Table 1: An event schema produced by our system, represented as a set of $(Actor, Rel, Actor)$ triples, and a set of instances for each actor $A1$, $A2$, etc. For clarity we show unstemmed verbs.

Until recently, all event schemas in use in NLP were hand-engineered, *e.g.*, the MUC templates and ACE event relations (ARPA, 1991; ARPA, 1998; Doddington et al., 2004). This led to technology that could only focus on specific domains of interest and has not been applicable more broadly.

The seminal work of Chambers and Jurafsky (2009) showed that event schemas can also be induced automatically from text corpora. Instead of labeled roles these schemas have a set of relations and actors that serve as arguments.[1] Their system is fully automatic, domain-independent, and scales to large text corpora.

However, we identify several limitations in the schemas produced by their system.[2] Their schemas

[1] In the rest of this paper we use event schemas to refer to these automatically induced schemas with actors and relations.

Actor	Rel	Actor
A1	caused	A2
A2	spread	A1
A2	burned	A1
-	extinguished	A1
A1	broke out	-
-	put out	A1
Actor Instances: A1: {fire, aids, infection, disease} A2: {virus, bacteria, disease, urushiol, drug}		

Table 2: An event schema from Chambers' system that mixes the events of fire spreading and disease spreading.

often lack coherence: mixing unrelated events and having actors whose entities do not play the same role in the schema. Table 2 shows an event schema from Chambers that mixes the events of fire spreading and disease spreading.

Much of the incoherence of Chambers' schemas can be traced to their representation that uses *pairs* of elements from an assertion, thus, treating subject-verb and verb-object separately. This often leads to subject-verb-object triples that do not make sense in the real world. For example, the assertions "fire caused virus" and "bacteria burned AIDS" are implicit in Table 2.

Another limitation in schemas Chambers released is that they restrict schemas to two actors, which can result in combining different actors. Table 4 shows an example of combining perpeterators and victims into a single actor.

1.1 Contributions

We present an event schema induction algorithm that overcomes these weaknesses. Our basic representation is *triples* of the form (Arg1, Relation, Arg2), extracted from a text corpus using Open Information Extraction (Mausam et al., 2012). The use of triples aids in agreement between subject and object of a relation. The use of Open IE leads to more expressive relation phrases (*e.g.*, with prepositions). We also assign semantic types to arguments, both to alleviate data sparsity and to produce coherent actors for our schemas.

Table 1 shows an event schema generated by our system. It has six relations and seven actors. The schema makes several related assertions about a person using a drug, failing a test, and getting suspended. The main actors in the schema include the person who failed the test, the drug used, and the agent that suspended the person.

Our first step in creating event schemas is to tabulate co-occurrence of tuples in a database that we call Rel-grams (relational n-grams) (Sections 3, 5.1). We then perform analysis on a graph induced from the Rel-grams database and use this to create event schemas (Section 4).

We compared our event schemas with those of Chambers on several metrics including whether the schema pertains to a coherent topic or event and whether the actors play a coherent role in that event (Section 5.2). Amazon Mechanical Turk workers judged that our schemas have significantly better coherence – 92% versus 82% have coherent topic and 81% versus 59% have coherent actors.

We release our open domain event schemas and the Rel-grams database[3] for further use by the NLP community.

2 System Overview

Our approach to schema generation is based on the idea that frequently co-occurring relations in text capture relatedness of assertions about real-world events. We begin by extracting a set of relational tuples from a large text corpus and tabulate occurrence of pairs of tuples in a database.

We then construct a graph from this database and identify high-connectivity nodes (relational tuples) in this graph as a starting point for constructing event schemas. We use graph analysis to rank the tuples and merge arguments to form the actors in the schema.

3 Modeling Relational Co-occurrence

In order to tabulate pairwise occurences of relational tuples we need a suitable relation-based representation. We now describe the extraction and representation of relations, a database for storing co-occurrence information, and our probabilistic model for the co-occurrence. We call this model Rel-grams, as it can be seen as a relational analog to the n-grams language model.

3.1 Relations Extraction and Representation

We extract relational triples from each sentence in a large corpus using the OLLIE Open IE system

...	...	...	...	...	...	...	...

Figure 1: Tables in the Rel-grams Database: *Tuples* maps tuples to unique identifiers, *BigramCounts* provides the co-occurrence counts (Count) within various distances (Dist.), and four types of argument equality counts (E11-E22). E11 is the number of times when T1.Arg1 = T2.Arg1, E12 is when T1.Arg1 = T2.Arg2 and so on.

(Mausam et al., 2012).[4] This provides relational tuples in the format (Arg1, Relation, Arg2) where each tuple element is a phrase from the sentence. The sentence "He cited a new study that was released by UCLA in 2008." produces three tuples:

1. (He, cited, a new study)
2. (a new study, was released by, UCLA)
3. (a new study, was released in, 2008)

Relational triples provide a more specific representation which is less ambiguous when compared to (subj, verb) or (verb, obj) pairs. However, using relational triples also increases sparsity. To reduce sparsity and to improve generalization, we represent the relation phrase by its stemmed head verb plus any prepositions. The relation phrase may include embedded nouns, in which case these are stemmed as well. Moreover, tuple arguments are represented as stemmed head nouns, and we also record semantic types of the arguments.

We selected 29 semantic types from WordNet, examining the set of instances on a small development set to ensure that the types are useful, but not overly specific. The set of types are: person, organization, location, time_unit, number, amount, group, business, executive, leader, effect, activity, game, sport, device, equipment, structure, building, substance, nutrient, drug, illness, organ, animal, bird, fish, art, book, and publication.

To assign types to arguments, we apply Stanford Named Entity Recognizer (Finkel et al., 2005)[5], and also look up the argument in WordNet 2.1 and record the first three senses if they map to our target semantic types. We use regular expressions to recognize dates and numeric expressions, and map personal pronouns to <person>. We associate all types found by this mechanism with each argument. The tuples in the example above are normalized to the following:

1. (He, cite, study)
2. (He, cite, <activity>)
3. (<person>, cite, study)
4. (<person>, cite, <activity>)
5. (study, be release by, UCLA)
6. (study, be release by, <organization>)
7. (study, be release in, 2008)
8. (study, be release in, <time_unit>)
9. (<activity>, be release by, UCLA)

...

In our preliminary experiments, we found that using normalized relation strings and semantic classes for arguments results in a ten-fold increase in the number of Rel-grams with a minimum support.

3.2 Co-occurrence Tabulation

We construct a database to hold co-occurrence statistics for pairs of tuples found in each document. Figure 1 shows examples for the types of statistics contained in the database. The database consists of two tables: 1) *Tuples* – Maps each tuple to a unique identifier and tabulates tuple counts. 2) *BigramCounts* – Stores the directional co-occurrence frequency, a count for tuple T followed by T' at a distance of k, and tabulates the number of times the same argument was present in the pair of tuples.

Equality Constraints: Along with the co-occurrence counts, we record the equality of arguments in Rel-grams pairs. We assert an argument

[4]Available at: http://knowitall.github.io/ollie/

[5]We used the system downloaded from: http://nlp.stanford.edu/software/CRF-NER.shtml and used the seven class CRF model distributed with it.

Table 3: Given a source tuple, the Rel-grams language model estimates the probability of encountering other relational tuples in a document. For clarity, we show the unstemmed version.

Top tuples related to (<person>, convicted of, murder)
1. (<person>, convicted in, <time_unit>)
2. (<person>, sentenced to, death)
3. (<person>, sentenced to, year)
4. (<person>, convicted in, <location>)
5. (<person>, sentenced to, life)
6. (<person>, convicted in, <person>)
7. (<person>, convicted after, trial)
8. (<person>, sent to, prison)

pair is equal if they are from the same token sequence in the source sentence or one argument is a co-referent mention of the other. We use the Stanford Co-reference system (Lee et al., 2013)[6] to detect co-referring mentions. There are four possible equalities depending on the specific pair of arguments in the tuples are the same, shown as E11, E12, E21 and E22 in Figure 1. For example, the E21 column has counts for the number of times the Arg2 of T1 was determined to be the same as the Arg1 of T2.

Implementation and Query Language: We populated the Rel-grams database using OLLIE extractions from a set of 1.8 Million New York Times articles drawn from the Gigaword corpus. The database consisted of approximately 320K tuples that have frequency ≥ 3 and 1.1M entries in the bigram table.

The Rel-grams database allows for powerful querying using SQL. For example, Table 3 shows the most frequent rel-grams associated with the query tuple (<person>, convicted of, murder).

3.3 Rel-grams Language Model

From the tabulated co-occurrence statistics, we estimate bi-gram conditional probabilities of tuples that occur within a window of k tuples from each other. Formally, we use $P_k(T'|T)$ to denote the conditional probability that T' follows T within a window of k tuples. To discount estimates from low-frequency tuples, we use a δ-smoothed estimate:

$$P_k(T'|T) = \frac{\#(T, T', k) + \delta}{\sum_{T'' \in V} \#(T, T'', k) + \delta \cdot |V|} \quad (1)$$

where, $\#(T, T', k)$ is the number of times T' follows T within a window of k tuples. $k = 1$ indicates adjacent tuples in the document. $|V|$ is the number of unique tuples in the corpus. For experiments in this paper, we set δ to 0.05.

Co-occurrence within a small window is usually more reliable but is also sparse, whereas co-occurrence within larger windows addresses sparsity but may lead to topic drift. To leverage the benefits of different window sizes, we also define a metric with a weighted average of window sizes from 1 to 10, where the weight decays as window size increases. For example, with α set to 0.5 in equation 2, a window of $k+1$ has half the weight of a window of k.

$$P(T'|T) = \frac{\sum_{k=1}^{10} \alpha^k P_k(T'|T)}{\sum_{k=1}^{10} \alpha^k} \quad (2)$$

We believe that Rel-grams is a valuable source of common-sense knowledge and may be useful for several downstream tasks such as improving information extractors, inference of implicit information, etc. We assess its usefulness in the context of generating event schemas.

4 Schema Generation

We now use Rel-grams to identify relations and actors pertaining to a particular event. Our schema generation consists of three steps. First, we build a relation graph of tuples (G) using connections identified by Rel-grams. Second, we identify a set of seed tuples as starting points for schemas. We use graph analysis to find the tuples most related to each seed. Finally, we merge the arguments in these tuples to create actors and output the final schema. Next we describe each of these steps in detail.

4.1 Rel-graph construction

We define a Rel-graph as an undirected weighted graph $G = (V, E)$, whose vertices (V) are relation tuples with edges (E), where an edge between vertices T and T' is weighted by the symmetric conditional probability $SCP(T, T')$ defined as

[6] Available for download at: http://nlp.stanford.edu/software/dcoref.shtml

$$SCP(T, T') = P(T|T') \times P(T'|T) \quad (3)$$

Both conditional probabilities are computed in Equation 2. Figure 2 shows a portion of a Rel-graph where the thickness of the edge indicates symmetric conditional probability.

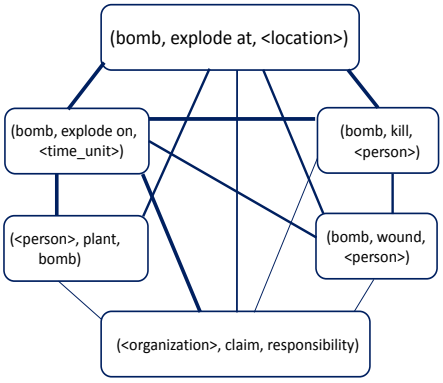

Figure 2: Part of a Rel-graph showing tuples strongly associated with *(bomb, explode at, <location>)*. Undirected edges are weighted by symmetric conditional probability with line thickness indicating weight.

4.2 Finding Related Tuples

Our goal is to find closely related tuples that pertain to an event or topic. First, we locate high-connectivity nodes in the Rel-graph to use as seeds. We sort nodes by the sum of their top 25 edge weights[7] and take the top portion of this list after filtering out redundant views of the same relation.

For each seed (Q), we find related tuples by extracting the sub-graph (G_Q) from Q's neighbors (within two hops from Q) in the Rel-graph. Graph analysis can detect the strongly connected nodes within this sub-graph, representing tuples that frequently co-occur in the context of the seed tuple.

Page rank is a well-known graph analysis algorithm that uses graph connectivity to identify important nodes within a graph (Brin and Page, 1998). We are interested in connectivity within a subgraph with respect to a designated query node (the seed). Connection to a query node can help minimize concept drift and ensure that the selected tuples are closely related to the main topic of the sub-graph.

[7]Limiting to the top 25 edges avoids overly general tuples that occur in many topics, which tend to have a large number of weak edges.

In this work, we adapt the Personalized PageRank algorithm (Haveliwala, 2002). The personalized version of PageRank returns ranks of various nodes with respect to a given query node and hence is more appropriate for our task than the basic PageRank algorithm. Within the subgraph G_Q for a given seed Q, we compute a solution to the following set of PageRank Equations:

$$\begin{aligned} & PR_Q(T) \\ &= (1-d) + d\sum_{T'} SCP(T,T')PR_Q(T') \quad \text{if } T = Q \\ &= d\sum_{T'} SCP(T,T')PR_Q(T') \quad \text{otherwise} \end{aligned}$$

Here $PR_Q(T)$ denotes the page rank of a tuple T personalized for the query tuple Q. It is a sum of all its neighbors' page ranks, weighted by the edge weights; d is the damping probability, which we set to be 0.85 in our implementation.

The solution is computed iteratively by initializing the page rank of Q to 1 and all others to 0, then recomputing page rank values until they converge to within a small ϵ. This computation remains scalable, since we restrict it to subgraphs a small number of hops away from the query node. This is a standard practice to handle large graphs (Agirre and Soroa, 2009; Mausam et al., 2010).

4.3 Creating Actors and Relations

We take the top n tuples from G_Q according to their Page rank scores. From each tuple $T : (Arg1, Rel, Arg2)$ in G_Q, we record two actors (A_1, A_2) corresponding to $Arg1$ and $Arg2$, and add Rel to the list of relations that they participate in.

Then, we merge actors in two steps. First, we collect the equality constraints for the tuples in G_Q. If the arguments corresponding to any pair of actors have a non-zero equality constraint then we merge them. Second, we merge actors that perform similar actions. A_1 and A_2 are merged if they are connected to the same actor A_3 through the same relation. For example, A1 and A2 in (A1:lawsuit, file by, A3:company) and (A2:suit, file by, A3:company), will be merged into a single actor. To avoid merging distinct actors, we use a small list of rules that specify the semantic type pairs that cannot be merged (*e.g.*, location-date). Also, we do not merge two actors, if it can result in a relation where the same actor

System	A_1	Rel	A_2
Relgrams	{bomb, missile, grenade, device}	explode in	{city, Bubqua, neighborhood}
	{bomb, missile, grenade, device}	explode kill	{people, civilian, lawmaker, owner, soldier}
	{bomb, missile, grenade, device}	explode on	{Feb., Fri., Tues., Sun., Sept.}
	{bomb, missile, grenade, device}	explode wound	{civilian, person, people, soldier, officer}
	{bomb, missile, grenade, device}	explode in	{Feb., Beirut Monday, Sept., Aug.}
	{bomb, missile, grenade, device}	explode injure	{woman, people, immigrant, policeman}

	{soldier, **child**, **civilian**, bomber, palestinian}	set off	{bomb, explosion, blast, **bomber**, mine, bombing}
	{bomb, explosion, blast, bomber, mine}	kill	{soldier, child, civilian, bomber, palestinian}
	{soldier, **child**, **civilian**, bomber, palestinian}	detonate	{bomb, explosion, blast, **bomber**, mine, bombing}
	{bomb, explosion, blast, bomber, mine}	injure	{soldier, child, civilian, bomber, palestinian}
	{soldier, **child**, **civilian**, bomber, palestinian}	plant	{bomb, explosion, blast, **bomber**, mine, **bombing**}
Relgrams	{Carey, John Anthony Volpe, Chavez, She }	veto	{legislation, bill, law, measure, version}
	{legislation, bill, law, measure, version}	be sign by	{Carey, John Anthony Volpe, Chavez, She }
	{legislation, bill, law, measure, version}	be pass by	{State Senate, State Assembly, House, Senate, Parliament}
	{Carey, John Anthony Volpe, Chavez, She }	sign into	{law}
	{Carey, John Anthony Volpe, Chavez, She }	to sign	{bill}
	{Carey, John Anthony Volpe, Chavez, She }	be governor of	{Massachusetts, state, South Carolina, Texas, California}
Chambers	{clinton, bush, **bill**, president, house}	oppose	{bill, measure, legislation, plan, law}
	{clinton, bush, **bill**, president, **house**}	sign	{bill, measure, legislation, plan, law}
	{clinton, bush, **bill**, president, house}	approve	{bill, measure, legislation, plan, law}
	{clinton, bush, **bill**, president, **house**	veto	{bill, measure, legislation, plan, law}
	{clinton, bush, **bill**, president, house}	support	{bill, measure, legislation, plan, law}
	{**clinton**, **bush**, **bill**, **president**, house}	pass	{bill, measure, legislation, plan, law}

Table 4: "Bombing" and "legislation" schema examples from Rel-grams and Chambers represented as a set of (A_1, Rel, A_2) tuples, where the schema provides a set of instances for each actor A_1 and A_2. Relations and arguments are in the stemmed form, e.g., 'explode kill' refers to 'exploded killing'. Instances in bold produce tuples that are not valid in the real world.

is both the Arg1 and Arg2.

Finally, we generate an ordered list of tuples using the final set of actors and their relations. The output tuples are sorted by the average page rank of the original tuples, thereby reflecting their importance within the sub-graph G_Q.

5 Evaluation

We present experiments to explore two main questions: How well do Rel-grams capture real world knowledge, and what is the quality of event schemas built using Rel-grams.

5.1 Evaluating Rel-grams

What sort of common-sense knowledge is encapsulated in Rel-grams? How often does it indicate an implication between a pair of statements, and how often does it indicate a common real-world event or topic? To answer these questions, we conducted an experiment to identify a subset of our Rel-grams database with high precision for two forms of common-sense knowledge:

- **Implication:** The Rel-grams express an implication from T to T' or from T' to T, a bi-directional form of the Recognizing Textual Entailment (RTE) guidelines (Dagan et al., 2005).
- **Common Topic:** Is there an underlying common topic or event to which both T and T' are relevant?

We also evaluated whether both T and T' are **valid tuples** that are well-formed and make sense in the real world, a necessary pre-condition for either implication or common topic.

We are particularly interested in the highest precision portion of our Rel-grams database. The database has 1.1M entries with support of at least three instances for each tuple. To find the highest precision subset of these, we identified tuples that have at least 25 Rel-grams, giving us 12,600 seed tuples with a total of over 280K Rel-grams. Finally, we sorted this subset by the total symmetrical conditional probability of the top 25 Rel-grams for each seed tuple.

We tagged a sample of this 280K set of Rel-grams for valid tuples, implication between T and T', and common topic. We found that in the top 10% of this set, 87% of the seed tuples were valid and 74% of the Rel-grams had both tuples valid. Of the Rel-grams

System	Id	A_1	Rel	A_2
Relgrams	R1	bomb	explode in	city
		bomb	explode kill	people
		bomb	explode on	Fri.
		...	...	...

		child	detonate	blast
		child	plant	bomb
		...	...	...

Table 5: A grounded instantiation of the schemas from Table 4, where each actor is represented as a randomly selected instance.

System	Id	A_1	Rel	A_2
Relgrams	R11	bomb	explode in	city
		missile	explode in	city
		grenade	explode in	city
		...	...	...
Relgrams	R21	missile	explode in	city
		missile	explode in	neighborhood
		missile	explode in	front
		...	...	...

Table 6: A schema instantiation used to test for actor coherence. Each of the top instances for A_1 or A_2 is presented, holding the relation and the other actor fixed.

with both tuples valid, 83% expressed an implication between the tuples, and 90% had a common topic.

There were several reasons for invalid tuples – parsing errors; binary projections of inherently n-ary relations, for example (<person>, put, <person>); head-noun only representation omitting essential information; and incorrect semantic types, primarily due to NER tagging errors.

While the Rel-grams suffer from noise in the tuple validity, there is clearly strong signal in the data about common topic and implication between tuples in the Rel-grams. As we demonstrate in the following section, an end task can use graph analysis techniques to amplify this strong signal, producing high-quality relational schemas.

5.2 Schemas Evaluation

In our schema evaluation, we are interested in assessing how well the schemas correspond to common-sense knowledge about real world events. To this end, we focus on three measures, *topical coherence*, *tuple validity*, and *actor coherence*.

A good schema must be topically coherent, i.e., the relations and actors should relate to some real world topic or event. The tuples that comprise a schema should be valid assertions that make sense in the real world. Finally, each actor in the schema should belong to a cohesive set that plays a consistent role in the relations. Since there are no good automated ways to make such judgments, we perform a human evaluation using workers from Amazon's Mechanical Turk (AMT).

We compare Rel-grams schemas against the state-of-the-art narrative schemas released by Chambers (Chambers and Jurafsky, 2009).[8] Chambers' schemas are less expressive than ours – they do not associate types with actors and each schema has a constant pre-specified number of relations. For a fair comparison we use a similarly expressive version of our schemas that strips off argument types and has the same number of relations per schema (six) as their highest quality output set.

5.2.1 Evaluation Design

We created two tasks for AMT annotators. The first task tests the coherence and validity of relations in a schema and the second does the same for the schema actors. In order to make the tasks understandable to unskilled AMT workers, we followed the accepted practice of presenting them with *grounded* instances of the schemas (Wang et al., 2013), e.g., instantiating a schema with a specific argument instead of showing the various possibilities for an actor.

First, we collect the information in schemas as a set of tuples: $S = \{T_1, T_2, \cdots, T_n\}$, where each tuple is of the form $T : (X, Rel, Y)$, which conveys a relationship *Rel* between actors X and Y. Each actor is represented by its highest frequency examples (instances). Table 4 shows examples of schemas from Chambers and Rel-grams represented in this format. Then, we create grounded tuples by randomly sampling from top instances for each actor.

Task I: Topical Coherence To test whether the relations in a schema form a coherent topic or event, we presented the AMT annotators with a schema as a set of grounded tuples, showing each relation in the schema, but randomly selecting one of the top 5 instances from each actor. We generated five such

[8] Available at http://www.usna.edu/Users/cs/nchamber/data/schemas/acl09

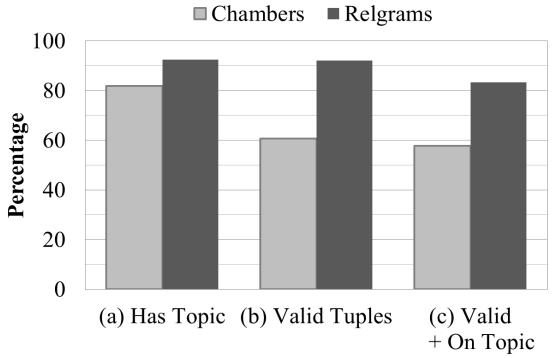

Figure 3: (a) Has Topic: Percentage of schema instantiations with a coherent topic. (b) Valid Tuples: Percentage of grounded statements that assert valid real-world relations. (c) Valid + On Topic: Percentage of grounded statements where 1) the instantiation has a coherent topic, 2) the tuple is valid and 3) the relation belongs to the common topic. All differences are statistically significant with a *p-value* < 0.01.

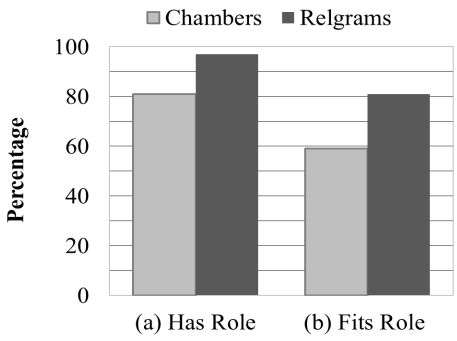

Figure 4: Actor Coherence: *Has Role* bars compare the percentage of tuples where the tested actors have a coherent role. *Fits Role* compares the percentage of top instances that fit the specified role for the tested actors. All differences are statistically significant with a *p-value* < 0.01.

instantiations for each schema. An example instantiation is shown in Table 5.

We ask three kinds of questions on each grounded schema: (1) is each of the grounded tuples valid (i.e. meaningful in the real world); (2) do the majority of relations form a coherent topic; and (3) does each tuple belong to the common topic. Similar to previous AMT studies we get judgments from multiple (five) annotators on each task and use the majority labels (Snow et al., 2008).

Our instructions specified that the annotators should ignore grammar and focus on whether a tuple may be interpreted as a real world statement. For example, the first tuple in R1 in Table 5 is a valid statement – "a bomb exploded in a city", but the tuples in C1 "a blast exploded a child", "a child detonated a blast", and "a child planted a blast" don't make sense.

Task II: Actor Coherence To test whether the instances of an actor form a coherent set, we held the relation and one actor fixed and presented the AMT annotators with the top 5 instances for the other actor. The first example R11 in Table 6 holds the relation "explode in" fixed, and A2 is grounded to the randomly selected instance "city". We present grounded tuples by varying A1 and ask annotators to judge whether these instances form a coherent topic and whether each instance belongs to that common topic. As with Task I, we create five random instantiations for each schema.

5.2.2 Results

We obtained a test set of 100 schemas per system by randomly sampling from the top 500 schemas from each system. We evaluate this test set using Task I and II as described above. For both tasks we obtained ratings from five turkers and use the majority labels as the final annotation.

Does the schema belong to a single topic? The *Has Topic* bars in Figure 3 show results for schema coherence. Rel-grams has a higher proportion of schemas with a coherent topic, 91% compared to 82% for Chambers'. This is a 53% reduction in incoherent schemas.

Do tuples assert valid real-world relations? The *Valid Tuples* bars in Figure 3 compare the percentage of valid grounded tuples in the schema instantiations. A tuple was labeled *valid* if a majority of the annotators labeled it to be meaningful in the real world. Here we see a dramatic difference – Rel-grams have 92% valid tuples, compared with Chambers' 61%.

What proportion of tuples belong? The *Valid + On Topic* bars in Figure 3 compare the percentage of tuples that are both *valid* and *on topic*, i.e., fits the main topic of the schema. Tuples from schema instantiations that did not have a coherent topic were labeled incorrect.

Rel-grams have a higher proportion of valid tuples belonging to a common topic, 82% compared to

58% for Chambers' schemas, a 56% error reduction. This is the strictest of the experiments described thus far – 1) the schema must have a topic, 2) the tuple must be valid, and 3) the tuple must belong to the topic.

Do actors represent a coherent set of arguments? We evaluated schema actors from the top 25 schemas in Chambers' and Rel-grams schemas, using grounded instances such as those in Table 6. Figure 4 compares the percentage of tuples where the actors play a coherent role (Has Role), and the percentage of instances that fit that role for the actor (Fits Role). Rel-grams has much higher actor coherence than Chambers', with 97% judged to have a topic compared to 81%, and 81% of instances fitting the common role compared with Chambers' 59%.

5.2.3 Error Analysis

The errors in both our schemas and those of Chambers are primarily due to mismatched actors and from extraction errors, although Chambers' schemas have a larger number of actor mismatch errors and the cause of the errors is different for each system.

Examining the data published by Chambers, the main source of invalid tuples are mismatch of subject and object for a given relation, which accounts for 80% of the invalid tuples. We hypothesize that this is due to the pair-wise representation that treats subject-verb and verb-object separately, causing inconsistent s-v-o tuples. An example is (boiler, light, candle) where (boiler, light) and (light, candle) are well-formed, yet the entire tuple is not. In addition, 43% of the invalid tuples seem to be from errors by the dependency parser.

Our schemas also suffer from mismatched actors, despite the semantic typing of the actors – we found a mismatch in 56% of the invalid tuples (5% of all tuples). A general type such as <person> or <organization> may still have an instance that does not play the same role as other instances. For example a relation (A1, graduated from, A2) has A2 that is mostly school names, but also includes "church" which leads to an invalid tuple.

Extraction errors account for 47% of the invalid tuples in our schemas, primarily errors that truncate an n-ary relation as a binary tuple. For example, the sentence "Mr. Diehl spends more time ... than the commissioner" is misanalysed by the Open IE extractor as (Mr. Diehl, spend than, commissioner).

6 Related Work

Prior work by Chambers and Jurafsky (2008; 2009; 2010) showed that event sequences (narrative chains) mined from text can be used to induce event schemas in a domain-independent fashion. However, our manual evaluation of their output showed key limitations which may limit applicability.

As pointed out earlier, a major weakness in Chambers' approach is the pair-wise representation of subject-verb and verb-object. Also, their released a set of schemas are limited to two actors, although this number can be increased by setting a chain splitting parameter.

Chambers and Jurafsky (2011) extended schema generation to learn domain-specific event templates and associated extractors. In work parallel to ours, Cheung et al. (2013), developed a probabilistic solution for template generation. However, their approach requires performing joint probability estimation using EM, which can limit scaling to large corpora.

In this work we developed an Open IE based solution to generate schemas. Following prior work (Balasubramanian et al., 2012), we use Open IE triples for modeling relation co-occurrence. We extend the triple representation with semantic types for arguments to alleviate sparisty and to improve coherence. We developed a page rank based schema induction algorithm which results in more coherent schemas with several actors. Unlike Chambers' approach this method does not require explicit parameter tuning for controlling the number of actors.

While our event schemas are close to being templates (because of associated types, and actor clustering), they do not have associated extractors. Our future work will focus on building extractors for these. It will also be interesting to compare with Cheung's system on smaller focused corpora.

Defining representations for events is a topic of active interest (Fokkens et al., 2013). In this work, we use a simpler representation, defining event schemas as a set of actors with associated types and a set of roles they play.

7 Conclusions

We present a system for inducing event schemas from text corpora based on Rel-grams, a language model derived from co-occurrence statistics of relational triples (Arg1, Relation, Arg2) extracted by a state-of-the-art Open IE system. By using triples rather than a pair-wise representation of subject-verb and verb-object, we achieve more coherent schemas than Chambers and Jurafsky (2009). In particular, our schemas have higher topic coherence (92% compared to Chambers' 82%; make a higher percentage of valid assertions (94% compared with 61%); and have greater actor coherence (81% compared with 59%).

Our schemas are also more expressive than those published by Chambers – we have semantic typing for the actors, we are not limited to two actors per schema, and our relation phrases include prepositions and are thus more precise and have higher coverage of actors involved in the event.

Our future plans are to build upon our event schemas to create an open-domain event extractor. This will extend each induced schema to have associated extractors. These extractors will operate on a document and instantiate an instance of the schema.

We have created a Rel-grams database with 1.1M entries and a set of over 2K event schemas from a corpus of 1.8M New York Times articles. Both are freely available to the research community[9] and may prove useful for a wide range of NLP applications.

Abstract

Cross-lingual topic modelling has applications in machine translation, word sense disambiguation and terminology alignment. Multilingual extensions of approaches based on latent (LSI), generative (LDA, PLSI) as well as explicit (ESA) topic modelling can induce an interlingual topic space allowing documents in different languages to be mapped into the same space and thus to be compared across languages. In this paper, we present a novel approach that combines latent and explicit topic modelling approaches in the sense that it builds on a set of explicitly defined topics, but then computes latent relations between these. Thus, the method combines the benefits of both explicit and latent topic modelling approaches. We show that on a cross-lingual mate retrieval task, our model significantly outperforms LDA, LSI, and ESA, as well as a baseline that translates every word in a document into the target language.

1 Introduction

Cross-lingual document matching is the task of, given a *query* document in some source language, estimating the similarity to a document in some target language. This task has important applications in machine translation (Palmer et al., 1998; Tam et al., 2007), word sense disambiguation (Li et al., 2010) and ontology alignment (Spiliopoulos et al., 2007). An approach that has become quite popular in recent years for cross-lingual document matching is Explicit Semantics Analysis (ESA, Gabrilovich and Markovitch (2007)) and its cross-lingual extension CL-ESA (Sorg and Cimiano, 2008). ESA indexes documents by mapping them into a topic space defined by their similarity to predefined explicit topics – generally articles from an encyclopaedia – in such a way that there is a one-to-one correspondence between topics and encyclopedic entries. CL-ESA extends this to the multilingual case by exploiting a background document collection that is aligned across languages, such as Wikipedia. A feature of ESA and its extension CL-ESA is that, in contrast to latent (e.g. LSI, Deerwester et al. (1990)) or generative topic models (such as LDA, Blei et al. (2003)), it requires no training and, nevertheless, has been demonstrated to outperform LSI and LDA on cross-lingual retrieval tasks (Cimiano et al., 2009).

A key choice in Explicit Semantic Analysis is the document space that will act as the topic space. The standard choice is to regard all articles from a background document collection – Wikipedia articles are a typical choice – as the topic space. However, it is crucial to ensure that these topics cover the semantic space evenly and completely. In this paper, we present an alternative approach where we remap the semantic space defined by the topics in such a manner that it is orthonormal. In this way, each document is mapped to a topic that is distinct from all other topics. Such a mapping can be considered as equivalent to a variant of Latent Semantic Indexing (LSI) with the main difference that our model exploits the matrix that maps topic vectors back into document space, which is normally discarded in LSI-based approaches. We dub our model *ONETA* (OrthoNormal Explicit Topic Analysis) and empirically show that on a cross-lingual retrieval

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1732–1740,
Seattle, Washington, USA, 18-21 October 2013.

task it outperforms ESA, LSI, and Latent Dirichlet Allocation (LDA) as well as a baseline consisting of translating each word into the target language, thus reducing the task to a standard monolingual matching task. In particular, we quantify the effect of different approximation techniques for computing the orthonormal basis and investigate the effect of various methods for the normalization of frequency vectors.

The structure of the paper is as follows: we situate our work in the general context of related work on topic models for cross-lingual document matching in Section 2. We present our model in Section 3 and present our experimental results and discuss these results in Section 4.

2 Related Work

The idea of applying topic models that map documents into an interlingual topic space seems a quite natural and principled approach to tackle several tasks including the cross-lingual document retrieval problem.

Topic modelling is the process of finding a representation of a document d in a lower dimensional space $\mathbb{R}^K$ where each dimension corresponds to one *topic* that abstracts from specific words and thus allows us to detect deeper semantic similarities between documents beyond the computation of the pure overlap in terms of words.

Three main variants of document models have been mainly considered for cross-lingual document matching:

Latent methods such as Latent Semantic Indexing (LSI, Deerwester et al. (1990)) induce a decomposition of the term-document matrix in a way that reduces the dimensionality of the documents, while minimizing the error in reconstructing the training data. For example, in Latent Semantic Indexing, a term-document matrix is approximated by a partial singular value decomposition, or in Non-Negative Matrix Factorization (NMF, Lee and Seung (1999)) by two smaller non-negative matrices. If we append comparable or equivalent documents in multiple languages together before computing the decomposition as proposed by Dumais et al. (1997) then the topic model is essentially cross-lingual allowing to compare documents in different languages once they have been mapped into the topic space.

Probabilistic or generative methods instead attempt to induce a (topic) model that has the highest likelihood of generating the documents actually observed during training. As with latent methods, these topics are thus interlingual and can generate words/terms in different languages. Prominent representatives of this type of method are Probabilistic Latent Semantic Indexing (PLSI, Hofmann (1999)) or Latent Dirichlet Allocation (LDA, Blei et al. (2003)), both of which can be straightforwardly extended to the cross-lingual case (Mimno et al., 2009).

Explicit topic models make the assumption that topics are explicitly given instead of being induced from training data. Typically, a background document collection is assumed to be given whereby each document in this corpus corresponds to one topic. A mapping from document to topic space is calculated by computing the similarity of the document to every document in the topic space. A prominent example for this kind of topic modelling approach is Explicit Semantic Analysis (ESA, Gabrilovich and Markovitch (2007)).

Both latent and generative topic models attempt to find topics from the data and it has been found that in some cases they are equivalent (Ding et al., 2006). However, this approach suffers from the problem that the topics might be artifacts of the training data rather than coherent semantic topics. In contrast, explicit topic methods can use a set of topics that are chosen to be well-suited to the domain. The principle drawback of this is that the method for choosing such explicit topics by selecting documents is comparatively crude. In general, these topics may be overlapping and poorly distributed over the semantic topic space. By comparison, our method takes the advantage of the pre-specified topics of explicit topic models, but incorporates a training step to learn latent relations between these topics.

3 Orthonormal explicit topic analysis

Our approach follows Explicit Semantic Analysis in the sense that it assumes the availability of a background document collection $B = \{b_1, b_2, ..., b_N\}$ consisting of textual representations. The mapping into the explicit topic space is defined by a language-specific function Φ that maps documents into $\mathbb{R}^N$ such that the j^{th} value in the vector is given by some *association measure* $\phi_j(d)$ for each background document b_j. Typical choices for this association measure ϕ are the sum of the TF-IDF scores or an information retrieval relevance scoring function such as BM-25 (Sorg and Cimiano, 2010).

For the case of TF-IDF, the value of the j-th element of the topic vector is given by:

$$\phi_j(d) = \overrightarrow{\text{tf-idf}}(b_j)^{\text{T}} \ \overrightarrow{\text{tf-idf}}(d)$$

Thus, the mapping function can be represented as the product of a TF-IDF vector of document d multiplied by an $W \times N$ matrix, $\mathbf{X}$, each element of which contains the TF-IDF value of word i in document b_j:

$$\Phi(d) = \begin{pmatrix} \overrightarrow{\text{tf-idf}}(b_1)^{\text{T}} \\ \vdots \\ \overrightarrow{\text{tf-idf}}(b_N)^{\text{T}} \end{pmatrix} \overrightarrow{\text{tf-idf}}(d) = \mathbf{X}^{\text{T}} \cdot \overrightarrow{\text{tf-idf}}(d)$$

For simplicity, we shall assume from this point on that all vectors are already converted to a TF-IDF or similar numeric vector form. In order to compute the similarity between two documents d_i and d_j, typically the cosine-function (or the normalized dot product) between the vectors $\Phi(d_i)$ and $\Phi(d_j)$ is computed as follows:

$$\text{sim}(d_i, d_j) = \cos(\Phi(d_i), \Phi(d_j)) = \frac{\Phi(d_i)^{\text{T}}\Phi(d_j)}{||\Phi(d_i)||||\Phi(d_j)||}$$

If we represent the above using our above defined $W \times N$ matrix $\mathbf{X}$ then we get:

$$\text{sim}(d_i, d_j) = \cos(\mathbf{X}^{\text{T}}d_i, \mathbf{X}^{\text{T}}d_j) = \frac{d_i^{\text{T}}\mathbf{X}\mathbf{X}^{\text{T}}d_j}{||\mathbf{X}^{\text{T}}d_i||||\mathbf{X}^{\text{T}}d_j||}$$

The key challenge with ESA is choosing a good background document collection $B = \{b_1, ..., b_N\}$. A simple minimal criterion for a good background document collection is that each document in this collection should be maximally similar to itself and less similar to any other document:

$$\forall i \neq j \ \ 1 = \text{sim}(b_j, b_j) > \text{sim}(b_i, b_j) \geq 0$$

While this criterion is trivially satisfied if we have no duplicate documents in our collection, our intuition is that we should choose a background collection that maximizes the *slack margin* of this inequality, i.e. $|\text{sim}(b_j, b_j) - \text{sim}(b_i, b_j)|$. We can see that maximizing this margin for all i,j is the same as minimizing the *semantic overlap* of the background documents, which is given as follows:

$$\text{overlap}(B) = \sum_{\substack{i=1,\ldots,N \\ j=1,\ldots,N \\ i \neq j}} \text{sim}(b_i, b_j)$$

We first note that we can, without loss of generality, normalize our background documents such that $||Xb_j|| = 1$ for all j, and in this case we can redefine the semantic overlap as the following matrix expression[1]

$$\text{overlap}(\mathbf{X}) = ||\mathbf{X}^{\text{T}}\mathbf{X}\mathbf{X}^{\text{T}}\mathbf{X} - \mathbf{I}||_1$$

It is trivial to verify that this equation has a minimum when $\mathbf{X}^{\text{T}}\mathbf{X}\mathbf{X}^{\text{T}}\mathbf{X} = \mathbf{I}$. This is the case when the topics are *orthonormal*:

$$(\mathbf{X}^{\text{T}}b_i)^{\text{T}}(\mathbf{X}^{\text{T}}b_j) = 0 \quad \text{if } i \neq j$$

$$(\mathbf{X}^{\text{T}}b_i)^{\text{T}}(\mathbf{X}^{\text{T}}b_i) = 1$$

Unfortunately, this is not typically the case as the documents have significant word overlap as well as semantic overlap. Our goal is thus to apply a suitable transformation to $\mathbf{X}$ with the goal of ensuring that the orthogonality property holds.

Assuming that this transformation of $\mathbf{X}$ is done by multiplication with some other matrix $\mathbf{A}$, we can define the learning problem as finding that matrix $\mathbf{A}$ such that:

$$(\mathbf{A}\mathbf{X}^{\text{T}}\mathbf{X})^{\text{T}}(\mathbf{A}\mathbf{X}^{\text{T}}\mathbf{X}) = I$$

[1] $||\mathbf{A}||_p = \sum_{i,j} |a_{ij}|^p$ is the p-norm. $||\mathbf{A}||_{\mathcal{F}} = \sqrt{||\mathbf{A}||_2}$ is the Frobenius norm.

If we have the case that $W \geq N$ and that the rank of $\mathbf{X}$ is N, then $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ is invertible and thus $\mathbf{A} = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}$ is the solution to this problem.[2]

We define the projection function of a document d, represented as a normalized term frequency vector, as follows:

$$\Phi_{\mathrm{ONETA}}(d) = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}d$$

For the cross-lingual case we assume that we have two sets of background documents of equal size, $B^1 = \{b_1^1, \ldots, b_N^1\}$, $B^2 = \{b_1^2, \ldots, b_N^2\}$ in languages l_1 and l_2, respectively and that these documents are aligned such that for every index i, b_i^1 and b_i^2 are documents on the same topic in each language. Using this we can construct a projection function for each language which maps into the same topic space. Thus, as in CL-ESA, we obtain the cross-lingual similarity between a document d_i in language l_1 and a document d_j in language l_2 as follows:

$$\mathrm{sim}(d_i, d_j) = \cos(\Phi^{l_1}_{\mathrm{ONETA}}(d_i), \Phi^{l_2}_{\mathrm{ONETA}}(d_j))$$

We note here that we assume that Φ could be represented as a symmetric inner product of two vectors. However, for many common choices of association measures, including BM25, this is not the case. In this case the expression $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ can be replaced with a kernel matrix specifying the association of each background document to each other background document.

3.1 Relationship to Latent Semantic Indexing

In this section we briefly clarify the relationship between our method ONETA and Latent Semantic Indexing. Latent Semantic Indexing defines a mapping from a document represented as a term frequency vector to a vector in $\mathbb{R}^K$. This transformation is defined by means of calculating the singular value decomposition (SVD) of the matrix $\mathbf{X}$ as above, namely

$$\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathrm{T}}$$

Where $\mathbf{\Sigma}$ is diagonal and $\mathbf{U}$ $\mathbf{V}$ are the eigenvectors of $\mathbf{X}\mathbf{X}^{\mathrm{T}}$ and $\mathbf{X}^{\mathrm{T}}\mathbf{X}$., respectively. Let $\mathbf{\Sigma}_K$ denote the $K \times K$ submatrix containing the largest eigenvalues, and $\mathbf{U}_K$,$\mathbf{V}_K$ denote the corresponding eigenvectors. Thus LSI can be defined as:

$$\Phi_{\mathrm{LSI}}(d) = \mathbf{\Sigma}_K^{-1}\mathbf{U}_K d$$

With regards to orthonormalized topics, we see that using the SVD, we can simply derive the following:

$$(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}} = \mathbf{V}\mathbf{\Sigma}^{-\mathbf{1}}\mathbf{U}^{\mathrm{T}}$$

When we set $K = N$ and thus choose the maximum number of topics, ONETA is equivalent to LSI modulo the fact that it multiplies the resulting topic vector by $\mathbf{V}$, thus projecting back into document space, i.e. into explicit topics.

In practice, both methods differ significantly in that the approximations they make are quite different. Furthermore, in the case that $W \gg N$ and $\mathbf{X}$ has n non-zeroes, the calculation of the SVD is of complexity $\mathcal{O}(nN + WN^2)$ and requires $\mathcal{O}(WN)$ bytes of memory. In contrast, ONETA requires computation time of $\mathcal{O}(N^a)$ for $a > 2$, which is the complexity of the matrix inversion algorithm[3], and only $\mathcal{O}(n + N^2)$ bytes of memory.

3.2 Approximations

The computation of the inverse has a complexity that, using current practical algorithms, is approximately cubic and as such the time spent calculating the inverse can grow very quickly. There are several methods for obtaining an approximate inverse. The most commonly used are based on the SVD or eigendecomposition of the matrix. As $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ is symmetric positive definite, it holds that:

$$\mathbf{X}^{\mathrm{T}}\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{U}^{\mathrm{T}}$$

Where $\mathbf{U}$ are the eigenvectors of $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ and $\mathbf{\Sigma}$ is a diagonal matrix of the eigenvalues. With $\mathbf{U}_K$,$\mathbf{\Sigma}_K$

[2] In the case that the matrix is not invertible we can instead solve $||\mathbf{X}^{\mathrm{T}}\mathbf{X}\mathbf{A} - \mathbf{I}||_{\mathcal{F}}$, which has a minimum at $\mathbf{A} = \mathbf{V}\mathbf{\Sigma}^{-1}\mathbf{U}^{\mathrm{T}}$ where $\mathbf{X}^{\mathrm{T}}\mathbf{X} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathrm{T}}$ is the singular value decomposition of $\mathbf{X}^{\mathrm{T}}\mathbf{X}$.

As usual we do not in fact compute the inverse for our experiments, but instead the LU Decomposition and solve by Gaussian elimination at test time.

[3] Algorithms with $a = 2.3727$ are known but practical algorithms have $a = 2.807$ or $a = 3$ (Coppersmith and Winograd, 1990)

as the first K eigenvalues and eigenvectors, respectively, we have:

$$(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1} \simeq \mathbf{U}_K \mathbf{\Sigma}_K^{-1} \mathbf{U}_K^{\mathrm{T}} \quad (1)$$

We call this the *orthonormal eigenapproximation* or *ON-Eigen*. The complexity of calculating $(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}$ from this is $\mathcal{O}(N^2K + Nn)$, where n is the number of non-zeros in $\mathbf{X}$.

Similarly, using the formula derived in the previous section we can derive an approximation of the full model as follows:

$$(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}} \simeq \mathbf{U}_K \mathbf{\Sigma}_K^{-1} \mathbf{V}_K^{\mathrm{T}} \quad (2)$$

We call this approximation *Explicit LSI* as it first maps into the latent topic space and then into the explicit topic space.

We can consider another approximation by noticing that $\mathbf{X}$ is typically very sparse and moreover some rows of $\mathbf{X}$ have significantly fewer non-zeroes than others (these rows are for terms with low frequency). Thus, if we take the first N_1 columns (documents) in $\mathbf{X}$, it is possible to rearrange the rows of $\mathbf{X}$ with the result that there is some W_1 such that rows with index greater than W_1 have only zeroes in the columns up to N_1. In other words, we take a subset of N_1 documents and enumerate the words in such a way that the terms occurring in the first N_1 documents are enumerated $1, \ldots, W_1$. Let $N_2 = N - N_1$, $W_2 = W - W_1$. The result of this row permutation does not affect the value of $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ and we can write the matrix $\mathbf{X}$ as:

$$\mathbf{X} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{0} & \mathbf{C} \end{pmatrix}$$

where $\mathbf{A}$ is a $W_1 \times N_1$ matrix representing term frequencies in the first N_1 documents, $\mathbf{B}$ is a $W_1 \times N_2$ matrix containing term frequencies in the remaining documents for terms that are also found in the first N_1 documents, and $\mathbf{C}$ is a $W_2 \times N_2$ containing the frequency of all terms not found in the first N_1 documents.

Application of the well-known divide-and-conquer formula (Bernstein, 2005, p. 159) for matrix inversion yields the following easily verifiable matrix identity, given that we can find $\mathbf{C}'$ such that $\mathbf{C}'\mathbf{C} = \mathbf{I}$.

$$\begin{pmatrix} (\mathbf{A}^{\mathrm{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}} & -(\mathbf{A}^{\mathrm{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{B}\mathbf{C}' \\ \mathbf{0} & \mathbf{C}' \end{pmatrix} \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{0} & \mathbf{C} \end{pmatrix} = \mathbf{I} \quad (3)$$

We denote the above equation using a matrix $\mathbf{L}$ as $\mathbf{L}^{\mathrm{T}}\mathbf{X} = \mathbf{I}$. We note that $\mathbf{L} \neq (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}$, but for any document vector d that is representable as a linear combination of the background document set (i.e., columns of $\mathbf{X}$) we have that $\mathbf{L}d = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}d$ and in this sense $\mathbf{L} \simeq (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}$.

We further relax the assumption so that we only need to find a $\mathbf{C}'$ such that $\mathbf{C}'\mathbf{C} \simeq \mathbf{I}$. For this, we first observe that $\mathbf{C}$ is very sparse as it contains only terms not contained in the first N_1 documents and we notice that very sparse matrices tend to be approximately orthogonal, hence suggesting that it should be very easy to find a left-inverse of $\mathbf{C}$. The following lemma formalizes this intuition:

Lemma: If $\mathbf{C}$ is a $W \times N$ matrix with M non-zeros, distributed randomly and uniformly across the matrix, and all the non-zeros are 1, then $\mathbf{D}\mathbf{C}^{\mathrm{T}}\mathbf{C}$ has an expected value on each non-diagonal value of $\frac{M}{N^2}$ and a diagonal value of 1 if $\mathbf{D}$ is the diagonal matrix whose values are given by $||c_i||^{-2}$, the square of the norm of the corresponding column of $\mathbf{C}$.

Proof: We simply observe that if $\mathbf{D}' = \mathbf{D}\mathbf{C}^{\mathrm{T}}\mathbf{C}$, then the $(i,j)^{\text{th}}$ element of $\mathbf{D}'$ is given by

$$d_{ij} = \frac{c_i^{\mathrm{T}} c_j}{||c_i||^2}$$

If $i \neq j$ then the $c_i^{\mathrm{T}} c_j$ is the number of non-zeroes overlapping in the i^{th} and j^{th} column of $\mathbf{C}$ and under a uniform distribution we expect this to be $\frac{M^2}{N^3}$. Similarly, we expect the column norm to be $\frac{M}{N}$ such that the overall expectation is $\frac{M}{N^2}$. The diagonal value is clearly equal to 1.■

As long as $\mathbf{C}$ is very sparse, we can use the following approximation, which can be calculated in $\mathcal{O}(M)$ operations, where M is the number of non-zeroes.

$$\mathbf{C}' \simeq \begin{pmatrix} ||c_1||^{-2} & & 0 \\ & \ddots & \\ 0 & & ||c_{N_2}||^{-2} \end{pmatrix} \mathbf{C}^{\mathrm{T}}$$

We call this method *L-Solve*. The complexity of calculating a left-inverse by this method is of

Frequency Normalization	Document Normalization: No	Document Normalization: Yes
TF	0.31	0.78
Relative	0.23	0.42
TFIDF	0.21	0.63
SQRT	0.28	0.66

Table 1: Effect of Term Frequency and Document Normalization on Top-1 Precision

order $\mathcal{O}(N_1^a)$, being much more efficient than the eigenvalue methods. However, it is potentially more error-prone as it requires that a left-inverse of $\mathbf{C}$ exists. On real data this might be violated if we do not have linear independence of the rows of $\mathbf{C}$, for example if $W_2 < N_2$ or if we have even one document which has only words that are also contained in the first N_1 documents and hence there is a row in $\mathbf{C}$ that consists of zeros only. This can be solved by removing documents from the collection until $\mathbf{C}$ is row-wise linear independent.[4]

3.3 Normalization

A key factor in the effectiveness of topic-based methods is the appropriate normalization of the elements of the document matrix $\mathbf{X}$. This is even more relevant for orthonormal topics as the matrix inversion procedure can be very sensitive to small changes in the matrix. In this context, we consider two forms of normalization, term and document normalization, which can also be considered as row/column normalizations of $\mathbf{X}$.

A straightforward approach to normalization is to normalize each column of $\mathbf{X}$ to obtain a matrix as follows:

$$\mathbf{X}' = \left(\frac{x_1}{||x_1||} \cdots \frac{x_N}{||x_N||} \right)$$

If we calculate ${\mathbf{X}'}^{\mathrm{T}}\mathbf{X}' = \mathbf{Y}$ then we get that the (i, j)-th element of $\mathbf{Y}$ is:

$$y_{ij} = \frac{x_i^{\mathrm{T}} x_j}{||x_i||||x_j||}$$

[4]In the experiments in the next section we discarded 4.2% of documents at $N_1 = 1000$ and 47% of documents at $N_1 = 5000$

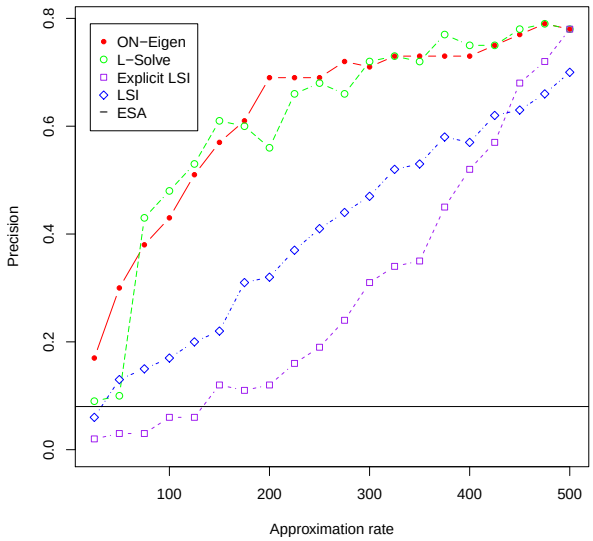

Figure 1: Effect on Top-1 Precision by various approximation method

Thus, the diagonal of $\mathbf{Y}$ consists of ones only and due to the Cauchy-Schwarz inequality we have that $|y_{ij}| \leq 1$, with the result that the matrix $\mathbf{Y}$ is already close to $\mathbf{I}$. Formally, we can use this to state a bound on $||{\mathbf{X}'}^{\mathrm{T}}\mathbf{X}' - \mathbf{I}||_{\mathcal{F}}$, but in practice it means that the orthonormalizing matrix has more small or zero values.

A further option for normalization is to consider some form of term frequency normalization. For term frequency normalization, we use *TF* (tf_{wn}), *Relative* ($\frac{\mathrm{tf}_{wn}}{F_w}$), *TFIDF* ($\mathrm{tf}_{wn} \log(\frac{N}{\mathrm{df}_w})$), and *SQRT* ($\frac{\mathrm{tf}_{wn}}{\sqrt{F_w}}$). Here, tf_{wn} is the term frequency of word w in document n, F_w is the total frequency of word w in the corpus, and df_w is the number of documents containing the words w. The first three of these normalizations have been chosen as they are widely used in the literature. The SQRT normalization has been shown to be effective for explicit topic methods in previous experiments not reported here.

4 Experiments and Results

For evaluation, we consider a cross-lingual mate retrieval task from English/Spanish on the basis of Wikipedia as aligned corpus. The goal is to, for each document of a test set, retrieve the aligned document or *mate*. For each test document, on the basis of

Table 2: Result on large-scale mate-finding studies for English to Spanish matching

the similarity of the query document to all indexed documents, we compute the value rank_i indicating at which position the mate of the i^{th} document occurs. We use two metrics: *Top-k Precision*, defined as the percentage of documents for which the mate is retrieved among the first k elements, and *Minimum Reciprocal Rank*, defined as

$$\mathrm{MRR} = \sum_{i \in \mathrm{test}} \frac{1}{\mathrm{rank}_i}$$

For our experiments, we first extracted a subset of documents (every 20th) from Wikipedia, filtering this set down to only those that have aligned pages in both English and Spanish with a minimum length of 100 words. This gives us 10,369 aligned documents in total, which form the background document collection B. We split this data into a training and test set of 9,332 and 1,037 documents, respectively. We then removed all words whose total frequencies were below 50. This resulted in corpus of 6.7 millions words in English and 4.2 million words in Spanish.

Normalization Methods: In order to investigate the impact of different normalization methods, we ran small-scale experiments using the first 500 documents from our dataset to train ONETA and then evaluate the resulting models on the mate-finding task on 100 unseen documents. The results are presented in Table 1, which shows the Top-1 Precision for the different normalization methods. We see that the effect of applying document normalization in all cases improves the quality of the overall result. Surprisingly, we do not see the same result for frequency normalization yielding the best result for the case where we do no normalization at all[5] . In the remaining experiments we thus employ document normalization and no term frequency normalization.

Approximation Methods: In order to evaluate the different approximation methods, we experimentally compare 4 different approximation methods: standard LSI, ON-Eigen (Equation 1), Explicit LSI (Equation 2), L-Solve (Equation 3) on the same small-scale corpus. For convenience we plot an *approximation rate* which is either K or N_1 depending on method; at $K = 500$ and $N_1 = 500$, these approximations become exact. This is shown in Figure 1. We also observe the effects of approximation and see that the performance increases steadily as we increase the computational factor. We see that the orthonormal eigenvector (Equation 1) method and the L-solve (Equation 3) method are clearly similar in approximation quality. We see that the explicit LSI method (Equation 2) and the LSI method both perform significantly worse for most of the approxi-

[5] A likely explanation for this is that low frequency terms are less evenly distributed and the effect of calculating the matrix inverse magnifies the noise from the low frequency terms

mation amounts. Explicit LSI is worse than the other approximations as it first maps the test documents into a K-dimensional LSI topic space, before mapping back into the N-dimensional explicit space. As expected this performs worse than standard LSI for all but high values of K as there is significant error in both mappings. We also see that the (CL-)ESA baseline, which is very low due to the small number of documents, is improved upon by even the least approximation of orthonormalization. In the remaining of this section, we report results using the L-Solve method as it has a very good performance and is computationally less expensive than ON-Eigen.

Evaluation and Comparison: We compare ONETA using the L-Solve method with N_1 values from 1000 to 9000 topics with (CL-)ESA (using SQRT normalization), LDA (using 1000 topics) and LSI (using 4000 topics). We choose the largest topic count for LSI and LDA we could to provide the best possible comparison. For LSI, the choice of K was determined on the basis of operating system memory limits, while for LDA we experimented with higher values for K without any performance improvement, likely due to overfitting. We also stress that for L-Solve ONETA, N_1 is not the topic count but an approximation rate of the mapping. In all settings we use N topics as with standard ESA, and so should not be considered directly comparable to the K values of these methods.

We also compare to a baseline system that relies on word-by-word translation, where we use the most likely single translation of a word as given by a phrase table generated by the Moses system (Koehn et al., 2007) on the EuroParl corpus (Koehn, 2005). Top 1, Top 5 and Top 10 Precision as well as Mean Reciprocal Rank are reported in Table 2.

Interestingly, even for a small number of documents (e.g., $N_1 = 6000$) our results improve both the word-translation baseline as well as all other topic models, ESA, LDA and LSI in particular. We note that at this level the method is still efficiently computable and calculating the inverse in practice takes less time than training the Moses system. The significance for results ($N_1 \geq 7000$) have been tested by means of a bootstrap resampling significance test, finding out that our results significantly improve on the translation base line at a 99% level.

Further, we consider a straightforward combination of our method with the translation system consisting of appending the topic vectors and the translation frequency vectors, weighted by the relative average norms of the vectors. We see that in this case the translations continue to improve the performance of the system (albeit not significantly), suggesting a clear potential for this system to help in improving machine translation results. While we have presented results for English and Spanish here, similar results were obtained for the German and French case but are not presented here due to space limitations.

In Table 2 we also include the user time and peak resident memory of each of these processes, measured on an 8 Core Intel Xeon 2.50 GHz server. We do not include the results for Word Translation as many hours were spent learning a phrase table, which includes translations for many phrases not in the test set. We see that the ONETA method significantly outperforms LSI and LDA in terms of speed and memory consumption. This is in line with the theoretical calculations presented earlier where we argued that inverting the $N \times N$ dense matrix $\mathbf{X}^{\mathrm{T}}\mathbf{X}$ when $W \gg N$ is computationally lighter than finding an eigendecomposition of the $W \times W$ sparse matrix $\mathbf{X}\mathbf{X}^{\mathrm{T}}$. In addition, as we do not multiply $(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}$ and $\mathbf{X}^{\mathrm{T}}$, we do not need to allocate a large $W \times K$ matrix in memory as with LSI and LDA.

The implementations of ESA, ONETA, LSI and LDA used as well as the data for the experiments are available at `http://github.com/jmccrae/oneta`.

5 Conclusion

We have presented a novel method for cross-lingual topic modelling, which combines the strengths of explicit and latent topic models and have demonstrated its application to cross-lingual document matching. We have in particular shown that the method outperforms widely used topic models such as Explicit Semantic Analysis (ESA), Latent Semantic Indexing (LSI) and Latent Dirichlet Allocation (LDA). Further, we have shown that it outperforms a simple baseline relying on word-by-word translation of the query document into the target language,

while the induction of the model takes less time than training the machine translation system from a parallel corpus. We have also presented an effective approximation method, i.e. L-Solve, which significantly reduces the computational cost associated with computing the topic models.

Abstract

Previous approaches for automated essay scoring (AES) learn a rating model by minimizing either the classification, regression, or pairwise classification loss, depending on the learning algorithm used. In this paper, we argue that the current AES systems can be further improved by taking into account the agreement between human and machine raters. To this end, we propose a rank-based approach that utilizes listwise learning to rank algorithms for learning a rating model, where the agreement between the human and machine raters is directly incorporated into the loss function. Various linguistic and statistical features are utilized to facilitate the learning algorithms. Experiments on the publicly available English essay dataset, Automated Student Assessment Prize (ASAP), show that our proposed approach outperforms the state-of-the-art algorithms, and achieves performance comparable to professional human raters, which suggests the effectiveness of our proposed method for automated essay scoring.

1 Introduction

Automated essay scoring utilizes the NLP techniques to automatically rate essays written for given prompts, namely, essay topics, in an educational setting (Dikli, 2006). Nowadays, AES systems have been put into practical use in large-scale English tests and play the role of one human rater. For example, before AES systems enter the picture, essays in the writing assessment of Graduate Record Examination (GRE) are rated by two human raters. A third human rater is needed when the difference of the scores given by the two human raters is larger than one in the 6-point scale. Currently, GRE essays are rated by one human rater and one AES system. A second human rater is required only when there exists a non-negligible disagreement between the first human rater and the machine rater. With the help of an AES system that highly agrees with human raters, the human workload can be reduced by half at most. Therefore, the agreement between the AES system and the human rater is an important indicator of an AES system's effectiveness.

There have been efforts in developing AES methods since the 1960s. Various kinds of algorithms and models based on NLP and machine learning techniques have been proposed to implement AES systems. Existing approaches consider essay rating as a classification (Larkey, 1998), regression (Attali and Burstein, 2006) or preference ranking problem (Yannakoudakis et al., 2011), where the loss function is the regression loss, classification loss and pairwise classification loss, respectively. In this paper, we argue that the purpose of AES is to predict the essay's rating that human raters would give. If an AES system frequently disagrees with the first human rater, a second human rater will be needed in most cases. Thus, the introduction of the AES system does not bring much benefit in reducing the human workload. It is therefore desirable to minimize the disagreement between the machine and human raters. However, this disagreement is not explicitly, if any, addressed in the current AES methods.

To this end, we propose a rank-based approach in this paper that utilizes a listwise learning to rank

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1741–1752,
Seattle, Washington, USA, 18-21 October 2013.

algorithm to address automated essay scoring in the view of directly optimizing the agreement between human raters and the AES system. Different from the preference ranking-based approach (Yannakoudakis et al., 2011) that maximizes the pairwise classification precision (Liu, 2009), our rank-based approach follows the listwise learning paradigm and the agreement between the machine and human raters is directly integrated into the loss function that is optimized by gradient boost regression trees.

To the best of our knowledge, this work is the first to apply listwise learning to rank approach for AES, which aims at the optimization of the agreement between the human and machine raters. Experimental results on the publicly available dataset ASAP indicate that our proposed method achieves high agreement with human raters, that is about 0.80, measured by quadratic weighted Kappa (Brenner and Kliebsch, 1996). Our proposed method also outperforms the previous classification, regression and preference ranking based approaches. As it is widely accepted that the agreement between human raters, measured by either quadratic weighted Kappa or Pearson's correlation coefficient, ranges from 0.70 to 0.80 (Powers et al., 2000) (Williamson, 2009), our proposed approach therefore performs as well as human raters.

The rest of this paper is organized as follows. In section 2, we introduce the research background of automated essay scoring and give a brief introduction to learning to rank. In section 3, a detailed description of our listwise learning to rank approach for automated essay scoring is presented. Section 4 explains the experimental setup and section 5 presents the experimental results. Finally, in section 6 we conclude this research.

2 Related Work and Background

Firstly, we give a brief description of existing approaches for AES in section 2.1. Then, an introduction to learning to rank is presented in section 2.2.

2.1 Existing AES Methods

In general, existing solutions consider AES as a learning problem. Based on a large number of predefined objectively measurable features, various learning techniques, including classification, regression and preference ranking, are applied (Larkey, 1998) (Yannakoudakis et al., 2011).

Regression-based approach treats feature values and essay score as independent variables and dependent variable, respectively, and then learns a regression equation by classical regression algorithms, such as support vector regression (Vapnik et al., 1996). In 1966, the first AES system, Project Essay Grader, was developed by Ellis Page upon the request of the American College Board. The PEG system defines a large set of surface text features from essays, e.g. fourth root of essay length, and uses regression-based approach to predict the score that human raters will give. E-rater, developed by Educational Testing Services (ETS) in America, in late 1990s, is a commercial AES system which has been put into practical use in the Graduate Record Examination (GRE) and the Test of English as a Foreign Language (TOEFL). The E-rater system uses natural language processing techniques to extract various kinds of linguistic features of essays, such as lexical, syntactic, grammar, etc.. Then it predicts the final score by the stepwise regression method (Attali and Burstein, 2006).

The classification-based approach sees essay scores as in-discriminative class labels and uses classical classification algorithms, e.g. the K-nearest neighbor (KNN) and the naive Bayesian model, to predict to which class an essay belongs, where a class is associated to a numeric rating. Intelligent Essay Assessor (IEA) (Foltz et al., 1999), developed also in late 1990s, evaluates essay by measuring semantic features. Each ungraded essay, represented by a semantic vector generated by Latent Semantic Analysis (LSA) (Dumais, 2005), is rated according to the similarity degree with semantic vectors of graded essays. Bayesian Essay Test Scoring sYstem, developed by Larkey in 2003, is based on naive Bayesian model. It is the only open-source AES system, but has not been put into practical use yet.

Besides classification and regression-based approaches, (Yannakoudakis et al., 2011) proposed a preference ranking based approach for learning a rating model, where a ranking function or model is learned to construct a global ordering of essays based on writing quality. It is also the first study of rank-based approach in automated essay scoring. Although "learning to rank" is not mentioned in

their paper, the algorithm they used, Ranking SVM (svm-light package with "-z p" option), is actually a pairwise approach. We will give a brief introduction to learning to rank in section 2.2.

The AES systems can be deployed in two different manners, namely prompt-specific and generic. A prompt-specific rating model is built for a specific prompt and designed to be the best rating model for the particular prompt (Williamson, 2009). For different prompts, the features used, their weights, and scoring criteria, may be different. It usually requires several hundreds of graded essays for training, which is time-consuming and usually impractical in a classroom environment. Generic rating model is trained from essays across a group of prompts and designed to be the best fit for predicting human scores for all prompts. It usually does not consider prompt-specific features and just takes writing quality into account. Generic rating model evaluates essays across all prompts with the same scoring criteria, which is more consistent with the human rubric that is usually the same for all prompts, and therefore has validity-related advantages (Attali et al., 2010).

2.2 Learning to Rank

Learning to rank, also called machine-learned ranking, was originally proposed to settle the ranking problem in information retrieval (IR) (Liu, 2009). It is a type of supervised or semi-supervised machine learning algorithm that automatically construct a ranking model or function from training data.

Current learning to rank algorithms fall into three categories, that is, the pointwise, pairwise, listwise approaches. Pointwise approach takes individual documents as training examples for learning a scoring function. In fact, both multiple linear regression and support vector regression (Vapnik et al., 1996), which have been widely used in automated essay scoring (Shermis and Burstein, 2002), can be seen as pointwise approaches. Pairwise approaches process a pair of documents each time and usually model ranking as a pairwise classification problem. Thus, the loss function is always a classification loss. Representative algorithms are ranking SVM (Joachims, 2006), RankNet (Li et al., 2007), etc.. (Yannakoudakis et al., 2011) apply pairwise approach, ranking SVM, to automated essay scoring and achieve better performance than support vector regression. In listwise approaches, ranking algorithms process a list of documents each time and the loss function aims at measuring the accordance between predicted ranking list and the ground truth label. Representative algorithms are LambdaMart (Wu et al., 2008), RankCosine (Qin et al., 2008), etc.. Listwise approach has not yet been used in automated essay scoring.

3 Automated Essay Scoring by Maximizing Human-machine Agreement

The main work-flow of our proposed approach is as follows. Firstly, a set of essays rated by professional human raters are gathered for the training. A listwise learning to rank algorithm learns a ranking model or function using this set of human rated essays represented by vectors of the pre-defined features. Then the learned ranking model or function outputs a model score for each essay, including both rated and unrated essays, from which a global ordering of essays is constructed. Finally, the model score is mapped to a predefined scale of valid ratings, such as an integer from 1 to 6 in a 6-point scale

In this section, we give a detailed description of our listwise learning to rank approach for AES in section 3.1. And features used in our approach are presented in section 3.2.

3.1 Listwise Learning to Rank for AES

Our choice of the listwise learning to rank algorithm is due to the fact that it takes the entire set of labeled essays associated to a given prompt, instead of the individual essays or essay pairs as in (Yannakoudakis et al., 2011), as training examples. This brings us the convenience of easily embedding the inter-rater agreement into the loss function for the learning.

In this paper, we deploy LambdaMART (Wu et al., 2008), a listwise learning to rank algorithm and then use Random Forests (RF) (Breiman, 2001) for the bagging of LambdaMART learners. Having been widely used in information retrieval applications, LambdaMART is one of the most effective learning to rank algorithms. For instance, it achieves the top results in the 2010 Yahoo! Learning to Rank challenge (Burges, 2010). Random Forests is an

ensemble learning method for classification and regression.

Previously, the loss function of LambdaMART is defined as the gradient loss of the retrieval effectiveness, measured by IR evaluation criteria such as Normalized Discounted Cumulative Gain (nDCG) (Wu et al., 2008). More specifically, it is a heuristic method that directly defines λ, the gradient of nDCG with respect to the model score of each document, and has been shown to work empirically for particular loss functions NDCG (Yue and Burges, 2007). Then, Multiple Additive Regression Trees (MART) (Friedman, 2000), also called Gradient Boosting Decision Tree (GBDT)[1], are used to "learn" these gradients iteratively. MART is a class of boosting algorithms that performs gradient descent in function space, using regression trees. Its output $F(x)$ can be written as $F(x) = \sum_i \alpha_i f_i(x), i = 1, 2, ...N$. Each $f_i(x)$ is a function modeled by a single regression tree and the α_i is the corresponding weight. Given that *n* trees have been trained, the *(n+1)*th regression tree, $f_{i+1}(x)$, models the derivative of the cost with respect to the current model score at each training point. Thus, what remains is to compute the derivative.

As for the automated essay scoring, LambdaMART is not readily available since its loss function is defined as a function of the gradient of IR evaluation measures. While such measures focus on the top-ranked documents that are of great importance to the IR applications, they are not suitable to our study. This is because for AES, the rating prediction of all essays equally matters, no matter what ratings they receive.

It is therefore necessary to re-define the λ. Specifically, we need to define the gradient of the evaluation criteria in AES, e.g. quadratic weighted Kappa (Brenner and Kliebsch, 1996) and Pearson's correlation coefficient, with respect to the model score of each essay. In this paper, we use quadratic weighted Kappa as the evaluation metric. Kappa (Cohen and others, 1960) is a statistical metric which is used to measure inter-rater agreement. Quadratic weighted Kappa takes the degree of disagreement between raters into account. This measuring method is widely accepted as a primary evaluation metric for the AES tasks. For instance, it is the official evaluation metric in the Automated Student Assessment Prize sponsored by Hewlett Foundation[2]. We denote our modified LambdaMART as K-LambdaMART in which K stands for the Kappa-based gradient function. Specific steps include the following:

To begin with, we re-define the $\lambda_{i,j}$ for each pair of essays. For a pair of essays, essay i and essay j, $\lambda_{i,j}$ is defined as the derivative of RankNet (Li et al., 2007) loss function multiplied by the Quadratic weighted Kappa gain after exchanging the two essays' ratings.

$$\lambda_{i,j} = \frac{-\delta}{1 + e^{\delta(s_i - s_j)}} |\Delta_{Kappa}| \tag{1}$$

s_i and s_j are the model scores for essay i and essay j, respectively. δ is a parameter which determines the shape of the sigmoid. Quadratic weighted Kappa are calculated as follows:

$$\kappa = 1 - \frac{\sum_{i,j} \omega_{i,j} O_{i,j}}{\sum_{i,j} \omega_{i,j} E_{i,j}} \tag{2}$$

In matrix O, $O_{i,j}$ corresponds to the number of essays that received a score i by human rater and a score j by the AES system. In matrix ω, $\omega_{i,j}$ is the difference between raters scores $\frac{(i-j)^2}{(N-1)^2}$, where N is the number of possible ratings. Matrix E is calculated as the outer product between the two raters vectors of scores, normalized such that E and O have the same sum.

It is necessary to define the quadratic weighted Kappa gain, namely Δ_{Kappa}, in an explicit manner. In each iteration, every essay is ranked by its model score and then rated according to its ranking position. For example, for five essays e_1, e_2, e_3, e_4, e_5 with actual ratings $5, 4, 3, 2, 1$, if the ranking (by model score) is e_3, e_4, e_1, e_5, e_2, we assume that e_3, e_4, e_1, e_5, e_2 will get ratings of $5, 4, 3, 2, 1$, over which quadratic weighted kappa gain can be calculated.

After the definition of $\lambda_{i,j}$ for each pair of essays, it is time to re-define the λ, the gradient for each essay. Let I denote the set of pairs of indices $\langle i, j \rangle$, in which essay i receive a higher rating than essay j.

[1]For space reason, we refer the readers to (Friedman, 2000), (Breiman, 2001) for details of MART, GBDT and Random Forests.

[2]http://www.kaggle.com/c/asap-sas

Set I must include each pair just once. Then, the λ gradient for each essay, e.g. essay i, is defined as,

$$\lambda_i = \sum_{j:\langle i,j\rangle \in I} \lambda_{i,j} - \sum_{j:\langle j,i\rangle \in I} \lambda_{i,j}; \qquad (3)$$

The rational behind the above formulae is as follows. For each of the essays in the whole essay collection associated with the same prompt, e.g. essay i, the gradient λ_i is incremented by a positive value $\lambda_{i,j}$ when coming across another essay j that has a lower rating. The value of $\lambda_{i,j}$ is weighted by the quadratic weighted Kappa gain after exchanging the two essays' ratings. On the contrary, the gradient λ_i will be incremented by a negative value $-\lambda_{i,j}$ when the another essay has a higher rating. As a result, after each iteration of MART, essays with higher rating tend to receive a higher model score while essays with lower rating tend to get a lower model score.

After the training process, the ranking model outputs an unscaled model score for each ungraded essay. To determine the final rating of each given unrated essay, we have to map this unscaled model score to the predefined scale, such as an integer from 1 to 6 in a 6 point scale. The mapping process is as follows. To begin with, the learned ranking model also computes an unscaled model score for each essay in the training set. As the model is trained by learning to rank algorithms, essays with higher model scores tend to get higher actual ratings. In other words, essays with close model scores tend to get the same rating. Therefore, we select the *k* essays whose model scores are closest to the given essay. We then remove the essays with the very highest and lowest model scores within the *k*. The final rating is the mean of the remaining $k-2$ essays' ratings. In this paper, *k* is empirically set to 5, obtained in our preliminary experiments on the ASAP validation set.

Finally, the Random Forests algorithm is used to bag K-LambdaMART learners. During the training process, both features and samples are randomly selected for each K-LambdaMART learner. In the testing phase, it outputs a score for each testing sample that is the mode of the scores output by each K-LambdaMART learner.

3.2 Pre-defined Features

We pre-define four types of features that indicate the essay quality, including lexical, syntactical, grammar and fluency, content and prompt-specific features. A brief description of these four classes of features is given below.

Lexical features: We define 4 subsets of lexical features. Each subset of features consists of one or several sub features.

– *Statistics of word length*: The number of words with length in characters larger than 4, 6, 8, 10, 12, respectively. The mean and variance of word length in characters.

– *word level*: All words in Webster dictionary [3] are divided into 8 levels according to the College Board Vocabulary Study (Breland et al., 1994). The higher level a word belongs to, the more sophisticated vocabulary usage it indicates. For example, words like thoroughfare, percolate are in level 8, while words with the same meanings, street, filter, belong to level 1. We count the number of words that belong to each level and calculate the mean word level of a given essay.

– *Unique words*: The number of unique words appeared in each essay, normalized by the essay length in words.

– *Spelling errors*: The number of spelling errors detected by the spelling check API provided by Google [4].

Syntactical features: There are 4 subsets of syntactical features.

– *Statistics of sentence length*: The number of sentences with length in words larger than 10, 18, 25, respectively. The mean and variance of sentence length in words.

– *Subclauses*: The mean number of subclauses in each sentence, normalized by sentence length in words. The mean subclause length in words. Subclauses are labeled as "SBAR" in the parser tree generated by a commonly used NLP tool, Stanford Core NLP (Klein and Manning, 2003), which is an integrated suite of natural language processing tools for English in Java[5], including part-of-speech tagging, parsing, co-reference, etc..

– *Sentence level*: The sum of the depth of all nodes in a parser tree generated by Stanford Core NLP. The height of the parser tree is also incorpo-

rated into the feature set.

– *Mode, preposition, comma*: The number of modes, prepositions and commas in each sentence respectively, normalized by sentence length in words. Part of speech (POS) is detected by Stanford Core NLP (Toutanova et al., 2003). The POS tags of modal verb and preposition are "MD" and "IN", respectively.

Grammar and fluency features: There are two subsets of grammar and fluency features.

– *Word bigram and trigram*: We evaluate the grammar and fluency of an essay by calculating mean tf/TF of word bigrams and trigrams (Briscoe et al., 2010) (tf is the term frequency in a single essay and TF is the term frequency in the whole essay collection). We assume a bigram or trigram with high tf/TF as a grammar error because high tf/TF means that this kind of bigram or trigram is not commonly used in the whole essay collection but appears in the specific essay.

– *POS bigram and trigram*: Mean tf/TF of POS bigrams and trigrams. The reason is the same with word bigrams and trigrams.

Content and prompt-specific features: We define four subsets of content and prompt-specific features.

– *Essay length*: Essay length in characters and words, respectively. The fourth root of essay length in words is proved to be highly correlated with the essay score (Shermis and Burstein, 2002).

– *Word vector similarity*: Mean cosine similarity of word vectors, in which the element is the term frequency multiplied by inverse document frequency (tf-idf) (Salton, 1971) of each word. It is calculated as the weighted mean of all cosine similarities and the weight is set as the corresponding essay score.

– *Semantic vector similarity*: Semantic vectors are generated by Latent Semantic Analysis (Dumais, 2005). The calculation of mean cosine similarity of semantic vectors is the same with word vector similarity.

– *Text coherence*: Coherence in writing means that all the ideas in a paragraph flow smoothly from one sentence to the next. We only consider nouns and pronouns in each sentence as they convey more information. The relevance degree between one sentence and its next in the same paragraph is calculated as the sum of the similarity degrees between nouns and pronouns appeared in the two sentences, normalized by the sum of the two sentences' length in words. The similarity degree between words is set to 1 if coreference exists, indicated by Stanford Core NLP (Lee et al., 2013). Otherwise, it is measured by WordNet similarity package (Pedersen et al., 2004). Finally, text coherence is computed as the average relevance degree of all pairs of neighbored sentences.

The rating model is learned off-line using a set of training essays. For a given target essay, it is the feature extraction that mainly accounts for the overhead. In our experiments, it usually costs in average no more than 10 seconds on a desktop PC with an Intel i5-2410M CPU running at 2.3GHZ to extract the pre-defined features and predict a rating for a given essay, which is affordable, compared to the cost of a human rater.

4 Experimental Setup

This section presents our the experimental design, including the test dataset used, configuration of testing algorithms, feature selection and the evaluation methodology.

4.1 Test Dataset

The dataset used in our experiments comes from the Automated Student Assessment Prize (ASAP)[1], which is sponsored by the William and Flora Hewlett Foundation. Dataset in this competition[6] consists of eight essay sets. Each essay set was generated from a single prompt. The number of essays associated with each prompt ranges from 900 to 1800 and the average length of essays in word in each essay set ranges from 150 to 650. All essays were written by students in different grades and received a resolved score, namely the actual rating, from professional human raters. Moreover, ASAP comes with a validation set that can be used for parameter training. There is no overlap between this validation set and the test set used in our evaluation.

In AES, the agreement between human-machine rater is the most important measurement of success. We use quadratic weighted Kappa to evaluate the agreement between the ratings given by the AES algorithm and the actual ratings. It is widely accepted

[3] http://www.merriam-webster.com/

[4] http://code.google.com/p/google-api-spelling-java/

[5] http://nlp.stanford.edu/software/corenlp.shtml

as a reasonable evaluation measure for AES systems (Williamson, 2009), and is also the official evaluation measure in the ASAP AES competition. It is calculated on all essay topics. If there are essays that come from n essay topics, we calculate the agreement degree on each essay topic first and then compute the overall agreement degree in the z-space. In addition, analysis of variance (ANOVA) (Scheffe, 1999) is conducted to test whether significant difference exists between the two groups of scores given by human and machine raters.

4.2 Configuration of Testing Algorithms

Random Forests bagging K-LambdaMart We denote our proposed method K-LambdaMART where K stands for the Kappa-based gradient. Our implementation of RF bagging K-LambdaMART is based on the open-source RankLib toolkit[7], a library of learning to rank algorithms, in which many popular learning to rank algorithms have been implemented, e.g. LambdaMART and RankNet (Li et al., 2007). Empirical settings of parameters obtained by preliminary experiments on the ASAP validation set are as follows. For bagging: the number of bags is set to 300, subsampling rate is 0.80 and feature sampling rate is 0.50. For LambdaMART in each bag: the number of trees is set to 1, the number of tree leaves is 100 and other parameters are set to default.

Baseline algorithms We use classical machine learning algorithms, support vector machine (SVM) for classification, regression (Vapnik et al., 1996) and preference ranking (Joachims, 2006), respectively, as the baselines. These three algorithms have been used for AES in the literature (Briscoe et al., 2010) (Yannakoudakis et al., 2011). Especially, the state-of-the-art AES approach proposed by (Yannakoudakis et al., 2011) utilizes the SVM for preference ranking, a pairwise learning to rank algorithm, for training a rating model. The linear kernel is used in the experiments. The parameter C, which controls the trade-off between empirical loss and regularizer, is set by grid search on the ASAP validation set.

The original LambdaMART is not included in the baseline algorithms as it has been shown that the performance of LambdaMART is inferior to ranking SVM on the same dataset (Chen et al., 2012).

4.3 Feature Selection

Although machine learning approaches usually use the all features available for training, we try to obtain an carefully selected feature set that can withstand the scrutiny of construct validity in assessment development (Chen and Zechner, 2011). Specific steps of feature selection conducted on individual features are as follows:

To begin with, the importance of the features is determined by computing each features Pearson correlation coefficient with human raters scores based on the training set (Chen and Zechner, 2011). Features whose absolute Pearson correlation coefficient with human scores are lower than 0.20 are removed from the feature set.

Next, we calculate the inter-correlation degrees between these features. For each pair of features whose Pearson correlation coefficient larger than 0.90, one of them should be removed. The criteria for feature removing is as follows. Firstly, at least one feature in each subset of features should be remained. Satisfying the first prerequisite condition, the removed one should be linguistically less meaningful than the remaining one.

For prompt-specific rating model, feature selection is conducted on the essays associated with the same prompt. For generic rating model, the final feature set used for training is the intersection of the 8 feature sets for prompt-specific rating model.

For space reason, here we briefly summarize the feature selection results. Among the lexical features, word length in characters larger than 8 and 10, number of words in each of the levels from 3 to 6, number of unique words, and number of spelling errors are mostly selected. As for the syntactical features, sentence length in words larger than 18 and 25, number of commas, mean clause length and the mean depth of parser tree are usually selected. Among the grammar and fluency features, mean tf/TF of word bigrams and mean tf/TF of POS trigrams are always selected. For content and prompt-specific features, essay length in words, word vector and semantic vector similarity with high rated essays, text coherence are usually selected for training a prompt-

[7] http://people.cs.umass.edu/ vdang/ranklib.html

Table 1: Cross-validation on ASAP dataset measured by quadratic weighted Kappa.

Algorithm	Prompt-specific	ANOVA		Generic	ANOVA
SVMc (baseline)	0.7302(9.75%)	Significant		0.6319(23.93%)	Significant
SVMr (baseline)	0.7861(1.95%)	Significant		0.7022(11.52%)	Significant
SVMp (baseline)	0.7876(1.75%)	Significant		0.7669(2.11%)	Not significant
RF bagging K-LambdaMART	**0.8014**	**Not significant**		**0.7831**	**Not significant**

specific rating model. When it comes to the generic rating model, the prompt-specific features like word vector similarity and semantic vector similarity, are removed.

4.4 Evaluation Methodology

We conduct three sets of experiments to evaluate the effectiveness of our listwise learning to rank approach for automated essay scoring.

The first set of experiments evaluates our proposed approach under a prompt-specific setting. We conduct 5-fold cross-validation, where the essays of each prompt are randomly partitioned into 5 subsets. In each fold, 4 subsets are used for training, and one is used for testing. To avoid bias introduced by the random partition, we repeat the 5-fold cross-validation for 5 times on 5 different random partitions. The overall quadratic weighted Kappa is averaged on all 25 test subsets.

It should be noticed that in random partition of the whole dataset, the overlap between any two partitions should be kept below $1.5*1/(\#folds)*100\%$. For example, in five-fold cross validation, the overlap should be kept below 30%. This is because: according to the Dirichlet principle (Courant, 2005), each subset in one partition overlaps more than 20% with at least one subset in another partition in five-fold cross-validation. The tolerance boundary parameter is then set to 1.5.

The objective of the second set of experiments is to test the performance of our listwise learning to rank approach for generic rating models. We also conduct 5 times 5-fold cross-validation like the first experiment. In 5-fold cross-validation, essays associated with the same prompt are randomly partitioned into 5 subsets. In this way, each fold consists of essays across all prompts. The overall performance is averaged on all 25 test subsets.

In the third set of experiments, we evaluate the quality of the features used in our rating model by feature ablation test and feature unique test. In ablation test, we evaluate our essay rating model's performance before and after the removal of a subset of features from the whole feature set. The performance difference indicates the removed features' contribution to the rating model's overall performance. In unique test, only a subset of features are used in the rating model construction and all other features are removed. The learned rating model's performance indicates to which extent the features are correlated with the actual essay ratings.

5 Experimental Results

5.1 Evaluation Results

Table 1 presents the first set of experimental results obtained on the ASAP dataset, measured by quadratic weighted Kappa. In Table 1, RF stands for random forests. SVMc, SVMr, SVMp are SVM for classification, regression and preference ranking, respectively. ANOVA stands for variance analysis, which aims to test whether significant difference exists between the scores given by human and machine raters. The improvement of our RF bagging K-LambdaMART over each baseline in percentage is also given.

For prompt-specific rating model, all of these algorithms achieve good performance comparable to human raters as literatures have revealed that the agreement between two professional human raters (measured by statistics for correlation analysis, e.g. quadratic weighted Kappa) is around 0.70 to 0.80 (Williamson, 2009) (Williamson, 2009). It is clear that our listwise learning to rank approach, Random Forests bagging K-LambdaMART, gives the best performance on the ASAP dataset. The variance analysis result on the six groups of scores (scores given by five times of five-fold cross-validation and the scores provided by human rater), no significant difference, suggests the robustness of our proposed approach. On the contrary, although pref-

erence ranking based approach, SVM for ranking, and regression based approach, SVM for regression, give very good result in human-machine agreement, their variance analysis results indicate that there exists significant difference between the scores given by human and machine raters. The result of the first set of experiments suggests the effectiveness and robustness of our listwise learning to rank approach in the building of prompt-specific rating model.

For generic rating model, one can conclude from Table 1 that RF bagging LambdaMART performs better than SVM for classification, regression and preference ranking on the ASAP dataset. The dataset used in our experiment consists of essays generated by 8 prompts and each prompt has its own features. With such a training set, both classification and regression based approaches produce not good results, as it is commonly accepted that rating model whose performance measured by inter-rater agreement lower than 0.70 is not applicable (Williamson, 2009). And the variance analysis results also reveal that there exists statistically significant difference between the scores given by human and machine raters, indicating a low robustness of these two baselines. The performance comparison of the generic rating models suggest that the rank based approaches, SVMp and RF bagging K-LambdaMART, are more effective than the classification based SVMc and the regression based SVMr, while our proposed RF bagging K-LambdaMART outperforms the state-of-the-art SVMp. Moreover, we find that there is no obvious performance difference when our proposed method is applied to prompt-specific and generic rating models. Considering the advantages generic rating models have, the result of the second set of experiments suggests the feasibility of building a rating model which is generalizable across different prompts while performs slightly inferior to the prompt-specific rating model.

5.2 Feature Analysis

Table 2 gives the results of feature ablation and unique test. In the table, "All features" stands for the use of all the features available, apart from the prompt-specific features that are not applicable to learning a generic model. In other rows, the feature subset name stands for the feature subset to be ablated in ablation test and the feature subset to be used in unique test. Note that we ablate (as in the ablation test) or use (as in the unique test) a subset of features such as the different statistics of word length as a whole since features belonging to the same subset are usually highly correlated.

Among the lexical features, the two feature subsets, word level and statistics of word length, are highly correlated with essay score in both prompt-specific and generic rating models. This observation was expected since word usage is an important notion of writing quality, regardless of essay topics.

In the syntactical features, the feature subset, sentence level, measured by the height and depth of the parser tree, correlates the most with essay score. One can infer that long sentences with nested subclauses tend to improve the final ratings.

All grammar and fluency features achieve performance around 0.60 in feature unique test for prompt-specific rating model. What is more, during feature selection, we find that the Pearson's correlation coefficient between the feature values and the final ratings in each essay prompt ranges from -0.20 to -0.60, which suggests that our method to estimate the number of grammar errors is applicable because it is widely accepted that in the evaluation of student essays, essays with more grammar errors tend to receive lower ratings.

Among the content and prompt-specific features, essay length and word vector similarity features give good results in feature unique test. The fourth root of essay length in words has been proved to be a highly correlated feature by many works on AES (Shermis and Burstein, 2002). Word vector similarity feature measures prompt-specific vocabulary usage, which is also important to essay evaluation.

In ablation test, there is no significant performance decrease no matter what feature subset is removed. It seems that each feature subset contributes little to the overall performance and therefore can be removed. However, the result of feature unique test suggests that most features used in our rating model are in fact highly correlated with the writing quality.

6 Conclusions and Future Work

We have proposed a listwise learning to rank approach to automated essay scoring (AES) by directly incorporating the human-machine agreement

Table 2: Results of feature ablation and unique test

Feature subset	Prompt-specific			Generic	
All Features	0.8014			0.7831	
	Ablation	Unique		Ablation	Unique
Lexical features					
Statistics of word length	0.7763	0.7512		0.7801	0.7350
Word level	0.7834	0.7582		0.7779	0.7306
Unique words	0.7766	0.6737		0.7692	0.6786
Spelling errors	0.7724	0.6863		0.7730	0.6742
Syntactical features					
Statistics of sentence length	0.7856	0.6410		0.7684	0.7025
Subclauses	0.7862	0.5473		0.7813	0.5050
Sentence level	0.7749	0.7046		0.7796	0.6955
Mode, preposition, comma	0.7847	0.5860		0.7807	0.5606
Grammar and fluency features					
Word bigrams and trigrams	0.7813	0.6017		0.7824	0.4395
POS bigrams and trigrams	0.7844	0.6410		0.7786	0.6022
Content and prompt-specific features					
Essay length	0.7930	0.7502		0.7736	0.7390
Word vector similarity	0.7658	0.7001		–	–
Semantic vector similarity	0.7924	0.5683		–	–
Text coherence	0.7863	0.6947		0.7798	0.6367

into the loss function. Experiments on the public English dataset ASAP show that our approach outperforms the state-of-the-art algorithms in both prompt-specific and generic rating settings. Moreover, it is widely accepted that the agreement between professional human raters ranges from 0.70 to 0.80, measured by quadratic weighted Kappa or Pearson's correlation (Powers et al., 2000) (Williamson, 2009). In the experiments, our approach achieves a quadratic weighted Kappa around 0.80 for prompt-specific rating and around 0.78 for generic rating, suggesting its potential in automated essay scoring.

Most existing research on AES focus on training a prompt-specific rating model. While such approaches have the advantage of providing a satisfactory rating accuracy for essays written for a specific topic, they also suffer from validity and feasibility problem as a significant amount of training data, namely essays with human ratings, are required for every given essay topic (Attali et al., 2010). It is therefore appealing to develop an approach that learns a generic model with acceptable rating accuracy, since it has both validity-related and logistical advantages. In our future work, we plan to continue the research on generic rating model. Because of the diversification of writing features of essays associated with different prompts, a viable approach is to explore more generic writing features that can well reflect the writing quality.

Success with Style: Using Writing Style to Predict the Success of Novels

Vikas Ganjigunte Ashok **Song Feng** **Yejin Choi**

vganjiguntea, songfeng, ychoi@cs.stonybrook.edu

Abstract

Predicting the success of literary works is a curious question among publishers and aspiring writers alike. We examine the quantitative connection, if any, between *writing style* and successful literature. Based on novels over several different genres, we probe the predictive power of statistical stylometry in discriminating successful literary works, and identify characteristic stylistic elements that are more prominent in successful writings. Our study reports for the first time that statistical stylometry can be surprisingly effective in discriminating highly successful literature from less successful counterpart, achieving accuracy up to 84%. Closer analyses lead to several new insights into characteristics of the writing style in successful literature, including findings that are contrary to the conventional wisdom with respect to good writing style and readability.

1 Introduction

Predicting the success of novels is a curious question among publishers, professional book reviewers, aspiring and even expert writers alike. There are potentially many influencing factors, some of which concern the intrinsic content and quality of the book, such as interestingness, novelty, style of writing, and engaging storyline, but external factors such as social context and even luck can play a role. As a result, recognizing successful literary work is a hard task even for experts working in the publication industries. Indeed, even some of the best sellers and award winners can go through several rejections before they are picked up by a publisher.[1]

Perhaps due to its obvious complexity of the problem, there has been little previous work that attempts to build statistical models that predict the success of literary works based on their intrinsic content and quality. Some previous studies do touch on the notion of stylistic aspects in successful literature, e.g., extensive studies in Literature discuss literary styles of significant authors (e.g., Ellegård (1962), McGann (1998)), while others consider content characteristics such as plots, characteristics of characters, action, emotion, genre, cast, of the best-selling novels and blockbuster movies (e.g., Harvey (1953), Hall (2012), Yun (2011)).

All these studies however, are qualitative in nature, as they rely on the knowledge and insights of human experts on literature. To our knowledge, no prior work has undertaken a systematic quantitative investigation on the overarching characterization of the writing style in successful literature. In consideration of widely different styles of authorship (e.g., Escalante et al. (2011), Peng et al. (2003), Argamon et al. (2003)), it is not even readily clear whether there might be common stylistic elements that help discriminating highly successful ones from less successful counterpart.

In this work, we present the first study that investigates this unstudied and unexpected connection between stylistic elements and the literary success. The key findings of our research reveal that there exists distinct linguistic patterns shared among suc-

[1] E.g., Paul Harding's "Tinkers" that won 2010 Pulitzer Prize for Fiction and J. K. Rowling's "Harry Potter and the Philosopher's Stone" that sold over 450 million copies.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1753–1764,
Seattle, Washington, USA, 18-21 October 2013.

cessful literature, at least within the same genre, making it possible to build a model with surprisingly high accuracy (up to 84%) in predicting the success of a novel. This result is surprising for two reasons. First, we tackle the hard task of predicting the success of novels written by *previously unseen* authors, avoiding incidental learning of authorship signature, since previous research demonstrated that one can achieve very high accuracy in authorship attribution (as high as 96% in some experimental setup) (e.g., Raghavan et al. (2010), Feng et al. (2012)). Second, we aim to discriminate highly successful novels from less successful, but nonetheless published books written by professional writers, which are undoubtedly of higher quality than average writings. It is important to note that the task we tackle here is much harder than discriminating highly successful works from those that have not even passed the scrutinizing eyes of publishers.

In order to quantify the success of literary works, and to obtain corresponding gold standard labels, one needs to first define *"success"*. For practical convenience, we largely rely on the download counts available at Project Gutenberg as a surrogate to quantify the success of novels. For a small number of novels however, we also consider award recipients (e.g., Pulitzer, Nobel), and Amazon's sales records to define a novel's success. We also extend our empirical study to movie scripts, where we quantify the success of movies based on the average review scores at `imdb.com`. We leave analysis based on other measures of literary success as future research.

In this study, we do not attempt to separate out success based on literary quality (award winners) from success based on popularity (commercial hit, often in spite of bad literary quality), mainly because it is not practically easy to determine whether the high download counts are due to only one reason or the other. We expect that in many cases, the two different aspects of success are likely to coincide, however. In the case of the corpus obtained from Project Gutenberg, where most of our experiments are conducted, we expect that the download counts are more indicative of success based on the literary quality (which then may have resulted in popularity) rather than popularity without quality.

We examine several genres in fiction and movie scripts, e.g., adventure stories, mystery, fiction, historical fiction, sci-fi, short stories, as well as poetry, and present systematic analyses based on lexical and syntactic features which have been known to be effective in a variety of NLP tasks ranging from authorship attribution (e.g., Raghavan et al. (2010)), genre detection (e.g., Rayson et al. (2001), Douglas and Broussard (2000)), gender identification (e.g., Sarawgi et al. (2011)) and native language detection (e.g., Wong and Dras (2011)).

GENRE	#BOOKS	τ^-	τ^+
Adventure	409	17	100
Detective / Mystery	374	25	90
Fiction	1148	7	125
Historical Fiction	374	25	115
Love Stories	342	16	85
Poetry	580	9	70
Science Fiction	902	30	100
Short Stories	1117	9	224

Table 1: # of books available per genre at Gutenberg with download thresholds used to define more successful ($\geq \tau^+$) and less successful ($\leq \tau^-$) classes.

Our empirical results demonstrate that (1) statistical stylometry can be surprisingly effective in discriminating successful literature, achieving accuracy up to 84%, (2) some elements of successful styles are genre-dependent while others are more universal. In addition, this research results in (3) findings that are somewhat contrary to the conventional wisdom with respect to the connection between successful writing styles and readability, (4) interesting correlations between sentiment / connotation and the literary success, and finally, (5) comparative insights between fiction and nonfiction with respect to the successful writing style.

2 Dataset Construction

For our experiments, we procure novels from project Gutenberg[2]. Project Gutenberg houses over $40,000$ books available for free download in electronic format and provides a catalog containing brief descriptions (title, author, genre, language, download count, etc.) of these books. We experiment with genres in Table 1, which have sufficient number of books allowing us to construct reasonably sized datasets.

We use the download counts in Gutenberg-catalog

[2] `http://www.gutenberg.org/`

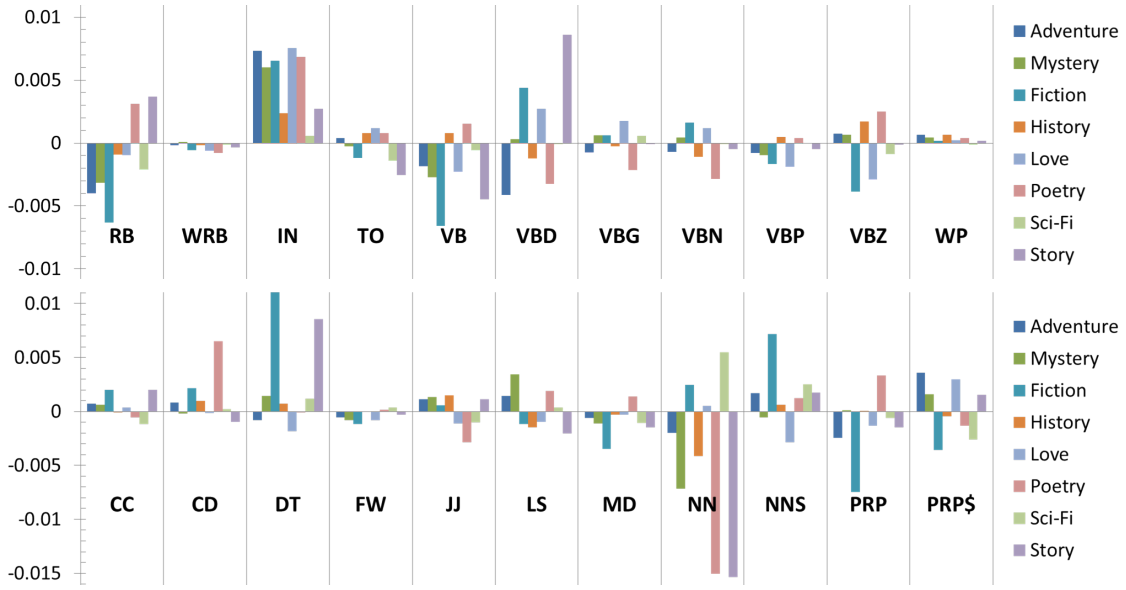

Figure 1: Differences in POS tag distribution between more successful and less successful books across different genres. Negative (positive) value indicates higher percentage in less (more) successful class.

as a surrogate to measure the degree of success of novels. For each genre, we determine a lower bound (τ_+) and an upper bound (τ_-) of download counts as shown in Table 1 to categorize the available books as more successful and less successful respectively. These thresholds are set to obtain at least 50 books for each class, and for each genre. To balance the data, for each genre, we construct a dataset of 100 novels (50 per class).

We make sure that no single author has more than 2 books in the resulting dataset, and in the majority of the cases, only one book has been taken from each author.[3] Furthermore, we make sure that the books from the same author do not show up in both training and test data. These constraints make sure that we learn general linguistic patterns of successful novels, rather than a particular writing style of a few successful authors.

3 Methodology

In what follows, we describe five different aspects of linguistic styles we measure quantitatively. The first three correspond to the features that have been frequently utilized in previous studies in related tasks, e.g., genre detection (e.g., Kessler et al. (1997)) and authorship attribution (e.g., Stamatatos (2009)), while the last two are newly explored in this work.

I. Lexical Choices: unigrams and bigrams.

II. Distribution of Word Categories: Many previous studies have shown that the distribution of part-of-speech (POS) tags alone can reveal surprising insights on genre and authorship (e.g., Koppel and Schler (2003)), hence we examine their distributions with respect to the success of literary works.

III. Distribution of Grammar Rules: Recent studies reported that features based on CFG rules are helpful in authorship attribution (e.g., Raghavan et al. (2010), Feng et al. (2012)). We experiment with four different encodings of production rules:

- Γ: lexicalized production rules (all production rules, including those with terminals)
- Γ^G: lexicalized production rules prepended with the grandparent node.
- γ: unlexicalized production rules (all production rules except those with terminals).
- γ^G: unlexicalized production rules prepended with the grandparent node.

[3]The complete list of novels used for each genre in our dataset is available at `http://www.cs.stonybrook.edu/~ychoi/successwithstyle/`

Feature	Genre								Avg	Avg w/o History
	Adven	Myster	Fiction	Histor	Love	Poetr	Sci-fi	Short		
POS	74.0	63.9	72.0	47.0	65.9	63.0	63.0	67.0	64.5	66.9

Table 2: Classification results in accuracy (%).

IV. Distribution of Constituents: PCFG grammar rules are overly specific to draw a big picture on the distribution of large, recursive syntactic units. We hypothesize that the distribution of constituents can serve this purpose, and that it will reveal interesting and more interpretable insights into writing styles in highly successful literature. Despite its relative simplicity, we are not aware of previous work that looks at the distribution of constituents directly. In particular, we are interested in examining the distribution of phrasal and/or clausal tags as follows: (i) Phrasal tag percent (PHR) - percentage distribution of phrasal tags.[4] (ii) Clausal tag percent (CLS) - percentage distribution of clausal tags.

V. Distribution of Sentiment and Connotation: Finally, we examine whether the distribution of sentiment and connotation words, and their polarity, has any correlation with respect to the success of literary works. We are not aware of any previous work that looks into this connection.

4 Prediction Performance

We use LibLinear SVM (Fan et al., 2008) with L2 tuned over training data, and all performance is based on 5-fold cross validation. We take 1000 sentences from the beginning of each book. POS features are encoded as unit normalized frequency and all other features are encoded as tf-idf.[5]

Prediction Results Table 2 shows the classification results. The best performance reaches as high as 84% in accuracy. In fact, in all genres except for history, the best performance is at least 74%, if not higher. Another notable observation is that even in the poetry genre, which is not prose, the accuracy gets as high as 74%. This level of performance is not entirely anticipated, given that (1) the test data consists of books written only by previously unseen authors, and (2) each author has widely different writing style, and (3) we do not have training data at scale, and (4) we aim to tackle the hard task of discriminating highly successful ones from less successful, but nonetheless successful ones, as all of them were, after all, good enough to be published.[6]

Prediction with Varying Thresholds of Download Counts Before we proceed to comprehensive analysis of writing style that are prominent in more successful literature (§5), in Table 3, we present how the prediction accuracy varies as we adjust the definition of more-successful and less-successful literature, by gradually increasing (decreasing) the threshold τ^- (τ^+). As we reduce the gap between τ^- and τ^+, the performance decreases, which shows that indeed there are notable statistical differences in linguistic patterns between novels with high and low download counts, and the stylistic difference monotonically increases (thereby higher prediction accuracy) as we increase the gap between two classes.

[4]The percentage of any phrasal tag is the count of occurrence of that tag over the sum of counts of all phrasal tags.

[5]POS tags are obtained using the Stanford POS tagger (Toutanova and Manning, 2000), and parse trees are based on the Stanford parser (Klein and Manning, 2003).

[6]In our pilot study, we also experimented with the binary classification task of discriminating highly successful ones from those that are not even published (unpublished online novels), and it was a much easier task as expected.

τ^-	τ^+	ACCURACY
17	100	84.0
25	90	78.4
35	80	77.6
45	70	76.4
55	60	73.5

Table 3: Accuracy (%) with varying thresholds of download counts for ADVENTURE with unigram features.

This is particularly interesting as the size of training data set is actually monotonically decreasing (making it harder to achieve high accuracy) while we increase the separation between τ^- and τ^+.

5 Analysis of Successful Writing Styles

5.1 Insights Based on Lexical Choices

It is apparent from Table 2 that unigram features yield curiously high performance in many genres. We therefore examine discriminative unigrams for ADVENTURE, shown in Table 4. Interestingly, less successful books rely on verbs that are explicitly descriptive of actions and emotions (e.g., "wanted", "took", "promised", "cried", "cheered", etc.), while more successful books favor verbs that describe thought-processing (e.g., "recognized", "remembered"), and verbs that serve the purpose of quotes and reports (e.g,. "say"). Also, more successful books use discourse connectives and prepositions more frequently, while less successful books rely more on topical words that could be almost cliché, e.g., "love", typical locations, and involve more extreme (e.g., "breathless") and negative words (e.g., "risk").

5.2 Distribution of Sentiment & Connotation

We also determine the distribution of sentiment and connotation words separately for each class (Table 5) to check if there exists a connection with respect to successful writing styles.[7] We first compare distribution of sentiment and connotation for the entire words. As can be seen in Table 5 – **Top**, there are not notable differences. However, when we compare distribution only with respect to discriminative unigrams only (i.e., features with non-zero weights), as shown in Table 5 – **Bottom**, we find substantial differences in all genres. In particular, discriminative unigrams that characterize less successful novels involve significantly more sentiment-laden words.

[7]We use MPQA subjectivity lexicon (Wilson et al., 2005) and connotation lexicon (Feng et al., 2013) for determining sentiment and connotation of words respectively.

Less Successful	
CATEGORY	UNIGRAMS
Negative	never, risk, worse, slaves, hard, murdered, bruised, heavy, prison,
Body Parts	face, arm, body, skins
Location	room, beach, bay, hills, avenue, boat, door
Emotional / Action Verbs	want, went, took, promise, cry, shout, jump, glare, urge
Extreme Words	never, very, breathless, sacred slightest, absolutely, perfectly
Love Related	desires, affairs
More Successful

Negation	not
Report / Quote	said, words, says
Self Reference	I, me , my
Connectives	and, which, though, that, as, after, but, where, what, whom, since, whenever
Prepositions	up, into, out, after, in, within
Thinking Verbs	recognized, remembered

Table 4: Discriminative unigrams for ADVENTURE.

5.3 Distribution of Word Categories

Summarized analysis of POS distribution across all genres is reported in Table 6. It can be seen that prepositions, nouns, pronouns, determiners and adjectives are predictive of highly successful books whereas less successful books are characterized by higher percentage of verbs, adverbs, and foreign words. Per genre distributions of POS tags are visualized in Figure 1. Interestingly, some POS tags show almost universal patterns (e.g., prepositions (IN), NNP, WP, VB), while others are more genre-specific.

In Relation to Journalism Style The work of Douglas and Broussard (2000) reveals that informative writing (journalism) involves increased use of nouns, prepositions, determiners and coordinating conjunctions whereas imaginative writing (novels) involves more use of verbs and adverbs, as has been also confirmed by Rayson et al. (2001). Comparing their findings with Table 6, we find that highly

	Adven		Myster		Fiction		Histor		Love		Poetr		Sci-fi		Short

Table 6: Top discriminative POS tags.

successful books tend to bear closer resemblance to informative articles.

5.4 Distribution of Constituents

It can be seen in Table 2 that deep syntactic features expressed in terms of different encodings of production rules consistently yield good performance across almost all genres. Production rules are overly specific to gain more generalized, interpretable, high-level insights however (Feng et al., 2012). Therefore, similarly as word categories (POS), we consider the categories of nonterminal nodes of the parse trees, in particular, phrasal and clausal tags, as they represent the gist of constituent structure that goes beyond shallow syntactic information represented by POS.

Table 8 shows how the distribution of phrasal and clausal tags differ for successful books when computed over all genres. Positive (negative) DIFF values indicate that the corresponding tags are favored in more successful (less successful) books when counted across all genres. We also report the number of genres (#Genres) in which the individual difference is positive / negative.

In terms of phrasal tags, we find that more successful books are composed of higher percentage of PP, NP and wh-noun phrases (WHNP), whereas less successful books are composed of higher percentage of VP, adverb phrases (ADVP), interjections (INTJ) and fragments (FRAG). Notice that this observation is inline with our earlier findings with respect to the distribution of POS.

In regard to clausal tags, more successful books involve more clausal tags that are necessary for complex sentence structure and inverted sentence structure (SBAR, SBARQ and SQ) whereas less successful books rely more on simple sentence structure (S). Figure 2 shows the visualization of the distribution of these phrasal and clausal tags.

It is also worth to mention that phrasal and clausal

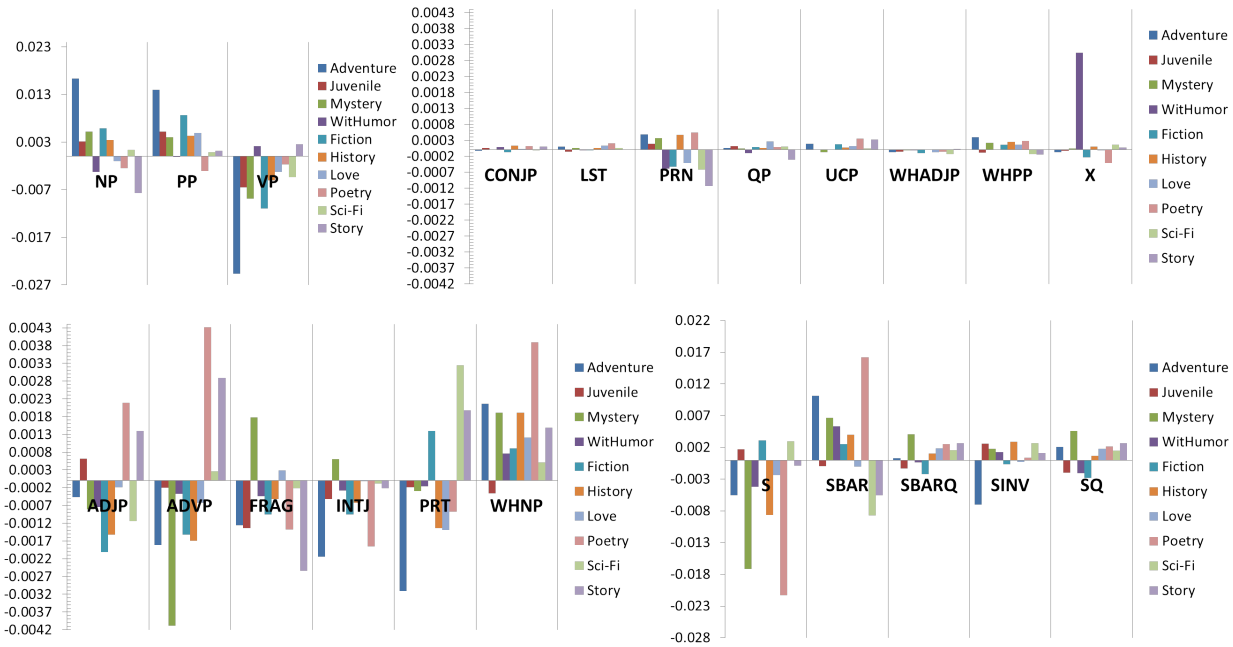

Figure 2: Difference between phrasal and clausal tag percentage distributions of more successful and less successful books across different genres. Specifically, we plot D^-–D^+, where D^+ is the phrasal tag distribution (in %) of more successful books and D^- is the phrasal tag distribution (in %) of less successful books.

READABILITY INDICES	More Succ.	Less Succ.
FOG index	9.88	**9.80**
Flesch index	87.48	**87.64**

Table 7: Readability: Lower FOG and higher Flesch indicate higher readability (numbers in Boldface).

tags alone can yield classification performance that are generally better than that of POS tags, in spite of the very small feature set (26 tags in total). In fact, constituent tags deliver the best performance in case of historical fiction genre (Table 2).

Connection to Readability Pitler and Nenkova (2008) provide comprehensive insights into assessment of readability. In their work, among the most discriminating features characterizing text with better readability is increased use of verb phrases (VP). Interestingly, contrary to the conventional wisdom – that readability is of desirable quality of good writings – our findings in Table 2 suggest that the increased use of VP correlates strongly with the writing style of the opposite spectrum of highly successful novels.

As a secondary way of probing the connection between readability and the writing style of successful literature, we also compute two different readability measures that have been used widely in prior literature (e.g., Sierra et al. (1992), Blumenstock (2008), Ali et al. (2010)): (i) Flesch reading ease score (Flesch, 1948), (ii) Gunning FOG index (Gunning, 1968). The overall weighted average readability scores are reported in Table 7. Again, we find that less successful novels have higher readability compared to more successful ones.

The work of Sawyer et al. (2008) provides yet another interesting contrasting point, where the authors found that award winning academic papers in marketing journals correlate strongly with increased readability, characterized by higher percentage of simple sentences. We conjecture that this opposite trend is likely to be due to difference between fiction and nonfiction, leaving further investigation as future research.

In sum, our analysis reveals an intriguing and unexpected observation on the connection between *readability and the literary success — that they correlate into the opposite directions*. Surely our findings only demonstrate correlation, not to be con-

Table 9: Prediction on books beyond Gutenberg. Shaded entries indicate incorrect predictions.

fused as causation, between readability and literary success. We conjecture that the conceptual complexity of highly successful literary work might require syntactic complexity that goes against readability.

6 Literature beyond Project Gutenberg

One might wonder how the prediction algorithms trained on the dataset based on Project Gutenberg might perform on books not included at Gutenberg. This section attempts to address such a question. Due to the limited availability of electronically available books that are free of charge however, we could not procure more than a handful of books.[8]

6.1 Highly Successful Books

First, we apply the classifiers trained on the Project Gutenberg dataset (all genres merged) on a few extremely successful novels (Pulitzer prize, National Award recipients, etc). Table 9 shows the results of two classification options: (1) KL-divergence based, and (2) unigram-feature based.

Although KL-divergence based prediction was not part of the classifiers that we explored in the previous sections, we include it here mainly to provide better insights as to which well-known books share closer structural similarity to either more or less successful writing style. As a probability model, we use the distributions of phrasal tags, as those can give us insights on deep syntactic structure while suppressing potential noises due to topical variances. Table 9 shows symmetrised KL-divergence between each of the previously unseen novels and the collection of books from Gutenberg corresponding to more successful (less successful) labels. For prediction, the label with smaller KL is chosen.

Based only on the distribution of 26 phrasal tags, the KL divergence classifier is able to make correct

[8]We report our prediction results on *all* books beyond Project Gutenberg of which we managed to get electronic copies, i.e., the results in Table 9 are not cherry-picked.

predictions on 7 out of 10 books, a surprisingly high performance based on mere 26 features. Of course, considering only the distribution of phrasal tags is significantly less informed than considering numerous other features that have shown substantially better performance, e.g., unigrams and CFG rewrite rules. Therefore, we also present the SVM classifier trained on unigram features. It turns out unigram features are powerful enough to make correct predictions for all ten books in Table 9.

Hemingway and Minimalism It is good to think about where and why KL-divergence-based approach fails. In fact, when we included Hemingway's *The Old Man and the Sea* into the test set, we were expecting some level of confusions when relying only on high-level syntactic structure, as Hemingway's signature style is minimalism, with 70% of his sentences corresponding to simple sentences. Not surprisingly, more adequately informed classifiers, e.g., SVM with unigram features, are still able to recognize Hemingway's writings as those of highly successful ones.

6.2 Less Successful Books

In order to obtain less successful books, we consider the *Amazon seller's rank* included in the product details of a book. The less successful books considered in Table 9 had an Amazon seller's rank beyond $200k$ (higher rank indicating less commercial success) except Dan Brown's *The lost symbol*, which we included mainly because of negative critiques it had attracted from media despite its commercial success. As shown in Table 9, all three classifiers make (arguably) correct predictions on Dan Brown's book.[9] This result also supports our earlier assumption on the nature of novels available at Project Gutenberg — that they would be more representative of literary success than general popularity (with or without literary quality).

7 Predicting Success of Movie Scripts

We have seen successful results in the novel domain, but can stylometry-based prediction work on very different domains, such as screenplays? Unlike novels, movie scripts are mostly in dialogues, which are likely to be more informal. Also, what to keep in mind is that much of the success of movies depends on factors beyond the quality of writing of the scripts, such as the quality of acting, the popularity of actors, budgets, artistic taste of directors and producers, editing and so forth.

[9]Most notable pattern based on phrasal tag analysis is a significantly increased use of fragments (FRAG), which associates strongly with less successful books in our dataset.

Table 10: Classification results on movie dialogue data (rating ≥ 8 vs rating ≤ 5.5).

We use the Movie Script Dataset introduced in Danescu-Niculescu-Mizil and Lee (2011). It includes the dialogue scripts of 617 movies. The average rating of all movies is 6.87. We consider movies with IMDb rating ≥ 8 as "more successful", the ones with IMDb rating ≤ 5.5 as "less successful". We combine all the dialogues of each movie and filter out the movies with less than 200 sentences. There are 11 genres ("ADVENTURE", "FANTASY", "ROMANCE", "THRILLER", "ACTION", "COMEDY", "CRIME", "DRAMA", "HORROR", "MYSTERY", "SCI-FI") with 15 movies or more per class, we take 15 movies per class and perform classification tasks with the same experiment setting as Table 2.

Table 10, we show some of the example genres with relatively successful outcome, reaching as high as 89.3% accuracy in FANTASY genre. We would like to note however that in many other genres, the prediction did not work as well as it did for the novel domain. We suspect that there are at least two reasons for this: it must be partly due to very limited data size — only 15 instances per class with the rating threshold we selected for defining the success of

movies. The second reason is due to many other external factors that can also influence the success of movies, as discussed earlier.

8 Related Work

Predicting success of novels and movies: To the best of our knowledge, our work is the first that provides quantitative insights into the unstudied connection between the writing style and the success of literary works. There have been some previous work that aims to gain insights into the secret recipe of successful books, but most were qualitative, based only on a dozen of books, focusing mainly on the high-level content of the books, such as the personalities of protagonists, antagonists, the nature of plots (e.g., Harvey (1953), Yun (2011)). In contrast, our work examines a considerably larger collection of books (800 in total) over eight different sub-genres, providing insights into lexical, syntactic, and discourse patterns that characterize the writing styles commonly shared among the successful literature. Another relevant work has been on a different domain of movies (Yun, 2011), however, the prediction is based only on external, non-textual information such as the reputation of actors and directors, and the power of distribution systems etc, without analyzing the actual content of the movie scripts.

Text quality and readability: Louis (2012) explored various features that measure the quality of text, which has some high-level connections to our work. Combining the insights from Louis (2012) with our results, we find that the characteristics of text quality explored in Louis (2012), readability of text in particular, do not correspond to the prominent writing style of highly successful literature. There have been a number of other work that focused on predicting and measuring readability (e.g., Kate et al. (2010), Pitler and Nenkova (2008), Schwarm and Ostendorf (2005), Heilman and Eskenazi (2006) and Collins-Thompson et al. (2004)) employing various linguistic features.

There is an important difference however, in regard to the nature of the selected text for analysis: most studies in readability focus on differentiating good writings from noticeably bad writings, often involving machine generated text or those written by ESL students. In contrast, our work essentially deals with differentiating good writings from even better writings. After all, all the books that we analyzed are written by expert writers who passed the scrutinizing eyes of publishers, hence it is reasonable to expect that the writing quality of even less successful books is respectful.

Predicting success among academic papers: In the domain of academic papers, which belongs to the broad genre of non-fiction, the work of Sawyer et al. (2008) investigated the stylistic characteristics of award winning papers in marketing journals, and found that the readability plays an important role. Combined with our study which focuses on fiction and creative writing, it suggests that the recipe for successful publications can be very different depending on whether it belongs to fiction or nonfiction. The work of Bergsma et al. (2012) is also somewhat relevant to ours in that their work included differentiating the writing styles of workshop papers from major conference papers, where the latter would be generally considered to be more successful.

9 Conclusion

We presented the first quantitative study that learns to predict the success of literary works based on their writing styles. Our empirical results demonstrated that statistical stylometry can be surprisingly effective in discriminating successful literature, achieving accuracy up to 84% in the novel domain and 89% in the movie domain. Furthermore, our study resulted in several insights including: lexical and syntactic elements of successful styles, the connection between successful writing style and readability, the connection between sentiment / connotation and the literary success, and last but not least, comparative insights between successful writing styles of fiction and nonfiction.

Abstract

We develop a novel generative model of conversation that jointly captures both the topical content and the speech act type associated with each utterance. Our model expresses both token emission and state transition probabilities as log-linear functions of separate components corresponding to topics and speech acts (and their interactions). We apply this model to a dataset comprising annotated patient-physician visits and show that the proposed joint approach outperforms a baseline univariate model.

1 Introduction

Communication involves at least two aspects: the words one says and the *acts* one performs in saying them. Examples of the latter include asking questions, issuing commands, and so on. These are referred to as *speech acts* under the sociolinguistic theory of Austin (1955), which was further developed by Searle (1969; 1985). Recognizing speech acts is crucial to understanding communication because a speaker's meaning is only partially captured by the words they use; much of their intent is expressed implicitly via speech acts (Searle, 1969).

On this view, conversational utterances can be assigned both a topic and a speech act. The former describes the subject matter of what was said and the latter captures the "social act" (e.g., promising) performed by saying it. For example, the utterance "Obama won the election" is topically *political* and is an example of an *information giving* speech act. "Did Obama win the election?", meanwhile, belongs to the same topic but is a *question*. Both aspects are necessary to understand conversation.

Role	Utterance	Topic	Speech act
D	Let me just write down some of these issues here so I get them straight in my mind.	*Logistics*	*Commissive*
P	Doctor you ain't got to tell me nuttin'.	*Socializing*	*Directive*
P	I'm in very good hands when I'm around you.	*Socializing*	*Give Info.*
P	If push comes to a shove, you open the window and throw me out.	*Socializing*	*Humor/Levity*
D	I wanted to ask you, too -	*Biomedical*	*Conv. Mgmt.*
D	you know you had that colonic polyp -	*Biomedical*	*Ask Q.*
D	- is it two years from now that they're going to be doing the repeat?	*Biomedical*	*Ask Q.*
P	Yeah.	*Biomedical*	*Conv. Mgmt.*
D	We'll do the repeat coloscopy in about two years.	*Biomedical*	*Give Info.*

Table 1: An excerpt from a patient-doctor interaction, annotated with topic and speech act codes. The *D* and *P* roles denote doctor and patient, respectively. *Conv. Mgmt.* abbreviates *conversation management*; *Ask Q.* abbreviates *ask question*.

Previous computational work on speech acts – which we review in Section 6 – has modeled them in isolation (Perrault and Allen, 1980; Stolcke et al., 1998; Stolcke et al., 2000; Kim et al., 2010), i.e., independent of topical content. But a richer model would account for both speech acts *and* the contextualizing topic of each utterance. To this end, we develop a novel joint, generative model of topics and speech acts.

We focus on physician-patient communication as a motivating domain. This is of interest because

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1765–1775,
Seattle, Washington, USA, 18-21 October 2013.

it is widely appreciated that effective communication is an integral part of clinical practice (Irwin and Richardson, 2006; Makoul, 2001; Teutsch, 2003). We provide an excerpt of a conversation between a patient and their doctor annotated with topics and speech acts in Table 1. Such annotations can provide substantive insights into how doctors communicate with patients (Ong et al., 1995).

A concrete example of this is the use of topic and speech act codes to assess the efficacy of an intervention meant to influence physician-patient communication regarding adherence to antiretroviral (ARV) medication (Wilson et al., 2010). To measure the effect of the intervention, investigators performed a randomized control trial in which they quantified change in communication patterns by tallying the number of *information giving* speech acts that fell under the *ARV adherence* topic. Without assigning both topics and speech acts to utterances, this analysis would not have been possible.

In this work, we develop a novel component-based generative model for bivariate, sequentially structured problems. Our approach extends the recently proposed Sparse Additive Generative (SAGE) model (Eisenstein et al., 2011) and similar recently developed additive models (Paul and Dredze, 2012; Paul et al., 2013) to the case of supervised sequential tasks to capture the joint conditional influence of topics and speech acts, both with respect to token generation and state transitions. For brevity, we refer to this generative Joint, Additive, Sequential model as *JAS*. In contrast to previous work on speech acts, JAS provides a single, coherent generative model of conversations. And because it is component-based, this model provides a flexible framework for analyzing communication patterns. We demonstrate that JAS outperforms a generative univariate baseline in topic/speech act prediction. Further, we automatically reproduce an analysis of the aforementioned randomized control trial, and in doing so show that JAS reproduces the results more faithfully than a univariate approach.

2 The Markov-Multinomial Model

We begin by considering a baseline generative approach to modeling topics and speech acts independently. This simple approach was used by Stolcke et al. (2000) to model speech acts. It accounts for only a single output at each time point $y_t \in \mathcal{Y}$, and hence here we model topics and speech acts independently.

A straight-forward (albeit naïve) alternative would be to treat the Cartesian product of topics and speech acts as a single output space on which emissions and transitions are conditioned, but this space is too large and sparse for this approach to be practicable. We note that the *fully coupled HMM* (Brand et al., 1997) suffers from a similar exponential output state problem. The related *factorial HMM* (FHMM) (Ghahramani and Jordan, 1997; Van Gael et al., 2008), meanwhile, imposes unwarranted (in our case) independence assumptions with respect to state transitions along parallel chains, does not obviously lend itself to discrete observations (typically Gaussians are assumed), and does not scale well enough (in terms of training time) to be feasible for our application.

The Markov-Multinomial (MM) comprises two components; transitions and emissions. The former is modeled by making a first-order Markov assumption, specifically:

$$P(y_t|y_0, ..., y_{t-1}) = P(y_t|y_{t-1}) = \lambda_{y_{t-1},y_t} \quad (1)$$

Emissions can be modeled via a multinomial that captures the conditional probabilities of tokens given labels. Denoting an utterance (an utterance comprises the words corresponding to a single speech act; see Section 4) at time t by u_t and its label by y_t, and making the standard naïve assumption that words are generated independently conditioned on a label, we have:

$$P(u_t|y_t) = \prod_{w \in u_t} P(w|y_t) = \prod_{w \in u_t} \tau_{y_t,w} \quad (2)$$

Both sets of parameters (the $\boldsymbol{\lambda}$'s and the $\boldsymbol{\tau}$'s) can be estimated straight-forwardly using maximum likelihood (i.e., using observed counts). We can use Viterbi decoding (Rabiner and Juang, 1986) to make predictions for new sequences, as usual. To make both topic and speech act predictions, we simply induce models for each and make predictions independently.

3 *JAS*: A Joint, Additive, Sequential Model

An obvious shortcoming of the simple MM model outlined above is that it treats topics and speech acts

as statistically independent. They are not (as confirmed at statistical significance $p < .001$ using a χ^2 test). One would prefer a more expressive model that conditions topic and speech act transitions as well as the production of utterances jointly on both the current topic and the current speech act.

More specifically, we would like a model that reflects the assumption that some latent *intent* gives rise to both the topic and the speech act associated with an utterance. This is consistent with Searle's (1969) notion of *perlocutionary* effects; one performs speech acts with the aim of getting someone to do something. Intent gives rise to the current topic and speech act, and the current intent affects the next; this induces a correlation between adjacent topics and speech acts. This conceptual model is depicted graphically in the left-half of Figure 1.

The latent intent may be, e.g., to encourage a patient to take their medication more regularly. In our application the topical content may be *ARV adherence* and the type of speech act would be selected by the provider (presumably to maximize the likelihood of patient adherence). For example, she may opt to urge imperatively ("You really need to take your medicine") or to implore with a question ("Will you please remember to take your medicine?"). Because we have no way of explicitly modeling intent (it is never observed), we instead rely on variables for which we have annotations (i.e., the topics and speech acts; see Figure 1). We next describe the model in more detail.

We refer to the topic set by $\mathcal{Y}$, the speech act set by $\mathcal{S}$ and the vocabulary as $\mathcal{W}$. We denote the (log of the) background probability of word w by θ_w, and we will denote components corresponding to deviations from θ_w due to a specific topic (speech act) by η_w^y (η_w^s). Further, we include the component $\eta_w^{y,s}$ to capture interaction effects between topics and speech acts. We assume that the conditional probability of word w belonging to an utterance u_t with corresponding topic y_t and speech act s_t is log-linear with respect to these components, i.e.:

$$P(w|y_t, s_t) = \frac{1}{Z_w} exp\{\theta_w + \eta_w^{y_t} + \eta_w^{s_t} + \eta_w^{s_t,y_t}\} \quad (3)$$

Where Z_w is a normalizing term (implicitly conditioned on y_t and s_t) defined as:

$$Z_w = \sum_{w' \in \mathcal{W}} exp\{\theta_{w'} + \eta_{w'}^{y_t} + \eta_{w'}^{s_t} + \eta_{w'}^{s_t,y_t}\} \quad (4)$$

We make the standard naïve assumption that words are generated independently, given the topic and speech act of the utterance to which they belong:

$$P(u_t|y_t, s_t) = \prod_{w \in u_t} P(w|y_t, s_t) \quad (5)$$

The per-token emission probability just described falls under the additive generative family of models recently proposed by Eisenstein et al. (2011). However, in addition to conditional token emission probabilities, here we need also to model the *transition* probabilities such that the likelihood of transitioning to topic y_t (and to speech act s_t) reflects both the previous topic *and* the previous speech act, capturing the dependencies illustrated in Figure 1. To this end, we model topic and speech act transition probabilities as log-linear functions of the preceding topic and speech act.

We denote log of the background topic frequencies by $\boldsymbol{\pi}^{\mathcal{Y}}$, and components capturing the influence of transitioning to topic y_t due to the preceding topic and speech act by σ_{y_{t-1},y_t} and σ_{s_{t-1},y_t} respectively. We also include a component $\sigma_{(y_{t-1},s_{t-1}),y_t}$ that corresponds to the interaction effect on topic transition probability due to the preceding topic/speech act pair. We then model the topic transition probability (given the preceding states) as:

$$P(y_t|y_{t-1}, s_{t-1}) = \frac{1}{Z_y} exp\{\pi_{y_t}^{\mathcal{Y}} + \sigma_{y_{t-1},y_t} + \sigma_{s_{t-1},y_t} + \sigma_{(y_{t-1},s_{t-1}),y_t}\} \quad (6)$$

Where Z_y is a normalizing term for the topic transitions (implicitly conditioned on s_{t-1}, y_{t-1}):

$$Z_y = \sum_{y' \in \mathcal{Y}} exp\{\pi_{y'}^{\mathcal{Y}} + \sigma_{y_{t-1},y'} + \sigma_{s_{t-1},y'} + \sigma_{(y_{t-1},s_{t-1}),y'}\} \quad (7)$$

Similarly, denoting by $\boldsymbol{\pi}^{\mathcal{S}}$ log-transformed speech act background frequencies, and including analogous components as above that correspond to the influence of the preceding topic, speech act and their interaction on transitioning into speech act s_t, we

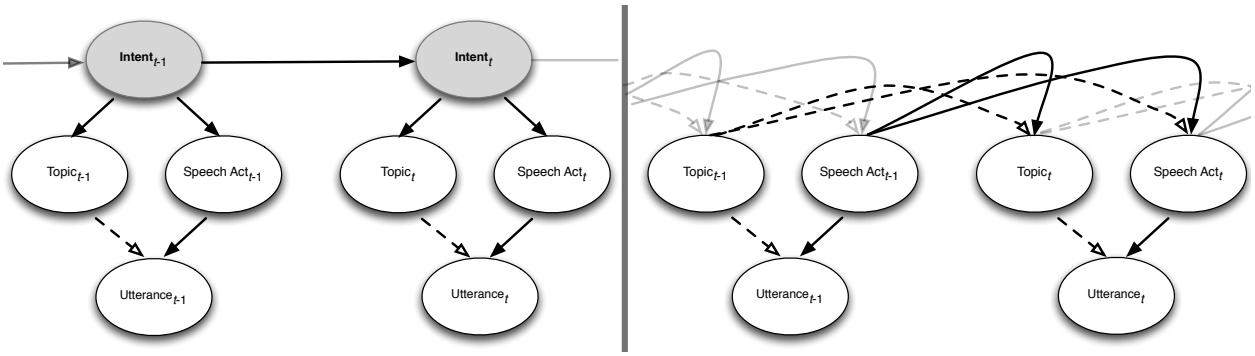

Figure 1: The generative story of utterances, depicted graphically. On the left we show our motivating conceptualization: a latent *intent* gives rise to both the topic and speech acts; these, in turn, jointly induce a distribution over words and transitions. On the right we show our operationalization of this concept. For clarity, we have denoted arrows capturing influence due to topics with dotted lines.

have:

$$P(s_t|s_{t-1}, y_{t-1}) = \frac{1}{Z_s} exp\{\pi^{\mathcal{S}}_{s_t} + \sigma_{s_{t-1},s_t} + \sigma_{y_{t-1},s_t} + \sigma_{(y_{t-1},s_{t-1}),s_t}\} \quad (8)$$

Where Z_s is a normalizing constant for speech acts analogous to Equation 7. Putting things together:

$$P(y_t, s_t|s_{t-1}, y_{t-1}, u_t) = P(u_t|y_t, s_t) \cdot P(y_t|y_{t-1}, s_{t-1}) \cdot P(s_t|s_{t-1}, y_{t-1}) \quad (9)$$

As implied by Figure 1, this model assumes that the topic and speech act at time t are conditionally independent given the preceding topic and speech act (y_{t-1} and s_{t-1}). This is intuitively agreeable because time intervenes as a blocking factor; conditioning the *current* topic on the *current* speech act (or vice versa) would contradict the fact that these occur simultaneously. Instead, the correlation is induced by the preceding topic/speech act pair. (That said, this is still a simplifying assumption, as one may instead choose to model speech act selection as conditional on topic (Traum and Larsson, 2003).)

Predictions can again be made via Viterbi decoding (Rabiner and Juang, 1986) over a matrix of *pairs* of joint topic/speech act states. The strategy of modeling (additive) components allows JAS to avoid problems due to sparsity in this large output space.

Model parameters can be estimated using standard optimization techniques. We fix the 'background' frequencies $\boldsymbol{\theta}$, $\boldsymbol{\pi}^{\mathcal{Y}}$, $\boldsymbol{\pi}^{\mathcal{S}}$ to the log of the corresponding observed proportions of words, topics and speech acts, respectively. For the remaining parameters, one can use descent-based optimization methods. The partial derivative for the topic-to-topic transition component $\sigma_{y,y'}$ with respect to the likelihood, for example, is:

$$\frac{\partial}{\partial \sigma_{y,y'}} = \sum_{s \in \mathcal{S}} C_{(y,s),y'} - P(y'|y, s) C_{(y,s),*} \quad (10)$$

Where $C_{(y,s),y'}$ denotes the observed count of transitions from topic/speech act pair (y, s) to y', and $C_{(y,s),*}$ denotes the total number of observed transitions out of this pair. The term $P(y'|y, s)$ is with respect to the current parameter estimates and is defined in Equation 6. The partial derivatives for the other component parameters (both transition and emission) are analogous. We use a Newton optimization method similar to the approach outlined by Eisenstein et al. (2011).[1] We assess convergence by calculating predictive performance on a held-out portion (5%) of the training dataset at each step, halting the descent when this declines.

4 Dataset

We use a corpus of patient-provider visits annotated with *Generalized Medical Interaction Anaylsis System* (GMIAS) codes. The GMIAS has been used to: characterize interaction processes in physician-patient communication about ARV adherence in the

[1] With the exception that we do not explicitly model the distribution over component variances.

Table 2: Topic/speech act pairs and their counts.

context of an intervention trial (Wilson et al., 2010); analyze communication about sexual risk behavior (Laws et al., 2011a); elucidate the association of visit length with constructs of patient-centeredness (Laws et al., 2011b); and to describe provider-patient communication regarding ARV adherence compared with communication about other issues (Laws et al., 2012). GMIAS annotation is described at length elsewhere,[2] but we summarize it here for completeness.

GMIAS segments conversation into *utterances*. An utterance is here defined as a single completed speech act. Previous coding systems have simply defined an utterance as conveying a single thought (Roter and Larson, 2002) or any independent or unrestrictive dependent clause of a sentence (Ford and Ford, 1995). Stolcke et al. (2000) followed Meteer et al. (1995) in using "sentence-level units". These definitions provide helpful guidance to coders, but many speech acts are poorly formed grammatically, and cannot be described as a "clause". Further, some speech acts cannot be said to convey a "thought" (or sentence) at all, but rather are pre-syntactical (e.g., interjections and non-lexical utterances like laughter). In any case, most natural segmentations of conversations probably largely agree with intuition, and are not likely to differ substantially.

The model we develop in this work assumes that transcripts have been manually segmented. While this comes at some cost, segmenting is still much cheaper than *annotating* transcripts. Manually annotating a single visit with GMIAS codes takes 2-4 hours and must be performed by someone with substantive domain expertise. By contrast, segmenting transcripts into utterances takes at most 1/4th of the time as annotation and can be done by a less highly-skilled individual. That said, in future work we hope to explore incorporating automatic segmentation methods (Galley et al., 2003; Eisenstein and Barzilay, 2008) into our approach.

Each utterance is assigned a single topic code and a single speech act code. Inter-rater agreement has been observed to be relatively high for this task: Kappa between three trained annotators and a reference annotation ranged from 0.89 to 1.0 for topics and 0.81 to 0.95 for speech acts. We next de-

[2] https://sites.google.com/a/brown.edu/m-barton-laws/home/gmias

scribe the topics and speech acts we consider in more detail; Table 2 enumerates all pairs of these and their respective counts in the corpus. We note that GMIAS defines a hierarchy of both topic and speech act codes, but here we only attempt to capture the highest level codes in these hierarchies.

Topics comprise six major categories: *ARV adherence*, *biomedical*, *logistics*, *missing/other*, *psycho-social* and *socializing*. *Antiretroviral (ARV) adherence* applies to utterances that address ARV medication usage. *Biomedical* utterances subsume clinical observations and diagnostic conclusions. Utterances that concern the business of conducting a physical examination fall under *logistics*. The *missing/other* topic covers a few cases, including utterances that are effectively outside of the GMIAS universe and inaudible utterances; however we note that *missing/other* is a topic explicitly assigned by human annotators. The *psycho-social* topic includes such issues as substance abuse, recovery, employment and relationships. Finally, *socializing* refers to casual conversation unrelated to the business of the medical visit, and to social rituals such as greetings.

There are 10 speech acts:[3] *ask question*, *commissive*, *continuation*, *conversation management*, *directive*, *empathy*, *give information*, *humor/levity*, *missing/other*, and *social-ritual*. *Ask question* is self-explanatory. Utterances in which the speaker makes a promise or resolves to take action are *commissives*. A *continuation* refers to the completion of a previously interrupted speech act (these are rare). *Conversation management* describes utterances that facilitate turn-taking or guide discussion ('talk about talk'). *Directives* refer to statements that look to control or influence the behavior of the interlocutor. Utterances that express responses to emotions, concerns or feelings are coded under *empathy*. Communication of (purported) facts falls under *give information*. *Humor/levity* captures jokes and jovial conversation. *Missing/other* is the same as for topics. Finally, *social-ritual* utterances represent formalities (e.g., "thank you").

The corpus we use includes 360 GMIAS annotated patient-provider interactions (median length: 605 utterances). This data originated as part of a study designed to assess the role of the patient-provider relationship in explaining racial/ethnic disparities in HIV care. Study subjects were HIV care providers and their patients at four US care sites. The group responsible for the data are awaiting a decision from the institutional review board (IRB) regarding whether we can make this data publicly available in some form.

5 Experimental Results

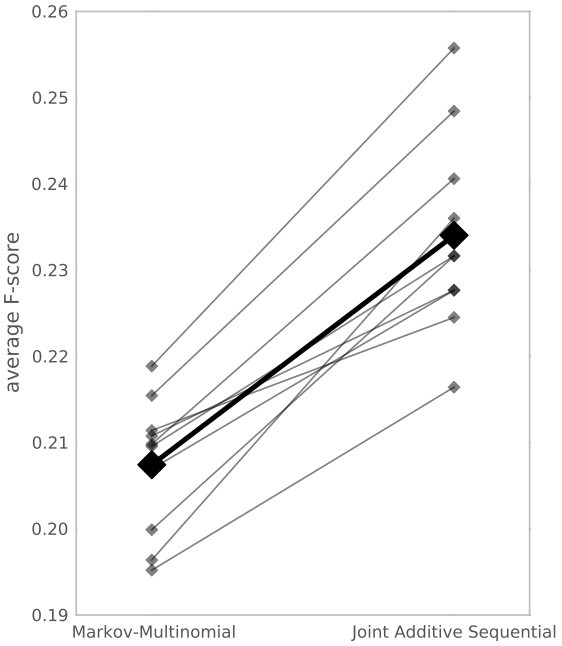

Figure 2: Mean F-scores across all topic/speech act pairs for the Markov-Multinomial (MM; left) and the proposed Joint Additive Sequential (JAS; right) models. The thick black line shows the mean difference over ten different folds; the thin grey lines describe per-fold differences. The proposed JAS model outperforms the baseline MM model for all folds

Our evaluation includes two parts.[4] First, we perform standard cross-validation over the aforementioned 360 annotated interactions, evaluating F-measure for each topic/speech act pair. Second, we look to automatically reproduce an analysis of

[3]These are high-level speech acts; technically each constitutes a *category* of speech act types.

[4]Source code at: https://github.com/bwallace/JAS; unfortunately we do not yet have permission to post the data.

a randomized control trial that assessed the efficacy of an intervention meant to alter physician-patient communication. We show that JAS outperforms the baseline approach with respect to both tasks.

We emphasize that while we are here comparing predictive performance, we are specifically interested in fully generative models of conversations due to the longer-term applications we have in mind. We would like, e.g., to use this model to assess the variation in communicative approaches across different doctors, and generative models are more naturally amenable to answering such exploratory questions. Indeed, perhaps the main strength of the additive component based sequential model we have proposed here is that it will allow us to easily incorporate physician-specific parameters that capture deviations in provider speech act and/or topic transition patterns. Further, we may soon have access to many unannotated transcripts, and we would like to learn from these; generative approaches allow straight-forward exploitation of unlabeled data. For these reasons, we did not experiment with discriminative models, e.g., Dynamic Conditional Random Fields (DCRFs) (Sutton et al., 2007) for this work.

5.1 Cross-fold Validation

Our aim is to measure model performance in terms of correctly identifying both the topic and speech act corresponding to each utterance. We quantify this via the F-score calculated for each topic/speech act pair that is observed at least once. One can see in Table 2 that many such pairs have low prevalence; this can result in undefined F-scores (e.g., when no utterances are assigned to a given pair). In this case, it is reasonable to treat these as zero values, as is commonly done (Forman and Scholz, 2010). This penalizes models when they completely fail to identify an entire class of utterances.

We first report macro-averages, that is, averages of the individual topic/speech act pair F-scores. Figure 2 displays the macro-averaged F-score for each of the 10 folds (grey lines connect folds) and the average of these (thick black line). The JAS model achieves an average macro-averaged F-score of .234 versus the .207 achieved by baseline Markov-Multinomial (MM) model; JAS outperforms MM on every fold.

For a more granular picture, Figure 3 displays average F-score differences with respect to every individual topic and speech act pair for which this difference was non-zero. This is the (signed) difference of the F-score achieved using JAS minus that achieved using the MM model; black lines thus correspond to pairs for which JAS outperformed MM, and red lines to pairs for which MM outperformed JAS. The latter achieves an improvement of $>= .05$ for 10 pairs, and results in an F-score of $> .02$ below that attained by MM only once.

The relatively low F-scores for the metrics quantifying performance with respect to the cross of topic and speech act codes belie relatively good *overall* (marginal) predictive performance. That is, we achieve much better performance with respect to metrics that measure topic and speech act predictions independently of one another. This is due to the very large output space under consideration (see Table 2). Specifically, averaged over ten runs, the MM model achieves a marginal mean topic F-score of .667 and marginal mean speech act F-score of .516. JAS begets a marginal mean topic F-score of .661 and a marginal mean speech act F-score of .544; hence the JAS model incurs an F-score loss of .006 (a 0.9% decrease) with respect to marginal topic code prediction, but improves the marginal speech act F-score by .028 (a 5.4% increase).

5.2 (Re-)Analysis of Randomized Control Trial

We also evaluated performance by tallying model predictions over 116 held-out cases collected from a randomized, cross-over study of an intervention aimed at improving physicians knowledge of patients anti-retroviral (ARV) adherence (Wilson et al., 2010). The intervention was a report given to the physician before a routine office visit that contained information regarding the patients ARV usage and their beliefs about ARV therapy. To explore the efficacy of this intervention, 58 paired (116 total) audio recorded visits were annotated with GMIAS; 58 correspond to visits before which the provider was not provided with the report (control cases), while the other 58 correspond to visits before which they were (intervention cases).

Wilson et al. (2010) demonstrated that the intervention indeed increased adherence-related dialogue, and specifically the number of *information giving* speech acts performed by the physician un-

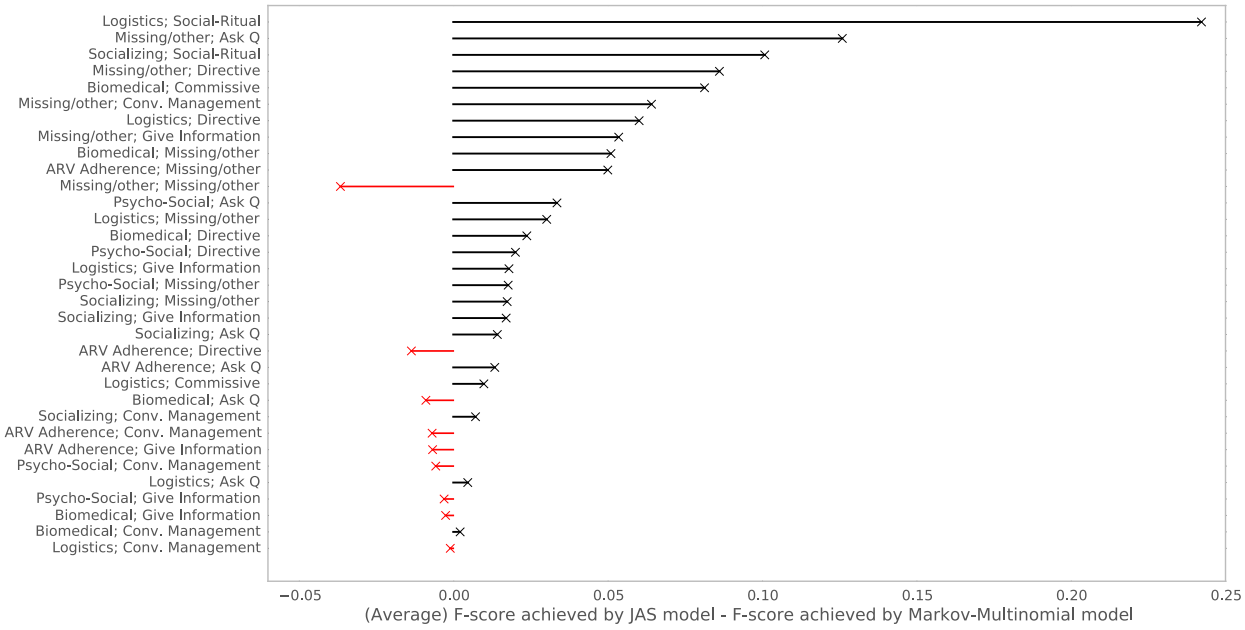

Figure 3: Average difference in F-scores corresponding to specific topic/speech act pairs, sorted by magnitude. Black lines (extending rightward) represent pairs for which JAS outperforms the baseline model; red lines (leftward) are pairs for which baseline performs better.

True		MM		JAS	
control	intervention	control	intervention	control	intervention
10 (4, 28)	23 (11, 39)	13 (5, 33)	27 (16, 44)	12 (5, 28)	23 (14, 40)

Table 3: Utterance counts {Median (25th, 75th percentile)} for the *ARV/information giving* topic and speech act pair. We show the 'gold standard' (True) tallies, which were assigned by humans, and the counts taken using the two models, MM and JAS. The JAS model predictions are closer to the true numbers.

derneath this topic. We attempted to reproduce this finding using automated rather manual annotations. To this end, we trained MM and JAS models over the aforementioned 360 annotated visits and then used this model to generate topic and speech act code predictions for the utterances comprising the 116 held-out visits used for the analysis (these were *not* part of the training set). We then assessed the direction and magnitude of the change in the number of *ARV adherence/information giving* utterances in the paired control versus intervention cases. We compared the results for this analysis calculated using the true (manually assigned) codes to the results calculated using the predicted codes.

Following the original analysis (Wilson et al., 2010), we report the median number of *ARV/information giving* utterances and corresponding 25th and 75th percentiles over the 58 control and intervention visits, as counted using the true (human) annotations and using the codes predicted by the MM and JAS models. These are reported in Table 3. The JAS model predictions better match the true labels in all except one case (the lower 25th for the controls, for which it predicts the same number as the MM model).

6 Related work

There is a relatively long history of research into modeling conversational speech acts in computational linguistics. Perrault and Allen (1980) conducted pioneering work on computationally formalizing speech acts, though their work pre-dates statistical NLP and is therefore not directly relevant to the present work.

Stolcke et al. (2000; 1998) proposed a probabilistic approach to modeling conversational speech acts based on the Hidden Markov Model (HMM) (Rabiner and Juang, 1986). They were interested in modeling an unrestricted set of conversations, and did not impose a hierarchy on the speech acts; they

therefore enumerated many more speech acts (42) than we do in the present work (recall that we use 10 'high-level' speech acts).[5] Their model has served as the baseline approach in the present work. Stolcke et al. also considered jointly performing speech *recognition* and speech act classification.

Others have investigated visual structures of patient-provider interactions to qualitatively assess communication in care. Specifically, (Cretchley et al., 2010) leveraged concept maps to explore conversations between people with schizophrenia and their carers. Briefly, this approach allowed them to (qualitatively) identify two distinct conversational strategies used by care-takers and their patients. Angus et al. (Angus et al., 2012) presented a similar approach in which they used text visualization software to explore patterns of (inferred) topics in consultations.

Another thread of research has investigated classifying speech acts in emails into one of a small set of "email speech acts", e.g., *request*, *propose*, *commit* (Cohen et al., 2004; Goldstein et al., 2006). Cohen et al. (2004) demonstrated that good performance can be achieved for this task via existing text classification technologies. Elsewhere, researchers have explored automatically inferring "speech acts" in various other online social mediums, including message board posts (Qadir and Riloff, 2011), Wikipedia talk pages (Ferschke et al., 2012) and Twitter (Zhang et al., 2012).

A separate line of inquiry concerns classifying dialogue acts in chat. Researchers have attempted dialogue act classification both for 1-on-1 (Kim et al., 2010) and multi-party (Kim et al., 2012; Clark and Popescu-Belis, 2004) online chats. Ang et al. (2005) considered the task of jointly segmenting and classifying utterances comprising multiparty meetings, while Hsueh and Moore (2006) proposed analogous methods for *topic* segmentation and labeling (other works on topic segmentation include (Galley et al., 2003) and (Eisenstein and Barzilay, 2008)). Incorporating such segmentation methods into the proposed model (rather than relying on inputs to be manually segmented beforehand) would be a natural extension of this work.

Additive component models of text have recently gained traction (Eisenstein et al., 2011; Paul, 2012; Paul and Dredze, 2012; Paul et al., 2013). To our knowledge, this is the first extension of supervised additive component models to a sequential task.[6]

7 Conclusions and Future Directions

We have proposed a novel Joint, Additive, Sequential (JAS) model of conversational topics and speech acts. In contrast to previous approaches to modeling conversational exchanges, this model factors both the current topic and the current speech act into token emission *and* state transition probabilities. We demonstrated that this model consistently outperforms a univariate generative baseline that treats speech acts and topics independently. Furthermore, we showed JAS can automatically re-produce the analysis of a randomized control trial designed to assess the efficacy of an intervention to alter physician communication habits with high-fidelity.

The generative component-based framework we have introduced in this work provides a means of exploring factors in patient-physician communication. One limitation of the model we have presented is that it makes several simplifying assumptions around dialogue. For example, we have ignored non-linearities and 'back-channels' in conversation, and we have ignored differences across physicians with respect to communication styles.

Going forward, we hope to address these limitations. We also plan on extending this model to investigate qualitative questions surrounding patient-physician communication quantitatively. For example, we are interested in investigating how communication varies across hospitals and physicians. To explore this, we can add additional components to the transition probability terms corresponding to different hospitals and doctors. Ultimately, we would like to correlate patterns in physician communication (as gleaned from the model) with objective, measured health outcomes (e.g., patient satisfaction and adherence to ARVs).

[5] We note that only 8 of the 42 speech acts appeared with greater than 1% frequency in Stolcke et al.'s corpus.

[6] Though Paul (2012) recently proposed 'mixed-membership' Markov models for *unsupervised* conversation modeling.

Harvesting Parallel News Streams to Generate Paraphrases of Event Relations

Congle Zhang, Daniel S. Weld
Computer Science & Engineering
University of Washington
Seattle, WA 98195, USA
{clzhang,weld}@cs.washington.edu

Abstract

The distributional hypothesis, which states that words that occur in similar contexts tend to have similar meanings, has inspired several Web mining algorithms for paraphrasing semantically equivalent phrases. Unfortunately, these methods have several drawbacks, such as confusing synonyms with antonyms and causes with effects. This paper introduces three Temporal Correspondence Heuristics, that characterize regularities in parallel news streams, and shows how they may be used to generate high precision paraphrases for event relations. We encode the heuristics in a probabilistic graphical model to create the NEWSSPIKE algorithm for mining news streams. We present experiments demonstrating that NEWSSPIKE significantly outperforms several competitive baselines. In order to spur further research, we provide a large annotated corpus of timestamped news articles as well as the paraphrases produced by NEWSSPIKE.

1 Introduction

Paraphrasing, the task of finding sets of semantically equivalent surface forms, is crucial to many natural language processing applications, including relation extraction (Bhagat and Ravichandran, 2008), question answering (Fader et al., 2013), summarization (Barzilay et al., 1999) and machine translation (Callison-Burch et al., 2006). While the benefits of paraphrasing have been demonstrated, creating a large-scale corpus of high precision paraphrases remains a challenge — especially for event relations.

Many researchers have considered generating paraphrases by mining the Web guided by the *distributional hypothesis*, which states that words occurring in similar contexts tend to have similar meanings (Harris, 1954). For example, DIRT (Lin and Pantel, 2001) and Resolver (Yates and Etzioni, 2009) identify synonymous relation phrases by the distributions of their arguments. However, the distributional hypothesis has several drawbacks. First, it can confuse antonyms with synonyms because antonymous phrases appear in similar contexts as often as synonymous phrases. For the same reasons, it also often confuses causes with effects. For example, DIRT reports that the closest phrase to *fall* is *rise*, and the closest phrase to *shoot* is *kill*.[1] Second, the distributional hypothesis relies on statistics over large corpora to produce accurate similarity statistics. It remains unclear how to accurately paraphrase less frequent relations with the distributional hypothesis.

Another common approach employs the use of parallel corpora. News articles are an interesting target, because there often exist articles from different sources describing the same daily events. This peculiar property allows the use of the temporal assumption, which assumes that phrases in articles published at the same time tend to have similar meanings. For example, the approaches by Dolan *et al.* (2004) and Barzilay *et al.* (2003) identify pairs of sentential paraphrases in similar articles that have appeared in the same period of time. While these approaches use temporal information as a coarse filter in the data generation stage, they still largely rely on text metrics in the prediction stage. This not only reduces precision, but also limits the discovery of paraphrases with dissimilar sur-

Seattle, Washington, USA, 18-21 October 2013.

face strings.

The goal of our research is to develop a technique to generate paraphrases for large numbers of event relation with high precision, using only minimal human effort. The key to our approach is a joint cluster model using the temporal attributes of news streams, which allows us to identify semantic equivalence of event relation phrases with greater precision. In summary, this paper makes the following contributions:

- We formulate a set of three *temporal correspondence heuristics* that characterize regularities over parallel news streams.
- We develop a novel program, NEWSSPIKE, based on a probabilistic graphical model that jointly encodes these heuristics. We present inference and learning algorithms for our model.
- We present a series of detailed experiments demonstrating that NEWSSPIKE outperforms several competitive baselines, and show through ablation tests how each of the temporal heuristics affects performance.
- To spur further research on this topic, we provide both our generated paraphrase clusters and a corpus of 0.5M time-stamped news articles[2], collected over a period of about 50 days from hundreds of news sources.

2 System Overview

The main goal of this work is to generate high precision paraphrases for relation phrases. News streams are a promising resource, since articles from different sources tend to use semantically equivalent phrases to describe the same daily events. For example, when a recent scandal hit, headlines read: *"Armstrong steps down from Livestrong"*; *"Armstrong resigns from Livestrong"* and *"Armstrong cuts ties with Livestrong"*. From these we can conclude that the following relation phrases are semantically similar: {*step down from, resign from, cut ties with*}.

To realize this intuition, our first challenge is to represent an event. In practice, a question like *"What happened to Armstrong and Livestrong on Oct 17?"* could often lead to a unique answer. It implies that using an argument pair and a time-stamp could be an effective way to identify an event (*e.g. (Armstrong, Livestrong, Oct 17)* for the previous question). Based on this observation, this paper introduces a novel mechanism to paraphrase relations as summarized in Figure 1.

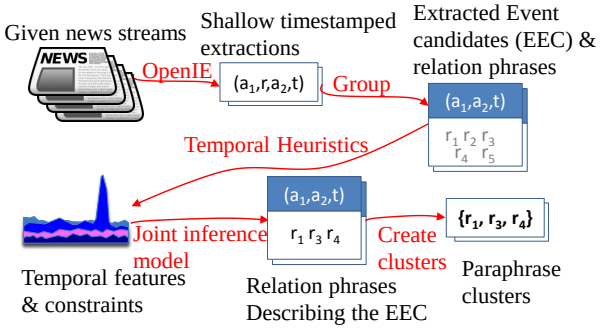

Figure 1: NEWSSPIKE first applies open information extraction to articles in the news streams, obtaining shallow extractions with time-stamps. Next, an *extracted event candidate* (EEC) is obtained after grouping daily extractions by argument pairs. Temporal features and constraints are developed based on our temporal correspondence heuristics and encoded into a joint inference model. The model finally creates the paraphrase clusters by predicting the relation phrases that describe the EEC.

NEWSSPIKE first applies the ReVerb open information extraction (IE) system (Fader et al., 2011) on the news streams to obtain a set of (a_1, r, a_2, t) tuples, where the a_i are the arguments, r is a relation phrase, and t is the time-stamp of the corresponding news article. When (a_1, a_2, t) suggests a real word event, the relation r of (a_1, r, a_2, t) is likely to describe that event (*e.g. (Armstrong, resign from, Livestrong, Oct 17*). We call every (a_1, a_2, t) an extracted event candidate (EEC), and every relation describing the event an *event-mention*.

For each EEC (a_1, a_2, t), suppose there are m extraction tuples $(a_1, r_1, a_2, t) \ldots (a_1, r_m, a_2, t)$ sharing the values of a_1, a_2, and t. We refer to this set of extraction tuples as the *EEC-set*, and denote it $(a_1, a_2, t, \{r_1 \ldots r_m\})$. All the event-mentions in the EEC-set may be semantically equivalent and are hence candidates for a good paraphrase cluster.

Thus, the paraphrasing problem becomes a prediction problem: for each relation r_i in the EEC-set, does it or does it not describe the hypothesized event? We solve this problem in two steps. The

[2] https://www.cs.washington.edu/node/9473/

next section proposes a set of temporal correspondence heuristics that partially characterize semantically equivalent EEC-sets. Then, in Section 4, we present a joint inference model designed to use these heuristics to solve the prediction problem and to generate paraphrase clusters.

3 Temporal Correspondence Heuristics

In this section, we propose a set of temporal heuristics that are useful to generate paraphrases at high precision. Our heuristics start from the basic observation mentioned previously — events can often be uniquely determined by their arguments and time. Additionally, we find that it is not just the *publication time* of the news story that matters, the *verb tenses* of the sentences are also important. For example, the two sentences *"Armstrong was the chairman of Livestrong"* and *"Armstrong steps down from Livestrong"* have past and present tense respectively, which suggests that the relation phrases are less likely to describe the same event and are thus not semantically equivalent. To capture these intuitions, we propose the *Temporal Functionality Heuristic*:

Temporal Functionality Heuristic. *News articles published at the same time that mention the same entities and use the same tense tend to describe the same events.*

Unfortunately, we find that not all the event candidates, (a_1, a_2, t), are equally good for paraphrasing. For example, today's news might include both *"Barack Obama heads to the White House"* and *"Barack Obama greets reporters at the White House"*. Although the two sentences are highly similar, sharing a_1 = "Barack Obama" and a_2 = "White House," and were published at the same time, they describe different events.

From a probabilistic point of view, we can treat each sentence as being generated by a particular hidden event which involves several actors. Clearly, some of these actors, like Obama, participate in many more events than others, and in such cases we observe sentences generated from a *mixture* of events. Since two event mentions from such a mixture are much less likely to denote the same event or relation, we wish to distinguish them from the better (semantically homogeneous) EECs like the *(Armstrong, Livestrong)* example. The question becomes "How one can distinguish good entity pairs from bad?"

Our method rests on the simple observation that an entity which participates in many different events on one day is likely to have participated in events in recent days. Therefore we can judge whether an entity pair is good for paraphrasing by looking at the *history of the frequencies* that the entity pair is mentioned in the news streams, which is the *time series* of that entity pair. The time series of the entity pair *(Barack Obama, the White House)* tends to be high over time, while the time series of the entity pair *(Armstrong, Livestrong)* is flat for a long time and suddenly spikes upwards on a single day. This observation leads to:

Temporal Burstiness Heuristic. *If an entity or an entity pair appears significantly more frequently in one day's news than in recent history, the corresponding event candidates are likely to be good to generate paraphrase.*

The temporal burstiness heuristic implies that a good EEC (a_1, a_2, t) tends to have a *spike* in the time series of its entities a_i, or argument pair (a_1, a_2), on day t.

However, even if we have selected a good EEC for paraphrasing, it is likely that it contains a few relation phrases that are related to (but not synonymous with) the other relations included in the EEC. For example, it's likely that the news story reporting *"Armstrong steps down from Livestrong."* might also mention *"Armstrong is the founder of Livestrong."* and so both "steps down from" and "is the founder of" relation phrases would be part of the same EEC-set. Inspired by the idea of one sense per discourse from (Gale et al., 1992), we propose:

One Event-Mention Per Discourse Heuristic. *A news article tends not to state the same fact more than once.*

The one event-mention per discourse heuristic is proposed in order to gain precision at the expense of recall — the heuristic directs an algorithm to choose, from a news story, the single "best" relation phrase connecting a pair of two entities. Of course, this doesn't answer the question of deciding which phrase is "best." In Section 4.3, we describe how to learn a probabilistic graphical model which does exactly this.

4 Exploiting the Temporal Heuristics

In this section we propose several models to capture the temporal correspondence heuristics, and discuss their pros and cons.

4.1 Baseline Model

An easy way to use an EEC-set is to simply predict that all r_i in the EEC-set are event-mentions, and hence are semantically equivalent. That is, given EEC-set $(a_1, a_2, t, \{r_1 \dots r_m\})$, the output cluster is $\{r_1 \dots r_m\}$.

This baseline model captures the most of the temporal functionality heuristic, except for the tense requirement. Our empirical study shows that it performs surprisingly well. This demonstrates that the quality of our input for the learning model is good: the EEC-sets are promising resources for paraphrasing.

Unfortunately, the baseline model cannot deal with the other heuristics, a problem we will remedy in the following sections.

4.2 Pairwise Model

The temporal functionality heuristic suggests we exploit the tenses of the relations in an EEC-set; while the temporal burstiness heuristic suggests we exploit the time series of its arguments. A pairwise model can be designed to capture them: we compare pairs of relations in the EEC-set, and predict whether each pair is synonymous or non-synonymous. Paraphrase clusters are then generated according to some heuristic rules (*e.g.* assuming transitivity among synonyms). The tenses of the relations and time series of the arguments are encoded as features, which we call *tense features* and *spike features* respectively. An example tense feature is whether one relation is past tense while the other relation is present tense; an example spike feature is the covariance of the time series.

The pairwise model can be considered similar to paraphrasing techniques which examine two sentences and determine whether they are semantically equivalent (Dolan and Brockett, 2005; Socher et al., 2011). Unfortunately, these techniques often based purely on text metrics and does not consider any temporal attributes. In section 5, we evaluate the effect of applying these techniques.

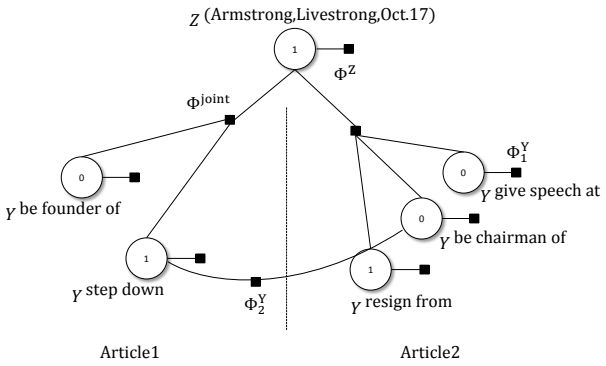

Figure 2: an example model for EEC (Armstrong, Livestrong, Oct 17). Y and Z are binary random variables. Φ^Y, Φ^Z and Φ^{joint} are factors. *be founder of* and *step down* come from article 1 while *give speech at*, *be chairman of* and *resign from* come from article 2.

4.3 Joint Cluster Model

The pairwise model has several drawbacks: *1)* it lacks the ability to handle constraints, such as the mutual exclusion constraint implied by the one-mention per discourse heuristic; *2)* ad-hoc rules, rather than formal optimizations, are required to generate clusters containing more than two relations.

A common approach to overcome the drawbacks of the pairwise model and to combine heuristics together is to introduce a joint cluster model, in which heuristics are encoded as features and constraints. Data, instead of ad-hoc rules, determines the relevance of different insights, which can be learned as parameters. The advantage of the joint model is analogous to that of cluster-based approaches for coreference resolution (CR). In particular, a joint model can better capture constraints on multiple variables and can yield higher quality results than pairwise CR models (Rahman and Ng, 2009).

We propose an undirected graphical model, NEWSSPIKE, which jointly clusters relations. Constraints are captured by factors connecting multiple random variables. We introduce random variables, the factors, the objective function, the inference algorithm, and the learning algorithm in the following sections. Figure 2 shows an example model for EEC *(Armstrong, Livestrong, Oct 17)*.

4.3.1 Random Variables

For the EEC-set $(a_1, a_2, t, \{r_1, \dots r_m\})$, we introduce one event variable and m relation variables, all boolean valued. The event variable $Z^{(a_1,a_2,t)}$ indi-

cates whether (a_1, a_2, t) is a good event for paraphrasing. It is designed in accordance with the temporal burstiness heuristic: for the EEC *(Barack Obama, the White House, Oct 17)*, Z should be assigned the value 0.

The relation variable Y^r indicates whether relation r describes the EEC (a_1, a_2, t) or not (*i.e.* r is an event-mention or not). The set of all event-mentions with $Y^r = 1$ define a paraphrase cluster, containing relation phrases. For example, the assignments $Y^{\textit{step down}} = Y^{\textit{resign from}} = 1$ produce a paraphrase cluster {*step down, resign from*}.

4.3.2 Factors and the Joint Distribution

In this section, we introduce a conditional probability model defining a joint distribution over all of the event and relation variables. The joint distribution is a function over *factors*. Our model contains *event factors*, *relation factors* and *joint factors*.

The event factor Φ^Z is a log-linear function with spike features, used to distinguish good events. A relation factor Φ^Y is also a log-linear function. It can be defined for individual relation variables (*e.g.* Φ_1^Y in Figure 2) with features such as whether a relation phrase comes from a clausal complement[3]. A relation factor can also be defined for a pair of relation variables (*e.g.* Φ_2^Y in Figure 2) with features capturing the pairwise evidence for paraphrasing, such as if two relation phrases have the same tense.

The joint factors Φ^{joint} are defined to apply constraints implied by the temporal heuristics. They play two roles in our model: *1)* to satisfy the temporal burstiness heuristic, when the value of the event variable is false, the EEC is not appropriate for paraphrasing, and so all relation variables should also be false; and *2)* to satisfy the one-mention per discourse heuristic, at most one relation variable from a single article could be true.

We define the joint distribution over these variables and factors as follows. Let $\mathbf{Y} = (Y^{r_1} \ldots Y^{r_m})$ be the vector of relation variables; let $\mathbf{x}$ be the features. The joint distribution is:

$$p(Z = z, \mathbf{Y} = \mathbf{y}|\mathbf{x}; \Theta) \stackrel{\text{def}}{=} \frac{1}{Z_x} \Phi^Z(z, \mathbf{x}) \times \prod_d \Phi^{\text{joint}}(z, \mathbf{y}_d, \mathbf{x}) \prod_{i,j} \Phi^Y(y_i, y_j, \mathbf{x})$$

where $\mathbf{y}_d$ indicates the subset of relation variables from a particular article d, and the parameter vector Θ is the weight vector of the features in Φ^Z and Φ^Y, which are log-linear functions; *i.e.*,

$$\Phi^Y(y_i, y_j, \mathbf{x}) \stackrel{\text{def}}{=} \exp\left(\sum_j \theta_j \phi_j(y_i, y_j, \mathbf{x})\right)$$

where ϕ_j is the jth feature function.

The joint factors Φ^{joint} are used to apply the temporal burstiness heuristic and the one event-mention per discourse heuristic. Φ^{joint} is zero when the EEC is not good for paraphrasing, but some $y^r = 1$; or when there is more than one r in a single article such that $y^r = 1$. Formally, it is calculated as:

$$\Phi^{\text{joint}}(z, \mathbf{y}_d, \mathbf{x}) \stackrel{\text{def}}{=} \begin{cases} 0 & \text{if } z = 0 \wedge \exists y^r = 1 \\ 0 & \text{if } \sum_{y^r \in \mathbf{y}_d} y^r > 1 \\ 1 & \text{otherwise} \end{cases}$$

4.3.3 Maximum a Posteriori Inference

The goal of inference is to find the predictions $z, \mathbf{y}$ which yield the greatest probability, *i.e.*,

$$z^*, \mathbf{y}^* = \arg\max_{z,\mathbf{y}} p(Z = z, \mathbf{Y} = \mathbf{y}|\mathbf{x}; \Theta)$$

This can be viewed as a MAP inference problem. In general, inference in a graphical model is challenging. Fortunately, the joint factors in our model are linear, and the event and relation factors are log-linear; we can cast MAP inference as an integer linear programming (ILP) problem, and then compute an approximation in polynomial time by means of linear programming using randomized rounding, as proposed in (Yannakakis, 1992).

We build one ILP problem for every EEC. The variables of the ILP are Z and $\mathbf{Y}$, which only take values of 0 or 1. The objective function is the sum of logs of the event and relation factors Φ^Z and Φ^Y. The temporal burstiness heuristic of Φ^{joint} is encoded as a linear inequality constraint $z \geq y_i$; the one-mention per discourse heuristic of Φ^{joint} is encoded as the constraint $\sum_{y_i \in \mathbf{y}_d} y_i \leq 1$.

[3]Relation phrases in clausal complement are less useful for paraphrasing because they often do not describe a fact. For example, in the sentence *He heard Romney had won the election*, the extraction (Romney, had won, the election) is not a fact at all.

4.3.4 Learning

Our training data consists a set of $N = 500$ labeled EEC-sets each in the form of $\{(R_i, R_i^{\text{gold}}) \mid_{i=1}^{N}\}$. Each R is the set of all relations in the EEC-set while R^{gold} is a manually selected subset of R containing relations describing the EEC. R^{gold} could be empty if the EEC was deemed poor for paraphrasing. For our model, the gold assignment $y^{r\,\text{gold}} = 1$ if $r \in R^{\text{gold}}$; the gold assignment $z^{\text{gold}} = 1$ if R^{gold} is not empty.

Given $\{(R_i, R_i^{\text{gold}}) \mid_{i=1}^{N}\}$, learning over similar models is commonly done via maximum likelihood estimation as follows:

$$L(\Theta) = \log \prod_i p(Z_i = z_i^{\text{gold}}, \mathbf{Y}_i = \mathbf{y}_i^{\text{gold}} \mid \mathbf{x}_i, \Theta)$$

For features in relation factors, the partial derivative for the ith model is:

$$\Phi_j(\mathbf{y}_i^{\text{gold}}, \mathbf{x}_i) - E_{p(z_i, \mathbf{y}_i|, \mathbf{x}_i, \Theta)} \Phi_j(\mathbf{y}_i, \mathbf{x}_i)$$

where $\Phi_j(\mathbf{y}_i, \mathbf{x}_i) = \sum \phi_j(X, Y, \mathbf{x})$, the sum of values for the jth feature in the ith model; and values of X, Y come from the assignment $\mathbf{y}_i$. For features in event factors, the partial derivative is derived similarly as

$$\phi_j(z_i^{\text{gold}}, \mathbf{x}_i) - E_{p(z_i, \mathbf{y}_i|, \mathbf{x}_i, \Theta)} \phi_j(z_i, \mathbf{x}_i)$$

It is unclear how to efficiently compute the expectations in the above formula, a brute force approach requires enumerating all assignments of $\mathbf{y}_i$, which is exponentially large with the number of relations. Instead, we opt to use a more tractable perceptron learning approach (Collins, 2002; Hoffmann et al., 2011). Instead of computing the expectations, we simply compute $\phi_j(z_i^*, \mathbf{x}_i)$ and $\Phi_j(\mathbf{y}_i^*, \mathbf{x}_i)$, where $z_i^*, \mathbf{y}_i^*$ is the assignment with the highest probability, generated by the MAP inference algorithm using the current weight vector. The weight updates are the following:

$$\Phi_j(\mathbf{y}_i^{\text{gold}}, \mathbf{x}_i) - \Phi_j(\mathbf{y}_i^*, \mathbf{x}_i) \quad (1)$$

$$\phi_j(z_i^{\text{gold}}, \mathbf{x}_i) - \phi_j(z_i^*, \mathbf{x}_i) \quad (2)$$

The updates can be intuitively explained as penalties on errors. In sum, our learning algorithm consists of iterating the following two steps: (1) infer the most probable assignment given the current weights; (2) update the weights by comparing inferred assignments and the truth assignment.

5 Empirical Study

We first introduce the experimental setup for our empirical study, and then we attempt to answer two questions in sections 5.2 and 5.3 respectively: First, does the NEWSSPIKE algorithm effectively exploit the proposed heuristics and outperform other approaches which also use news streams? Secondly, do the proposed temporal heuristics paraphrase relations with greater precision than the distributional hypothesis?

5.1 Experimental Setup

Since we were unable to find any elaborate time-stamped, parallel, news corpus, we collected data using the following procedure:

- Collect RSS news seeds, which contain the title, time-stamp, and abstract of the news items.
- Use these titles to query the Bing news search engine API and collect additional time-stamped news articles.
- Strip HTML tags from the news articles using Boilerpipe (Kohlschütter et al., 2010); keep only the title and first paragraph of each article.
- Extract shallow relation tuples using the OpenIE system (Fader et al., 2011).

We performed these steps every day from January 1 to February 22, 2013. In total, we collected 546,713 news articles, for which 2.6 million extractions had 529 thousand unique relations.

We used several types of features for paraphrasing: *1)* spike features obtained from time series; *2)* tense features, such as whether two relation phrases are both in the present tense; *3)* cause-effect features, such as whether two relation phrases often appear successively in the news articles; *4)* text features, such as whether sentences are similar; *5)* syntactic features, such as whether a relation phrase appears in a clausal complement; and *6)* semantic features, such as whether a relation phrase contains negative words.

Text and semantic features are encoded using the relation factors of section 4.3.2. For example, in Figure 2, the factor Φ_2^Y includes the textual similarity between the sentences containing the phrases *"step down"* and *"be chairman of"* respectively; it also includes the feature that the tense of *"step down"* (present) is different from the tense of *"be chairman*

output	{**go into**, **go to**, *speak*, *return*, **head to**}
gold	{**go into**, **go to**, *approach*, **head to**}
gold$_{\text{div}}$	{**go** $*$, *approach*, **head to**}
P/R	precision $= 3/5$ recall $= 3/4$
P/R$_{\text{div}}$	precision$_{\text{div}} = 2/4$ recall$_{\text{div}} = 2/3$

Figure 3: an example pair of the output cluster and the gold cluster, and the corresponding precision recall numbers.

of" (past).

5.2 Comparison with Methods using Parallel News Corpora

We evaluated NEWSSPIKE against other methods that also use time-stamped news. These include the models mentioned in section 3 and state-of-the-art paraphrasing techniques.

Human annotators created gold paraphrase clusters for 500 EEC-sets; note that some EEC-sets yield no gold cluster, since at least two synonymous phrases. Two annotators were shown a set of candidate relation phrases in context and asked to select a subset of these that described a shared event (if one existed). There was 98% phrase-level agreement. Precision and recall were computed by comparing an algorithm's output clusters to the gold cluster of each EEC. We consider paraphrases with minor lexical diversity, *e.g. (go to, go into)*, to be of lesser interest. Since counting these trivial paraphrases tends to exaggerate the performance of a system, we also report precision and recall on *diverse clusters i.e.*, those whose relation phrases all have different head verbs. Figure 3 illustrates these metrics with an example; note under our diverse metrics, all phrases matching *go* * count as one when computing both precision and recall. We conduct 5-fold cross validation on our labeled dataset to get precision and recall numbers when the system requires training.

We compare NEWSSPIKE with the models in Section 4, and also with the state-of-the-art paraphrase extraction method:

Baseline: the model discussed in Section 4.1. This system does not need any training, and generates outputs with perfect recall.

Pairwise: the pairwise model discussed in Section 4.2 and using the same set of features as used by NEWSSPIKE. To generate output clusters, transitivity is assumed inside the EEC-set. For example, when the pairwise model predicts that (r_1, r_2) and (r_1, r_3) are both paraphrases, the resulting cluster is $\{r_1, r_2, r_3\}$.

System	P/R		P/R diverse	
	prec	rec	prec	rec
Baseline	0.67	1.00	0.53	1.00
Pairwise	0.90	0.60	0.81	0.37
Socher	0.81	0.35	0.68	0.29
NEWSSPIKE	**0.92**	0.55	**0.87**	0.31

Table 1: Comparison with methods using parallel news corpora

Socher: Socher *et al.* (2011) achieved the best results on the Dolan *et al.* (2004) dataset, and released their code and models. We used their off-the-shelf predictor to replace the classifier in our Pairwise model. Given sentential paraphrases, aligning relation phrases is natural, because OpenIE has already identified the relation phrases.

Table 1 shows precision and recall numbers. It is interesting that the basic model already obtains 0.67 precision overall and 0.53 in the diverse condition. This demonstrates that the EEC-sets generated from the news streams are a promising resource for paraphrasing. Socher's method performs better, but not as well as Pairwise or NEWSSPIKE, especially in the diverse cases. This is probably due to the fact that Socher's method is based purely on text metrics and does not consider any temporal attributes. Taking into account the features used by NEWSSPIKE, Pairwise significantly improves the precision, which demonstrates the power of our temporal correspondence heuristics. Our joint cluster model, NEWSSPIKE, which considers both temporal features and constraints, gets the best performance in both conditions.

We conducted ablation testing to evaluate how spike features and tense features, which are particularly relevant to the temporal aspects of news streams, can improve performance. Figure 4 compares the precision/recall curves for three systems in the diverse condition: (1) NEWSSPIKE; (2) w/oSpike: turning off all spike features; and (3) w/oTense: turning off all features about tense. (4) w/oDiscourse: turning off one event-mention per discourse heuristic. There are some dips in

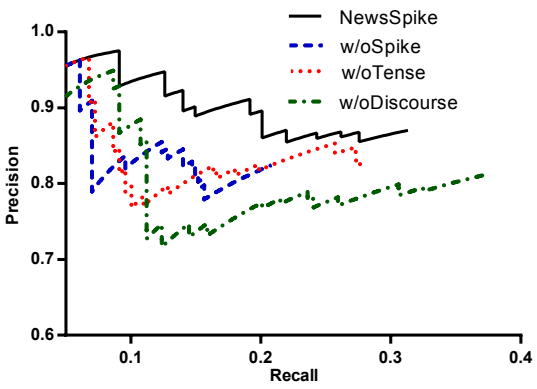

Figure 4: Precision recall curves on hard, diverse cases for NewsSpike, w/oSpike, w/oTense and w/oDiscourse.

the curves because they are drawn after sorting the predictions by the value of the corresponding ILP objective functions, which do not perfectly reflect prediction accuracy. However, it is clear that NEWSSPIKE produces greater precision over all ranges of recall.

5.3 Comparison with Methods using the Distributional Hypothesis

We evaluated our model against methods based on the distributional hypothesis. We ran NEWSSPIKE over all EEC-sets except for the development set and compared to the following systems:

Resolver: Resolver (Yates and Etzioni, 2009) uses a set of extraction tuples in the form of (a_1, r, a_2) as the input and creates a set of relation clusters as the output paraphrases. Resolver also produces argument clusters, but this paper only evaluates relation clustering. We evaluated Resolver's performance with an input of the 2.6 million extractions described in section 5.1, using Resolver's default parameters.

ResolverNYT: Since Resolver is supposed to perform better when given more accurate statistics from a larger corpus, we tried giving it more data. Specifically, we ran ReVerb on 1.8 million NY Times articles published between 1987 and 2007 obtain 60 million extractions (Sandhaus, 2008). We ran Resolver on the union of this and our standard test set, but report performance only on clusters whose relations were seen in our news stream.

System	all		diverse	
	prec	#rels	prec	#rels
Resolver	0.78	129	0.65	57
ResolverNyt	0.64	1461	0.52	841
ResolverNytTop	0.83	207	0.72	79
Cosine	0.65	17	0.33	9
CosineNyt	0.56	73	0.46	59
NEWSSPIKE	**0.93**	24843	**0.87**	5574

Table 2: Comparison with methods using the distributional hypothesis

ResolverNytTop: Resolver is designed to achieve good performance on its top results. We thus ranked the ResolverNYT outputs by their scores and report the precision of the top 100 clusters.

Cosine: Cosine similarity is a basic metric for the distributional hypothesis. This system employs the same setup as Resolver in order to generate paraphrase clusters, except that Resolver's similarity metric is replaced with the cosine. Each relation is represented by a vector of argument pairs. The similarity threshold to merge two clusters was 0.5.

CosineNYT: As for ResolverNYT, we ran CosineNYT with an extra 60 million extractions and reported the performance on relations seen in our news stream.

We measured the precision of each system by manually labeling all output if 100 or fewer clusters were generated (*e.g.* ResolverNytTop), otherwise 100 randomly chosen clusters were sampled. Annotators first determined the meaning of every output cluster and then created a gold cluster by choosing the correct relations. The gold cluster could be empty if the output cluster was nonsensical. Unlike many papers that simply report recall on the most frequent relations, we evaluated the total number of returned relations in the output clusters. As in Section 5.2, we also report numbers for the case of lexically diverse relation phrases.

As can be seen in Table 2, NEWSSPIKE outperformed methods based on the distributional hypothesis. The performance of the Cosine and CosineNyt was very low, suggesting that simple similarity metrics are insufficient for handling the paraphrasing problem, even when large-scale input is involved. Resolver and ResolverNyt employ an advanced similarity measurement and achieve better results. However, it is surprising that Resolver results in a greater precision than ResolverNyt. It

is possible that argument pairs from news streams spanning 20 years sometimes provide incorrect evidence for paraphrasing. For example, there were extractions like *(the Rangers, be third in, the NHL)* and *(the Rangers, be fourth in, the NHL)* from news in 2007 and 2003 respectively. Using these phrases, ResolverNyt produced the incorrect cluster {*be third in, be fourth in*}. NEWSSPIKE achieves greater precision than even the best results from ResolverNyt-Top, because NEWSSPIKE successfully captures the temporal heuristics, and does not confuse synonyms with antonyms, or causes with effects. NEWSSPIKE also returned on order of magnitude more relations than other methods.

5.4 Discussion

Unlike some domain-specific clustering methods, we tested on all relation phrases extracted by OpenIE on the collected news streams. There are no restrictions on the types of relations. Output paraphrases cover a broad range, including politics, sports, entertainment, health, science, etc. There are 10 thousand nonempty clusters over 17 thousand distinct phrases with average size 2.4. Unlike methods based on distributional similarity, NewsSpike correctly clusters infrequently appearing phrases.

Since we focus on high precision, it is not surprising that most clusters are of size 2 and 3. These high precision clusters can contribute a lot to generate larger paraphrase clusters. For example, one can invent the technique to merge smaller clusters together. The work presented here provides a foundation for future work to more closely examine these challenges.

While this paper gives promising results, there are still behaviors found in news streams that prove challenging. Many errors are due to the discourse context: the two sentences are synonymous in the given EEC-set, but the relation phrases are not paraphrases in general. For example, consider the following two sentences: *"DA14 narrowly misses Earth"* and *"DA14 flies so close to Earth"*. Statistics information from large corpus would be helpful to handle such challenges. Note in this paper, in order to fairly compare with the distributional hypothesis, we purposely forced NEWSSPIKE not to rely on any distributional similarity. But NEWSSPIKE's graphical model has the flexibility to incorporate any similarity metrics as features. Such a hybrid model has great potential to increase both precision and recall, which is one goal for future work.

6 Related Work

The vast majority of paraphrasing work falls into two categories: approaches based on the distributional hypothesis or those exploiting on correspondences between parallel corpora (Androutsopoulos and Malakasiotis, 2010; Madnani and Dorr, 2010).

Using Distribution Similarity: Lin and Pantel's (2001) DIRT employ mutual information statistics to compute the similarity between relations represented in dependency paths. Resolver (Yates and Etzioni, 2009) introduces a new similarity metric called the Extracted Shared Property (ESP) and uses a probabilistic model to merge ESP with surface string similarity.

Identifying the semantic equivalence of relation phrases is also called *relation discovery* or *unsupervised semantic parsing*. Often techniques don't compute the similarity explicitly but rely implicitly on the distributional hypothesis. Poon and Domingos' (2009) USP clusters relations represented with fragments of dependency trees by repeatedly merging relations having similar context. Yao *et al.* (2011; 2012) introduces generative models for relation discovery using LDA-style algorithm over a relation-feature matrix. Chen *et al.* (2011) focuses on domain-dependent relation discovery, extending a generative model with meta-constraints from lexical, syntactic and discourse regularities.

Our work solves a major problem with these approaches, avoiding errors such as confusing synonyms with antonyms and causes with effects. Furthermore, NEWSSPIKE doesn't require massive statistical evidence as do most approaches based on the distributional hypothesis.

Using Parallel Corpora: Comparable and parallel corpora, including news streams and multiple translations of the same story, have been used to generate paraphrases, both sentential (Barzilay and Lee, 2003; Dolan et al., 2004; Shinyama and Sekine, 2003) and phrasal (Barzilay and McKeown, 2001; Shen et al., 2006; Pang et al., 2003). Typical methods first gather relevant articles and then pair sentences that are potential paraphrases. Given a training set of paraphrases, models are learned and applied to unlabeled pairs (Dolan and Brockett, 2005;

Socher et al., 2011). Phrasal paraphrases are often obtained by running an alignment algorithm over the paraphrased sentence pairs.

While prior work uses the temporal aspects of news streams as a coarse filter, it largely relies on text metrics, such as context similarity and edit distance, to make predictions and alignments. These metrics are usually insufficient to produce high precision results; moreover they tend to produce paraphrases that are simple lexical variants (*e.g.* {*go to, go into*}.). In contrast, NEWSSPIKE generates paraphrase clusters with both high precision and high diversity.

Others: Textual entailment (Dagan et al., 2009), which finds a phrase implying another phrase, is closely related to the paraphrasing task. Berant *et al.* (2011) notes the flaws in distributional similarity and proposes local entailment classifiers, which are able to combine many features. Lin *et al.* (2012) also uses temporal information to detect the semantics of entities. In a manner similar to our approach, Recasens *et al.* (2013) mines parallel news stories to find opaque coreferent mentions.

7 Conclusion

Paraphrasing event relations is crucial to many natural language processing applications, including relation extraction, question answering, summarization, and machine translation. Unfortunately, previous approaches based on distribution similarity and parallel corpora, often produce low precision clusters. This paper introduces three Temporal Correspondence Heuristics that characterize semantically equivalent phrases in news streams. We present a novel algorithm, NEWSSPIKE, based on a probabilistic graphical model encoding these heuristics, which harvests high-quality paraphrases of event relations.

Experiments show NEWSSPIKE's improvement relative to several other methods, especially at producing lexically diverse clusters. Ablation tests confirm that our temporal features are crucial to NEWSSPIKE's precision. In order to spur future research, we are releasing an annotated corpus of time-stamped news articles and our harvested relation clusters.

Relational Inference for Wikification

Abstract

Wikification, commonly referred to as Disambiguation to Wikipedia (D2W), is the task of identifying concepts and entities in text and disambiguating them into the most specific corresponding Wikipedia pages. Previous approaches to D2W focused on the use of local and global statistics over the given text, Wikipedia articles and its link structures, to evaluate context compatibility among a list of probable candidates. However, these methods fail (often, embarrassingly), when some level of text understanding is needed to support Wikification. In this paper we introduce a novel approach to Wikification by incorporating, along with statistical methods, richer relational analysis of the text. We provide an extensible, efficient and modular Integer Linear Programming (ILP) formulation of Wikification that incorporates the entity-relation inference problem, and show that the ability to identify relations in text helps both candidate generation and ranking Wikipedia titles considerably. Our results show significant improvements in both Wikification and the TAC Entity Linking task.

1 Introduction

Wikification (D2W), the task of identifying concepts and entities in text and disambiguating them into their corresponding Wikipedia page, is an important step toward supporting deeper textual understanding, by augmenting the ability to ground text in existing knowledge and facilitating knowledge expansion.

D2W has been studied extensively recently (Cucerzan, 2007; Mihalcea and Csomai, 2007; Milne and Witten, 2008; Ferragina and Scaiella, 2010; Ratinov et al., 2011) and has already found broad applications in NLP, Information Extraction, and Knowledge Acquisition from text, from coreference resolution (Ratinov and Roth, 2012) to entity linking and knowledge population (Ellis et al., 2011; Ji et al., 2010; Cucerzan, 2011).

Given a document D containing a set of concept and entity mentions M (referred to later as *surface*), the goal of Wikification is to find the most accurate mapping from mentions to Wikipedia *titles* T; this mapping needs to take into account our understanding of the text as well as background knowledge that is often needed to determine the most appropriate title. We also allow a special NIL title that captures all mentions that are outside Wikipedia.

Earlier approaches treated this task as a word-sense disambiguation (WSD) problem, which was later enhanced with a certain level of global reasoning, but essentially all approaches focused on generic statistical features in order to achieve robust disambiguation. It was shown that by disambiguating to the most likely title for every surface, independently maximizing the conditional probability $\Pr(title|surface)$, we already achieve a very competitive baseline on several Wikification datasets (Ratinov et al., 2011). This strong statistical baseline makes use of the relatively comprehensive coverage of the existing Wikipedia links from surface strings to Wikipedia titles. Although more involved statistical features are required in order to make substantial improvements, global features such as context TF-IDF, better string similarity, etc., statistics-based Wikification systems give a fairly coherent set of disambiguation when sufficient context is available. Consider the following example: *Earth's biosphere*

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1787–1796,
Seattle, Washington, USA, 18-21 October 2013.

*then significantly altered the atmospheric and other basic physical conditions, which enabled the proliferation of organisms. The **atmosphere** is composed of 78.09% nitrogen, 20.95% oxygen, 0.93% argon, 0.039% carbon dioxide, and small amounts of...*

The baseline system we adopted (Ratinov et al., 2011), one of the best Wikification systems, already disambiguates **atmosphere** correctly to the title *Earth's atmosphere* instead of the more general title *Atmosphere*, making use of the concept *Earth* in its local context to resolve the mention to the more specific title that better coheres with the topic. However, consider the following example:

Ex. 1 "As **Mubarak**, the wife of deposed Egyptian President Hosni Mubarak got older, her influence..."

The bold faced name should be mapped to *Suzanne Mubarak*, but all existing Wikification systems map both names in this sentence to the dominant page (the most linked page) of *Hosni Mubarak*, failing to understand the relation between them, which should prevent them from being mapped to the same page. A certain level of text understanding is required even to be able to generate a good list of title candidates. For example, in:

Ex. 2 "...ousted long time Yugoslav President Slobodan Milošević in October. Mr. Milošević's **Socialist Party**..."

the bold-faced concept should be mapped to the page of the *Socialist Party of Serbia*, which is far down the list of titles that could be related to "Socialist Party"; making this title a likely candidate requires understanding the possessive relation with Milošević and then making the knowledge-informed decision that he is more related to *Socialist Party of Serbia* than any other possible titles. Finally, in

Ex. 3 "James Senn, director of **Robinson College**'s Center for Global Business Leadership at Georgia State University..."

we must link *Robinson College* to *J. Mack Robinson College of Business* which is located at *Georgia State University* instead of *Robinson College, Cambridge*, which is the only probable title linked by the surface *Robinson College* in the version of the Wikipedia dump we used.

These examples further illustrate that, along with understanding the relation expressed in the text, we need to access background knowledge sources and to deal with variability in surface representation across the text, Wikipedia, and knowledge, in order to reliably address the Wikification problem.

In this paper we focus on understanding those natural language constructs that will allow eliminating these "obvious" (to a human reader) mistakes from Wikification. In particular, we focus on resolving coreference and a collection of local syntactico-semantic relations (Chan and Roth, 2011); better understanding the relational structure of the text allows us to generate title candidates more accurately given the text, rank these candidates better and determine when a mention in text has no corresponding title in Wikipedia and should be mapped to NIL, a key problem in Wikification. Moreover, it allows us to access external knowledge based resources more effectively in order to support these decisions.

We incorporate the outcome of our relational analysis, along with the associated features extracted from external sources and the "standard" wikification statistical features, into an ILP-based inference framework that globally determines the best assignment of mentions to titles in a given document. We show that by leveraging a better understanding of the textual relations, we can substantially improve the Wikification performance. Our system significantly outperforms all the top Wikification systems on the widely adopted standard datasets and shows state-of-the-art results when evaluated (without being trained directly) on the TAC 2011 Entity Linking task.

2 The Wikification Approach

A general Wikification decision consists of three computational components: (1) generating a ranked list of title candidates for each mention, (2) ranking candidates globally, and (3) dealing with NIL mentions. For (1), the "standard" way of using $\Pr(title|surface)$ is often not sufficient; consider the case where the mention is the single word "*President*"; disambiguating such mentions depends heavily on the context, i.e. to determine the relevant country or organization. However, it is intractable to search the entire surface-to-title space, and using an arbitrary top-K list will inevitably leave out a large number of potential solutions. For (2), even though

the anchor texts cover many possible ways of paraphrasing the Wikipedia article titles and thus using the top $\Pr(title|surface)$ is proven to be a fairly strong baseline, it is never comprehensive. There is a need to disambiguate titles that were never linked by any anchor text, and to disambiguate mentions that have never been observed as the linked text. For (3) the Wikifier needs to determine when a mention corresponds to no title, and map it to a NIL entity. Simply training a classifier using coherency features or topical models turns out to be insufficient, since it has a predetermined granularity at which it can distinguish entities.

Next we provide a high-level description (Alg. 1) of our approach to improve Wikification by leveraging textual relations in these three stages.

Algorithm 1 Relational Inference for Wikification

*N*ote: $\Gamma : M \rightarrow T$ is the sought after mapping from all mentions in the document to all candidate titles in Wikipedia.

Require: Document D, Knowledge Base K consisting of relation triples $\sigma = (t_a, p, t_b)$, where p is the relation predicate.

1: Generate initial mentions $M = \{m_i\}$ from D.
2: Generate candidates $t_i = \{t_i^k\}$ for mention m_i and initialize candidate priors $\Pr(t_i^k|m_i)$ with existing Wikification system, for all $m_i \in M$.
3: Instantiate non-coreference relational constraints and add relational candidates.
4: Instantiate coreference relational constraints and add relational candidates.
5: Construct an ILP objective function and solve for the $\arg\max_\Gamma \Pr(\Gamma)$.
6: **return** Γ.

Most of our discussion addresses the relational analysis and its impact on stage (2) and (3) above. We will only briefly discuss improvements to the standard candidate generation stage in Sec. 4.4

3 Problem Formulation

We now describe how we formulate our global decision problem as an Integer Linear Program (ILP).

We use two types of boolean variables: e_i^k is used to denote whether we disambiguate m_i to t_i^k ($\Gamma(m_i) = t_i^k$) or not. $r_{ij}^{(k,l)}$ is used to denote if titles t_i^k and t_j^l are chosen simultaneously, that is, $r_{ij}^{(k,l)} = e_i^k \wedge e_j^l$.

Our models determine two types of score for the boolean variables above: $s_i^k = \Pr(e_i^k) = \Pr(\Gamma(m_i) = t_i^k)$, represents the initial score for the kth candidate title being chosen for mention m_i. For a pair of titles (t_i^k, t_j^l), we denote the confidence of finding a relation between them by $w_{ij}^{(k,l)}$. Its value depends on the textual relation type and on how coherent it is with our existing knowledge.

Our goal is to find the best assignment to variables e_i^k, such that it satisfies some legitimacy (hard) constraints and the soft constraints dictated by the relational constraints (via scores $w_{ij}^{(k,l)}$). To accomplish that we define our objective function as a Constrained Conditional Model (CCM) (Roth and Yih, 2004; Chang et al., 2012) that is used to reward or penalize a pair of candidates t_i^k, t_j^l by $w_{ij}^{(k,l)}$ when they are chosen in the same document. Specifically, we choose the assignment Γ_D that optimizes:

$$\Gamma_D = \arg\max_\Gamma \sum_i \sum_k s_i^k e_i^k + \sum_{i,j} \sum_{k,l} w_{ij}^{(k,l)} r_{ij}^{(k,l)}$$

$$\begin{aligned}
s.t. \quad & r_{ij}^{(k,l)} \in \{0,1\} && \text{Integral constraints} \\
& e_i^k \in \{0,1\} && \text{Integral constraints} \\
& \forall i \textstyle\sum_k e_i^k = 1 && \text{Unique solution} \\
& 2r_{ij}^{(k,l)} \leq e_i^k + e_j^l && \text{Relation definition}
\end{aligned}$$

Note that as in most NLP problems, the problem is very sparse, resulting in a tractable ILP that is solved quickly by off-the-shelf ILP packages (Gurobi Optimization, 2013). In our case the key reason for the sparseness is that $w_{ij}^{(k,l)} = 0$ for most pairs considered, which does not require explicit instantiation of $r_{ij}^{(k,l)}$.

4 Relational Analysis

The key challenge in incorporating relational analysis into the Wikification decision is to systematically construct the relational constraints (the solid edges between candidates in Figure 1) and incorporate them into our inference framework. Two main components are needed: first, we need to extract high precision textual relations from the text; then,

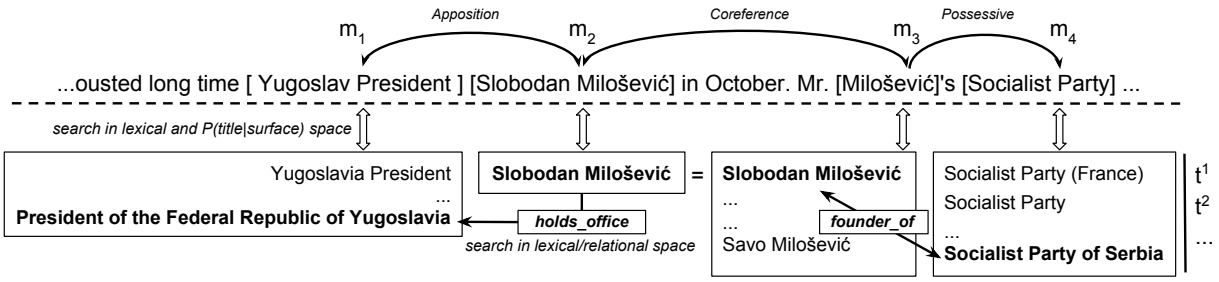

Figure 1: Textual relation inference framework: The goal is to maximize the objective function assigning mentions to titles while enforcing coherency with relations extracted from both text and an external knowledge base. Here, searching the external KB reveals that *Slobodan Milošević* is the founder of the *Socialist Party of Serbia*, which can be referred to by the surface *Socialist Party*; we therefore reward the output containing this pair of candidates. The same idea applies for the relation "*Slobodan Milošević* holds office as *President of the Federal Republic of Yugoslavia*" as well as to the coreference relation between two mentions of *Slobodan Milošević*.

we need to assign weights to these semantic relations. We determine the weights by combining type and confidence of the relation extracted from text with the confidence in relations retrieved from an external Knowledge Base (KB) by using the mention pairs as a query. It is noteworthy that although context window based coherency objective functions capture many proximity relations, using these unfiltered relations as constraints in our experiments introduced excessive amount of false-positives for the intrinsically sparse textual relations and resulted in severe performance hit.

In Sec. 4.1 we describe how we extract relations from text; our goal is to reliably identify *arguments* that we hypothesize to be in a relation; we show that this is essential both to our candidate generation, our ranking and the mapping to NIL. Sec. 4.2 describes how we use an external KB to verify that these arguments are indeed in a relation. Finally, Sec. 4.3 shows how we generate scores for the mentions and relations, as coefficients in the objective function of Sec. 3. The process is illustrated in Figure 1. Overall, our approach is an ambiguity-aware approach that identifies, filters and scores the relevant relations; this is essential due to the ambiguity, variability and noise inherent in directly matching surface forms to titles.

4.1 Relation Extraction

Even though relation extraction is an open problem, analysis on the ACE2004 Relation Detection and Characterization (RDC) dataset shows that approximately 80% of the relations are expressed through syntactico-semantic structures (Chan and Roth, 2011) that are easy to extract with high precision. Unlike the general ACE RDC task, we can restrict relation arguments to be named entities and thus leverage the large number of known relations in existing databases (e.g. Wikipedia infoboxes). We also consider conference relations that potentially aid mapping different mentions to the same title.

4.1.1 Syntactico-semantic Relations

We introduce our approach using the following example. Consider a news article discussing Israeli politics while briefly mentioning:

Ex. 4 An official at the [Iranian]$_1$ [Ministry of Defense]$_2$ told Tehran Radio that...

A purely statistical approach would very likely map the entity *[Ministry of Defense]*$_2$ to *Ministry of Defense (Israel)* instead of *Ministry of Defense and Armed Forces Logistics (Iran)* because the context is more coherent with concepts related to Israel rather than to Iran. Nevertheless, the pre-modifier relation between *[Iranian]*$_1$ and *[Ministry of Defense]*$_2$ demands the answer to be tightly related to Iran. Even though human readers may not know the correct title needed here, understanding the pre-modifier relation allows them to easily filter through a list of candidates and enforce constraints that are derived jointly from the relation expressed in the text and their background knowledge.

In our attempt to mimic this general approach, we employ several high precision classifiers to resolve

a range of local relations that are used to retrieve relevant background knowledge, and consequently integrated into our inference framework. Our input for relation extraction is any segment matched by the regular expression to be mentioned in section 4.4 in the candidate generation stage; we analyze its constituents by decomposing it into the two largest sub-entities that have (in Wikipedia) corresponding candidates. In the above example, *Iranian Ministry of Defense* would be decomposed into **Iranian** and **Ministry of Defense** and our relation extraction process hypothesizes a relation between these arguments.

Note that we do not use any full parsing since it does not address our needs directly nor does it scale well with the typical amount of data used in Wikification.

4.1.2 Coreference Relations

In addition to syntactico-semantic relations, we could also encounter other textual relations. The following example illustrates the importance of understanding co-reference relations in Wikification:

Ex. 5 [Al Goldman]$_1$, chief market strategist at A.G. Edwards, said ... [Goldman]$_2$ told us that...

There is no Wikipedia entry (or redirection) that matches the name *Al Goldman*. Clearly *[Goldman]*$_2$ refers to the same person and should be mapped to the same entity (or to NIL) rather than popular entities frequently referred to as *Goldman*, coherent with context or not, such as *Goldman Sachs*. To accomplish that, we cluster named entities that share tokens or are acronyms of each other when there is no ambiguity (e.g. no other longer named entity mentions containing *Goldman* in the document) and use a voting algorithm (Algorithm 2) to generate candidates locally from within the clusters. We also experimented with using full-fledged coference systems, but found it to be time consuming while providing no significant end-to-end performance difference.

4.1.3 Coreferent Nominal Mentions

Document level coreference also provides important relations between named entities and nominal mentions. Extracting these relations proved to be very useful for classifying NIL entities, as unfamiliar concepts tend to be introduced with these succinct appositional nominal mentions. These descriptions provide a clean "definition" of the entity, allowing us to abstract the inference to a limited "noun phrase entailment problem". That is, it allows us to determine whether the target mention corresponds to a candidate title. Consider, for example, wikifying *Dorothy Byrne* in: **Dorothy Byrne***, a state coordinator for the Florida Green Party, ...*
Identifying the apposition relation allows us to determine that this *Dorothy Byrne* is *not* the baseline Wikipedia title. We use the TF-IDF cosine similarity between the nominal description and the lexical context (Ratinov et al., 2011) of the candidate page, head word attributes and entity relation (i.e. between *Dorothy Byrne* and *Florida Green Party*) to determine whether any candidates of *Dorothy Byrne* can entail the nominal mention.

4.2 Relational Queries

Statistics based candidate generation algorithms always generate the same list of candidates given the same surface string; even though this approach has a competitive coverage rate, it will not work well in some "obvious" (to human) cases; for example, it offers very little information on highly ambiguous surface strings such as "President" for which it is even intractable to rank all the candidates. Top-K lists which were used in previous literature suffer from the same problem. Instead, we make use of relational queries to generate a more likely set of candidates.

Once mention pairs are generated from text using the syntactico-semantic structures and coreference, we use these to query our KB of relational triples. We first indexed all Wikipedia links and DBpedia relations as unordered triples $\sigma = (t_i, p, t_j)$, where the arguments t_i, t_j are tokenized, stemmed and lowercased for best recall. p is either a relation predicate from the DBpedia ontology or the predicate $LINK$ indicating a hyperlink relation. Since our baseline system has approximately 80% accuracy at this stage, it is reasonable to assume that at least one of the argument mentions is correctly disambiguated. Therefore we prune the search space by making only two queries for each mention pair (m_i, m_j): $q_0 = (t_i^*, m_j)$ and $q_1 = (m_i, t_j^*)$ where t_i^*, t_j^* are the strings representing the top titles chosen by the current model for mentions m_i, m_j re-

spectively.

We also aggressively prune the search results in a way similar to the process in Sec. 4.4, only keeping the arguments that are known to be possible or very likely candidates of the mention, based on the ambiguity that exists in the query result.

4.3 Relation Scoring

For the final assignment made using our objective function (Sec. 3) we need to normalize and rescale the output of individual components of our system as they come from different scoring functions. We consider adding new title candidates from two sources, through the coreference module and through the combined DBpedia and Wikipedia inter-page link structures. Next we describe how to compute and combine these scores.

4.3.1 Scoring Knowledge Base Relations

Our model uses both explicit relations $p \neq LINK$ from DBpedia and Wikipedia hyperlinks $p = LINK$ (implicit relation). We want to favor relations with explicit predicate, each weighted as ϕ implicit relation (we use $\phi = 5$ in our experiments, noting the results are insensitive to slight changes of this parameter).

For each query, we denote the score returned by our KB search engine[1] given query q and triple σ as $Sim_{\sigma,q}$. The relational weight $w_{i,j}^{k,l}$ between two candidates (see Sec. 3) is determined as:

$$w_{i,j}^{k,l} = \frac{1}{Z} \sum_{\sigma} \alpha_\sigma Sim_{\sigma,q}$$

where the sum is over the top 20 KB triples, α_σ is the relation type scaling constant (ϕ or 1), and Z is a normalization factor that normalizes all $w_{i,j}^{k,l}$ to the range $[0, 1]$.

Note that we do not check the type of the relation against the textual relation. The key reason is that explicit relations are not as robust, especially considering that we restrict one of the arguments in the relation and constraining the other argument's lexical form. Moreover, we back off to restricting the relations to be between known candidates when multiple lexically matched arguments are retrieved with high ambiguity. Additionally, most of our relations do not have explicit predicates in the text anyhow, and extracting a type would add noise to our decision.

[1] `http://lucene.apache.org/`

Algorithm 2 Coreferent Candidates Voting

Require: Coreference cluster C

Vote collector v_t denotes the score for a candidate t, which by default is 0.
$t_i = \{t_i^1 \dots t_i^n\}$ is the set of candidates of mention m_i.
l_i is the token count of m_i
for all $m_i \in C, l_i \geq 2$ **do**

4.3.2 Scoring Coreference Relations

For coreference relations, we simply use hard constraints by assigning candidates in the same coreference cluster a high relational weight, which is a cheap approximation to penalizing the output where the coreferent mentions disambiguate to different titles. In practice, using a weight of 10 is sufficient. Another important issue here is that the correct coreferent candidate might not exist in the candidate list of the shorter mentions in the cluster. For example, if a mention has the surface *Richard*, the number of potential candidates is so large that any top K list of titles will not be informative. We therefore ignore candidates generated from short surface strings and give it the same candidate list as the head mentions in its cluster. Figure 2 shows the voting algorithm we use to elect the potential candidates for the cluster.

The reason for separating the votes of longer and shorter mentions is that shorter mentions are inherently more ambiguous. Once a coreferent relation

is determined, longer mentions in the cluster should dictate what this cluster should collectively refer to.

4.4 Candidate Generation

Beyond the algorithmic improvements, the mention and candidate generation stage is aided by a few systematic preprocessing improvement briefly described below.

4.4.1 Mention Segmentation

Since named entities may sometimes overlap with each other, we use regular expressions to match longer surface forms that are often incorrectly segmented or ignored by NER [2] due to different annotation standards. For example, this will capture: *Prime Minister of the United Kingdom*. The regular expression pattern we used for Step 1 in Algorithm 1 simply adds mentions formed by any two consecutive capitalized word chunks connected by up to 2 punctuation marks, prepositions, and the tokens "the", "'s" & "and". These segments are also used as arguments for relation extraction.

4.4.2 Lexical Search

We link certain mentions directly to their exact matching titles in Step 3 when there is very low ambiguity. Specifically, when no title is known for a mention that is relatively long and fuzzily matches the lexically retrieved title, we perform this aggressive linking. The lexical similarity metrics are computed using the publicly available NESim [3] package (Do et al., 2009) with a threshold tuned on a subset of Wikipedia redirects, and by insisting that ORG type entities must have the same head word as the candidate titles. We only accept the link if there exists exactly one title in the lexical searching result after pruning.

5 Experiments and Evaluation

This section describes our experimental evaluation. We compare our system against the top D2W systems and perform several experiments to analyze and better understand the power of our approach. We based our work on the GLOW system from (Ratinov et al., 2011) to initialize the candidates and corresponding priors s_i^k in our objective function. Both the baseline system and our new system are publicly available [4].

5.1 Comparison with other Wikification systems

We first evaluate on the same 4 datasets[5] used in (Ratinov et al., 2011). The AQUAINT dataset, originally introduced in (Milne and Witten, 2008), resembles the Wikipedia annotation structure in that only the first mention of a title is linked, and is thus less sensitive to coreference capabilities. The MSNBC dataset is from (Cucerzan, 2007) and includes many mentions that do not easily map to Wikipedia titles due to rare surface or other idiosyncratic lexicalization (Cucerzan, 2007; Ratinov et al., 2011). Both of these datasets came from the news domain and do not contain any annotated NIL entities. The ACE and Wikipedia datasets are both taken from (Ratinov et al., 2011) where ACE is a subset of ACE2004 Coreference documents annotated by Amazon Mechanical Turkers in a similar standard as in AQUAINT but with NIL entities. The Wikipedia dataset is a sample of Wikipedia pages with its original hyperlink annotation.

The evaluation methodology Bag of Titles (BOT) F1 was used in both (Milne and Witten, 2008; Ratinov et al., 2011). For each document, the gold *bag* of titles is evaluated against our *bag* of system output titles requiring exact segmentation match.

	Dataset			
System	ACE	MSNBC	AQUAINT	Wiki
M&W	72.76	68.49	83.61	80.32
R&R	77.25	74.88	83.94	90.54
RI	**85.30**	**81.20**	**88.88**	**93.09**

Table 1: Performance on Wikification datasets, BOT F1 Performance. Our system, **Relational Inference (RI)** exhibits significant improvements over M&W (Milne and Witten, 2008) and R&R (Ratinov et al., 2011).

[2] We used the IllinoisNER package http://cogcomp.cs.illinois.edu/page/software_view/4

[3] http://cogcomp.cs.illinois.edu/page/software_view/22

[4] http://cogcomp.cs.illinois.edu/page/download_view/Wikifier

[5] http://cogcomp.cs.illinois.edu/page/resource_view/4

5.2 Ablation study

We incrementally add various components to the system and study their impact on the end performance. Due to the changes in Wikipedia since the datasets were generated, some of the pages no longer exist; in order to minimize the interference caused by these inconsistencies to an accurate evaluation of various componenents, we consider all non-NIL gold annotations that do not exist in the current Wikipedia index as NIL entities. Additionally in the MSNBC dataset, 127 out of 756 surface forms are known to be non-recallable. This explains the performance difference between the final rows in Tab. 1 and 2.

	Dataset			
Components	ACE	MSNBC	AQUAINT	Wiki
Baseline	80.68	83.00	83.93	91.93
+Lexical Match	83.47	84.13	88.88	93.41
+Coreference	83.40	87.88	88.88	93.09
RI	85.83	88.16	88.88	93.09

Table 2: Ablation study on Wikification datasets, BOT F1 Performance

The *Baseline* refers to the best performing configuration that was used in (Ratinov et al., 2011) except for using the current Wikipedia redirects. The *Lexical Match* refers to the applying solely the methodology introduced in Sec. 4.4. The *Coreference* performance includes all the inference performed without the KB triples, while the **Relational Inference (RI)** line represents all aspects of the proposed relational inference. It is clear that different datasets show somewhat different characteristics and consequently different gains from the various aspects of our approach but that, overall, all aspects contribute to improved performance.

5.3 TAC Entity Linking 2011

Next we evaluate our approach on the TAC English Entity Linking Task, which provides standardized evaluation metrics, allowing us to compare to a large number of other systems. We did not evaluate on the 2012 English Entity Linking due to the significant amount of ambiguous NIL entities included (Ellis et al., 2011) in the queries and the need to cluster them, which our D2W task definition does not address in depth. We compare our system with the Top 3 TAC 2011 systems (LCC, MS-MLI and NUSchime) as well as our baseline system GLOW that participated in TAC 2011 English Entity Linking (Ratinov and Roth, 2011) in table 3. The evaluation metric is the official modified B^3 and Micro-Average explained in (Ji et al., 2011).

Given the TAC Knowledge Base (TKB), which is a subset of the 2009 Wikipedia Dump, the TAC Entity Linking objective is to answer a named entity query string with either a TKB entry ID or a NIL entity ID, where the NIL entity IDs should be clustered across documents.

It is important to note that we did not retrain our system on the TAC data as the top three systems did, even though the objective function is slightly different. Instead, we ran our system on the TAC documents directly without any query expansion. For the final output of each query, we simply use the most confident candidate among all matched mentions. Due to the clustering requirement, we also trivially cluster NIL entities that either are mapped to the same out-of-KB Wikipedia URL or have the same surface form.

	Performance			
System	MA	B^3 P	B^3 R	B^3 F1
LCC	86.1	84.4	84.7	84.6
MS-MLI	86.8	84.8	83.4	84.1
RI	86.1	82.9	84.5	83.7
NUSchime	86.3	81.5	84.9	83.1
RI-0	81.4	78.6	79.1	78.8
Cogcomp	78.7	75.7	76.5	76.1

Table 3: TAC2011 Entity Linking performance. MA is Micro-Average. LLC (Monahan et al., 2011) is the best performing system in terms of B^3 F1 while MS-MLI (Cucerzan, 2011) is the best in terms of Micro-Average. Cogcomp (Ratinov and Roth, 2011) is the GLOW based system that participated in TAC 2011.**RI** is the complete relational inference system described in this paper; as described in the text, **RI** was not trained on the TAC data, unlike the other top systems.

We performed two runs on the TAC2011 data to study the effects of relational inference. The first run, **RI-0**, uses the current Wikipedia index and

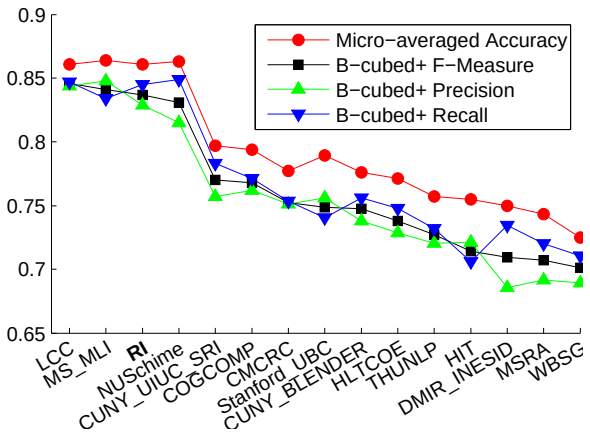

Figure 2: The **RI** compared with the other top 14 TAC2011 English Entity Linking systems ranked by modified B^3 F1 measure. Original figure from (Ji et al., 2011).

redirects for lexical matching without any inference, which scored 2.7% higher than the original GLOW system (Cogcomp). We can regard this performance as the new baseline that benefited from the fuzzy lexical matching capabilities that we have added, as well as the broader set of surface forms and redirects from the current Wikipedia dump. In the second run, **RI**, the complete relational inference described in this paper, scored 4.9% higher than the new baseline and sits on par with the top tier systems despite not being trained on the given data. The LCC system used sophisticated clustering algorithms trained on the TAC development set (Monahan et al., 2011). The second-ranked MS-MLI system relied on topic modeling, external web search engine logs as well as training on the development data (Cucerzan, 2011). This shows the robustness of our methods as well as the general importance of understanding textual relations in the task of Entity Linking and Wikification.

6 Related Work and Discussion

Earlier works on Wikification formulated the task as a WSD problem (Bunescu and Pasca, 2006; Mihalcea and Csomai, 2007) and focused primarily on training a model using local context. Later, various global statistical approaches were proposed to emphasize different coherence measures between the titles of the disambiguated mentions in the same document (Cucerzan, 2007; Milne and Witten, 2008; Ratinov et al., 2011). Built on top of the statistical models, our work focuses on leveraging deeper understanding of the text to more effectively and accurately utilize existing knowledge.

We have demonstrated that, by incorporating textual relations and semantic knowledge as linguistic constraints in an inference framework, it is possible to significantly improve Wikification performance. In particular, we have shown that our system is capable of making "intelligent" inferences that makes use of basic text understanding and has the ability to reason with it and verify it against relevant information sources. This allows our Relational Inference approach to resolve a variety of difficult examples illustrated in the Introduction.

Our system features high modularity since the relations are considered only at inference time; consequently, we can use any underlying Wikification system as long as it outputs a distribution of title candidates for each mention.

One possibility for future work is to supply this framework with a richer set of relations from the text, such as verbal relations. It will also be interesting to incorporate high-level typed relations and relax the relation arguments to be general concepts rather than only named entities.

Event Schema Induction with a Probabilistic Entity-Driven Model

Nathanael Chambers
United States Naval Academy
Annapolis, MD 21402
nchamber@usna.edu

Abstract

Event schema induction is the task of learning high-level representations of complex events (e.g., a *bombing*) and their entity roles (e.g., *perpetrator* and *victim*) from unlabeled text. Event schemas have important connections to early NLP research on frames and scripts, as well as modern applications like template extraction. Recent research suggests event schemas can be learned from raw text. Inspired by a pipelined learner based on named entity coreference, this paper presents the first generative model for schema induction that integrates coreference chains into learning. Our generative model is conceptually simpler than the pipelined approach and requires far less training data. It also provides an interesting contrast with a recent HMM-based model. We evaluate on a common dataset for template schema extraction. Our generative model matches the pipeline's performance, and outperforms the HMM by 7 F1 points (20%).

1 Introduction

Early research in language understanding focused on high-level semantic representations to drive their models. Many proposals, such as frames and scripts, used rich event schemas to model the situations described in text. While the field has since focused on more shallow approaches, recent work on schema induction shows that event schemas might be learnable from raw text. This paper continues the trend, addressing the question, can event schemas be induced from raw text without prior knowledge? We present a new generative model for event schemas, and it produces state-of-the-art induction results, including a 7 F1 point gain over a different generative proposal developed in parallel with this work.

Event schemas are unique from most work in information extraction (IE). Current relation discovery (Banko et al., 2007a; Carlson et al., 2010b) focuses on atomic facts and relations. Event schemas build relations into coherent event structures, often called *templates* in IE. For instance, an election template jointly connects that *obama won a presidential election* with *romney was the defeated*, *the election occurred in 2012*, and *the popular vote was 50-48*. The entities in these relations fill specific semantic roles, as in this template schema:

Template Schema for Elections
(*events*: nominate, vote, elect, win, declare, concede)

Date:	Timestamp
Winner:	Person
Loser:	Person
Position:	Occupation
Vote:	Number

Traditionally, template extractors assume foreknowledge of the event schemas. They know a Winner exists, and research focuses on supervised learning to extract winners from text. This paper focuses on the other side of the supervision spectrum. The learner receives no human input, and it first induces a schema before extracting instances of it.

Our proposed model contributes to a growing line of research in schema induction. The majority of previous work relies on ad-hoc clustering algorithms (Filatova et al., 2006; Sekine, 2006; Chambers and Jurafsky, 2011). Chambers and Jurafsky is a pipelined approach, learning events first, and later learning syntactic patterns as fillers. It requires

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1797–1807,
Seattle, Washington, USA, 18-21 October 2013.

several ad-hoc metrics and parameters, and it lacks the benefits of a formal model. However, central to their algorithm is the use of coreferring entity mentions to knit events and entities together into an event schema. We adapt this entity-driven approach to a single model that requires fewer parameters and far less training data. Further, experiments show state-of-the-art performance.

Other research conducted at the time of this paper also proposes a generative model for schema induction (Cheung et al., 2013). Theirs is not entity-based, but instead uses a sequence model (HMM-based) of verb clauses. These two papers thus provide a unique opportunity to compare two very different views of document structure. One is entity-driven, modeling an entity's role by its coreference chain. The other is clause-driven, classifying individual clauses based on text sequence. Each model makes unique assumptions, providing an interesting contrast. Our entity model outperforms by 7 F1 points on a common extraction task.

The rest of the paper describes in detail our main contributions: (1) the first *entity-based* generative model for schema induction, (2) a direct pipeline/formal model comparison, (3) results improving state-of-the-art performance by 20%, and (4) schema induction from the smallest amount of training data to date.

2 Previous Work

Unsupervised learning for information extraction usually learns binary relations and atomic facts. Models can learn relations like *Person is married to Person* without labeled data (Banko et al., 2007b), or rely on seed examples for ontology induction (*dog is a mammal*) and attribute extraction (*dogs have tails*) (Carlson et al., 2010b; Carlson et al., 2010a; Huang and Riloff, 2010; Durme and Pasca, 2008). These do not typically capture the deeper connections modeled by event schemas.

Algorithms that do focus on event schema extraction typically require both the schemas and labeled corpora, such as rule-based approaches (Chinchor et al., 1993; Rau et al., 1992) and modern supervised classifiers (Freitag, 1998; Chieu et al., 2003; Bunescu and Mooney, 2004; Patwardhan and Riloff, 2009; Huang and Riloff, 2011). Classifiers rely on the labeled examples' surrounding context for features (Maslennikov and Chua, 2007). Weakly supervised learning removes some of the need for labeled data, but most still require the event schemas. One common approach is to begin with unlabeled, but clustered event-specific documents, and extract common word patterns as extractors (Riloff and Schmelzenbach, 1998; Sudo et al., 2003; Riloff et al., 2005; Filatova et al., 2006; Patwardhan and Riloff, 2007; Chen et al., 2011). Bootstrapping with seed examples of known slot fillers has been shown to be effective (Yangarber et al., 2000; Surdeanu et al., 2006).

Shinyama and Sekine (2006) presented *unrestricted relation discovery* to discover relations in unlabeled documents. Their algorithm used redundant documents (e.g., all describe Hurricane Ivan) to observe repeated proper nouns. The approach requires many documents about the exact same event instance, and relations are binary (not schemas) over repeated named entities. Our model instead learns *schemas* from documents with mixed topics that don't describe the same event, so repeated proper nouns are less helpful.

Chen et al. (2011) perform relation extraction with no supervision on earthquake and finance domains. Theirs is a generative model that represents relations as predicate/argument pairs. As with others, training data is pre-clustered by event type and there is no schema connection between relations.

This paper builds the most on Chambers and Jurafsky (2011). They learned event schemas with a three-stage clustering algorithm that included a requirement to retrieve extra training data. This paper removes many of these complexities. We present a formal model that uniquely models coreference chains. Advantages include a *joint* clustering of events and entities, and a formal probabilistic interpretation of the resulting schemas. We achieve better performance, and do so with far less training data.

Cheung et al. (2013) is most related as a generative formulation of schema induction. They propose an HMM-based model over latent event variables, where each variable generates the observed clauses. Latent schema variables generate the event variables (in the spirit of preliminary work by O'Connor (2012)). There is no notion of an entity, so learning uses text mentions and relies on the local HMM win-

message: id	dev-muc3-0112 (bellcore, mitre)

perp: organization	"shining path"

Figure 1: A subset of the slots in a MUC-4 template.

dow for event transitions. Their model was created in parallel with our work, and provides a nice contrast in both approach and results. Ours outperforms their model by 20% on a MUC-4 evaluation.

In summary, this paper extends most previous work on event schema induction by removing the supervision. Of the recent 'unsupervised' work, we present the first entity-driven generative model, and we experiment on a mixed-domain corpus.

3 Dataset: The MUC-4 Corpus

The corpus from the Message Understanding Conference (MUC-4) serves as the challenge text (Sundheim, 1991), and will ground discussion of our model. MUC-4 is also used by the closest previous work. It contains Latin American newswire about terrorism events, and it provides a set of hand-constructed event schemas that are traditionally called template schemas. It also maps labeled templates to the text, providing a dataset for template extraction evaluations. Until very recently, only extraction has been evaluated. We too evaluate our model through extraction, but we also compare our learned schemas to the hand-created template schemas. An example of a filled in MUC-4 template is given in Figure 1.

The MUC-4 corpus defines six template types: **Attack**, **Kidnapping**, **Bombing**, **Arson**, **Robbery**, and **Forced Work Stoppage**. Documents are often labeled with more than one template and type. Many include multiple events at different times in different locations. The corpus is particularly challenging because template schemas are inter-mixed and entities can play multiple roles across instances.

The training corpus contains 1300 documents, 733 of which are labeled with at least one schema. 567 documents are not labeled with any schemas. These unlabeled documents are articles that report on non-specific political events and speeches. They make the corpus particularly challenging. The development and test sets each contain 200 documents.

4 A Generative Model for Event Schemas

This paper's model is an entity-based approach, similar in motivation to Haghighi and Klein (2010) and the pipelined induction of Chambers and Jurafsky (2011). Coreference resolution guides the learning by providing a set of pre-resolved entities. Each entity receives a schema role label, so it allows *all mentions* of the entity to inform that role choice. This important constraint links coreferring mentions to the same schema role, and distinguishes our approach from others (Cheung et al., 2013).

4.1 Illustration

The model represents a document as a set of entities. An entity is a set of entity mentions clustered by coreference resolution. We will use the following two sentences for illustration:

> *A truck bomb exploded near the embassy.*
> *Three militia planted it, and then they fled.*

This text contains five entity mentions. A perfect coreference resolution system will resolve these five mentions into three entities:

Entity Mentions	**Entities**	**Roles**
a truck bomb	(a truck bomb, it)	Instrument
the embassy	(the embassy)	Target
three militia	(three militia, they)	Perpetrator
it		
they		

The schema roles, or template *slots*, are the type of target knowledge we want to learn. Each entity will be labeled with both a slot variable s and a template variable t (e.g., the *s=perpetrator* of a *t=bombing*). The lexical context of the entity mentions guides the learning model to this end.

4.2 Definitions

A document $d \in D$ is represented as a set of entities E_d. Each entity $e \in E_d$ is a triple: $e = (h, M, F)$

1. h_e is the canonical word for the entity (typically the first mention's head word)

Text

A truck bomb exploded near the embassy.
Three militia planted it, and then they fled.

Entity Representation

entity 1: h = *bomb*, F = {PHYS-OBJ},
M = { (p=explode, d=subject-explode)
(p=plant, d=object-plant) }
entity 2: h = *militia*, F = {PERSON, ORG},
M = { (p=plant, d=subject-plant),
(p=flee, subject-flee) }
entity 3: h = *embassy*, F = {PHYS-OBJ, ORG},
M = { (p=explode, d=prep_near-explode) }

Figure 2: Example text mapped to our entities.

2. M_e is a set of entity mentions $m \in M_e$. Each mention is a pair $m = (p, d)$: the predicate, and the typed dependency from the predicate to the mention (e.g., *push* and *subject-push*).

3. F_e is a set of binary entity features. This paper only uses named entity types as features, but generalizes to other features as well.

A document is thus reduced to its entities, their grammatical contexts, and entity features. Figure 2 continues our example using this formulation. h_e is chosen to be e's longest non-pronoun mention $m \in M_e$. Mentions are labeled with NER and WordNet synsets to create an entity's features $F_e \subseteq \{$*Person, Org, Loc, Event, Time, Object, Other*$\}$. We use the Stanford NLP toolkit to parse, extract typed dependencies, label with NER, and run coreference.

4.3 The Generative Models

Similar to topics in LDA, each document d in our model has a corresponding multinomial over *schema types* θ_d, drawn from a Dirichlet. For each entity in the document, a hidden variable t is drawn according to θ_d. These t variables represent the high level schema types, such as *bombing* or *kidnapping*. The predicates associated with each of the entity's mentions are then drawn from the schema's multinomial over predicates P_t. The variable t also generates a hidden variable s from its distribution over slots, such as *perpetrator* and *victim*. Finally, the entity's canonical head word is generated from β_s, all entity mentions' typed dependencies from δ_s, and named entity types from γ_s.

The most important characteristic of this model is the separation of event words from the lexical properties of specific entity mentions. The schema type variables t only model the distribution of event words (bomb, plant, defuse), but the slot variables s model the syntax (subject-bomb, subject-plant, object-arrest) and entity words (suspect, terrorist, man). This allows the high-level schemas to first select predicates, and then forces predicate arguments to prefer slots that are in the parent schema type.

Formally, a document d receives a labeling Z_d where each entity $e \in E_d$ is labeled $Z_{d,e} = (t, s)$ with a schema type t and a slot s. The joint distribution of a document and labeling is then as follows:

$$
\begin{aligned}
P(d, Z_d) = & \prod_{e \in E_d} P(t|\theta) \times P(s|t) \\
& \times \prod_{e \in E_d} P(h_e|s) \\
& \times \prod_{e \in E_d} \prod_{f \in F_e} P(f|s) \\
& \times \prod_{e \in E_d} \prod_{m \in M_e} P(d_m|s) * P(p_m|t) \qquad (1)
\end{aligned}
$$

The plate diagram for the model is given in Figure 3. The darker circles correspond to the observed entity components in Figure 2. We assume the following generative process for a document d:

Generate θ_d from Dir(α)
for each schema type $t = 1...m$ **do**
  Generate P_t from Dir(η)
  for each slot $s_t = 1...k$ **do**
    Generate β_s from Dir(μ)
    Generate γ_s from Dir(ν)
    Generate δ_s from Dir(φ)
for each entity $e \in E_d$ **do**
  Generate schema type t from Multinomial(θ_d)
  Generate slot s from UniformDist(k)
  Generate head word h from Multinomial(β_s)
  for each mention $m \in M_e$ **do**
    Generate predicate token p from Multinomial(P_t)
    Generate typed dependency d from Multinomial(δ_s)
  for each entity type $i = 1..|F_e|$ **do**
    Generate entity type f from Multinomial(γ_s)

The number of schema types m and the number of slots per schema k are chosen based on training set performance.

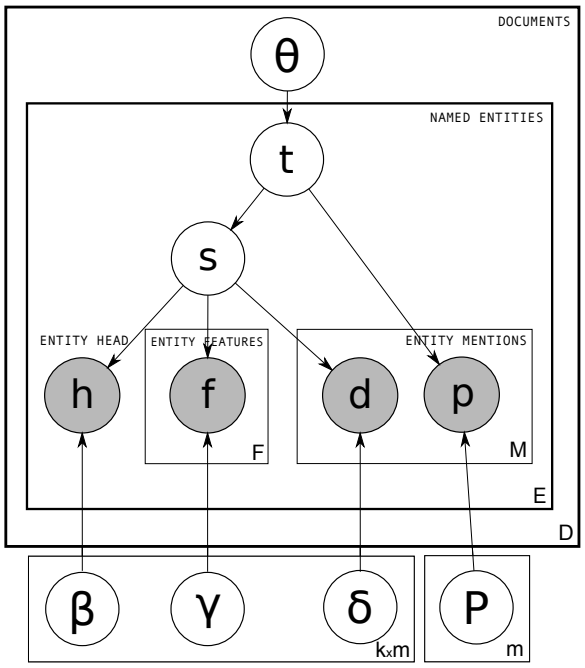

Figure 3: The full plate diagram for the event schema model. Hyper-parameters are omitted for readability.

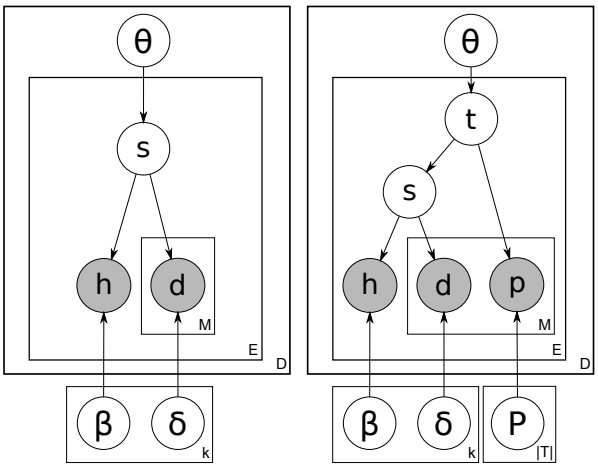

Figure 4: Simplified plate diagrams comparing the flat relation model to the full template model. The observed $f \in F$ variables are not included for clarity.

The Flat Relation Model

We also experiment with a *Flat Relation Model* that removes the hidden t variables, ignoring schema types. Figure 4 visually compares this flat model with the full model. We found that the predicate distribution P_t hurts performance in a flat model. Predicates are more informative at the higher level, but less so for slots where syntax is more important. We thus removed P_t from the model, and everything else remains the same. This flat model now learns a large set of k slots S that aren't connected by a high-level schema variable. Each slot $s \in S$ has a corresponding triple of multinomials (h, M, F) similar to above: (1) a multinomial over the head mentions β_s, (2) a multinomial over the grammatical relations of the entity mentions δ_s, and (3) a multinomial over the entity features γ_s. For each entity in a document, a hidden slot $s \in S$ is first drawn from Θ, and then the observed entity (h, M, F) is drawn according to the multinomials $(\beta_s, \gamma_s, \delta_s)$. We later evaluate this flat model to show the benefit of added schema structure.

4.4 Inference

We use collapsed Gibbs sampling for inference, sampling the latent variables $t_{e,d}$ and $s_{e,d}$ in sequence conditioned on a full setting of all the other variables (Griffiths and Steyvers, 2004). Initial parameter values are set by randomly setting t and s variables from the uniform distribution over schema types and slots, then computing the other parameter values based on these initial settings. The hyperparameters for the dirichlet distributions were chosen from a small grid search (see Experiments).

Beyond standard inference, we added one constraint to the model that favors grammatical distributions δ_s that do not contain conflicts. The subject and direct object of a verb should not both receive high probability mass under the same schema slot δ_s. For instance, the *victim* of a *kidnapping* should not favor both the subject and object of a single verb. Semantic roles should (typically) select one syntactic slot, so this constraint encourages that behavior. During sampling of $s_{e,d}$, we use a penalty factor λ to make conflicting relations less likely. Formally, $P(s_{e,d} = s|\theta, h_e, F_e, M_e) = \lambda$ iff there exists an $m \in M_e$ such that $P(m|\sigma_s) < P(inv(m)|\sigma_s)$ and $P(inv(m)|\sigma_s) > 0.1$, where $inv(m) = object$ if $m = subject$ and vice versa. Otherwise, the probability is computed as normal. We normalize the distributions after penalties are computed.

4.5 Entity Extraction for Template Filling

Inducing event schemas is only one benefit of the model. The learned model can also extract specific instances of the learned schemas without ad-

ditional complexity. To evaluate the effectiveness of the model, we apply the model to perform standard template extraction on MUC-4. Previous MUC-4 induction required an extraction algorithm separate from induction because induction created hard clusters (Chambers and Jurafsky, 2011). Cluster scores don't have a natural interpretation, so extraction required several parameters/thresholds to tune. Our model instead simply relies on model inference.

We run inference as described above and each entity receives a template label $t_{e,d}$ and a template slot label $s_{e,d}$. These labels are the extractions, and it requires no other parameters. The model thus requires far less machinery than a pipeline, and the experiments below further show that this simpler model outperforms the pipeline.

Beyond parameters, the question of "irrelevant" documents is a concern in MUC-4. Approximately half the corpus are documents that are not labeled with a template, so past algorithms required extra processing stages to filter out these irrelevant documents. Patwardhan and Riloff (2009) and Chambers and Jurafsky (2011) make initial decisions as to whether they should extract or not from a document. Huang and Riloff (2011) use a genre detector for this problem. Even the generative HMM-based model of Cheung et al. (Cheung et al., 2013) requires an extra filtering parameter. Our formal model is unique in not requiring additional effort. Ours is the only approach that doesn't require document filtering.

5 Evaluation Setup

Evaluating on MUC-4 has a diverse history that complicates comparison. The following balances comparison against previous work and enables future comparison to our results.

5.1 Template Schema Slots

Most systems do not evaluate performance on all MUC-4 template slots. They instead focus on four main slots, ignoring the parameterized slots that involve deeper reasoning (such as 'stage of execution' and 'effect of incident'). The four slots and example entity fillers are shown here:

Perpetrator:	Shining Path members
Victim:	Sergio Horna
Target:	public facilities
Instrument:	explosives

We also focus only on these four slots. We merged MUC's two perpetrator slots (individuals and orgs) into one gold Perpetrator. Previous work has both split the two and merged the two. We merge them because the distinction between an individual and an organization is often subtle and not practically important to analysts. This is also consistent with the most recent event schema induction in Chambers and Jurafsky (2011) and Cheung et al. (2013).

One peculiarity in MUC-4 is that some templates are labeled as optional (i.e., all its slots are optional), and some required templates contain optional slots (i.e., a subset of slots are optional). We ignore both optional templates and specific optional slots *when computing recall*, as in previous work (Patwardhan and Riloff, 2007; Patwardhan and Riloff, 2009; Chambers and Jurafsky, 2011).

Comparison between the extracted strings and the gold template strings uses head word scoring. We do not use gold parses for the text, so head words are defined simply as the rightmost word in the noun phrase. The exception is when the extracted phrase is of the form "A of B", then the rightmost word in "A" is used as the head. This is again consistent with previous work[1]. The standard evaluation metrics are precision, recall, and F1 score.

5.2 Mapping Learned Slots

Induced schemas need to map to gold schemas before evaluation. Which learned slots correspond to MUC-4 slots? There are two methods of mapping. The first ignores the schema type variables t, and simply finds the best performing s variable for each gold template slot[2]. We call this the *slot-only mapping* evaluation. The second approach is to map each template variable t to the best gold template type g, and limit the slot mapping so that only the slots under t can map to slots under g. We call this the *template mapping* evaluation. The slot-only mapping can result in higher scores since it is not constrained to preserve schema structure in the mapping.

Chambers and Jurafsky (2011) used template mapping in their evaluation. Cheung et al. (2013) used slot-only mapping. We run both evaluations in this paper and separately compare both.

[1] Personal communications with Patwardhan and Riloff

[2] bombing-victim is a template slot distinct from kidnap-victim. Both need to be mapped.

6 Experiments

We use the Stanford CoreNLP toolkit for text processing and parsing. We developed the models on the 1300 document MUC-4 training set. We then learned once on the entire 1700 training/dev/test set, and report extraction numbers from the inferred labels on the 200 document test set. Each experiment was repeated 10 times. Reported numbers are averaged across these runs.

There are two structure variables for the model: the number of schema types and the number of slots under each type. We searched for the optimal values on the training set before evaluating on test. The hyperparameters for all evaluations were set to $\alpha = \eta = \mu = \nu = 1$, $\varphi = .1$ based on a grid search.

6.1 Template Schema Induction

The first evaluation compares the learned schemas to the gold schemas in MUC-4.

Since most previous work assumes this knowledge ahead of time, we align our schemas with the main MUC-4 template types to measure quality. We inspected the learned event schemas that mapped to MUC-4 schemas based on the *template mapping* extraction evaluation.

Figure 5 shows some of the learned distributions for two mapped schemas: kidnappings and bombings. The predicate distribution for each event schema is shown, as well as the top 5 head words and grammatical relations for each slot. The words and events that were jointly learned in these examples appear quite accurate. The bombing and kidnap schemas learned all of the equivalent MUC-4 gold slots. Interestingly, our model also learned Locations and Times as important entities that appear in the text. These entities are not traditionally included in the MUC-4 extraction task.

Figure 6 lists the MUC-4 slots that we did and did not learn for the four most prevelant types. We report 71% recall, with almost all errors due to the model's failure to learn about arsons. Arson templates only occur in 40 articles, much less than the 200 bombing and over 400 attack. We show below that overall extraction performs well despite this. The learned distributions for Attack end up extracting Arson perpetrators and Arson victims in the actual extraction evaluation.

	Bomb	Kidnap	Attack	Arson
Perpetrator	✓	✓	✓	x
Victim	✓	✓	✓	✓
Target	✓	-	✓	x
Instrument	✓	-	x	x
Location	✓	✓	✓	✓
Date/Time	✓	✓	✓	x

Figure 6: The MUC-4 gold slots that were learned. The bottom two are not in the traditional evaluation, but were learned by our model nonetheless.

Evaluation: Template Mapping

	Prec	Recall	F1
C & J 2011	**.48**	.25	.33
Formal Template Model	.42	**.27**	.33

Table 1: MUC-4 extraction with template mapping. A learned schema first maps to a gold MUC template. Learned slots can then only map to slots in that template.

6.2 Extraction Experiments

We now present the full extraction experiment that is traditionally used for evaluating MUC-4 performance. Although our learned schemas closely match gold schemas, extraction depends on how well the model can extract from diverse lexical contexts. We ran inference on the full training and test sets, and used the inferred labels as schema labels. These labels were mapped and evaluated against the gold MUC-4 labels as discussed in Section 5.

Performance is compared to two state-of-the-art induction systems. Since these previous two models used different methods to map their learned schemas, we compare separately. Table 1 shows the *template mapping* evaluation with Chambers and Jurafsky (C&J). Table 2 shows the *slot-only mapping* evaluation with Cheung et al.

Our model achieves an F1 score comparable to C&J, and 20% higher than Cheung et al. Part of the greater increase over Cheung et al. is the mapping difference. For each MUC-4 type, such as *bombing*, any four learned slots can map to the four MUC-4 bombing slots. There is no constraint that the learned slots must come from the same schema type. The more strict *template mapping* (Table 1) ensures that entire schema types are mapped together, and it reduces our performance from .41 to .33.

Kidnapping Entities

Victim (Person 88%)		**Perpetrator** (Person 62%, Org 30%)		**Date** (TimeDate 89%)	
businessman	object-kidnap	guerrilla	subject-kidnap	TIME	tmod-kidnap
citizen	object-release	ELN	subject-hold	February	prep_on-kidnap
Soares	prep_of-kidnapping	group	subject-attack	hours	tmod-release
Kent	possessive-release	extraditables	subject-demand	morning	prep_on-release
hostage	object-found	man	subject-announce	night	tmod-take

Bombing Entities

Victim (Person 86%, Location 8%)		**Physical Target** (Object 65%, Event 42%)		**Instrument** (Event 56%, Object 39%)	
person	object-kill	building	object-destroy	bomb	subject-explode
guerrilla	object-wound	office	object-damage	explosion	subject-occur
soldier	subject-die	explosive	object-use	attack	object-cause
man	subject-blow_up	station	and-office	charge	object-place
civilian	subject-try	vehicle	prep_of-number	device	subject-destroy

Evaluation: Slot-Only Mapping

	Prec	Recall	F1
Cheung et al. 2013	.32	.37	.34
Flat Relation Model	.26	**.45**	.33
Formal Template Model	**.41**	.41	**.41**

Table 2: MUC-4 extraction with slot-only mapping. Any learned slot is allowed to map to any gold slot.

Entity Role Performance

	Prec	Recall	F1
Perpetrator	.40	.20	.26
Victim	.42	.31	.34
Target	.38	.28	.31
Instrument	.57	.39	.45

Table 3: Results for each MUC-4 template slot using the template-mapping evaluation.

The macro-level F1 scores can be broken down into individual slot performance. Table 3 shows these results ranging from .26 to .45. The Instrument role proves easiest to learn, consistent with C&J.

A large portion of MUC-4 includes irrelevant documents. Cheung et al. (2013) evaluated their model without irrelevant documents in the test set that to see how performance is affected. We compare against their numbers in Table 4. Results are closer now with ours outperforming .46 to .43 F1. This suggests that the HMM-based approach stumbles more on spurious documents, but performs better on relevant ones.

Gold Document Evaluation

	Prec	Recall	F1
Cheung et al. 2013	.41	**.44**	.43
Formal Template Model	**.49**	.43	**.46**

Table 4: Full MUC-4 extraction with *gold document classification*. These results ignore false positives extracted from "irrelevant" documents in the test set.

6.3 Model Ablation

Table 2 shows that the flat relation model (no latent type variables t) is inferior to the full schema model. F1 drops 20% without the explicit modeling of both schema types t and their entity slots s. The entity features F_e are less important. Experiments without them show a slight drop in performance (2 F1 points), small enough that they could be removed for efficiency. However, it is extremely useful to learn slots with NER labels like Person or Location.

Finally, we experimented without the subject/object constraint (Section 4.4). Performance drops 5-10% depending on the number of schemas learned. Anecdotally, it merges too many schema slots that should be separate. We recommend using this constraint as it has little impact on CPU time.

6.4 Extension: Reduce Training Size

One of the main benefits of this generative model appears to be the reduction in training data. The pipelined approach in C&J required an information retrieval stage to bring in hundreds of other docu-

ments from an external corpus. This paper's generative model doesn't require such a stage.

We thus attempted to induce and extract event schemas from just the 200 test set documents, with no training or development data. We repeated this experiment 30 times and averaged the results, setting the number of templates $t = 20$ and slots $s = 10$ as in the main experiment. The resulting F1 score for the template-mapping evaluation fell to 0.27 from the full data experiment of 0.33 F1. Adding more training documents in another experiment did not significantly increase performance over 0.27 until all training and development documents were included. This could be explained by the development set being more similar to the test set than training. We did not investigate further to prevent over-experimentation on test.

7 Discussion

Our model is one of the first generative formulations of schema induction. It produces state-of-the-art performance on a traditional extraction task, and performs with less training data as well as a more complex pipelined approach. Further, our unique entity-driven approach outperforms an HMM-based model developed in parallel to this work.

Our entity-driven proposal is strongly influenced by the ideas in the pipeline model of Chambers and Jurafsky (2011). Coreference chains have been used in a variety of learning tasks, such as narrative learning and summarization. Here we are the first to show how it can be used for schema induction in a probabilistic model, connecting predicates across a document in a way that is otherwise difficult to represent. The models perform similarly, but ours also includes significant benefits like a reduction in complexity, reproducibility, and a large reduction in training data requirements.

This paper also implies that learning and extraction need not be independent algorithms. Our model's inference procedure to learn schemas is the same one that labels text for extraction. C&J required 3-4 separate pipelined steps. Cheung et al. (2013) required specific cutoffs for document classification before extraction. Not only does our model perform well, but it does so without these steps.

Highlighted here are key differences between this proposal and the HMM-based model of Cheung et al. (2013). One of the HMM strengths is the inclusion of sequence-based knowledge. Each slot label is influenced by the previous label in the text, encouraging syntactic arguments of a predicate to choose the same schema. This knowledge is only loosely present in our document distribution θ. Cheung et al. also include a hidden event variable between the template and slot variables. Our model collapses this event variable and makes fewer dependency assumptions. This difference requires further investigation as it is unclear if it provides valuable information, or too much complexity.

We also note a warning for future work on proper evaluation methodology. This task is particularly difficult to compare to other models due to its combination of both induction and then extraction. There are many ways to map induced schemas to gold answers, and this paper illustrates how extraction performance is significantly affected by the choice. We suggest the template-mapping evaluation to preserve learned structure.

Finally, these induced results are far behind supervised learning (Huang and Riloff, 2011). There is ample room for improvement and future research in event schema induction.

Using Soft Constraints in Joint Inference for Clinical Concept Recognition

Abstract

This paper introduces IQPs (Integer Quadratic Programs) as a way to model joint inference for the task of concept recognition in clinical domain. IQPs make it possible to easily incorporate soft constraints in the optimization framework and still support exact global inference. We show that soft constraints give statistically significant performance improvements when compared to hard constraints.

1 Introduction

In this paper, we study the problem of concept recognition in the clinical domain. State-of-the-art approaches (de Bruijn et al., 2011; Patrick et al., 2011; Torii et al., 2011; Minard et al., 2011; Jiang et al., 2011; Xu et al., 2012; Roberts and Harabagiu, 2011; Jindal and Roth, 2013) for concept recognition in clinical domain (Uzuner et al., 2011) use sequence-prediction models like CRF (Lafferty et al., 2001), MEMM (McCallum et al., 2000) etc. These approaches are limited by the fact that they can model only local dependencies (most often, first-order models like linear chain CRFs are used to allow tractable inference).

Clinical narratives, unlike newswire data, provide a domain with significant knowledge that can be exploited systematically to improve the accuracy of the prediction task. Knowledge in this domain can be thought of as belonging to two categories: (1) *Background Knowledge* captured in medical ontologies like UMLS (Url1, 2013), MeSH and SNOMED CT and (2) *Discourse Knowledge* driven by the fact that the narratives adhere to a specific writing style. While the former can be used by generating more expressive knowledge-rich features, the latter is more interesting from our current perspective, since it provides global constraints on what *output* structures are likely and what are not. We exploit this structural knowledge in our global inference formulation.

Integer Linear Programming (ILP) based approaches have been used for global inference in many works (Roth and Yih, 2004; Punyakanok et al., 2004; Punyakanok et al., 2008; Marciniak and Strube, 2005; Bramsen et al., 2006; Barzilay and Lapata, 2006; Riedel and Clarke, 2006; Clarke and Lapata, 2007; Clarke and Lapata, 2008; Denis et al., 2007; Chang et al., 2011). However, in most of these works, researchers have focussed only on hard constraints while formulating the inference problem.

Formulating all the constraints as hard constraints is not always desirable because the constraints are not perfect in many cases. In this paper, we propose Integer Quadratic Programs (IQPs) as a way of formulating the inference problem. IQPs is a richer family of models than ILPs and it enables us to easily incorporate soft constraints into the inference procedure. Our experimental results show that soft constraints indeed give much better performance than hard constraints.

2 Identifying Medical Concepts

Task Description Our input consists of clinical reports in free-text (unstructured) format. The task is: (1) to identify the boundaries of medical concepts and (2) to assign types to such concepts. Each concept can have 3 possible types: (1) Test, (2) Treatment, and (3) Problem. We would refer to these three types by `TEST`, `TRE` and `PROB` in the following discussion.

Our Approach In the first step, we identify the concept boundaries using a CRF (with BIO encod-

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1808–1814,
Seattle, Washington, USA, 18-21 October 2013.

(a) Example 1

(b) Example 2

Figure 1: This figure motivates the global inference procedure we used. For discussion, please refer to §2.

ing). Features used by the CRF include the constituents given by MetaMap (Aronson and Lang, 2010; Url2, 2013), shallow parse constituents, surface form and part-of-speech (Url3, 2013) of words in a window of size 3. We also use conjunctions of the features.

After finding concept boundaries, we determine the probability distribution for each concept over 4 possible types (`TEST`, `TRE`, `PROB` or `NULL`). These probability distributions are found using a multi-class SVM classifier (Chang and Lin, 2011). Features used for training this classifier include concept tokens, full text of concept, bi-grams, headword, suffixes of headword, capitalization pattern, shallow parse constituent, Metamap type of concept, MetaMap type of headword, occurrence of concept in MeSH (Url4, 2013) and SNOMED CT (Url5, 2013), MeSH and SNOMED CT descriptors.

Inference Procedure: The final assignment of types to concepts is determined by an inference procedure. The basic principle behind our inference procedure is: "*Types of concepts which appear close to one another are often closely related. For some concepts, type can be determined with more confidence. And relations between concepts' types guide the inference procedure to determine the types of other concepts.*" We will now explain it in more detail with the help of examples. Figure 1 shows two sentences in which the concepts are shown in brackets and correct (gold) types of concepts are shown above them.

First, consider first and second concepts in Figure 1a. These concepts follow the pattern: *[Concept1] gave positive evidence for [Concept2].* In clinical narratives, such a pattern strongly suggests that *Concept1* is of type `TEST` and *Concept2* is of type `PROB`. Table 1 shows additional such patterns. Next, consider different concepts in Figure 1b. All these concepts are separated by commas and hence, form a list. It is highly likely that such concepts should have the same type.

	Pattern
1	using [TRE] for [PROB]
2	[TEST] showed [PROB]
3	Patient presents with [PROB] status post [TRE]
4	use [TRE] to correct [PROB]
5	[TEST] to rule out [PROB]
6	Unfortunately, [TRE] has caused [PROB]

Table 1: Some patterns that were used in constraints.

3 Modeling Global Inference

Inference is done at the level of sentences. Suppose there are m concepts in a sentence. Each of the m concepts has to be assigned one of the following types: `TEST`, `TRE`, `PROB` or `NULL`. To represent this as an inference problem, we define the indicator variables $x_{i,j}$ where i takes values from 1 to m (corresponding to concepts) and j takes values from 1 to 4 (corresponding to 4 possible types). $p_{i,j}$ refers to the probability that the i^{th} concept has type j.

We can now write the following optimization problem to find the optimal concept types:

$$\max_{x} \sum_{i=1}^{m} \sum_{j=1}^{4} x_{i,j} \cdot p_{i,j} \tag{1}$$

$$\text{subject to } \sum_{j=1}^{4} x_{i,j} = 1 \qquad \forall i \tag{2}$$

$$x_{i,j} \in \{0, 1\} \qquad \forall i, j \tag{3}$$

The objective function in Equation (1) expresses the fact that we want to maximize the expected number of correct predictions in each sentence. Equation (2) enforces the constraint that each concept has

a unique type. We would refer to these as **Type-1** constraints.

3.1 Constraints Used

In this subsection, we will describe two additional types of constraints (**Type-2** and **Type-3**) that were added to the optimization procedure described above. Whereas **Type-1** constraints described above were formulated as *hard constraints*, **Type-2** and **Type-3** constraints are formulated as *soft constraints*.

3.1.1 Type-2 Constraints

Certain constructs like comma, conjunction, etc. suggest that the 2 concepts appearing in them should have the same type. Figure 1b shows an example of such a constraint. Suppose that there are n_2 such constraints. Also, assume that the l^{th} constraint says that the concepts $\mathcal{R}_l$ and $\mathcal{S}_l$ should have the same type. To model this, we define a variable w_l as follows:

$$w_l = \sum_{m=1}^{4} (x_{\mathcal{R}_l,m} - x_{\mathcal{S}_l,m})^2 \tag{4}$$

Now, if the concepts $\mathcal{R}_l$ and $\mathcal{S}_l$ have the same type, then w_l would be equal to 0; otherwise, w_l would be equal to 2. So, the l^{th} constraint can be enforced by subtracting $(\rho_2 \cdot \frac{w_l}{2})$ from the objective function given by Equation (1). Thus, a penalty of ρ_2 would be enforced iff this constraint is violated.

3.1.2 Type-3 Constraints

Some short patterns suggest possible types for the concepts which appear in them. Each such pattern, thus, enforces a constraint on the types of corresponding concepts. Figure 1a shows an example of such a constraint. Suppose that there are n_3 such constraints. Also, assume that the k^{th} constraint says that the concept $\mathcal{A}_{1,k}$ should have the type $\mathcal{B}_{1,k}$ and that the concept $\mathcal{A}_{2,k}$ should have the type $\mathcal{B}_{2,k}$. Equivalently, the k^{th} constraint can be written as follows in boolean algebra notation: $(x_{\mathcal{A}_{1,k},\mathcal{B}_{1,k}} = 1) \wedge (x_{\mathcal{A}_{2,k},\mathcal{B}_{2,k}} = 1)$. For the k^{th} constraint, we introduce one more variable $z_k \in \{0, 1\}$ which satisfies the following condition:

$$z_k = 1 \Leftrightarrow x_{\mathcal{A}_{1,k},\mathcal{B}_{1,k}} \wedge x_{\mathcal{A}_{2,k},\mathcal{B}_{2,k}} \tag{5}$$

Using boolean algebra, it is easy to show that Equation (5) can be reduced to a set of linear inequalities. Thus, we can incorporate the k^{th} constraint in the optimization problem by adding to it the constraint given by Equation (5) and by subtracting $(\rho_3(1 - z_k))$ from the objective function given by Equation (1). Thus, a penalty of ρ_3 is imposed iff k^{th} constraint is not satisfied ($z_k = 0$).

$$\max_x \sum_{i=1}^{m}\sum_{j=1}^{4} x_{i,j} \cdot p_{i,j} - \sum_{k=1}^{n_3} \rho_3(1 - z_k) - \sum_{l=1}^{n_2} \left(\rho_2 \cdot \frac{\sum_{m=1}^{4} (x_{\mathcal{R}_l,m} - x_{\mathcal{S}_l,m})^2}{2} \right) \tag{6}$$

$$\text{subject to } \sum_{j=1}^{4} x_{i,j} = 1 \qquad \forall i \tag{7}$$

$$x_{i,j} \in \{0, 1\} \qquad \forall i, j \tag{8}$$

$$z_k = 1 \Leftrightarrow x_{\mathcal{A}_{1,k},\mathcal{B}_{1,k}} \wedge x_{\mathcal{A}_{2,k},\mathcal{B}_{2,k}} \forall k \in \{1...n_3\} \tag{9}$$

Figure 2: Final Optimization Problem (an IQP)

3.2 Final Optimization Problem - An IQP

After incorporating all the constraints mentioned above, the final optimization problem (an IQP) is shown in Figure 2. We used Gurobi toolkit (Url6, 2013) to solve such IQPs. In our case, it solves 76 IQPs per second on a quad-core server with Intel Xeon X5650 @ 2.67 GHz processors and 50 GB RAM.

4 Experiments and Results

4.1 Datasets and Evaluation Metrics

For our experiments, we used the datasets provided by i2b2/VA team as part of 2010 i2b2/VA shared task (Uzuner et al., 2011). The datasets used for this shared task contained de-identied clinical reports from three medical institutions: Partners Healthcare (`PH`), Beth-Israel Deaconess Medical Center (`BIDMC`) and the University of Pittsburgh Medical Center (UPMC). UPMC data was divided into 2 sections, namely discharge (`UPMCD`) and progress notes (`UPMCP`). A total of 349 training reports and 477 test reports were made available to the participants. However, data which came from UPMC (more than 50% data) was not made available for public use. As a result, we had only 170 clinical reports for training and 256 clinical reports for testing. Table 3 shows the number of clinical reports made available by different institutions. The

	B			BK			BC			BKC

Test	133	123	~~102~~	~~119~~

Table 3: Dataset Characteristics

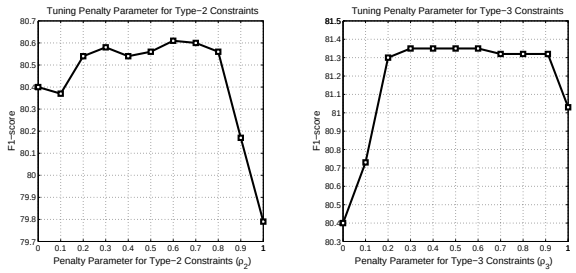
strikethrough text in this table indicates that the data was not made available for public use and hence, we couldn't use it. We used about 20% of the training data as a development set. For evaluation, we report precision, recall and F1 scores.

4.2 Results

In this section, we would refer to following 4 systems: (1) *Baseline* **(B)**, (2) *Baseline + Knowledge* **(BK)**, (3) *Baseline + Constraints* **(BC)** and (4) *Baseline + Knowledge + Constraints* **(BKC)**. Please note that the difference between **B** and **BK** is that **B** does not use the features derived from domain-specific knowledge sources (namely MetaMap, UMLS, MeSH and SNOMED CT) for training the classifiers. Both **B** and **BK** do not use the inference procedure. **BKC** uses all the features and also the inference procedure. In addition to these 4 systems, we would refer to another system, namely, **BKC-HARD**. This is similar to **BKC** system. However, it sets $\rho_2 = \rho_3 = 1$ which effectively turns **Type-2** and **Type-3** constraints into hard constraints by imposing very high penalty.

4.2.1 Importance of Soft Constraints

Figures 3a and 3b show the effect of varying the penalties (ρ_2 and ρ_3) for **Type-2** and **Type-3** constraints respectively. These figures show the F1-score of **BKC** on the development set. Penalty of 0 means that the constraint is not active. As we increase the penalty, the constraint becomes stronger. As the penalty becomes 1, the constraint becomes hard in the sense that final assignments must respect



(a) Type-2 Constraints **(b)** Type-3 Constraints

Figure 3: These figures show the result of tuning the penalty parameters (ρ_2 and ρ_3) for soft constraints.

	BKC-HARD	**BKC**
TEST	84.7	**85.8**
TRE	84.7	**85.7**
PROB	85.6	**86.7**
OVERALL	85.1	**86.1**

Table 4: Soft constraints **(BKC)** consistently perform much better than hard constraints **(BKC-HARD)**.

the constraint. We observe from Figures 3a and 3b that for **Type-2** and **Type-3** constraints, global maxima is attained at $\rho_2 = 0.6$ and $\rho_3 = 0.3$ respectively.

Hard vs Soft Constraints Table 4 compares the performance of **BKC-HARD** with that of **BKC**. First 3 rows in this table show the performance of both systems for the individual categories (TEST, TRE and PROB). The fourth row shows the overall score of both systems. **BKC** outperformed **BKC-HARD** on all the categories by statistically significant differences at $p = 0.05$ according to Bootstrap Resampling Test (Koehn, 2004). For the OVERALL category, **BKC** improved over **BKC-HARD** by 1.0 F1 points.

Figure 4: This figure shows the effect of training data size on performance of concept recognition.

4.2.2 Comparing with state-of-the-art baseline

In the 2010 i2b2/VA shared task, majority of top systems were CRF-based models, motivating the use of CRF as our baseline. Table 2 compares the performance of 4 systems: **B**, **BK**, **BC** and **BKC**. As pointed out before, our **BK** system uses CRF for boundary detection, employs all the knowledge-based features and is very similar to the top-performing systems in i2b2 challenge. We see from Table 2 that **BKC** consistently performed the best for individual as well as overall categories[1]. This result is statistically significant at $p = 0.05$ according to Bootstrap Resampling Test (Koehn, 2004). It should also be noted that **BC** performed significantly better than **B** for all the categories. Thus, the constraints are helpful even in the absence of knowledge-based features. Since we report results on publicly available datasets, future works would be able to compare their results with ours.

4.2.3 Effect of training data size

In Figure 4, we report the overall F1-score on a part of the development set as we vary the size of the training data from 40 documents to 130 documents. We notice that the performance increases steadily as more and more training data is provided. This suggests that if we could train on full training data as was made available in the challenge, the final scores could be much higher. We also notice from the figure that **BKC** consistently outperforms the state-of-the-art **BK** system as we vary the size of the training data, indicating the robustness of the joint inference procedure.

[1]Please note that the results reported in Table 2 can not be directly compared with those reported in the challenge because we only had a fraction of the original training and testing data.

5 Discussion and Related Work

In this paper, we chose to train a rather simple sequential model (using CRF), and focused on incorporating global constraints only at inference time[2]. While it is possible to jointly train the model with the global constraints (as illustrated by Chang et al. (2007), Mann and McCallum (2007), Mann and McCallum (2008), Ganchev et al. (2010) etc.), this process will be a lot less efficient, and prior work (Roth and Yih, 2005) has shown that it may not be beneficial.

Roth and Yih (2004, 2007) suggested the use of integer programs to model joint inference in a fully supervised setting. Our paper follows their conceptual approach. However, they used only hard constraints in their inference formulation. Chang et al. (2012) extended the ILP formulation and used soft constraints within the Constrained Conditional Model formulation (Chang, 2011). However, their implementation performed only approximate inference. In this paper, we extended the integer linear programming to a quadratic formulation, arguing that it simplifies the modeling step[3], and showed that it is possible to do exact inference efficiently.

Conclusion

This paper presented a global inference strategy (using IQP) for concept recognition which allows us to model structural knowledge of the clinical domain as soft constraints in the optimization framework. Our results showed that soft constraints are more effective than hard constraints.

[2]In another experiment, we replaced the CRF with an MEMM. Surprisingly, MEMM performed as well as CRF.

[3]It should be noted that it is possible to reduce IQPs to ILPs using variable substitution. However, the resulting ILPs can be exponentially larger than original IQPs.

Abstract

Different demographics, e.g., gender or age, can demonstrate substantial variation in their language use, particularly in informal contexts such as social media. In this paper we focus on learning gender differences in the use of subjective language in English, Spanish, and Russian Twitter data, and explore cross-cultural differences in emoticon and hashtag use for male and female users. We show that gender differences in subjective language can effectively be used to improve sentiment analysis, and in particular, polarity classification for Spanish and Russian. Our results show statistically significant relative F-measure improvement over the gender-independent baseline 1.5% and 1% for Russian, 2% and 0.5% for Spanish, and 2.5% and 5% for English for polarity and subjectivity classification.

1 Introduction

Sociolinguistics and dialectology have been studying the relationships between language and speech at the phonological, lexical and morphosyntactic levels and social identity for decades (Picard, 1997; Gefen and Ridings, 2005; Holmes and Meyerhoff, 2004; Macaulay, 2006; Tagliamonte, 2006). Recent studies have focused on exploring demographic language variations in personal email communication, blog posts, and public discussions (Boneva et al., 2001; Mohammad and Yang, 2011; Eisenstein et al., 2010; O'Connor et al., 2010; Bamman et al., 2012). However, one area that remains largely unexplored is the effect of demographic language variation on subjective language use, and whether these differences may be exploited for automatic sentiment analysis. With the growing commercial importance of applications such as personalized recommender systems and targeted advertising (Fan and Chang, 2009), detecting helpful product review (Ott et al., 2011), tracking sentiment in real time (Resnik, 2013), and large-scale, low-cost, passive polling (O'Connor et al., 2010), we believe that sentiment analysis guided by user demographics is a very important direction for research.

In this paper, we focus on gender demographics and language in social media to investigate differences in the language used to express opinions in Twitter for three languages: English, Spanish, and Russian. We focus on Twitter data because of its volume, dynamic nature, and diverse population worldwide.[1] We find that some words are more or less likely to be positive or negative in context depending on the the gender of the author. For example, the word *weakness* is more likely to be used in a positive way by women (*Chocolate is my weakness!*) but in a negative way by men (*Clearly they know our weakness. Arggggg*). The Russian word достичь (achieve) is used in a positive way by male users and in a negative way by female users.

Our goals of this work are to (1) explore the gender bias in the use of subjective language in social media, and (2) incorporate this bias into models to improve sentiment analysis for English, Spanish, and Russian. Specifically, in this paper we:

- investigate multilingual lexical variations in the use of subjective language, and cross-cultural

[1] As of May 2013, Twitter has 500m users (140m of them in the US) from more than 100 countries.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1815–1827,
Seattle, Washington, USA, 18-21 October 2013.

emoticon and hashtag usage on a large scale in Twitter data;[2]

- show that gender bias in the use of subjective language can be used to improve sentiment analysis for multiple languages in Twitter.
- demonstrate that simple, binary features representing author gender are insufficient; rather, it is the combination of lexical features, together with set-count features representing gender-dependent sentiment terms that is needed for statistically significant improvements.

To the best of our knowledge, this work is the first to show that incorporating gender leads to significant improvements for sentiment analysis, particularly subjectivity and polarity classification, for multiple languages in social media.

2 Related Work

Numerous studies since the early 1970's have investigated gender-language differences in interaction, theme, and grammar among other topics (Schiffman, 2002; Sunderland et al., 2002). More recent research has studied gender differences in telephone speech (Cieri et al., 2004; Godfrey et al., 1992) and emails (Styler, 2011). Mohammad and Yang (2011) analyzed gender differences in the expression of sentiment in love letters, hate mail, and suicide notes, and emotional word usage across genders in email.

There has also been a considerable amount of work in subjectivity and sentiment analysis over the past decade, including, more recently, in microblogs (Barbosa and Feng, 2010; Bermingham and Smeaton, 2010; Pak and Paroubek, 2010; Bifet and Frank, 2010; Davidov et al., 2010; Li et al., 2010; Kouloumpis et al., 2011; Jiang et al., 2011; Agarwal et al., 2011; Wang et al., 2011; Calais Guerra et al., 2011; Tan et al., 2011; Chen et al., 2012; Li et al., 2012). In spite of the surge of research in both sentiment and social media, only a limited amount of work focusing on gender identification has looked at differences in subjective language across genders within social media. Thelwall (2010) found that men and women use emoticons to differing degrees on MySpace, e.g., female users express positive emoticons more than male users. Other researchers included subjective patterns as features for gender classification of Twitter users (Rao et al., 2010). They found that the majority of emotion-bearing features, e.g., emoticons, repeated letters, exasperation, are used more by female than male users, which is consistent with results reported in other recent work (Garera and Yarowsky, 2009; Burger et al., 2011; Goswami et al., 2009; Argamon et al., 2007). Other related work is that of Otterbacher (2010), who studied stylistic differences between male and female reviewers writing product reviews, and Mukherjee and Liu (2010), who applied positive, negative and emotional connotation features for gender classification in microblogs.

Although previous work has investigated gender differences in the use of subjective language, and features of sentiment have been used in gender identification, to the best of our knowledge no one has yet investigated whether gender differences in the use of subjective language can be exploited to improve sentiment classification in English or any other language. In this paper we seek to answer this question for the domain of social media.

3 Data

For the experiments in this paper, we use three sets of data for each language: a large pool of data (800K tweets) labeled for gender but *unlabeled* for sentiment, plus 2K development data and 2K test data labeled for both sentiment and gender. We use the unlabeled data to bootstrap Twitter-specific lexicons and investigate gender differences in the use of subjective language. We use the development data for parameter tuning while bootstrapping, and the test data for sentiment classification.

For English, we download tweets from the corpus created by Burger et al. (2011). This dataset contains 2,958,103 tweets from 184K users, excluding retweets. Retweets are omitted because our focus is on the sentiment of the person tweeting; in retweets, the words originate from a different user. All users in this corpus have gender labels, which Burger et al. automatically extracted from self-reported gender on Facebook or MySpace profiles linked to by the Twitter users. English tweets are identified using a compression-based language identification (LID)

[2]Gender-dependent and independent lexical resources of subjective terms in Twitter for Russian, Spanish and English can be found here: `http://www.cs.jhu.edu/~svitlana/`

tool (Bergsma et al., 2012). According to LID, there are 1,881,620 (63.6%) English tweets from which we select a random, gender-balanced sample of 0.8M tweets. Burger's corpus does not include Russian and Spanish data on the same scale as English. Therefore, for Russian and Spanish we construct a new Twitter corpus by downloading tweets from followers of region-specific news and media Twitter feeds. We use LID to identify Russian and Spanish tweets, and remove retweets as before. In this data, gender is labeled automatically based on user first and last name morphology with a precision above 0.98 for all languages.

Sentiment labels for tweets in the development and test sets are obtained using Amazon Mechanical Turk. For each tweet we collect annotations from five workers and use majority vote to determine the final label for the tweet. Snow et al. (2008) show that for a similar task, labeling emotion and valence, on average four non-expert labelers are needed to achieve an expert level of annotation. Below are the example Russian tweets labeled for sentiment:

- **Pos**: Как же приятно просто лечь в постель после тяжелого дня... (It is a great pleasure to go to bed after a long day at work...)
- **Neg**: Уважаемый господин Прохоров купите эти выборы! (Dear Mr. Prokhorov just buy the elections!)
- **Both**: Затолкали меня на местном рынке! но зато закупилась подарками для всей семьи :) (It was crowded at the local market! But I got presents for my family:-))
- **Neutral**: Киев очень старый город (Kiev is a very old city).

Table 1 gives the distribution of tweets over sentiment and gender labels for the development and test sets for English (EDEV, ETEST), Spanish (SDEV, STEST), and Russian (RDEV, RTEST).

Data	Pos	Neg	Both	Neut	♀	♂
EDEV	617	357	202	824	1,176	824
ETEST	596	347	195	862	1,194	806
SDEV	358	354	86	1,202	768	1,232
STEST	317	387	93	1203	700	1,300
RDEV	452	463	156	929	1,016	984
RTEST	488	380	149	983	910	1,090

Table 1: Gender and sentiment label distribution in the development and test sets for all languages.

4 Subjective Language and Gender

To study the intersection of subjective language and gender in social media, ideally we would have a large corpus labeled for both. Although our large corpus is labeled for gender, it is not labeled for sentiment. Only the 4K tweets for each language that compose the development and test sets are labeled for both gender and sentiment. Obtaining sentiment labels for all tweets would be both impractical and expensive. Instead we use large multilingual sentiment lexicons developed specifically for Twitter as described below. Using these lexicons we can begin to explore the relationship between subjective language and gender in the large pool of data labeled for gender but unlabeled for sentiment. We also look at the relationship between gender and the use of different hashtags and emoticons. These can be strong indicators of sentiment in social media, and in fact are sometimes used to create noisy training data for sentiment analysis in Twitter (Pak and Paroubek, 2010; Kouloumpis et al., 2011).

4.1 Bootstrapping Subjectivity Lexicons

Recent work by Banea et.al (2012) classifies methods for bootstrapping subjectivity lexicons into two types: corpus-based and dictionary-based. Corpus-based methods extract subjectivity lexicons from unlabeled data using different similarity metrics to measure the relatedness between words, e.g., Pointwise Mutual Information (PMI). Corpus-based methods have been used to bootstrap lexicons for ENGLISH (Turney, 2002) and other languages, including ROMANIAN (Banea et al., 2008) and JAPANESE (Kaji and Kitsuregawa, 2007).

Dictionary-based methods rely on relations between words in existing lexical resources. For example, Rao and Ravichandran (2009) construct HINDI and FRENCH sentiment lexicons using relations in WordNet (Miller, 1995), Rosas et. al. (2012) bootstrap a SPANISH lexicon using SentiWordNet (Baccianella et al., 2010) and OpinionFinder,[3] Clematide and Klenner (2010), Chetviorkin et al. (2012) and Abdul-Mageed et. al. (2011) automatically expand and evaluate GERMAN, RUSSIAN and ARABIC subjective lexicons.

[3] www.cs.pitt.edu/mpqa/opinionfinder

We use the corpus-based, language-independent approach proposed by Volkova et al. (2013) to bootstrap Twitter-specific subjectivity lexicons. To start, the new lexicon is seeded with terms from the initial lexicon L_I. On each iteration, tweets in the unlabeled data are labeled using the current lexicon. If a tweet contains one or more terms from the lexicon it is marked subjective, otherwise neutral. Tweet polarity is determined in a similar way, but takes into account negation. For every term not in the lexicon with a frequency threshold, the probability of that word appearing in a subjective sentence is calculated. The top k terms with a subjective probability are then added to the lexicon. Bootstrapping continues until there are no more new terms meeting the criteria to add to the lexicon. The parameters are optimized using a grid search on the development data using F-measure for subjectivity classification. In Table 2 we report size and term polarity from the initial L_I and the bootstrapped L_B lexicons. Although more sophisticated bootstrapping methods exist, this approach has been shown to be effective for atomically learning subjectivity lexicons in multiple languages on a large scale without any external, rich, lexical resources, e.g., WordNet, or advanced NLP tools, e.g., syntactic parsers (Wiebe, 2000) or information extraction tools (Riloff and Wiebe, 2003).

For English, seed terms for bootstrapping are the strongly subjective terms in the MPQA lexicon (Wilson et al., 2005). For Spanish and Russian, the seed terms are obtained by translating the English seed terms using a bi-lingual dictionary, collecting subjectivity judgments from MTurk on the translations, filtering out translations that are not strongly subjective, and expanding the resulting word lists with plurals and inflectional forms.

To verify that bootstrapping does provide a better resource than existing dictionary-expanded lexicons, we compare our Twitter-specific lexicons L_B to the corresponding initial lexicons L_I and the existing state-of-the-art subjective lexicons including:

- 8K strongly subjective English terms from SentiWordNet χ^E (Baccianella et al., 2010);
- 1.5K full strength terms from the Spanish sentiment lexicon χ^S (Perez-Rosas et al., 2012);
- 5K terms from the Russian sentiment lexicon χ^R (Chetviorkin and Loukachevitch, 2012).

For that we apply rule-based subjectivity classification on the test data.[4] This subjectivity classifier predicts that a tweet is subjective if it contains at least one, or at least two subjective terms from the lexicon. To make a fair comparison, we automatically expand χ^E with plurals and inflectional forms, χ^S with the inflectional forms for verbs, and χ^R with the inflectional forms for adverbs, adjectives and verbs. We report precision, recall and F-measure results in Table 3 and show that our bootstrapped lexicons outperform the corresponding initial lexicons and the external resources.

	English		**Spanish**		**Russian**	
	L_I^E	L_B^E	L_I^S	L_B^S	L_I^R	L_B^R
Pos	2.3	16.8	2.9	7.7	1.4	5.3
Neg	2.8	4.7	5.2	14.6	2.3	5.5
Total	**5.1**	**21.5**	**8.1**	**22.3**	**3.7**	**10.8**

4.2 Lexical Evaluation

With our Twitter-specific sentiment lexicons, we can now investigate how the *subjective use* of these terms differs depending on gender for our three languages. Figure 1 illustrates what we expect to find. $\{F\}$ and $\{M\}$ are the sets of subjective terms used by females and males, respectively. We expect that some terms will be used by males, but never by females, and vice-versa. The vast majority, however, will be used by both genders. Within this set of shared terms, many words will show little difference

[4] A similar rule-based approach using terms from the MPQA lexicon is suggested by (Riloff and Wiebe, 2003).

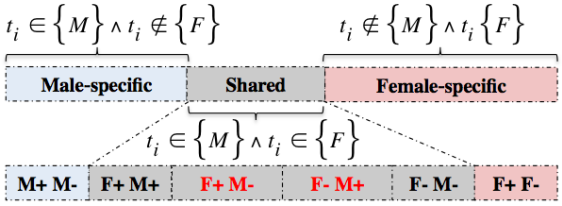

Figure 1: Gender-dependent vs. independent subjectivity terms (+ and - indicates term polarity).

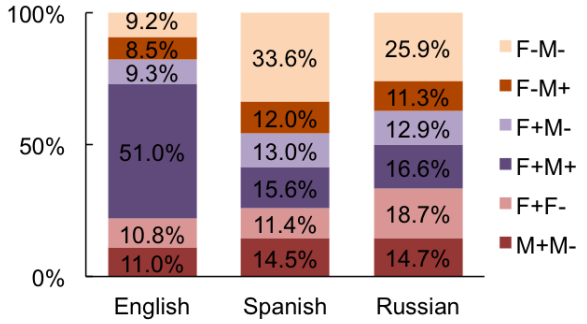

Figure 2: The distribution of gender-dependent $GDep$ and gender-independent $GInd$ sentiment terms.

in their subjective use when considering gender, but there will be some words for which gender will have an influence. Of particular interest for our work are words in which the polarity of a term as it is used in context is gender-influenced, the extreme case being terms that flip their polarity depending on the gender of the user. Polarity may be different because the concept represented by the term tends to be viewed in a different light depending on gender. There are also words like *weakness* in which a more positive or more negative word sense tends to be used by men or women. In Figure 2 we show the distribution of gender-specific and gender-independent terms from the L_B lexicons for all languages.

To identify gender-influenced terms in our lexicons, we start by randomly sampling 400K male and 400K female tweets for each language from the data. Next, for both genders we calculate the probability of term t_i appearing in a tweet with another subjective term (Eq.1), and the probability of it appearing with a positive or negative term (Eq.2-3) from L_B.

$$p_{t_i}(subj|g) = \frac{c(t_i, P, g) + c(t_i, N, g)}{c(t_i, g)}, \quad (1)$$

where $g \in F, M$ and P and N are positive and negative sets of terms from the *initial* lexicon L_I.

$$p_{t_i}(+|g) = \frac{c(t_i, P, g)}{c(t_i, P, g) + c(t_i, N, g)} \quad (2)$$

$$p_{t_i}(-|g) = \frac{c(t_i, N, g)}{c(t_i, P, g) + c(t_i, N, g)} \quad (3)$$

We introduce a novel metric $\Delta p^+_{t_i}$ to measure polarity change across genders. For every subjective term t_i we want to maximize the difference[5]:

$$\Delta p^+_{t_i} = |p_{t_i}(+|F) - p_{t_i}(+|M)|$$
$$s.t.$$
$$\left|1 - \frac{tf^{subj}_{t_i}(F)}{tf^{subj}_{t_i}(M)}\right| \leq \lambda, \; tf^{subj}_{t_i}(M) \neq 0, \quad (4)$$

where $p(+|F)$ and $p(+|M)$ are probabilities that term t_i is positive for females and males respectively; $tf^{subj}_{t_i}(F)$ and $tf^{subj}_{t_i}(M)$ are corresponding term frequencies (if $tf^{subj}_{t_i}(F) > tf^{subj}_{t_i}(M)$ the fraction is flipped); λ is a threshold that controls the level of term frequency similarity[6]. The terms in which polarity is most strongly gender-influenced are those with $\lambda \to 0$ and $\Delta p^+_{t_i} \to 1$.

Table 4 shows a sample of the most strongly gender-influenced terms from the initial L_I and the bootstrapped L_B lexicons for all languages. A plus (+) means that the term tends to be used positively by women and minus (−) means that the term tends to be used positively by men. For instance, in English we found that *perfecting* is used with negative polarity by male users but with positive polarity by female users; the term *dogfighting* has negative polarity for women but positive polarity for men.

4.3 Hashtags

People may also express positive or negative sentiment in their tweets using hashtags. From our balanced samples of 800K tweets for each language, we extracted 611, 879, and 71 unique hashtags for English, Spanish, and Russian, respectively. As we did for terms in the previous section, we evaluated the subjective use of the hashtags. Some of these are clearly expressing sentiment (*#horror*), while others seem to be topics that people are frequently opinionated about (*#baseball, #latingrammy, #spartak*).

[5] One can also maximize $\Delta p^-_{t_i} = |p_{t_i}(-|F) - p_{t_i}(-|M)|$.

[6] $\lambda = 0$ means term frequencies are identical for both genders; $\lambda \to 1$ indicates increasing gender divergence.

English Initial Terms L_I^E	Δp^+	λ	**English Bootstrapped Terms** L_B^E	Δp^+	λ
perfecting	+ 0.7	0.2	pleaseeeeee	+ 0.7	0.0
weakened	+ 0.1	0.0	adorably	+ 0.6	0.4
saddened	– 0.1	0.0	creatively	– 0.6	0.5
misbehaving	– 0.4	0.0	dogfighting	– 0.7	0.5

Table 4: Sample of subjective terms sorted by Δp^+ to show lexical differences and polarity change across genders (module is not applied as defined in Eq.1 to demonstrate the polarity change direction).

English	Δp^+	λ	**Spanish**	Δp^+	λ	**Russian**	Δp^+	λ
#parenting	+ 0.7	0.0	#rafaelnarro (politician)	+ 1.0	0.0	#совет (advise)	+ 1.0	0.0
#vegas	– 0.2	0.8	#amores (loves)	+ 0.2	1.0	#ukrlaw	+ 1.0	1.0
#horror	– 0.6	0.7	#britneyspears	+ 0.1	0.3	#spartak (soccer team)	– 0.7	0.9
#baseball	– 0.6	0.9	#latingrammy	– 0.5	0.1	#сны (dreams)	– 1.0	0.0
#wolframalpha	– 0.7	1.0	#metallica (music band)	– 0.5	0.8	#iphones	– 1.0	1.0

Table 5: Hashtag examples with opposite polarity across genders for English, Spanish, and Russian.

Table 5 gives the hashtags, correlated with subjective language, that are most strongly gender-influenced. Analogously to Δp^+ values in Table 4, a plus (+) means the hashtag is more likely to be used positively by women, and a minus (–) means the hashtag is more likely to be used positively by men. For example, in English we found that male users tend to express positive sentiment in tweets mentioning $\#baseball$, while women tend to be negative about this hashtag. The opposite is true for the hashtag $\#parenting$.

4.4 Emoticons

We investigate how emoticons are used differently by men and women in social media following the work by (Bamman et al., 2012). For that we rely on the lists of emoticons from Wikipedia[7] and present the cross-cultural and gender emoticon differences in Figure 3. The frequency of each emoticon is given on the right of each language chart, with probability of use by a male user in that language given on the x-axis. The top 8 emoticons are the same across languages and sorted by English frequency.

We found that emoticons in English data are used more overall by female users, which is consistent with previous findings in Schnoebelen's work.[8] In addition, we found that some emoticons like :-) *(smile face)* and :-o *(surprised)* are used equally by both genders, at least in Twitter. When comparing English emoticon usage to other languages, there are some similarities, but also some clear differences. In Spanish data, several emoticons are more likely to be used by male than by female users, e.g., :-o *(surprised)* and :-& *(tongue-tied)*, and the difference in probability of use by males and females is greater for the emoticons, as compared to the same emoticons for English. Interestingly, in Russian Twitter

[7]List of emoticons from Wikipedia http://en.wikipedia.org/wiki/List_of_emoticons

[8]Language and emotion (talks, essays and reading notes) www.stanford.edu/~tylers/emotions.shtml

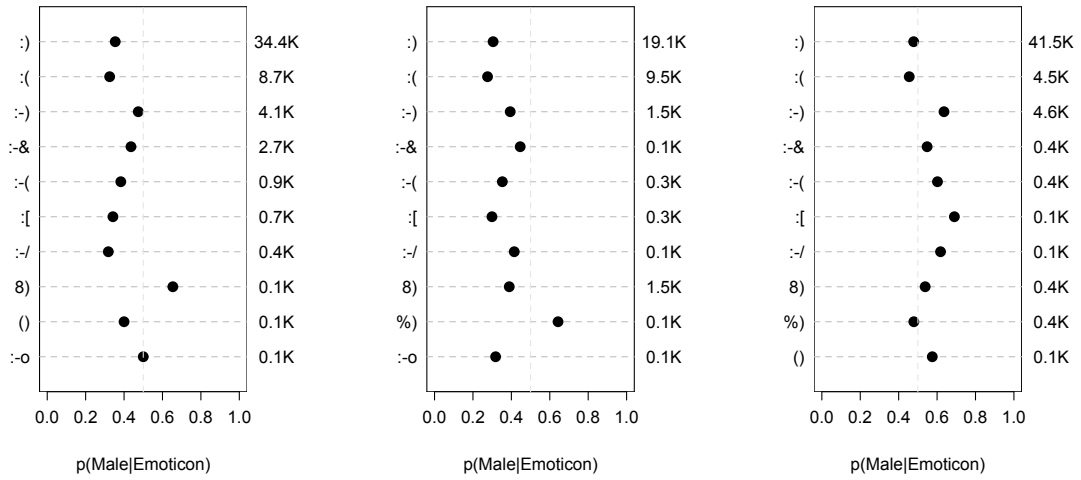

Figure 3: Probability of gender and emoticons for English, Spanish and Russian (from left to right).

data emoticons tend to be used more or equally by male users rather than female users.

5 Experiments

The previous section showed that there are gender differences in the use of subjective language, hashtags, and emoticons in Twitter. We aim leverage these differences to improve subjectivity and polarity classification for the informal, creative and dynamically changing multilingual Twitter data.[9] For that we conduct experiments using gender-independent $GInd$ and gender-dependent $GDep$ features and compare the results to evaluate the influence of gender on sentiment classification.

We experiment with two classification approaches: (I) rule-based classifier which uses only subjective terms from the lexicons designed to verify if the gender differences in subjective language create enough of a signal to influence sentiment classification; (II) state-of-the-art supervised models which rely on lexical features as well as lexicon set-count features.[10,11] Moreover, to show that the gender-sentiment signal can be learned by more than one classifier we apply a variety of classifiers implemented in Weka (Hall et al., 2009). For that we do 10-fold cross validation over English, Spanish, and Russian test data (ETEST, STEST and RTEST) labeled with subjectivity (pos, neg, both vs. neut) and polarity (pos vs. neg) as described in Section 3.

5.1 Models

For the rule-based $GInd^{RB}_{subj}$ classifier, tweets are labeled as subjective or neutral as follows:

$$GInd^{RB}_{subj} = \begin{cases} 1 & \text{if } \vec{w} \cdot \vec{f} \geq 0.5, \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

where $\vec{w} \cdot \vec{f}$ stands for weighted set features, e.g., terms from L_I only, emoticons E, or different part-of-speech tags (POS) from L_B weighted using $w = p(subj) = p(subj|M) + p(subj|F)$ subjectivity score as shown in Eq.1. We experiment with the POS tags to show the contribution of each POS to sentiment classification.

Similarly, for the rule-based $GInd^{RB}_{pol}$ classifier, tweets are labeled as positive or negative:

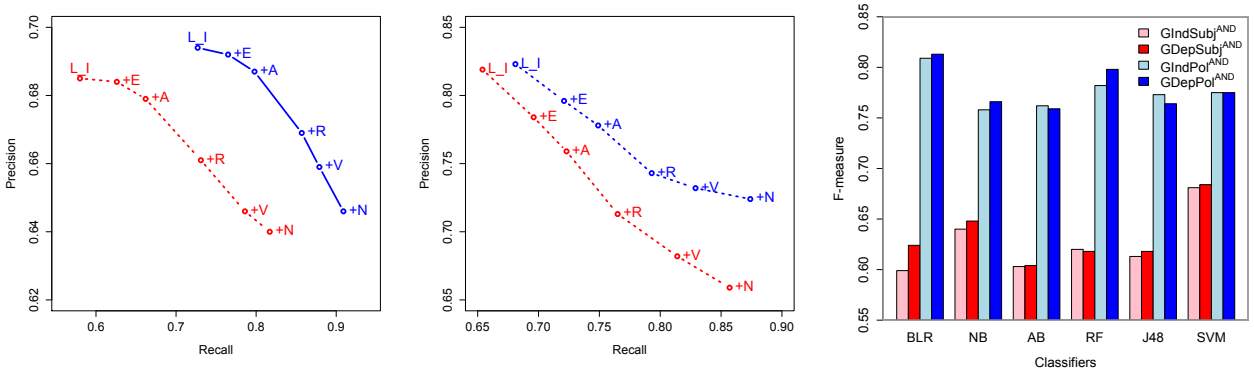
$$GInd^{RB}_{pol} = \begin{cases} 1 & \text{if } \vec{w^+} \cdot \vec{f^+} \geq \vec{w^-} \cdot \vec{f^-}, \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

where $\vec{f}^+$, $\vec{f}^-$ are feature sets that include only positive and negative features from L_I or L_B; w^+ and w^-

[9] For polarity classification we distinguish between positive and negative instances, which is the approach typically reported in the literature for recognizing polarity (Velikovich et al., 2010; Yessenalina and Cardie, 2011; Taboada et al., 2011)

[10] A set-count feature is a count of the number of instances from a set of terms that appears in a tweet.

[11] We also experimented with repeated punctuation (*!!, ??*) and letters ($nooo, reealy$), which are often used in sentiment classification in social media. However, we found these features to be noisy and adding them decreased performance.



(a) Rule-based subjectivity (b) Rule-based polarity (c) SL subjectivity and polarity

Figure 4: Rule-based (RB) and Supervised Learning (SL) sentiment classification results for English. L_I - the initial lexicon, E - emoticons, A, R, V, N are adjectives, adverbs, verbs, nouns from L_B.

are positive and negative polarity scores estimated using Eq.2 - 3 such as: $w^+ = p(+|M) + p(+|F)$ and $w^- = p(-|M) + p(-|F)$.

The *gender-dependent* rule-based classifiers are defined in a similar way. Specifically, $\vec{f}$ is replaced by $\vec{f}^M$ and $\vec{f}^F$ in Eq.5 and $\vec{f}^-, \vec{f}^+$ are replaced by $\vec{f}^{M-}, \vec{f}^{F-}$ and $\vec{f}^{M+}, \vec{f}^{F+}$ respectively in Eq.6. We learn subjectivity $\vec{s}$ and polarity $\vec{p}$ score vectors using Eq.1-3. The difference between $GInd$ and $GDep$ models is that $GInd$ scores $\vec{w}$, $\vec{w^+}$ and $\vec{w^-}$ are not conditioned on gender.

For *gender-independent* classification using supervised models, we build feature vectors using lexical features V represented as term frequencies, together with set-count features from the lexicons:

$$\vec{f}^{GInd}_{subj} = [L_I, L_B, E, V];$$
$$\vec{f}^{GInd}_{pol} = [L^+_I, L^+_B, E^+, L^-_I, L^-_B, E^-, V].$$

Finally, for *gender-dependent* supervised models, we try different feature combinations. (A) We extract set-count features for gender-dependent subjective terms from L_I, L_B, and E jointly:

$$\vec{f}^{GDep-J}_{subj} = [L^M_I, L^M_B, E^M, L^F_I, L^F_B, E^F, V];$$
$$\vec{f}^{Dep-J}_{pol} = [L^{M+}_I, L^{M+}_B, E^{M+}, L^{F+}_I, L^{F+}_B, E^{F+}$$
$$L^{M-}_I, L^{M-}_B, E^{M-}, L^{F-}_I, L^{F-}_B, E^{F-}, V].$$

(B) We extract disjoint (prefixed) gender-specific features (in addition to lexical features V) by relying only on female set-count features when classifying female tweets; and only male set-count features for male tweets. We refer to the joint features as $GInd-J$ and $GDep-J$, and to the disjoint features $GInd-D$ and $GDep-D$.

5.2 Results

Figures 4a and 4b show performance improvements for subjectivity and polarity classification under the rule-based approach when taking into account gender. The left figure shows precision-recall curves for subjective *vs.* neutral classification, and the middle figure shows precision-recall curves for positive *vs.* negative classification. We measure performance starting with features from L_I, and then incrementally add emoticon features E and features from L_B one part of speech at a time to show the contribution of each part of speech for sentiment classification.[12] This experiment shows that there is a clear improvement for the models parameterized with gender, at least for the simple, rule-based model.

For the supervised models we experiment with a variety of learners for English to show that gender differences in subjective language improve sentiment classification for many learning algorithms. We present the results in Figure 4c. For subjectivity classification, Support Vector Machines (SVM), Naive Bayes (NB) and Bayesian Logistic Regression (BLR) achieve the best results, with improvements in F-measure ranging from 0.5 - 5%. The polarity classifiers overall achieve much higher scores, with improvements for $GDep$ features ranging from 1-2%. BLR with Gaussian prior is the top scorer

Table 6: Sentiment classification results obtained using gender-dependent and gender-independent joint and disjoint features for Logistic Regression (LR) and SVM models.

for polarity classification with an F-measure of 82%. We test our results for statistical significance using McNemar's Chi-squared test (p-value < 0.01) as suggested by Dietterich (1998). Only three classifiers, J48, AdaBoostM1 (AB) and Random Forest (RF) do not always show significant improvements for $GDep$ features over $GInd$ features. However, for the majority of classifiers, $GDep$ models outperform $GInd$ models for both tasks, demonstrating the robustness of $GDep$ features for sentiment analysis.

In Table 6 we report results for subjectivity and polarity classification using the best performing classifiers (as shown in Figure 4c) :

- Logistic Regression (LR) (Genkin et al., 2007) for $GInd-J$ and $GDep-J$ models.
- SVM model with radial-based kernel for $GInd-D$ and $GDep-D$ models. We use LibSVM implementation (EL-Manzalawy and Honavar, 2005).

Each $\Delta R(\%)$ row shows the relative percent improvements in terms of precision P, recall R, F-measure F and accuracy A for $GDep$ compared to $GInd$ models. Our results show that differences in subjective language across genders can be exploited to improve sentiment analysis, not only for English but for multiple languages. For Spanish and Russian results are lower for subjectivity classification, we suspect, because lexical features V are already inflected for gender and set-count features are down-weighted by the classifier. For polarity classification, on the other hand, gender-dependent features provide consistent, significant improvements (1.5-2.5%) across all languages.

As a reality check, Table 6 also reports accuracies (in A^{rand} columns) for experiments that use random permutations of male and female subjective terms, which are then encoded as gender-dependent set-count features as before. We found that all gender-dependent models, $GDep-J$ and $GDep-D$, outperformed their random equivalents for both subjectivity and polarity classification (as reflected by relative accuracy decrease ↓ for A^{rand} compared to A). These results further confirm the existence of gender bias in subjective language for any of our three languages and its importance for sentiment analysis.

Finally, we check whether encoding gender as a binary feature would be sufficient to improve sentiment classification. For that we encode fea-

	English		Spanish		Russian

(b)	0.72	0.94	0.69	0.64	0.66	0.74
(c)	0.78	0.83	0.71	0.63	0.66	0.72
(d)	0.69	0.93	0.71	0.62	0.65	0.76
(e)	**0.80**	**0.83**	**0.72**	**0.65**	**0.68**	**0.73**

Table 7: Precision and recall results for polarity classification: encoding gender as a binary feature vs. gender-dependent features $GDep - J$.

tures such as: (a) unigram term frequencies V, (b) term frequencies and gender binary $V + GBin$, (c) gender-independent $GInd$, (d) gender-independent and gender binary $GBin + GInd$, and (e) gender-dependent $GDep - J$. We train logistic-regression model for polarity classification and report precision and recall results in Table 7. We observe that including gender as a binary feature does not yield significant improvements compared to $GDep - J$ for all three languages.

6 Conclusions

We presented a qualitative and empirical study that analyses substantial and interesting differences in subjective language between male and female users in Twitter, including hashtag and emoticon usage across cultures. We showed that incorporating author gender as a model component can significantly improve subjectivity and polarity classification for English (2.5% and 5%), Spanish (1.5% and 1%) and Russian (1.5% and 1%). In future work we plan to develop new models for joint modeling of personalized sentiment, user demographics e.g., age and user preferences e.g., political favorites in social media.

Opinion Mining in Newspaper Articles by Entropy-based Word Connections

Thomas Scholz and **Stefan Conrad**
Heinrich-Heine-University
Institute of Computer Science
D-40225 Düsseldorf, Germany
{scholz,conrad}@cs.uni-duesseldorf.de

Abstract

A very valuable piece of information in newspaper articles is the tonality of extracted statements. For the analysis of tonality of newspaper articles either a big human effort is needed, when it is carried out by media analysts, or an automated approach which has to be as accurate as possible for a Media Response Analysis (MRA). To this end, we will compare several state-of-the-art approaches for Opinion Mining in newspaper articles in this paper. Furthermore, we will introduce a new technique to extract entropy-based word connections which identifies the word combinations which create a tonality. In the evaluation, we use two different corpora consisting of news articles, by which we show that the new approach achieves better results than the four state-of-the-art methods.

1 Introduction

The Web keeps many potentially valuable opinions in news articles which are partly new online articles or uploaded print media articles. Many companies or organisations such as political parties or even distinguished public figures perform a Media Response Analysis (MRA) (Watson and Noble, 2007) in order to analyse the output of their effort in public relations. So, an opinion-oriented analysis of news articles is important, because the tonality (Watson and Noble, 2007; Scholz et al., 2012a) is the key indicator of a MRA. A purely manual solution implies a big human effort for so-called media analysts, because they have to read and rate approx. 200 to 800 news articles each week.

As a consequence, an automated Opinion Mining solution is very attractive. At the same time, Opinion Mining in newspaper articles appears to be difficult, because not all parts of news articles are as subjective (Balahur et al., 2010) as reviews, for example. Also, different parts of one article can contain different opinions (Watson and Noble, 2007). Therefore, we work with extracted statements of news articles, in which a sequence of consecutive sentences has the same tonality value. At the same time, some approaches focus more on differentiating only between positive and negative news and leave out neutral examples (Taboada et al., 2011; Scholz et al., 2012b). Conversely, we have noticed that even if the used words in the news domain are quite similar, the tonality which the words express can be different, especially if neutral examples are involved (cf. section 3.1). We propose this task formulation:

Problem definition: Let $s \subseteq d$ be a statement and document d represents a newspaper article. The task is to determine the tonality y for a given statement s, consisting of k words:

$$t : s = (w_1, w_2, ..., w_k) \mapsto \\ y \in \{\text{positive,neutral,negative}\} \quad (1)$$

Normally, a statement consists of one up to four sentences. But also longer statements are possible, but they appear less frequently in a MRA. An automated approach (Scholz and Conrad, 2013) for the extraction of statements already exists. The approach applies machine learning to extract relevant sentences from a collection of news articles and combine them to statements. So, we concentrate on the tonality classification, which is not provided by

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1828–1839,
Seattle, Washington, USA, 18-21 October 2013.

the approach for the statements extraction (Scholz and Conrad, 2013). Furthermore, we define the polarity of sentiment as the distinction between positive and negative sentiment and the subjectivity as the distinction between subjective (positive and negative) statements and neutral statements.

The following example is a positive statement from an article in The Telegraph (8th Aug 2012) which deals with the prospects of British companies in Africa:

- **Example statement (positive):** *There are structural factors behind the African growth story: a growing and sizeable population which is increasingly urbanised with disposable income; growing political stability; and a financial services industry that is still in its infancy.*

The so-called pressrelations dataset (Scholz et al., 2012a), which represents a publicly available corpus[1] of a MRA on German news articles, contains 1,521 annotated statements. Since this is the only publicly available corpus of a MRA as far as we know, we perform our experiments in German. We are aware of the fact that viewpoints play a significant role in a newspaper, but since we concentrate on the determination of the tonality, the extraction of viewpoints can be solved in a separate step (Scholz and Conrad, 2012). This is possible, because the tonality of a statement can be determined without knowledge of the viewpoint in almost all cases. The only exception is a statement with multiple viewpoints and different tonalities, but these statements are very rare (cf. also section 4.1).

Our approach learns a graph from an annotated collection of statements, in which nodes and edges model tonality-bearing word connections. For unseen statements, we recognize subgraphs of the learned graph, compare two weighting methods for extracting different tonality features, and classify the statements by a support vector machine.

In this paper, we describe four state-of-the-art techniques for Opinion Mining in the next section about related work. In the third section, we introduce our graph-based and entropy-based approach to calculate the tonality features T. We will evaluate our approach against the state-of-the-art methods in section 4, before we conclude in the last section.

2 Related Work

Opinion Mining and Sentiment Analysis represent a broad subject area (Pang and Lee, 2008).

The different contributions reach from applying Opinion Mining in reviews and recommending new multimedia products for individuals (Qumsiyeh and Ng, 2012) to sentiment analyses for different topics in social media (Wang et al., 2011) or the creation of sentiment dictionaries (Baccianella et al., 2009). In this paper, we focus on state-of-the-art methods for Opinion Mining which differ from each other in their methodology.

In the news domain, Wilson et al. (2009) developed a word-based classification approach which can extract contextual polarity. This method (denoted as **Wilson**) uses a lexicon and POS-tagging to generate word features and sentence features. Moreover, it also uses deep natural language analyses with dependency parse trees in order to calculate (general and polarity) modification features and structure features. Finally, they compute 32 features for neutral-polar classification and 10 features for the polarity classification. These features can be used by different kinds of machine learning techniques such as Ripper (Cohen, 1996) or BoosTexter (Schapire and Singer, 2000).

Based on a sentiment lexicon, Taboada et al. (2011) calculate the semantic orientation of opinion-bearing words (**SO-CAL**). They begin with a fine-grained dictionary of adjectives, adverbs, verbs, and nouns which have a score from -5 to +5. "Masterpiece" has a score of +5 and "monstrosity" of -5, for example. In addition, the approach takes intensifiers, negations, and irrealis (Taboada et al., 2011) into account and thereby modifies the score of the words through rules and formulas. SO-CAL identifies some special expressions and constructions, which tell the reader, that this text part does not really contain an actual opinion or sentiment. The linguistic term for this situation is called irrealis. Also, text-level features weight the final score by mere presence of the words.

In the field of customer reviews, Ding et al. (2008) also work with a dictionary, which even includes context-dependent words (positive, neutral, and negative words) as well as rules to identify the sentiment orientation of words (**Opinion**

Observer). The rules deal with negations, inter-sentence conjunctions, but-clauses, and the modifier "too". Furthermore, they extract relations between opinion words and corresponding product features. Thereby, a detailed analysis of product reviews is possible.

Sarvabhotla et al. (2011) propose to extract the subjective excerpt of a text (**RSUMM**). They construct two word-vectors: An average document frequency vector represents the most important and most specific word features for the given domain. Subsequently, an average subjective measure vector selects the most subjective terms. As a result, they require hardly any natural language preprocessing except a sentence splitter and a tokenizer. The final classification is accomplished by a SVM (SVM-Light (Joachims, 1999)).

For product reviews, graph-based approaches (Goldberg and Zhu, 2006; Wu et al., 2009) can increase the performance in cross-domain tasks (Ponomareva and Thelwall, 2012). By contrast, our graph nodes do not represent documents, but words to overcome the problem of similar bag-of-words representations (cf. next section).

One important resource for Opinion Mining in news is the MPQA corpus (Wiebe et al., 2005) which contains word and phrase-based annotation for 523 news articles. Unfortunately, since the corpus does not have statements and a statement-based tonality, it is not designed as a MRA. A slightly larger corpus, the pressrelations dataset (Scholz et al., 2012a) with 617 articles, is the result of a MRA in German. We use this corpus as one part of our evaluation.

3 Learning Tonality with Entropy-based Word Connections

3.1 Graph Model for Word Connections

To solve the Opinion Mining task for a MRA, we propose a graph-based approach to capture the opinion-bearing words and modifiers such as negations. In this way, our approach is able to recognize tonality-indicating structures (subgraphs) which provide precise information about the tonality, even if statements have a very similar bag-of-words representation and at the same time different tonalities. One could also say that we create a graph instead of a sentiment dictionary from training examples, as other approaches (Kaji and Kitsuregawa, 2007; Du et al., 2010) proceed.

In figure 1, simple examples are shown with a possible graph (the nodes and edges are taken from the given statements; of course, the graphs and weights become larger in practice). These simple examples are concentrated on nouns, verbs, and adverbs, but also examples with combinations of other categories are possible, such as, for example, different combinations of adjectives, nouns, and verbs: "This is a black day for the company", "The company is in the black", "The company is in the red" and "The company prevents to be in the red". Thus, even though the word representation is quite similar, the tonality can be different.

For opinion-bearing words, we use adjectives, nouns, verbs, and adverbs, which are widely acknowledged as opinion-bearing word categories (Bollegala et al., 2011; Remus et al., 2010; Taboada et al., 2011). Furthermore, we also include negation particles. Therefore, the vocabulary V is the set of words in lemma for one set of statements S. Thus, for every lemma $w \in V$, the approach creates one node v in the graph. A node v also contains the type information (adjective, noun, verb, adverb, or negation).

The edge e_{ij} shows the appearance of node v_i and v_j in combination with tonality y by means of a weight $\varepsilon_{i,j}$ (the sequence of the values in equation 2 is also used in figure 1 and 2).

$$\varepsilon_{ij} = (y_{ij\pi}, y_{ijo}, y_{ij\nu}) \tag{2}$$

$y_{ij\pi}$ is the number of co-occurrences of node v_i and v_j in positive statements within the same sentence. In analogy, y_{ijo} belongs to sentences of neutral statements and $y_{ij\nu}$ to sentences of negative statements. Figure 1 shows a small example for this calculation, too.

3.2 Generating Features for Learning

From a learned graph, we can combine different edges to calculate tonality features for an unseen statement s. An unseen statement is a statement, which is of course not used to learn the graph. We use all edges of the subgraph G_{sl} which contains the nodes for every lemma w_i in the l-th sentence of s.

1)	This solves the crisis.	(positive)
2)	This solves the crisis slowly.	(neutral)
3)	This intensifies the crisis.	(negative)

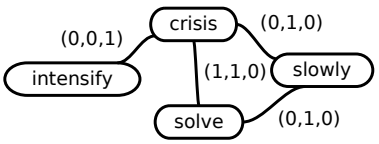

Figure 1: An example for different statements and a graph: The weights base on the three examples and their notation is (positive,neutral,negative).

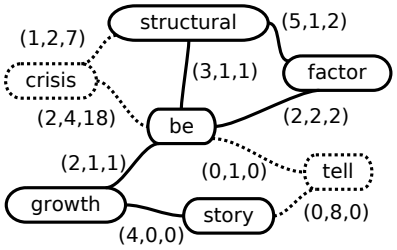

Figure 2: An example of a learned graph: The nodes and edges, which are drawn in solid lines, represent the recognized subgraph G_{sl} for the sentence "There are structural factors behind the African growth story.".

We explain this with an example. Assuming that our learned graph is shown in figure 2. It contains seven nodes and nine edges (also the nodes and edges in dashed lines). If we further assume that an unseen statement is the example of section 1. To keep this example short, we take the part until the colon as the first sentence of the statement: "There are structural factors behind the African growth story."

Our approach recognizes the nodes for "be", "structural", "factors", "growth", and "story". Thus, the subgraph G_{sl} for the first sentence ($l = 0$) would be the graph which is drawn in solid lines in figure 2. In this example, it is a connected graph, but it does not have to be.

We could also look for complete or connected graphs in the statement instead of using all edges. The largest complete graph would consist of the nodes "structural", "factor", and "be" in our example. But using all edges achieves better results, because this method provides all information. In addition, this method is quicker (search for largest complete or connected graph can be omitted, which would be an additional check).

If we have found our subgraphs G_{sl}, we can then compute the vectorial sum of all edges for one node v_i and we get the probability for a tonality y, if we observe v_i in the l-th sentence:

$$P(pos|v_i) = \frac{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi}}{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi} + y_{ij\nu}} \quad (3)$$

$$P(neg|v_i) = \frac{\sum\limits_{e_{ij} \in Gsl} y_{ij\nu}}{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi} + y_{ij\nu}} \quad (4)$$

$$P(sub|v_i) = \frac{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi} + y_{ij\nu}}{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi} + y_{ijo} + y_{ij\nu}} \quad (5)$$

$$P(neu|v_i) = \frac{\sum\limits_{e_{ij} \in Gsl} y_{ijo}}{\sum\limits_{e_{ij} \in Gsl} y_{ij\pi} + y_{ijo} + y_{ij\nu}} \quad (6)$$

For the subjective class (sub), we add the appearance in positive statements ($y_{ij\pi}$) and negative statements ($y_{ij\nu}$). Otherwise we take the appearances in statements of the same class. The denominators of the polarity refer only to positive and negative appearances, while the denominators for the subjectivity refer to every tonality.

By calculating the vectorial sum, we combine several edges in order to estimate precise tonality scores. In this way, we can get the correct tonality score for the noun "crisis", if a sentence contains also "solve" and "slowly" ($\rightarrow$ more neutral) or "intensify" ($\rightarrow$ more negative) (cf. figure 1). And we get the correct tonality score for the adjective "structural", if a sentence includes also "crisis" ($\rightarrow$ negative) or the nodes "factor", "be", "growth", and "story" ($\rightarrow$ positive) (cf. figure 2).

We distinguish between different word categories (we have noticed that this creates better results than

just having a single feature for one statement). Thus, every category gets its own feature and every node only has a tonality value, if it belongs to the category of the feature. This does not mean that we only consider edges which connect two nodes with the same category; we divide the influence of different categories into different features:

$$T_{cat,z}(v_i) = \begin{cases} f_z(v_i) & \text{if } v_i \in cat \\ 0 & \text{if } v_i \notin cat \end{cases} \quad (7)$$

$cat \in \{adj, adv, n, v\}$ indicates the category of the node (adjectives, adverbs, nouns, or verbs) and z specifies the type of feature. One type shows the difference between positive and negative polarity ($z = pol$), for the other type we replace the positive class by the subjective one (the sum of positive and negative) and the negative by a neutral one in order to differentiate between neutral and non-neutral examples ($z = sub$). As a result, we calculate eight features (see table 1) for the tonality, two for each important word category. For the weighting, we apply and compare two methods, presented in the next sections.

3.2.1 Kullback-Leibler Weighting

For the final score, we can use the Kullback-Leibler divergence (relative entropy) (Kullback and Leibler, 1951) of P_2 from P_1:

$$D_{KL}(P_1||P_2) = \sum_{x \in X} P_1(x) \log \frac{P_1(x)}{P_2(x)} \quad (8)$$

To measure the information about tonality, we can define our tonality scores based on the divergence between the two category pairs:

$$f_{pol}(v_i) = D_{KL}(P(pos|v_i)||P(neg|v_i)) \quad (9)$$

$$f_{sub}(v_i) = D_{KL}(P(sub|v_i)||P(neu|v_i)) \quad (10)$$

Here, we measure the information lost, if $P(neg|v_i)$ approximates $P(pos|v_i)$, for example. The Kullback-Leibler is an asymmetric measure, so a switch of the distributions would give a different result. This is one reason why we prefer our second method, but we evaluate both in order to find out how important the choice of the weighting method is.

3.2.2 Entropy-summand Weighting

Also, the basic idea of the entropy (Shannon, 1948) can be applied to extract the importance of the edges for the tonality.

$$H(X) = -\sum_{i=1}^{n} p(x_i) \log_2(p(x_i)) \quad (11)$$

Here, the $p(x_i)$ refer to the probabilities in the equations 3 to 6. We add or subtract the entropy-summand of the assumed tonality class for one node v_i to/from a perfect state (normalized to 1 and -1):

$$f_{pol}(v_i) = \begin{cases} 1 + P(pos|v_i) * \log_2(P(pos|v_i)) \\ \text{if } P(neg|v_i) \leq P(pos|v_i) \\ -1 - P(neg|v_i) * \log_2(P(neg|v_i)) \\ \text{otherwise} \end{cases} \quad (12)$$

$$f_{sub}(v_i) = \begin{cases} 1 + P(sub|v_i) * \log_2(P(sub|v_i)) \\ \text{if } P(neu|v_i) \leq P(sub|v_i) \\ -1 - P(neu|v_i) * \log_2(P(neu|v_i)) \\ \text{otherwise} \end{cases} \quad (13)$$

In this way, we measure how much disorder one node v_i provides for a certain tonality class. For a clearly positive node (appears only in positive statements), e.g., the disorder will be 0 and so $f_{pol}(v_i) = 1$ and also $f_{sub}(v_i) = 1$.

3.3 Final Scores and Classification

To compute the eight final features values (four for each z-class), we calculate the average scores of all nodes, which share the same category, over all sentences of the statement. If no nodes/edges could be recognized in an unseen statement, all features would be zero. We use a SVM[2] to classify the statements by the extracted features. This works according to the one-versus-all strategy for a non-binary classification, which achieved slightly better results than a one-versus-one strategy or a subjective-objective classification first and then a positive-negative classification. Linear kernels are used and the parameters are the default ones. This

[2]Rapidminer standard implementation (http://rapid-i.com/)

Polarity Features	Subjectivity Features
$T_{v,pol}$: polarity for edges with verbs	$T_{v,sub}$: subjectivity for edges with verbs
$T_{n,pol}$: polarity for edges with nouns	$T_{n,sub}$: subjectivity for edges with nouns
$T_{adv,pol}$: polarity for edges with adverbs	$T_{adv,sub}$: subjectivity for edges with adverbs
$T_{adj,pol}$: polarity for edges w. adjectives	$T_{adj,sub}$: subjectivity for edges w. adjectives

Table 1: Polarity and subjectivity features based on word connections

means that every class has the same priority, for instance.

By using only 8 features, we actually achieve better results if compared with the use of one edge as a feature, because we abstract from individual word combinations in order to prevent overfitting. We will demonstrate that in section 4, where this method of using all edges as features is denoted as the **graph edges** method. Another positive aspect of restricting the number of features to a constant limit is that we save computing time (for the calculation of distances within machine learning, e.g.), because the graphs can be large (cf. section 4).

4 Experiments

4.1 Data and Experimental Setup

We use two different datasets for our evaluation: The pressrelations dataset[3] (called **PDS**) contains 1,521 statements (446 positive, 492 neutral, 583 negative), and a real world dataset contains 8,500 statements (2,125 positive, 2,125 negative, 4,250 neutral) from 5,352 news items about a financial service provider, the so-called **Finance** dataset. Up to ten media analysts (professional experts in the field of MRA) annotate the extracted statements with a tonality. We have investigated their inter-annotator agreement. So, four analysts annotate the same statements from a small part of the statements. They achieve an agreement of 81.8% by using the simple accuracy metric. The PDS has an inter-annotator agreement of 88.06% (Cohen's kappa) (Scholz et al., 2012a). We do not use the viewpoint information contained in the PDS. This is not a problem, because the tonality of statements can be estimated without knowledge of the viewpoint in the most cases.

Nevertheless, a statement can have two different viewpoints in a MRA. This is the case for 116 statements (approx. 7.62%) of the pressrelations dataset and 279 statements of the Finance dataset (approx. 3.28%). Statements can have two different tonalities for different viewpoints, but this is rarely the case (for less than 3.56% of the pressrelations statements and less than 0.17% of the statements of the Finance dataset). One of these examples is the following statement, which is a translated statement of the PDS:

- **Example:** *The logical consequence would be a substantial increase of the subsidies, which the SPD fraction has demanded several times. But the government has limited the funding for 2011 and a too slight rise is planned for 2012.* (Code A: positive, SPD; Code B: negative, CDU)

At the time of the creation of this dataset, the SPD is the biggest opposing party of the CDU in Germany. The CDU is the governing party under its chairwoman Chancellor Merkel. We keep these statements within the dataset, because this case can occur in a MRA. However, we will show that this situation does not irritate our approach too much.

We use approx. 30% of the statements, that is 420 statements (the first 140 positive, neutral, or negative statements) or 2,500 statements (the first 625 positive or negative and the first 1,250 neutral statements) in order to create our graph (the graph has 41,470 or 154,001 edges, resp.). For POS-tagging, identification of negations, and lemmatisation, we apply the TreeTagger (Schmid, 1995). Unless otherwise stated, 20% of the remaining statements (220 and 1,200 statements) are the training set for the SVM and the rest is test set. The size of the test is so large, because we are aiming at a real significance of the solution which can actually be operated in practice.

[3] http://www.pressrelations.de/research/

4.2 Adapting the State-of-the-Art Approaches for a German MRA

For the approaches of Ding et al. (2008), Wilson et al. (2009), and Taboada et al. (2011) we need a sentiment dictionary. Thus, we use the same statements which we use for the creation of our graphs for the creation of a dictionary as one variant.

To create the lexicon of subjectivity clues for the method of **Wilson** et al. (2009), all words which appear more often in neutral statements get the *prior polarity* neutral. For all other words, we calculate the number of appearances in positive statements minus the appearances in negative statements divided by all appearances. A positive word has a value of over 0.2, a negative word has a value of less than -0.2 and the rest has the prior polarity *both*. A positive word with a value above 0.6 belongs to the reliability class *strongsubj*, the other positive words are *weaksubj*. We treat the negative words analogously. We use the Stanford Parser for German (Rafferty and Manning, 2008) to calculate the dependency trees for the sentences (Wilson et al., 2009), in order to extract the General Modification Features, the Polarity Modification Features and the Structure Features. The lists of intensifiers, copular verbs, modals, negations, and polarity shifters are translated by a domain expert, who also added such elements which are not direct translations, but have the same function. The result of this method is a classification of words and phrases. Thus, for a statement classification, we classify the words of the statements and the class of the most frequently used words is the class of the statement (ambiguous statements are classified as the most frequent class). According to the authors, we apply the best machine learning techniques for the word classification (BoosTexter for tonality classification and Ripper for Subjectivity Analysis with parameters as in (Wilson et al., 2009)).

For **Opinion Observer** (Ding et al., 2008), we also identify neutral words if they appear more often in neutral than in subjective statements and subjective words are positive if they appear more often in positive than in negative statements and vice versa for negative words. In contrast to Opinion Mining in customer reviews, we exchange product features through statements and calculate the orientation of opinions for all statements with their opinion orientation algorithm. For this purpose, we adapt the negation rules, the but-clause rule, the inter-sentence conjunction rule, and the "too" rules for German (by translating important words such as "but" or the negations).

SO-CAL (Taboada et al., 2011) needs dictionaries with sentiment values from -5 to +5 with intervals of one. Thus, we use the same scores as the Wilson method and a word with a value above 0.818 to 1 gets a sentiment score of +5 and so on. This means, that neutral words also exist. Our domain expert translated the list of intensifiers (amplifiers and downtoners) and negations, as well as the expert also added missing elements. The authors propose two approaches for the negation search. We use the second, more conservative approach, because this approach works better according to the authors. Also, we use the value 4 for the negation shift. Furthermore, we implement the algorithm of irrealis blocking and translate the list of irrealis markers (modal verbs, conditional markers, negative polarity items, private-state verbs (Taboada et al., 2011)).

For all dictionary-based methods (Wilson, Opinion Observer, SO-CAL), we also evaluate an additional variant which use a sentiment dictionary and not the statements which we use to construct the graphs on each fold. We apply the SentiWS (Remus et al., 2010) for this purpose. As the SentiWS has sentiment values between -1 and 1, we apply similar procedures to construct the method-specific dictionaries as described above: For SO-CAL, it is the same procedure by using the SentiWS values, positive words has a score above 0.33 for Wilson and Opinion Observer, *strongsubj* words have an absolute value above 0.66 and so on. The methods are denoted as *method* (dictionary).

RSUMM (Sarvabhotla et al., 2011) needs less specific adaptation, because only a sentence splitter and a tokenizer are needed. So, RSUMM is very language-independent. We test two versions of this method: one includes the optimization step to estimate the best values for X and Y (notated as RSUMM(X%, Y%)) and the other version (RSUMM(100%)) does without this step, because we believe that every sentence is important in the statements and also because more words mean more information about the tonality in our domain.

We use the sets for the creation of the graphs and lexicons as the validation dataset (VDS) (Sarvabhotla et al., 2011) and the subjectivity dataset (SDS) (Sarvabhotla et al., 2011). As in (Sarvabhotla et al., 2011), we apply the SVMLight package[4] for classification.

Opinion Observer (Ding et al., 2008) and SO-CAL (Taboada et al., 2011) do not use supervised learning. Therefore, we have also added our SVM in order to classify the statements based on the scores of Opinion Observer and SO-CAL (as shown in tables with (+ SVM)).

4.3 Results

Table 2 and 4 (left side) show the results on the pressrelations dataset (PDS) and table 3 and 4 (right side) show the results on Finance. Table 2 and 3 present the tonality classification (positive, neutral, negative) and table 4 displays the Subjectivity Analysis (subjective, neutral).

Word connections (Entropy-summand) achieve the best results with 63.45% accuracy on PDS (more than 15% better than Wilson, which is the best of the 'classical' state-of-the-art methods) and best results on Finance with 65.17% (more than 4% better than RSUMM, which comes in second). The weighting of the edges through the Entropy-summand performs better than the Kullback-Leibler weighting on both datasets, so we use the Entropy-summand weighting for all further experiments.

Also, the improved methods (RSUMM(100%), Opinion Observer (+ SVM), and SO-CAL(+ SVM)) get better results in the majority of cases (the improvement of SO-CAL is more than 13% on PDS and more than 4% on Finance, e.g.). Furthermore, the variants of the methods, which are expanded by a general sentiment dictionary, perform rather worse. The 'classical' Opinion Observer performs better with a general sentiment dictionary, while Wilson tends to achieve worse results in this variant.

Wilson (without an additional dictionary) achieves an accuracy of 42.91% on PDS (Subjectivity Analysis 69.36%) and 48.67% on Finance (Subjectivity Analysis 60.96%) for their word classification. The accuracy of the dictionary variant is 43.44% on PDS and 40.12% on Finance. Therefore, the tonality classification by the most frequent word class seems appropriate for this task and method, because this method achieves better results in the classification of statements than on the word level.

The findings of RSUMM are ambiguous. The 'classical' RSUMM with parameter optimization does not perform very well on PDS, but it performs well on Finance with a high proportion of sentences and words (RSUMM(90%,95%)). Also, if we use all sentences and all features (RSUMM(100%)) we obtain better results on Finance and PDS. This fits in with our assumption that every sentence of a statement is important and that more words lead to more tonality information. The number of word features for RSUMM(100%) is 4,985 features for one statement on PDS and 13,608 features on Finance. After the parameter optimization the size is 974 word features on PDS (RSUMM(80%,20%)) and 12,248 features on Finance (RSUMM(90%,95%)).

The outcomes of this study suggest that methods which include machine learning techniques tend to perform better than unsupervised techniques. The results of the approaches which we expand with a SVM support this conclusion. As mentioned before, only the graph edges obtain a not so high accuracy. This shows the importance of the aggregation of the edges and entropy-based weighting.

We evaluate the influence of the different input sizes and so we performed experiments with 5%, 10%, 40%, and 80% training for machine learning as well as 210 and 840 statements for the creation of dictionaries/graphs on PSD (0.17% training for 210 statements and 0.32% training for 840 statements in order to create the same size of training according to the results of 420 statements). The results are shown in table 5. Opinion Observer and SO-CAL are written in italics, because the results on the left side (size of the training set) belongs to their (+ SVM) variants and the results on the right side are the 'classical' methods with no supervised learning. These experiments show that our word connections remain very stable if the training set is decreased. However, it does not benefit from more training, especially when the training set is very large (80%). Opinion Observer and RSUMM(80%,20%) has the same problem. Nevertheless, it still receives the second-best results, even if another method gets a higher accuracy. However, in our opinion, it is more important

Table 6: Significance of the tonality features T to the baselines Wilson and SO-CAL

to obtain good results on small training sizes, because over 75% for training would mean that a possible practical implementation would not save much human effort.

4.4 Statistical Significance of the Features

We perform a 10-fold cross validation with our method, Wilson (as the best 'classical' state-of-the-art-method) and SO-CAL (+ SVM) on the pressrelations dataset in order to evaluate the contribution of single tonality features. Our approach (Entropy-summand with all features) achieves an accuracy of 61.94%, while Wilson gets 56.36% and SO-CAL 46.68%. As an analogy to Wilson et al. (2009), we carry out a two-sided t-test with Wilson and SO-CAL (+ SVM) as baselines. The results are shown in table 6. The pluses indicate a significant increase to the baseline, the minuses show a significant decrease. For one sign, changes are significant at the level $p \leq 0.1$, two signs mean $p \leq 0.05$, three signs $p \leq 0.025$, four signs $p \leq 0.01$ and five signs indicate $p \leq 0.005$. "nsc" stands for no significant change.

As shown in table 6, the features with type $z = sub$ are more important than the polarity features. In the categories, the nouns and verbs are more significant than adjectives and adverbs (adverbs are a little stronger in the polarity difference). Combining all features produces a very significant increase against both baselines.

5 Conclusion

We have shown that the word connections outperform state-of-the-art-methods in most cases of tonality classification for a MRA. As a major advantage, our approach does not need much training data. The combination of all tonality features is a significant increase against both baselines, too. The findings show that the word connections in combination with the entropy weighting allow to learn the tonality structure of different word combinations accurately, even though the training size is small. This is a major advantage for a solution, which operates in practice for media analysts, which have to analyse articles for a MRA.

So, this approach in combination with an extraction of statements (Scholz and Conrad, 2013) and the determination of viewpoints (Scholz and Conrad, 2012) represents a fully automated solution in order to perform Opinion Mining for a MRA.

Abstract

Microblog messages pose severe challenges for current sentiment analysis techniques due to some inherent characteristics such as the length limit and informal writing style. In this paper, we study the problem of extracting opinion targets of Chinese microblog messages. Such fine-grained word-level task has not been well investigated in microblogs yet. We propose an unsupervised label propagation algorithm to address the problem. The opinion targets of all messages in a topic are collectively extracted based on the assumption that similar messages may focus on similar opinion targets. Topics in microblogs are identified by hashtags or using clustering algorithms. Experimental results on Chinese microblogs show the effectiveness of our framework and algorithms.

1 Introduction

Microblogging services such as Twitter[1], Sina Weibo[2] and Tencent Weibo[3] have swept across the globe in recent years. Users of microblogs range from celebrities to ordinary people, who usually express their emotions or attitudes towards a broad range of topics. It is reported that there are more than 340 million tweets per day on Twitter and more than 200 million on Sina Weibo. A tweet means a post on Twitter. Since we mainly focus on Chinese microblogs instead of Twitter in this paper, we will refer to a post as a message. Each message is limited to 140 Chinese characters and usually contains several sentences.

Currently, researches on microblog sentiment analysis have been conducted on polarity classification (Barbosa and Feng, 2010; Jiang el al., 2011; Speriosu et al., 2011) and have been proved to be useful in many applications, such as opinion polling (Tang et al., 2012), election prediction (Tumasjan et al., 2010) and even stock market prediction (Bollen et al., 2011). However, classifying microblog texts at the sentence level is often insufficient for applications because it does not identify the opinion targets. In this paper, we will study the task of opinion target extraction for Chinese microblog messages.

Opinion target extraction aims to find the object to which the opinion is expressed. For example, in the sentence "The sound quality is good!", "sound quality" is the opinion target. This task is mostly studied in customer review texts in which opinion targets are often referred as features or aspects (Liu, 2012). Most of the opinion target extraction approaches rely on dependency parsing (Zhuang et al., 2006; Jakob and Gurevych, 2010; Qiu et al., 2011) and are regarded as a domain-dependent task (Li et al., 2012a). However, such approaches are not suitable for microblogs because the natural language processing tools perform poorly on microblog texts due to their inherent characteristics. Studies show that one of the state-of-the-art part-of-speech taggers - OpenNLP only achieves the accuracy of 74% on tweets (Liu et al. 2011). The syntactic analysis tool that generates dependency relation may perform even worse. Besides, microblog messages may express opinion in different ways and do not always contain opinion words, which lowers the performance of methods utilizing opinion words to find opinion targets.

In this study, we propose an unsupervised method to collectively extract the opinion targets from opinionated sentences in the same topic.

Seattle, Washington, USA, 18-21 October 2013.

Topics are directly identified by hashtags. We first present a dynamic programming based segmentation algorithm for Chinese hashtag segmentation. By leveraging the contents in a topic, our segmentation algorithm can successfully identify out-of-vocabulary words and achieve promising results. Afterwards, all the noun phrases in each sentence and the hashtag segments are extracted as opinion target candidates. We propose an unsupervised label propagation algorithm to collectively rank the candidates of all sentences based on the assumption that similar sentences in a topic may share the same opinion targets. Finally, for each sentence, the candidate which gets the highest score after unsupervised label propagation is selected as the opinion target.

Our contributions in this study are summarized as follows: 1) our method considers not only the explicit opinion targets within the sentence but also the implicit opinion targets in the hashtag or mentioned in the previous sentence. 2) We develop an efficient algorithm to segment Chinese hashtags. It can successfully identify out-of-vocabulary words by leveraging contextual information and help to improve the segmentation performance of the messages in the topic. 3) We develop an unsupervised label propagation algorithm for collective opinion target extraction. Label propagation (Zhu and Ghahramani, 2002) aims to spread label distributions from a small training set throughout the graph. However, our unsupervised algorithm leverages the connection between two adjacent unlabeled nodes to find the correct labels for both of them. The proposed unsupervised method does not need any training corpus which will cost much human labor especially for fine-grained annotation. 4) To the best of our knowledge, the task of opinion target extraction in microblogs has not been well studied yet. It is more challenging than microblog sentiment classification and opinion target extraction in review texts.

2 Characteristics of Chinese Microblogs

Most of previous microblog sentiment analysis researches focus on Twitter and especially in English. However, the analysis of Chinese microblogs has some differences with that of Twitter: 1) Chinese word segmentation is a necessary step for Chinese sentiment analysis, but the existing segmentation tool performs poorly on microblogs because the microblog texts are much different from regular texts. 2) Wang et al. (2011) find that hashtags in English tweets are used to highlight the sentiment information such as “ #love”, “#sucks” or serve as user-annotated coarse topics such as “#news”, “#sports”. But in Chinese microblogs, most of the hashtags are used to indicate fine-grained topics such as #NBA 总决赛第七场# (#NBAFinalG7#). Besides, hashtags in Twitter always appear within a sentence such as “I love #BarackObama!” while hashtags in Chinese microblogs are always isolated and are surrounded by two # symbols such as “#巴拉克奥巴马# 我爱他!” (“#BarackObama# I love him！”).

It is noteworthy that topics aggregated by the same hashtag play an important role in Chinese microblog websites. These websites often provide an individual webpage[4] to list hot topics and invite people to participate in the discussion, where each topic consists of tens of thousands of messages with the same hashtag. The hot topics have a wide coverage of timely events and entities. Analyzing the opinion targets of these topics can help to get a deeper overview of the public attitudes towards the entities involved in the hot topics.

3 Motivation

As described above, #hashtags# in Chinese microblogs often indicate fine-grained topics. In this study, we aim to collectively extract the opinion targets of messages with the same hashtag, i.e. in the same topic. Opinion target of a sentence can be divided into two types, one of which called *explicit target* appears in the sentence such as “I love *Obama*”, and the other one called *implicit target*

Topic	Sentence
#官员财产公示# #Property publicity of government offic-ials#	1. 纯属作秀！ (Just for show！)
	2. 财产公示在中国就是作秀。 (Property publicity is just a show in China.)
#菲军舰恶意撞击# #Philippine navy vessel hits Chinese fishing boat#	1. 政府还是不够强硬。 (The government is not tough enough.)
	2. 政府为何不能强硬一些？ (Why cannot the government take a tougher line?)

Table 1. Motivation Examples

[4] http://huati.weibo.com/

may appear out of the sentence, for example, the sentence "Just for show!" in Table 1 directly comments on the target in the hashtag "#Property publicity of government officials#" . Such implicit opinion targets are not considered in previous works and are more difficult to extract than explicit targets. However, we believe that the contextual information will help to locate both of the two kinds of opinion targets because similar sentences in a topic may share the same opinion target, which provides the possibility for collective extraction.

Table 1 shows the motivation examples of two topics and four sentences. The two sentences in each topic are considered to be similar because they share several Chinese words. In the topic #官员财产公示# (#Property publicity of government officials#), the first sentence omits the opinion target. However, the second one contains an explicit target "财产公示" ("property publicity") in the sentence. If we find the correct opinion target for sentence 2, we can infer that sentence 1 may have an implicit opinion target similar to the opinion target in sentence 2. In the second topic, both sentences contain a noun word "政府" ("government"). The similarity between these two sentences may indicate that both of the two sentences are expressing opinion on "政府".

Based on the above observation, we can assume that similar sentences in a topic may have the same opinion targets. Such assumption can help to locate both explicit and implicit opinion targets. Following this idea, we firstly extract all the noun phrases in each sentence as opinion target candidates after applying Chinese word segmentation and part-of-speech tagging. Afterwards, an unsupervised label propagation algorithm is proposed to rank these candidates for all sentences in the topic.

In our methods, hashtags are used to find gold-standard topics. For messages without hashtags, an alternative way is to generate pseudo topics by clustering microblogs messages and then apply the proposed algorithm to each pseudo topic. The detailed discussion of such general circumstance is shown in Section 5.7.

4 Methodology

4.1 Context-Aware Hashtag Segmentation

In our approach, the Chinese word segmentations of hashtags and topic contents are treated separately. Existing Chinese word segmentation tools work poorly on microblog texts. The segmentation errors especially on opinion target words will directly influence the results of part-of-speech tagging and candidate extraction. However, some of the opinion target words in a topic are often included in the hashtag. By finding the correct segments of a hashtag and adding them to the user dictionary of the Chinese word segmentation tool, we can remarkably improve the overall segmentation performance.

The following example can help to understand the idea better. In the topic #90 后打老人# (means "A young man hits an old man"), "90 后" (literally "90 later" and means a young man born in the 90s) is an important word because it is the opinion target of many sentences. However, existing Chinese word segmentation tools will regard it as two separate words "90" and "后" ("later"). Then in the part-of-speech tagging stage, "90" will be tagged as number and "后" will be tagged as localizer. As we only extract noun phrases as opinion target candidates, the wrong segmentation on "90 后" makes it impossible to find the right opinion target. Such error may occur many times in sentences that mention the word "90 后" and express opinion on it. In our method, the message texts of the topic are utilized to identify such out-of-vocabulary words based on its frequency in the topic. For example, the high frequency of "90 后" is a strong indication that it should be regard as a single word. After segmenting the hashtag correctly into "90 后/打/老人", we can add the hashtag segments to the user dictionary of the segmentation tool to further segment the message texts of the topic.

The basic idea for our hashtag segmentation algorithm is to regard strings that appear frequently in a topic as words. Formally, given a hashtag h that contains n Chinese characters $c_1c_2...c_n$. We want to segment into several words $w_1w_2...w_m$, where each word is formed by one of more characters.

Firstly, we define the stickiness score for a Chinese string $c_1c_2...c_n$ based on the Symmetrical Conditional Probability (SCP) (Silva and Lopes, 1999):

$$SCP(c_1c_2...c_n) = \frac{\Pr(c_1c_2...c_n)^2}{\frac{1}{n-1}\sum_{i=1}^{n}\Pr(c_1...c_i)\Pr(c_{i+1}...c_n)} \quad (1)$$

and $SCP(c_1) = \Pr(c_1)^2$ for string with only one character. $\Pr(c_1c_2...c_n)$ is the occurrence frequency of the string in the topic.

Following (Li et al., 2012b), we smooth the SCP value by taking logarithm calculation. Besides, the length of the string is taken into consideration,

$$SCP'(c_1c_2...c_n) = n \times \log SCP(c_1c_2...c_n) \quad (2)$$

where n is the number of characters in the string.

Then the stickiness score is defined by the sigmoid function as follows:

$$Stickiness(c_1c_2...c_n) = \frac{2}{1+e^{-SCP'(c_1c_2...c_n)}} \quad (3)$$

For the hashtag $h = c_1c_2...c_n$, we want to segment it into m words $w_1w_2...w_m$ which maximize the following equation,

$$\max \sum_{i=1}^{m} Stickness(w_i) \quad (4)$$

The optimization of Equation (4) can be solved efficiently by dynamic programming which iteratively segments a string into two substrings. Different from (Li et al., 2012b) which calculates the SCP value of each string based on Microsoft Web N-Gram, our hashtag segmentation algorithm only uses the topic content and do not need any additional corpus.

4.2 Candidate Extraction

After segmenting the hashtag, all the hashtag segments with length greater than one are added to the user dictionary of the Chinese word segmentation tool ICTCLAS[5] to further segment the message texts of the topic. It also assigns the part-of-speech tag for each word after segmentation. The noun phrases in each sentence is extracted by the following regular expression: $(noun|adj)(noun|adj|的)*noun$. That means a noun phrase can only include nouns, adjectives and the Chinese word "的" ("of"). It should begin with a noun or adjective and end with a noun. For example, in the following sentence, "中国/n 的/u 教育/n 制度/n 有/v 问题/n 。/w" ("Chinese education system has problems."), "中国的教育制度" ("Chinese education system") and "问题" ("problem") are extracted as noun phrases.

The character number of a noun phrase is limited between two and seven Chinese characters. For each sentence, all phrases that match the regular expression and meet the length restriction are extracted as explicit opinion target candidates. The hashtag segments are regarded as implicit candidates for all sentences. Besides, some opinionated sentences in microblogs do not contain any noun phase, such as "无聊至极！" ("*So boring*!"). These sentences may express opinion on object that has been mentioned before. Therefore, the explicit candidates of the previous sentence in the same message are also taken as the implicit candidates for such sentences.

We do not use any syntactic parsing tool to extract noun phrases because the parsing results on microblogs are not reliable. A performance comparison of our rule based method and the state-of-the-art syntactic parser will be shown in Section 5.

4.3 Unsupervised Label Propagation for Candidate Ranking

We simply assume that each opinionated sentence has one opinion target, which is consistent with

Algorithm 1 Unsupervised Label Propagation

Input:

Graph: $G = < V, E, \tilde{W} >$

Candidate Similarity: $S \in R_+^{M \times M}$

Prior labeling: $Y_v \in R_+^{1 \times M}$ for $v \in V$

Filtering Matrix: $F_v \in R_+^{M \times M}$ for $v \in V$

Probability: p^{inj} and p^{cont}

Output:

Label vector: $\hat{Y}_v \in R_+^{1 \times M}$

1: **for all** $v \in V$ **do**
2: $\hat{Y}_v \leftarrow Y_v$
3: **end for**
4: **repeat**
5: **for all** $v \in V$ **do**
6: $D_v \leftarrow \sum_{u \in V, u \neq v} \tilde{W}_{uv} \left(\hat{Y}_u \times S \right) \times F_v$
7: $\hat{Y}_v \leftarrow p^{inj} Y_v + p^{cont} D_v$
8: **end for**
9: **until convergence**

[5] http://www.ictclas.org/

the statistical result of our dataset that over 93% sentences have only one opinion target and each sentence has an average of 1.09 targets. Therefore, the most confident candidate of each sentence will be selected as the opinion target. In this section, we introduce an unsupervised graph-based label propagation algorithm to collectively rank the candidates of all sentences in a topic.

Label propagation (Zhu and Ghahramani, 2002; Talukdar and Crammer, 2009) is a semi-supervised algorithm which spreads label distributions from a small set of nodes seeded with some initial label information throughout the graph. The basic idea is to use information from the labeled nodes to label the adjacent nodes in the graph. However, our idea is to use the connection between different nodes to find the correct labels for all of them. Our unsupervised label propagation algorithm is summarized in Algorithm 1. Sentences are regarded as nodes and candidates of each sentence are regarded as labels. The label vector for each node is initialized based on the results of the candidate extraction step, which means no manually-labeled instances are needed in our model. In each iteration, the label vector of one node is propagated to the adjacent nodes. Both the sentence (node) similarity and the candidate (label) similarity are considered during propagation. Finally, we select the candidate with the highest score in the label vector as the opinion target for each sentence. The details of Algorithm 1 are presented as follows.

Formally, an undirected graph $G = < V, E, \tilde{W} >$ is built for each topic. A node $v \in V$ represents a sentence in the topic and an edge $e = (a, b) \in E$ indicates that the labels of the two vertices should be similar. $\tilde{W}$ is the normalized weight matrix to reflect the strength of this similarity. The similarity between two nodes W_{ab} is simply calculated by using the cosine measure (Salton et al., 1975) of the two sentences.

$$W_{ab} = cos(T_a, T_b) = \frac{T_a \cdot T_b}{\|T_a\| \cdot \|T_b\|} \quad (5)$$

where T_a and T_b are the term vectors of sentences a and b represented by the standard vector space model and weighted by term frequency. After calculating the similarity matrix W, we get the weight matrix $\tilde{W}$ by normalizing each row of W such that $\sum_b \tilde{W}_{ab} = 1$.

For each sentence (node) v, a candidate set C_v is extracted in the previous step. The candidate set CT for the whole topic is the union of all C_v,

$$CT = \bigcup C_v \quad (6)$$

The total number of candidates in the topic is denoted by $M = |CT|$. We calculate the candidate similarity matrix $S \in R_+^{M \times M}$ based on Jaccard Index:

$$S_{ij} = \frac{\left|A(CT_i) \cap A(CT_j)\right|}{\left|A(CT_i) \cup A(CT_j)\right|} \quad 1 \le i \ne j \le M \quad (7)$$

where $A(CT_i)$ and $A(CT_j)$ are the Chinese character sets of the i-th and j-th candidates in CT respectively.

Candidates are regarded as labels in our model and without loss of generality we assume that the possible labels for the whole topic are $L = \{1 \ldots M\}$ and each label in L corresponds to a unique candidate in CT. For each node $v \in V$, a label vector $Y_v \in R_+^{1 \times M}$ is initialized as

$$(Y_v)_k = \begin{cases} w & L_k \in C_v \\ 0 & L_k \notin C_v \end{cases} \quad 1 \le k \le M \quad (8)$$

where w is the initial weight of the candidate. We set $w = w_e$ if L_k is an explicit candidate (extracted noun phrase) of v and $w = w_i$ if L_k is an implicit candidate (hashtag segment or inherited from previous sentence) of v. If L_k is not a candidate of the current sentence, then the corresponding value in the label vector is 0. These values which are initialized as zero should always remain zero during the propagation algorithm because the corresponding label does not belong to the candidate set C_v of node v. To reset the values on these positions, a diagonal matrix $F_v \in R_+^{M \times M}$ is created for all nodes v,

$$(F_v)_{kk} = \begin{cases} 1 & (Y_v)_k > 0 \\ 0 & (Y_v)_k = 0 \end{cases} \quad 1 \le k \le M \quad (9)$$

where the subscript kk denotes the k-th position in the diagonal of matrix F_v. We can right-multiply Y_v by F_v to clear the values of the invalid candi-

dates. Figure 1 shows an example of creating the filtering matrix for a label vector.

$$Y_v = [1 \;\; 1 \;\; 0.5 \;\; 0] \;\rightarrow\; F_v = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

Figure 1. Example of filtering matrix

The propagation process is formalized via two possible actions: inject and continue, with predefined probabilities p^{inj} and p^{cont}. Their sum is unit: $p^{inj} + p^{cont} = 1$. In each iteration, every node is influenced by its adjacent nodes. The propagation influence for each node v is

$$D_v = \sum_{u \in V, u \neq v} \tilde{W}_{uv} \left(\hat{Y}_u \times S \right) \times F_v \qquad (10)$$

where $\hat{Y}_u$ is the label vector of node u at the previous iteration. By multiplying the candidate similarity matrix S, we aim to propagate the score of the i-th candidate of node u not only to the i-th candidate of node v, but also to all the other candidates. W_{uv} measures the strength of such propagation. The filtering matrix F_v is used to clear the values of the invalid candidates as described above.

Then the label vector of node v is updated as follow,

$$\hat{Y}_v = p^{inj} Y_v + p^{cont} D_v \qquad (11)$$

When the positions of the largest values in all label vectors keep unchanged in ten iterations, it is regarded that the algorithm has already converged.

5 Experiments

5.1 Dataset

We use the dataset from the 2012 Chinese Microblog Sentiment Analysis Evaluation (CMSAE)[6] held by China Computer Federation (CCF). There are three tasks in the evaluation: subjectivity classification, polarity classification and opinion target extraction. The dataset contains 20 topics collected from Tencent Weibo, a popular Chinese microblogging website. All the messages in a topic contain the same hashtag. The dataset has a total of 17518 messages and 31675 sentences. In each topic, 100 messages are manually annotated with subjectivity, polarity and opinion targets. A total of 2361opinion targets are annotated for 2152 opinionated sentences.

5.2 Evaluation Metric

Precision, recall and F-measure are used in the evaluation. Since expression boundaries are hard to define exactly in annotation guidelines (Wiebe et al., 2005), both the strict evaluation metric and the soft evaluation metric are used in CMSAE.

Strict Evaluation: For a proposed opinion target, it is regarded as correct only if it covers the same span with the annotation result. Note that, in CMSAE, an opinion target should be proposed along with its polarity. The correctness of the polarity is also necessary.

Soft Evaluation: The soft evaluation metric presented in (Johansson and Moschitti, 2010) is adopted by CMSAE. The *span coverage c* between each pair of the proposed target span *s* and the gold standard span *s'* is calculated as follows,

$$c(s, s') = \frac{|s \cap s'|}{|s'|} \qquad (12)$$

In Equation 12, the operator $|\cdot|$ counts Chinese characters, and the intersection $\cap$ gives the set of characters that two spans have in common.

Using the span coverage, the span set coverage C of a set of spans S with respect to another set S' is

$$C(S, S') = \sum_{s \in S} \sum_{s' \in S'} c(s, s') \qquad (13)$$

The soft precision P and recall R of a proposed set of spans $\hat{S}$ with respect to a gold standard set S is defined as follows:

$$\text{Precision} = \frac{C(\hat{S}, S)}{|\hat{S}|} \quad \text{Recall} = \frac{C(\hat{S}, S)}{|S|} \qquad (14)$$

Note that the operator $|\cdot|$ counts spans in Equation 14. The soft F-measure is the harmonic mean of soft precision and recall.

5.3 Comparison Methods

Our proposed approach is first compared with the CMSAE teams.

CMSAE Teams: Sixteen teams participated in the opinion target extraction task of CMSAE. The methods of the top 3 teams are used as baselines

[6] http://tcci.ccf.org.cn/conference/2012/pages/page04_eva.html. The dataset can also be publicly accessed on the website.

here. They are denoted as **Team-1**, **Team-2** and **Team-3** respectively. The average result of all the sixteen teams is also included and is denoted as **Team-Avg**. We will briefly introduce the best team's method. The most important component of their model is a topic-dependent opinion target lexicon which is called object sheet. If a word or phrase in the object sheet appears in a sentence or a hashtag, it is extracted as opinion target. The object sheet is manually built for each topic, which means their method cannot be applied to new topics.

The following models are also used for comparison.

AssocMi: We implement the unsupervised method for opinion target extraction based on (Hu and Liu, 2004), which relies on association mining and a sentiment lexicon to extract frequent and infrequent product features.

CRF: The CRF-based method used in (Jakob and Gurevych, 2010) is also used for comparison. We implement both the single-domain and cross-domain models. Both models are evaluated using 5-fold cross-validation. More specifically, the single-domain model, denoted as **CRF-S**, trains different models for different topics. In each cross-validation round, 80 percent of each topic is used for training and the other 20 percent is used for test. The cross-domain model, denoted as **CRF-C**, uses 16 topics for training and the rest 4 topics for test in each round.

5.4 Comparison Results

CMSAE requires all the teams to perform the subjectivity and polarity classification task in advance. The opinion targets are extracted only for opinionated sentences and should be proposed along with their polarity. To make a fair comparison, we directly use the subjectivity and polarity classification results of Team-1. Then our unsupervised label propagation (**ULP**) method is used to extract the opinion targets for the proposed opinionated sentences. The parameters of our method are simply set as $p^{inj} = p^{cont} = 0.5$, $w_e = 1$ and $w_i = 0.5$.

Table 2 lists the comparison results with CMSAE teams. The average F-measure of all teams is 0.12 and 0.20 in strict and soft evaluation, respectively. It shows that opinion target extraction is a quite hard problem in Chinese microblogs. Our method performs better than all the teams. It increases by 10% and 13% in the two kinds of F-measure compared to the best team. Besides, we do not need any prior information of the topics while Team-1 has to manually build an opinion target lexicon for each topic.

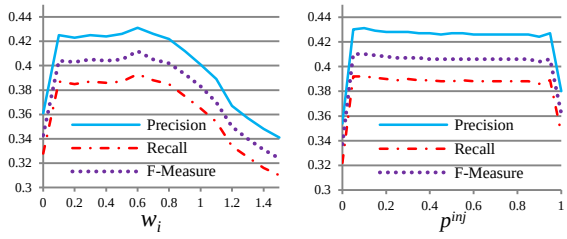
To compare with the other opinion target extraction methods, we only use gold-standard opinionated sentences for evaluation and do not classify the polarity of the opinion targets. Table 3 shows the experimental results of the four models. Our approach achieves the best result among them. AssocMi performs worst in strict evaluation but gets better results than the two CRF-based models in soft evaluation. The two CRF-based models achieve high precision but low recall. We can also observe that CRF-S is much more effective than CRF-C. It achieves high results because it has already seen the opinion targets in the training set. However, it is impossible to build such single-domain model in practical applications because

Method.	Strict			Soft		
	Precision	Recall	F-measure	Precision	Recall	F-measure
Team-Avg	0.17	0.09	0.12	0.29	0.15	0.20
Team-3	0.26	0.16	0.20	0.40	0.25	0.31
Team-2	0.31	0.18	0.23	0.40	0.22	0.29
Team-1	0.30	**0.27**	0.29	0.39	0.36	0.37
ULP	**0.37**	**0.27**	**0.32**	**0.48**	**0.37**	**0.42**

Table 2. Comparison results with CMSAE teams (with subjectivity and polarity classification in advance)

Method	Strict			Soft		
	Precision	Recall	F-Measure	Precision	Recall	F-Measure
AssocMi	0.22	0.20	0.21	0.47	0.43	0.45
CRF-C	0.59	0.15	0.24	0.70	0.18	0.28
CRF-S	**0.61**	0.27	0.35	**0.73**	0.31	0.41
ULP	0.43	**0.39**	**0.41**	0.61	**0.55**	**0.58**

Table 3. Comparison results with baseline methods (only gold-standard opinionated sentences are used)



(a) Initial Candidate Weight (b) Injection Probability

Figure 2. Influence of the parameters

labeled instances are not available for new topics. Our proposed method does not require any training data and gets an increase of 17% over CRF-S and 70% over CRF-C in strict evaluation. In terms of soft evaluation, we achieve an increase of 41% and 107% over the two CRF models.

5.5 Parameter Sensitivity Study

In this section, we study the parameter sensitivity. There are two major parameters in our algorithm: the initial weight w for both explicit and implicit candidates in Equation 8 and the injection probability p^{inj} in Equation 11.

The initial weights of explicit and implicit candidates are set differently because the explicit candidates are more likely to be the opinion targets. These two kinds of initial weights are denoted as w_e and w_i for explicit and implicit candidate, respectively. To study the impact of the initial weights, we fix w_e at 1 and tune w_i because we only care about the relative contribution of them. The injection probability is fixed at 0.5. Figure 2(a) displays the opinion target extraction performance when w_i varies from 0 to 1.5. Due to limited space, we only list the strict F-measure of opinion target extraction evaluated on opinioned sentences (same experimental setup as Table 3).

In particular, when w_i is equal to 0, only explicit candidates are considered. When w_i becomes larger than 1, the implicit candidates become more important than explicit candidates. From the curve in Figure 2(a), we can observe that the implicit candidates help to improve the performance significantly when w_i varies from 0 to 0.1. The performance reaches the peak when w_i = 0.7 and declines rapidly when w_i gets larger than 1.

To study the impact of injection probability p^{inj}, we fix the initial weights for explicit and implicit candidates as 1 and 0.5, respectively. Figure 2(b) shows the results of opinion target extraction with respect to different values of the injection probability. We can observe that the performance keeps steady except for the two extreme values 0 and 1. From the above two figures, we can conclude that our proposed method performs well and robustly with a wide range of parameter values.

Method	Total	Correct	F-Measure of Opinion Target Extraction	
			Strict	Soft
Berkley Parser	4554	877	0.36	0.56
Rule	4105	918	0.37	0.56
HS + Rule	4094	1042	0.41	0.58

Table 4. Performance of candidate extraction and opinion target extraction

5.6 Analysis of Candidate Extraction

Candidate extraction is an important step in our proposed method. If the correct opinion target is not extracted as a candidate, the ranking step will be in vain. As described in Section 3, we develop a hashtag segmentation algorithm and use a rule based method to extract noun phrases from each sentence. We do not use any parsing tool because we believe the performance of these tools is not good enough when applied on microblogs. A quantitative comparison is shown in this section.

We use one of the state-of-the-art syntactic analysis tools - **Berkeley Parser** (Petrov et al., 2006) for comparison here. Noun phrases are directly extracted from the parsing results. Our method **HS+Rule** leverages the hashtag segments to enhance the segmentation result and extracts explicit candidate using a regular expression. To demonstrate the effectiveness of our hashtag segmentation algorithm, the second comparison baseline **Rule** directly uses ICTCLAS to segment the whole topic content and labels each word with its part-of-speech tag. The explicit candidates are extracted by using the same regular expression.

The performance on candidate extraction is compared in Table 4. The second column shows the number of all extracted candidates for all the opinionated sentences by different methods. The third column shows the number of correct opinion targets among them. We can find that the two rule-based models both outperform Berkeley Parser and our **HS+Rule** method finds 14% more correct opinion targets than **Rule**. It proves the effectiveness of our hashtag segmentation algorithm. The

total number of candidates extracted by **HS+Rule** is also less than the other two methods. Therefore, the performance of label propagation will be improved when there are fewer candidates to rank. It can be demonstrated by the F-measure of opinion target extraction in the fourth and fifth columns. The experiments are conducted on opinionated sentence only as above. By using **HS+Rule** to extract candidates, our label propagation algorithm gets the highest F-measure in both evaluation metrics.

5.7 Performance on Pseudo Topics by Message Clustering

In our collective extraction algorithm, topics are directly identified by hashtags. For messages without hashtags, we can first employ clustering algorithms to obtain pseudo topics (clusters) and then exploiting the topic-oriented algorithm for collective opinion target extraction. To test the performance of the proposed method in such circumstance, we use the popular clustering algorithm - Affinity Propagation (Frey and Dueck, 2007) to generate topics. The experimental results are shown in Table 5. **APCluster** means that the messages are clustered after removing all the hashtags. **APCluster+HS** means that all the hashtags are retained as normal texts for calculating message similarity. Therefore, the clustering performance can be largely improved. The standard cosine similarity is used to measure the distance between microblog messages for Affinity Propagation in the above two methods. The last method denoted as **GoldCluster** directly uses hashtags to identify the gold-standard topics which shows the upper bound of the performance. After clustering microblogs, the opinion targets of messages in each cluster are collectively extracted by the proposed unsupervised label propagation algorithm. The experiments are conducted on opinionated sentences only.

From the results, we can see that clustering microblogs without hashtags is a quite difficult job which only gets an F-Measure of 0.27. However, the corresponding opinion target extraction performance is still promising, which outperforms the AssocMi and CRF-C methods in Table 3. With the help of hashtags, the clustering performance of **APCluster+HS** is largely improved and the opinion target extraction performance is also increased.

Clustering Method	F-Measure of Clustering	F-Measure of Opinion Target Extraction	
		Strict	Soft
APCluster	0.27	0.35	0.50
APCluster+HS	0.71	0.37	0.55
GoldCluster	1.00	0.41	0.58

Table 5. Performance of clustering and opinion target extraction

It outperforms all the baseline methods in Table 3. The above results reveal that our proposed unsupervised label propagation algorithm works well in pseudo topics and the performance can be increased with better clustering results. Therefore, we can try to incorporate other social network information to improve the message clustering performance, which will be studied in our future work.

6 Related Work

Sentiment analysis, a.k.a. opinion mining, is the field of studying and analyzing people's opinions, sentiments, evaluations, appraisals, attitudes, and emotions (Liu, 2012). Most of the previous sentiment analysis researches focus on customer reviews (Pang et al., 2002; Hu and Liu, 2004) and some of them focus on news (Kim and Hovy, 2006) and blogs (Draya et al., 2009). However, sentiment analysis on microblogs has recently attracted much attention and has been proved to be very useful in many applications.

Classification of opinion polarity is the most common task studied in microblogs. Go et.al (2009) follow the supervised machine learning approach of Pang et al. (2002) to classify the polarity of each tweet by distant supervision. The training dataset of their method is not manually labeled but automatically collected using the emoticons. Barbosa and Feng (2010) use the similar pseudo training data collected from three online websites which provide Twitter sentiment analysis services. Speriosu et al. (2009) explore the possibility of exploiting the Twitter follower graph to improve polarity classification.

Opinion target extraction is a fine-grained word-level task of sentiment analysis. Currently, this task has not been well studied in microblogs yet. It is mostly performed on product reviews where opinion targets are always described as product features or aspects. The pioneering research on this task is conducted by Hu and Liu

(2004) who propose a method which extracts frequent nouns and noun phrases as the opinion targets. Jakob and Gurevych (2010) model the problem as a sequence labeling task based on Conditional Random Fields (CRF). Qiu et al. (2011) propose a double propagation method to extract opinion word and opinion target simultaneously. Liu et al. (2012) use the word translation model in a monolingual scenario to mine the associations between opinion targets and opinion words.

7 Conclusion and Future Work

In this paper, we study the problem of opinion target extraction in Chinese microblogs which has not been well investigated yet. We propose an unsupervised label propagation algorithm to collectively rank the opinion target candidates of all sentences in a topic. We also propose a dynamic programming based algorithm for segmenting Chinese hashtags. Experimental results show the effectiveness of our method.

In future work, we will try to collect and annotate data for microblogs in other languages to test the robustness of our method. The repost and reply messages can also be integrated into our graph model to help improve the results.

Detecting Promotional Content in Wikipedia

Shruti Bhosale **Heath Vinicombe** **Raymond J. Mooney**
Department of Computer Science

{shruti,vini,mooney}@cs.utexas.edu

Abstract

This paper presents an approach for detecting promotional content in Wikipedia. By incorporating stylometric features, including features based on n-gram and PCFG language models, we demonstrate improved accuracy at identifying promotional articles, compared to using only lexical information and meta-features.

1 Introduction

Wikipedia is a free, collaboratively edited encyclopedia. Since normally anyone can create and edit pages, some articles are written in a promotional tone, violating Wikipedia's policy requiring a neutral viewpoint. Currently, such articles are identified manually and tagged with an appropriate Cleanup message[1] by Wikipedia editors. Given the scale and rate of growth of Wikipedia, it is infeasible to manually identify all such articles. Hence, we present an approach to automatically detect promotional articles.

Related work in quality flaw detection in Wikipedia (Anderka et al., 2012) has relied on meta-features based on edit history, Wikipedia links, structural features and counts of words, sentences and paragraphs. However, we hypothesize that there are subtle differences in the linguistic style that distinguish promotional tone, which we attempt to capture using stylometric features, particularly deeper syntactic features. We model the style of promotional and normal articles using language models based on both n-grams and Probabilistic Context Free Grammars (PCFGs). We show that using such stylometric features improves over using only shallow lexical and meta-features.

2 Related Work

Anderka et al. (2012) developed a general model for detecting ten of Wikipedia's most frequent quality flaws. One of these flaw types, "Advert"[2], refers to articles written like advertisements. Their classifiers were trained using a set of lexical, structural, network and edit-history related features of Wikipedia articles. However, they used no features capturing syntactic structure, at a level deeper than Part-Of-Speech (POS) tags.

A related area is that of vandalism detection in Wikipedia. Several systems have been developed to detect vandalizing edits in Wikipedia. These fall into two major categories: those analyzing author information and edit metadata (Wilkinson and Huberman, 2007; Stein and Hess, 2007); and those using NLP techniques such as n-gram language models and PCFGs (Wang and McKeown, 2010; Harpalani et al., 2011). We combine relevant features from both these categories to train a classifier that distinguishes promotional content from normal Wikipedia articles.

3 Dataset Collection

We extracted a set of about 13,000 articles from English Wikipedia's category, "Category:All arti-

[1] http://en.wikipedia.org/wiki/Wikipedia:Template_messages/Cleanup

[2] "Advert" is the flaw-type of majority of the articles in the Category 'Articles with a promotional tone'.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1851–1857,
Seattle, Washington, USA, 18-21 October 2013.

cles with a promotional tone" as a set of positive examples. We extracted a set of 26,000 untagged articles to form a noisy set of negative examples, which may contain some promotional articles that have not yet been tagged by Wikipedia editors. To counter this noise, we repeated the experiment using Wikipedia's Featured Articles and Good Articles (approx. 11,000) as a set of clean negative examples. We used 70% of the articles in each category to train language models for each of the three categories (promotional articles, featured/good articles, untagged articles), and used the remaining 30% to evaluate classifier performance using 10-fold cross-validation.

4 Features

4.1 Content and Meta Features of an Article

We used the content and meta features proposed by Anderka et al. (2012) as given in Tables 1-4. We also

[3] http://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Words_to_watch

added a new feature, "Overall Sentiment Score" for an article. This feature is the average of the sentiment scores assigned by SentiWordnet (Baccianella et al., 2010) to all positive and negative sentiment bearing words in an article. In total, this results in 58 basic document features.

4.2 N-Gram Language Models

Language models are commonly used to measure stylistic differences in language usage between authors. For this work, we employed them to model the difference in style of neutral vs. promotional Wikipedia articles. We trained trigram word language models and trigram character language models[5] with Witten-Bell smoothing to produce probabilistic models of both classes.

4.3 PCFG Language Models

Probabilistic Context Free Grammars (PCFG) capture the syntactic structure of language by modeling sentence generation using probabilistic CFG productions. We hypothesize that sentences in promotional articles and those in neutral articles tend to have different kinds of syntactic structures and therefore, we explored the utility of PCFG models for detecting this difference. Since we do not have ground-truth parse trees for sentences in our dataset,

[5] Modeling longer character sequences did not help.

Features based on PCFG models and n-gram Language models
Difference in the probabilities assigned to an article by the positive and the negative class *character trigram language models* (LM_char_trigram)
Difference in the probabilities assigned to an article by the positive and the negative class *word trigram language models* (LM_word_trigram)
Difference in the *mean* values of the probabilities assigned to sentences of an article by the positive and negative class *PCFG models* (PCFG_mean)
Difference in the *maximum* values of the probabilities assigned to sentences of an article by the positive and negative class *PCFG models* (PCFG_max)
Difference in the *minimum* values of the probabilities assigned to sentences of an article by the positive and negative class *PCFG models* (PCFG_min)
Difference in the *standard deviation* values of the probabilities of sentences of an article by the positive and negative class *PCFG models* (PCFG_std_deviation)

Table 4: Edit-History Features of a Wikipedia Article

we followed the method of (Raghavan et al., 2010; Harpalani et al., 2011), which uses the output of the Stanford parser to train PCFG models for stylistic analysis. We used the PCFG implementation of Klein and Manning (2003) to learn a PCFG model for each category.

4.4 Classification

The n-gram and PCFG language models were used to create a set of additional document features. We used the probability assigned by the language models to each sentence in a test document to calculate document-wide statistics such as the mean, maximum, and minimum probability and standard deviation in probabilities of the set of sentences in an article. The language-modeling features used are shown in Table 5.

Since we have a wide variety of features, we experimented with various ensemble learning techniques and found that LogitBoost performed best empirically. We used the Weka implementation of LogitBoost (Friedman et al., 2000) to train a classifier using various combinations of features. We used Decision Stumps as a base classifier and ran boosting for 500 iterations.

5 Experimental Evaluation

5.1 Methodology

We used 10-fold cross-validation to test the performance of our classifier using various combinations of features. We ran the classifier on the portion (30%) of the dataset not used for language modeling.[6] We measured overall classification accuracy as well as precision, recall, F-measure, and area under the ROC curve for all experiments. We tested performance in two settings (Anderka et al., 2012):

- *Pessimistic Setting*: The negative class consists of articles from the Untagged set. Since some of these could be manually undetected promotional articles, the accuracy measured in this setting is probably an under-estimate.
- *Optimistic Setting*: The negative class consists of articles from the Featured/Good set. These articles are at one end of the quality spectrum, making it relatively easier to distinguish them from promotional articles.

The true performance of the classifier is likely somewhere between that achieved in these two settings.

[6] We maintain an equal number of positive and negative test cases in both the settings.

Features	Pessimistic Setting				Optimistic Setting			
	P	R	F1	AUC	P	R	F1	AUC
Bag-of-words Baseline	0.823	0.820	0.821	0.893	0.931	0.931	0.931	0.979
PCFG	0.881	0.870	0.865	0.903	0.910	0.910	0.910	0.961
Character trigrams	0.889	0.887	0.888	0.952	0.858	0.843	0.841	0.877
Word trigrams	0.863	0.863	0.863	0.931	0.887	0.883	0.882	0.931
Character trigrams + Word trigrams	0.89	0.888	0.889	0.952	0.908	0.907	0.907	0.962
PCFG+Char. trigrams+Word trigrams	0.914	0.915	0.914	0.974	0.950	0.950	0.950	0.983
58 Content and Meta Features	0.866	0.867	0.867	0.938	0.986	0.986	0.986	0.996
All Features	**0.940**	**0.940**	**0.940**	**0.986**	**0.989**	**0.989**	**0.989**	**0.997**

Table 6: Performance (Precision(P), Recall(R), F1 score, AUC) of the classifier in the two settings

5.2 Results for Pessimistic Setting

From Table 6, we see that all features perform better than the bag-of-words baseline. We also see that character trigrams, one of the simplest features, gives the best individual performance. However, deeper syntactic features using PCFGs also performs quite well. Combining all of the language-modeling features (PCFG + character trigrams + Word trigrams) further improves performance. Compared to the 58 content and meta features utilized by Anderka et al., (2012) described in Section 4.1, the PCFG and character trigram features give much better performance, both individually and when combined. It is interesting to note that adding Anderka et al.'s features to the language-modeling ones gives a fairly small improvement in performance. This validates our hypothesis that promotional articles tend to have a distinct linguistic style that is captured well using language models.

5.3 Results for Optimistic Setting

In the Optimistic Setting, as shown in Table 6, the content and meta features give the best performance, which improves only slightly when combined with language-modeling features. The bag-of-words baseline performs better than all the language modeling features. This performance could be because there is a much clearer distinction between promotional articles and featured/good articles that can be captured by simple features alone. For example, featured/good articles are generally longer than usual Wikipedia articles and have more references.

5.4 Top Ranked Features and their Performance

To analyze the performance of different features, we determined the top ranked features using Information Gain. In the Pessimistic Setting, the top six features are all language-modeling features (character trigram model feature works best), followed by basic meta-features such as character count, word count, category count and sentence count. The new feature we introduced, "Overall Sentiment Score" is the 18th most informative feature in the pessimistic setting, indicating that the cumulative sentiment of a bag of words is not as discriminative as we would intuitively assume. Using the 10 top-ranked features, we get an F1 of 0.93, which is only slightly worse than that achieved using all features (F1 = 0.94).

In the Optimistic Setting, the top-ranked features are the number of references and the number of references per section. This is consistent with the observation that featured/good articles have very long and comprehensive lists of references, since Wikipedia's fundamental policy is to maintain verifiability by citing relevant sources. Features based on the n-gram and PCFG models also appear in the list of ten best features. Using only the top 10 features, gives an F1 of 0.988, which is almost as good as using all features (F1 = 0.989).

5.5 Optimistic and Pessimistic Settings

In the optimistic setting, there is a clear distinction between the positive (promotional) and negative (featured/good) classes. But there are only subtle differences between the positive and negative (untagged articles) classes in the pessimistic setting.

Best Features in Pessimistic Setting	Best Features in Optimistic Setting
LM_char_trigram	Number of References
LM_word_trigram	Number of References per Section
PCFG_min	LM_word_trigram
PCFG_max	Number of Words
PCFG_mean	PCFG_mean
PCFG_std_deviation	Number of Sentences
Number of Characters	LM_char_trigram
Number of Words	Number of Words
Number of Categories	Number of Characters
Number of Sentences	Number of Backlinks

Table 7: Top 10 Features (listed in order) in both Settings ranked using Information Gain

These two classes are superficially similar, in terms of length, reference count, section count etc. Stylometric features based on the trained language models are successful at detecting the subtle linguistic differences in the two types of articles. This is useful because the pessimistic setting is closer to the real-world setting of articles in Wikipedia.

5.6 Error Analysis

Since the pessimistic setting is close to the real setting of Wikipedia articles, it is useful to do an error analysis of the classifier's performance in this setting. There is an approximately equal proportion of false positives and false negatives.

A significant number of false positives seem to be cases of manually undetected promotional articles. This demonstrates the practical utility of our classifier. But there are also many false positives that seem to be truly unbiased. These articles appear to have been poorly written, without following Wikipedia's editing policies. Examples include use of very long lists of nouns, use of ambiguous terms like "many believe" and excessive use of superlatives. Other common characteristics of most of the false positives are presence of a considerable number of complex sentences with multiple subordinate clauses. These stylistic cues seem to be misleading the classifier.

A common thread underlying most of the false negatives is the fact that they are written in a narrative style or they have excessive details in terms of the content. Examples include narrating a detailed story of a fictional character in an unbiased manner or writing a minutely detailed account of the history of an organization. Another source of false negatives comes from biographical Wikipedia pages which are written in a resume style, listing all their qualifications and achievements. These cues could help one manually detect that the article, though not promotional in style, is probably written with the view of promoting the entity. As possible future work, we could incorporate features derived from language models for narrative style trained using an appropriate external corpus of narrative text. This might enable the classifier to detect some cases of unbiased promotional articles.

6 Conclusion

Our experiments and analysis show that stylometric features based on n-gram language models and deeper syntactic PCFG models work very well for detecting promotional articles in Wikipedia. After analyzing the errors that are made during classification, we realize that though promotional content is non-neutral in majority of the cases, there do exist promotional articles that are neutral in style. Adding additional features based on language models of narrative style could lead to a better model of Wikipedia's promotional content.

Abstract

We explore Debatepedia, a community-authored encyclopedia of sociopolitical debates, as evidence for inferring a low-dimensional, human-interpretable representation in the domain of issues and positions. We introduce a generative model positing latent topics and cross-cutting positions that gives special treatment to person mentions and opinion words. We evaluate the resulting representation's usefulness in attaching opinionated documents to arguments and its consistency with human judgments about positions.

1 Introduction

The social web has evolved into a forum for large portions of the population to discuss and debate complex issues of societal importance. Websites like Debatepedia,[1] an online, community-authored encyclopedia of debates (§2), seek to organize some of this exchange into structured information resources that summarize arguments and link externally to texts (editorials, blog posts, etc.) that express and evoke them. Empirical NLP, we propose, has a role to play in creating a more compact and easily-interpretable way to understand the opinion space. In particular, we envision applications to computational journalism, where there is high demand for transformation of and pattern discovery in unmanageable, unstructured, evolving data (including text) to inform the public (Cohen et al., 2011).

In this paper, we develop a generative model for discovering such a representation (§3), using Debatepedia as a corpus of evidence. We draw inspiration from Lin et al. (2008) and Ahmed and Xing (2010), who used generative models to infer **topics**—distributions over words—and other word-associated variables representing perspectives or ideologies. We view topics as lexicons, and propose that *grounding* a topic model with evidence beyond bags of words can lead to more lexicon-like representations. Specifically, our generative topic model grounds topics using the hierarchical organization of arguments within Debatepedia. Further, we use named entity recognition as a preprocessing step, an existing sentiment lexicon to construct an informed prior, and we incorporate a latent, discrete **position** variable that cuts across debates.[2]

We evaluate the model informally and formally (§4). Subjectively, the model identifies reasonable topic and perspective terms, and it associates topics sensibly with important public figures. In quantitative evaluations, we find the model's representation superior to topics from vanilla latent Dirichlet allocation (Blei et al., 2003) and the joint sentiment topic model (Lin and He, 2009) in matching external texts to debates. Further, the position variables can be used to infer the *side* of an argument within a debate; our model performs with an accuracy of 86% on position prediction of the debate argument. The cross-cutting position variable is not especially consistent with human judgments, suggesting that further knowledge sources may be required to improve interpretability across issues.

2 Data

Debatepedia, like Wikipedia, is constructed by volunteer contributors and has a system of community

[1] http://dbp.idebate.org

[2] This variable might serve to cluster debate sides according to "abstract beliefs commonly shared by a group of people," sometimes called *ideologies* (Van Dijk, 1998). We do not claim that our model infers ideologies (see §4).

Argument: Gun sports have economic benefits. Field sports bring money into poor rural economies and provide a motivation for landowners to value environmental protection.

Table 1: An example of a Debatepedia debate on the topic "Gun control."

moderation. Many of the debate issues covered are controversial and salient in current public discourse. Because it is primarily expressed as text, Debatepedia is a *corpus* of debate topics, but it is organized hierarchically, with multiple issues in each debate topic, questions within each issue, and arguments on two sides of each question. An important feature of the corpus is the widespread quotation and linking to external articles on the web, including news stories, blog postings, wiki pages, and social media forums; here we use these external articles in evaluation (§4).

Table 1 shows excerpts from a debate page[3] from Debatepedia. Each debate contains "questions," which reflect the different aspects of a debate. In this particular debate, there are 13 questions (2 shown), ranging from economic benefits to enforceability to social impacts. For each question, there are two distinct sides, each with its own set of supporting arguments. Many of these arguments also contains links to online articles where the quotes are extracted from (not shown in Table 1). For example, in the second argument on the "No" side, there is an inline link to the article written by Congressman Drinan.[4]

Within a debate topic, the sides cut across different questions, aligning arguments together. In general, the questions are phrased so that a consistent "pro" and "con" structure is apparent throughout each debate, aligned to a high-level question (i.e., the "Yes" sides of all the questions are consistent with the same side of the larger debate). The example of Table 1 deviates from this pattern, with the self-defense "Yes" arguing "no" to the high-level debate question—*Should laws be passed to limit gun ownership further?*—and the economic "Yes" arguing "yes" to the high-level question.

Debates	1,303
Arguments	33,556
Articles linked by exactly one argument	3,352
Tokens	1,710,814
Types (excluding NE mentions)	59,601
Person named entity mentions	9,496

Table 2: Debatepedia corpus statistics. Types and tokens include unigrams, bigrams and person named entities.

Table 2 presents statistics of our corpus.

2.1 Preprocessing

We scraped the Debatepedia website and extracted the debate, question, argument, and side structure of the debate topics. We crawled the external web articles that were linked from the Debatepedia arguments. For the web articles, we extracted the main text content (ignoring boilerplate elements such as navigation and advertisments) using Boil-

[3] http://dbp.idebate.org/en/index.php/Debate:_Gun_control

[4] http://www.saf.org/LawReviews/Drinan1.html

erpipe (Kohlschütter et al., 2010).[5] We tokenized the text and filtered stopwords.[6] We considered both unigrams and bigrams in our model, keeping all unigrams and removing bigram types that appeared less than 5 times in the corpus. Although our modeling approach ultimately treats texts as bags of terms (unigrams and bigrams), one important preprocessing step was taken to further improve the interpretability of the inferred representation: named entity mentions of persons. We identified these mentions of persons using Stanford NER (Finkel et al., 2005) and treated each person mention as a single token. In our qualitative analysis of the model (§4.2), we will show how this special treatment of person mentions enables the association of well-known individuals with debate topics. Though not part of our experimental evaluation in this paper, such associations are, we believe, an interesting direction for future applications of the model.

3 Model

Our model defines a probability distribution over terms[7] that are observed in the corpus. Each term occurs in a context defined by the tuple $\langle d, q, s, a\rangle$ (respectively, a *debate*, a *question* within the debate, a *side* within the debate, and an *argument*). At each level of the hierarchy is a different latent variable:

- Each question q within debate d is associated with a distribution over topics, denoted $\boldsymbol{\theta}_{d,q}$.[8]
- Each side s of the debate d is associated with a position, denoted $i_{d,s}$ and we posit a global distribution ι that cuts across different questions and arguments. In our experiments, there are two positions, and the two sides of a debate are constrained to associate with opposing positions. As illustrated by Table 1, this assumption is not always correct, though it tends to hold most of the time.
- Each term $w_{d,q,s,a,n}$ (n is the position index of the term within an argument) is associated with one of five *functional term types*, denoted $y_{d,q,s,a,n}$. This variable is latent, except when it takes the value "entity" (e) for terms marked as named entity mentions. When it is not an entity, it takes one of the other four values: "general position" (i), "topic-specific position" (o), "topic" (t), or "background" (b). Thus, every term w is drawn from one of these 5 types of bags, and y acts as a switching variable to select the type of bag.
- For some term types (the ones where $y \in \{\mathsf{o}, \mathsf{t}\}$), each term $w_{d,q,s,a,n}$ is associated with one of T discrete topics, as indexed by $z_{d,q,s,a,n}$.

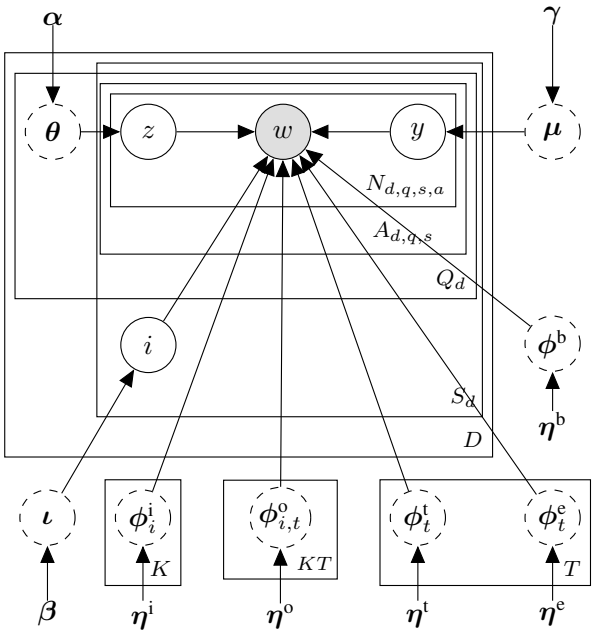

Figure 1: Plate diagram. K is the number of positions, and T is number of topics. The shaded variables are observed and dashed variables are marginalized. $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\gamma}$ and all $\boldsymbol{\eta}$ are fixed hyperparameters (§3.1).

Figure 1 illustrates the plate diagram for the graphical model underlying our approach. The generative story is given in Figure 2.

3.1 Priors

Typical probabilistic topic models assume a symmetric Dirichlet prior over its term distributions or

[5] http://code.google.com/p/boilerpipe

[6] www.ranks.nl/resources/stopwords.html

[7] Recall that our model includes bigrams. We treat each unigram and bigram token (after filtering discussed in §2.1) as a separate term.

[8] In future work, more sharing across questions within a debate, or more differentiation among the topic distributions for arguments under a question, might be explored. Wallach (2006) describes suitable techniques using hierarchical Dirichlet draws, and Eisenstein et al. (2011) suggests the use of sparse shocks to log-odds at different levels. Here we work on the assumption that Debatepedia's questions are the most topically coherent level, and work with a single topic mixture at this level.

1. $\forall$ topics t, draw topic-term distribution $\boldsymbol{\phi}^{\mathsf{t}}_t \sim \text{Dirichlet}(\boldsymbol{\eta}^{\mathsf{t}})$ and topic-entity distribution $\boldsymbol{\phi}^{\mathsf{e}}_t \sim \text{Dirichlet}(\boldsymbol{\eta}^{\mathsf{e}})$.
2. $\forall$ positions i, draw position-term distribution $\boldsymbol{\phi}^{\mathsf{i}}_i \sim \text{Dirichlet}(\boldsymbol{\eta}^{\mathsf{i}})$.
3. $\forall$ topics t, $\forall$ positions i, draw topic-position term distribution $\boldsymbol{\phi}^{\mathsf{o}}_{i,t} \sim \text{Dirichlet}(\boldsymbol{\eta}^{\mathsf{o}})$.
4. Draw background term distribution $\boldsymbol{\phi}^{\mathsf{b}} \sim \text{Dirichlet}(\boldsymbol{\eta}^{\mathsf{b}})$.
5. Draw functional term type distribution $\boldsymbol{\mu} \sim \text{Dirichlet}(\boldsymbol{\gamma})$.
6. Draw position distribution $\boldsymbol{\iota} \sim \text{Dirichlet}(\boldsymbol{\beta})$.
7. $\forall$ debates d:
   a. Draw $i_{d,1}, i_{d,2} \sim \text{Multinomial}(\boldsymbol{\iota})$, assigning each of the two sides to a position.
   b. $\forall$ questions q in d:
      i. Draw topic mixture proportions $\boldsymbol{\theta}_{d,q} \sim \text{Dirichlet}(\boldsymbol{\alpha})$.
      ii. $\forall$ arguments a under question q and term positions n in a:
         A. Draw topic label $z_{d,q,s,a} \sim \text{Multinomial}(\boldsymbol{\theta}_{d,q})$.
         B. Draw functional term type $y_{d,q,s,a} \sim \text{Multinomial}(\boldsymbol{\mu})$.
         C. Draw term $w_{d,q,s,a} \sim \text{Multinomial}\left(\boldsymbol{\phi}^{y_{d,q,s,a}} \mid i_{d,1}, i_{d,2}, z_{d,q,s,a}\right)$.

Figure 2: Generative story for our model of Debatepedia.

apply empirical Bayesian techniques to estimate the hyperparameters. Motivated by past efforts to exploit prior knowledge (Zhao et al., 2010; Lin and He, 2009), we use the OpinionFinder sentiment lexicon[9] (Wilson et al., 2005) to construct $\boldsymbol{\eta}^{\mathsf{i}}$ and $\boldsymbol{\eta}^{\mathsf{o}}$. Specifically, terms w in the lexicon were given parameters $\eta^{\mathsf{i}}_w = \eta^{\mathsf{o}}_w = 0.01$, and other terms were given $\eta^{\mathsf{i}}_w = \eta^{\mathsf{o}}_w = 0.001$, capturing our prior belief that opinion-expressing terms are likely to be used in expressing positions. 5,451 types were given a "boost" through this prior.

Information retrieval has long exploited the observation that a term's document frequency (i.e., the number of documents a term occurs in) is inversely related its usefulness in retrieval (Jones, 1972). We encode this in $\boldsymbol{\eta}^{\mathsf{b}}$, the prior over the background term distribution, by setting each value to the logarithm of the term's argument frequency.

The other priors were set to be symmetric: $\eta^{\mathsf{e}} = 0.01$ (entity topics), $\eta^{\mathsf{t}} = 0.001$ (topics), $\alpha = 50/T = 1.25$ (topic mixture coefficients), $\beta = 0.01$ (positions), and $\gamma = 0.01$ (functional term types). Preliminary tests showed that final topics are relatively insensitive to the values of the hyperparameters.

3.2 Inference and Parameter Estimation

Exact inference under this model, like most latent-variable topic models, is intractable. We apply collapsed Gibbs sampling, a standard approach for such models (Griffiths and Steyvers, 2004).[10] The notable deviations from typical uses of collapsed Gibbs sampling are: (i) we jointly sample $i_{d,1}$ and $i_{d,2}$ to respect the constraint that they differ; and (ii) we fix the priors, in some cases to be asymmetric, as discussed in §3.1. We perform Gibbs sampling for 2,000 iterations over the dataset, discarding the first 500 iterations for burn-in, and averaging over every 10th iteration thereafter to get estimates for our term distributions.

3.3 T and K

In all experiments, we use $T = 40$ topics and $K = 2$ positions. We did not extensively explore different values for T and K; preliminary exploration suggested that interpretability, gauged informally by the authors, degraded for higher values of either.

4 Evaluation

Recall that the aim of this work is to infer a low-dimensional representation of debate text. We estimated our model on the Debatepedia debates (not including hyperlinked articles), and conducted several evaluations of the model, each considering a different aspect of the goal. We exploit external articles hyperlinked from Debatepedia described in §2 as supporting texts for arguments, treating each one's association to an argument as variable to be predicted. Firstly, we evaluate our model on the article associating task. Secondly, we evaluate our model on the position prediction task. Then, we compare

[9] http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/

[10] Because this technique is well known in NLP, details are relegated to supplementary material.

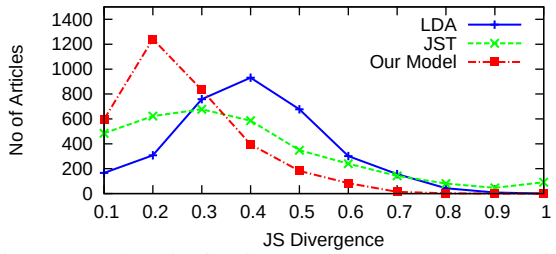

Figure 3: The distribution over Jensen-Shannon divergences between a hyperlinked article and the corresponding Debatepedia argument, $n = 3,352$.

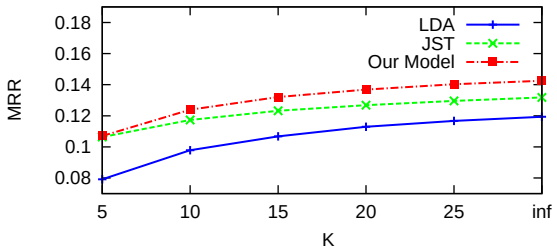

Figure 4: Mean reciprocal ranks for the association task.

our model's positional assignment of arguments to human annotated clusterings. Finally, we present qualitative discussion.

4.1 Quantitative Evaluation

4.1.1 Topics

As described in §2, our corpus includes 3,352 articles hyperlinked by Debatepedia arguments.[11] Our model can be used to infer the posterior over topics associated with such an article, and we compare that distribution to that of the Debatepedia article that links to it. Calculating the similarity of these distributions, we get an estimate of how closely our model can associate text related to a debate with the specific argument that linked to it. We compare with LDA (Blei et al., 2003), which ignores sentiment, and the joint sentiment topic (JST) model (Lin and He, 2009), an unsupervised model that jointly captures sentiment and topic.[12] Using Jensen-Shannon divergence, we find that our approach embeds these pairs significantly closer than LDA and JST (also trained with 40 topics), under a Wilcoxon signed rank test ($p < 0.001$). Figure 3 shows the histogram of divergences between our model, JST, and LDA.

Associating external articles. More challenging, of course, is *selecting* the argument to which an external article should be associated. We used the Jensen-Shannon divergence between topic distributions of articles and arguments to rank the latter, for each article. The mean reciprocal rank scores (Voorhees, 1999) for LDA, JST, and our model were 0.1272, 0.1421, and 0.1507, respectively; the difference is significant (Wilcoxon signed rank test, $p < 0.001$). We found the same pattern for MRR@k, $k \in \{5, 10, 15, 20, 25, \infty\}$, as shown in Figure 4.

It is likely possible to engineer more accurate models for attaching articles to arguments, but the attachment task is our aim only insofar as it contributes to an overall assessment of an inferred representation's quality.

4.1.2 Positions

Positional distance by topic. We next consider the JS divergences of position term distributions by topic; for each topic t, we consider the divergence between inferred values for $\phi^{\circ}_{1,t}$ and $\phi^{\circ}_{2,t}$. Figure 5 shows these measurements sorted from most to least different; these might be taken as evidence for which issue areas' arguments are more *lexically* distinguishable by side, perhaps indicating less common ground in discourse or (more speculatively) greater controversy. For example, our model suggests that debates relating to topics like presidential politics, foreign policy, teachers, women's health, religion, and Israel/Palestine are more heated (within the Debatepedia community at the time the debates took place) than those about the minimum wage, Iran as a nuclear threat, or immigration.

Predicting positions for arguments. We tested our model's ability to infer the positions of arguments. In this experiment (only), we held out 3,000 arguments during parameter estimation. The held-out arguments were selected so that every debate side maintained at least one argument whose inferred side could serve as the correct answer for the held-out argument. We then inferred i for each held-out argument from debate d and side s, given the parameters, and compared it with the value of $i_{d,s}$ inferred during parameter estimation. The model achieved 86% accuracy (Table 3 shows the confu-

[11] We consider only those articles linked by a single Debatepedia argument.

[12] JST multiplies topics out by the set of sentiment labels, assigning each token to both a topic and a sentment. We use the OpinionFinder lexicon in JST's prior in the same way it is used in our model.

sion matrix). Note that JST does not provide a baseline for comparison, since it does not capture debate sides.

	$i=1$	$i=2$
$i^*=1$	1,272	216
$i^*=2$	199	1,313

Table 3: Confusion matrix for position prediction on held-out *arguments*.

Predicting positions for external articles. We can also use the model to predict the position adopted in an external text. For articles linked from within Debatepedia, we have a gold standard: from which side of a debate was it linked? After using the model to infer a position variable for such a text, we can check whether the inferred position variable matches that of the argument that links to it. Table 4 shows that our model does not successfully complete this task, assigning about 60% of both kinds of articles $i = 1$.

	$i=1$	$i=2$
$i^*=1$	1,042	623
$i^*=2$	1,043	644

Table 4: Confusion matrix for position prediction on hyperlinked *articles*.

Genre. We manually labeled 500 of these articles into six genre categories. We had two annotators for this task (Cohen's $\kappa = 0.856$). These categories, in increasing order of average Jensen-Shannon divergence, are: blogs, editorials, wiki pages, news, other, and government. Figure 6 shows the results. While the only difference between the first and last groups are surprising by chance, we are encouraged by our model's suggestion that blogs and editorials may be more "Debatepedia argument-like" than news and government articles.

Note that our model is learned only from text *within* Debatepedia; it does not observe the text of external linked articles. Future work might incorporate this text as additional evidence in order to capture effects on language stemming from the interaction of position and genre.

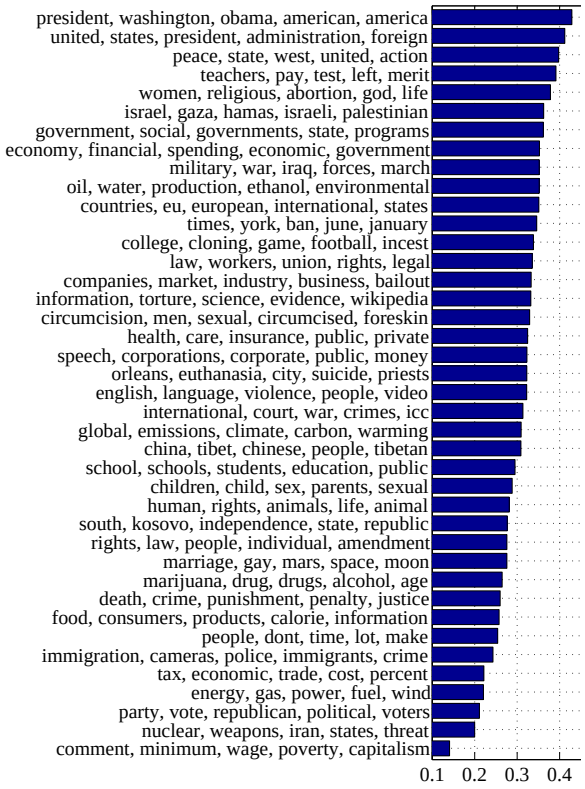

Figure 5: Jensen-Shannon divergences between topic-specific positional term distributions, for each topic. Topics are labeled by their most frequent terms from ϕ^t.

4.1.3 Comparison to Human Judgments of Positions

We compared our model's inferred positions to human judgments. For each of the 11 topics in Table 8, we selected two associated debates with more arguments than average (24.99). The debates were provided to each of three human annotators,[13] who

[13] All were native English-speaking American graduate students not otherwise involved in this research. Each is known by the authors to have basic literacy with issues and debates in

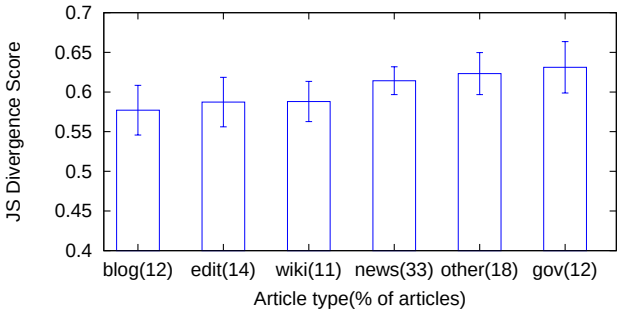

Figure 6: Position prediction on 500 hyperlinked *articles* by genre.

	"Israel-Palestine"	"Same-sex marriage"	"Drugs"	"Healthcare"	"Death penalty"	"Abortion"

+	peace	civil	disease	care	power	care
	independence	rights	nature	universal	clean	suicide
	self-determination	affirmative	potential	uninsured	waste	death

b. JST: sentiments associated with six selected topics manually aligned to our model's topics.

Table 6: Terms associated with selected topics. The labels and alignments between the two models' topics were assigned manually. (a.) Our model: topic-specific position bigrams which are ranked by comparing the log odds conditioned on the position and topic: $\log \phi^o_{i_1,t,w} - \log \phi^o_{i_2,t,w}$. We show the top three terms for each position (b.) JST: we show the top three terms for each sentiment (negative and positive).

	A1 (11)	A2 (5)	A3 (16)
Model (2)	3.21	2.58	3.45
A1 (11)		2.15	2.15
A2 (5)			2.63

Table 5: Variation of information scores for each pairing of annotators and model.

were instructed to group the 44 sides of the debates. The instructions stated:

> Our goal is to see what you think about how the different sides of different debates can be lined up. You might find it convenient to think of these in terms of political philosophies, contemporary political party platforms, or something else. Any of these is fine; we want you to tell us the grouping you find most reasonable.

All three annotators (hereafter denoted A1, A2, and A3) used fairly involved labeling schemes; the annotators used 37, 30, and 16 unique labels, respectively.[14] A1 used keyword lists to label items; we coarsened his labels manually by removing or merging less common keywords (resulting in: *Republican*, *Democrat*, *science/environment*, *nanny*, *political reform*, *fiscal liberal*, *fiscal conservative*, *libertarian*, *Israel*, *Palestine*, and one unlabeled side). A2 provided a coarse annotation along with each fine-grained one (*liberal*, *conservative*, *?*, and two unlabeled sides). We used 100 samples from our Gibbs sampler to estimate posteriors for each $i_{d,s}$; these were always 99% or more in agreement, so we mapped each debate side into its single most probable cluster. Recall that the two sides of each debate must be in different clusters.

Table 5 shows the variation of information measure (Meila, 2003) for each pairing among the three annotators and our model. The model agrees with A2's coarse clustering most closely, and in fact is closer to A2's clustering than A2 is to A3's; it also agrees with A2's coarse clustering better than A2's coarse and fine clusterings agree (3.36, not shown in the table). This is promising, but we do not have confidence that the positional dimension is being captured especially well in this model; for those debate-sides labeled *liberal* or *conservative* by A2, the best match of our two positions was still only in agreement only about 60% of the time, and agreement with each human annotator is within the interval of what would be expected if each debate's sides were assigned uniformly at random to positions.[15]

Remarks. Within debates and within topics, the model uses the position variable to distinguish sides well. For external text, the model performs well on articles such as blogs and editorials but on others the positional categories do not seem meaning-

American politics.

[14] In a small number of cases, an annotator declined to label a side. Each unlabeled item received its own cluster.

[15] This was determined using a Monte Carlo simulation with 1,000 samples.

Topic	$i = 1$	$i = 2$
None (ϕ^{i})	vice president, c sections, twenty four, cross pressures, pre dates, anti ballistic, cost effectiveness, anti landmine, court appointed, child poverty	cross examination, under runs, hand outs, half million, non christians, break down, counter argument, seventy five, co workers, run up
"Israel-Palestine"	pre emptive, israeli palestinian, open and shut, first time, hamas controlled, democratically elected	two state, long term, self destructive, secretary general, right wing, all out, near daily, short term
"Same-sex marriage"	same sex, long term, second class, blankenhorn rauch, wrong headed, self denial, left handed	opposite sex, well intentioned, day time, planet wide, day night, child rearing, low earth, one way, one third
"Drugs"	hands free, performance enhancing, in depth, hand held, best kept, non pharmaceutical, anti marijuana	long term, high speed, short term, peer reviewed, alcohol related, mind altering, inner city, long lasting
"Healthcare"	single payer, so called, self sustaining, public private, for profit, long run, high cost, multi payer	government run, government approved, high risk, two tier, government appointed, low cost, set up
"Death penalty"	anti death, non violent, african american, self help, cut and cover, heavy handed, dp equivalent	semi automatic, high profile, hate crime, assault weapons, military style, high dollar, self protective
"Abortion"	pro choice, pro life, non muslim, well educated, anti abortion, much needed, church state, birth control	would be, full time, late term, judeo christian, life style, day to day, non christian, child bearing

Table 7: General position (first row) and topic-specific position bigrams associated with six selected topics.

Topic	Terms	Person entity mentions
"Israel-Palestine"	israel, gaza, hamas, israeli, palestinian	Benjamin Netanyahu, Al Jazeera, Mavi Marmara, Nicholas Kristoff, Steven R. David
"Same-sex marriage"	marriage, gay, mars, space, moon	Buzz Aldrin, Andrew Sullivan, Moon Base, Scott Bidstrup, Ted Olson
"Drugs"	marijuana, drug, drugs, alcohol, age	Four Loko, Evo Morales, Toni Meyer, Sean Flynn, Robert Hahn
"Healthcare"	health, care, insurance, public, private	Kent Conrad, Paul Hsieh, Paul Krugman, Ezra Klein, Jacob Hacker
"Death penalty"	death, crime, punishment, penalty, justice	Adam Bedau, Thomas R. Eddlem, Jeff Jacoby, John Baer, Peter Bronson
"Abortion"	women, religious, abortion, god, life	Ronald Reagan, John Paul II, Sara Malkani, Mother Teresa, Marcella Alsan

Table 8: For 6 selected topics (labels assigned manually), top terms (ϕ^{t}) and person entities (ϕ^{e}). Bigrams were included but did not rank in the top five for these topics. The model has conflated debates relating to same-sex marriage with the space program.

ful, perhaps due to the less argumentative nature of other kinds of articles. Noting the vast literature focusing on ideological positions expressed in text, we believe this failure suggests (i) that broad-based positions that hold across many topics may require richer textual representations (see, e.g., the "syntactic priming" of Greene and Resnik, 2009), or (ii) that an alternative representation of positions, such as the spatial models favored by political scientists (Poole and Rosenthal, 1991), may be more discoverable. Aside from those issues, a stronger theory of positions may be required. Such a theory could be encoded in a more informative prior or weaker independence assumptions across debates. Finally, exploiting explicitly ideological texts alongside the moderated arguments of Debatepedia might also help to identify textual associations with general positions (Sim et al., 2013). We leave these directions to future work.

4.2 Qualitative Analysis

Of the $T = 40$ topics our model inferred, we subjectively judged 37 to be coherent; a glimpse of each is given in Figure 5. We manually selected six of the most interpretable topics for further evaluation.

As a generative modeling approach, our model was designed for the purpose of reducing the dimensionality of the sociopolitical debate space, as evidenced by Debatepedia. It is like other topic models in this regard, but we believe that some effects of our design choices are noteworthy. Table 6 compares the positional bigrams of our model to the sentiments inferred by JST. We observe the benefit of our model in identifying terms associated with positions on social issues, while JST selects more general sentiment terms.

Table 7 shows bigrams most strongly associated with general position distributions ϕ^{i} and selected topic-position distributions ϕ°.[16] We see the potential benefit of multiword expressions. Although we have used frequent bigrams as a poor man's approximation to multiword expression analysis, we find the topic-specific positions terms to be subjectively evocative. While somewhat internally coherent, we do not observe consistent alignment across topics, and the general distributions ϕ^{i} are not suggestive.

The separation of personal name mentions into their own distributions, shown for some topics in Table 8, gives a distinctive characterization of topics based on relevant personalities. Subjectively, the top individuals are relevant to the subject matter associated with each topic (though the topics are not always pure; same-sex marriage and the space program are merged, for example).

5 Related Work

Insofar as debates are subjective, our study is related to **opinion mining**. Subjective text classification (Wiebe and Riloff, 2005) leads to opinion mining tasks such as opinion extraction (Dave et al., 2003), positive and negative polarity classification (Pang et al., 2002), sentiment target detection (Hu and Liu, 2004; Ganapathibhotla and Liu, 2008), and feature-opinion extraction (Wu et al., 2009). The above studies are conducted mostly on product reviews, a domain with a simpler opinion landscape and more concrete rationales for those opinions, compared to sociopolitical debates.

Generative **topic models** have been successfully implemented in opinion mining tasks such as feature identification (Titov and McDonald, 2008), entity-topic extraction (Newman et al., 2006), mining contentious expressions and interactions (Mukherjee and Liu, 2012) and specific aspect-opinion word extraction from labeled data (Zhao et al., 2010). Most relevant to this research is work on feature-sentiment extraction (Lin and He, 2009; Mei et al., 2007). Mei et al. (2007) built on PLSI, which is problematic for generalizing beyond the training sample. The JST model of Lin and He (2009) is an LDA-based topic model in which each word token is assigned both a sentiment and a topic; they exploited a sentiment lexicon in the prior distribution. Our model is closely related, but introduces a switching variable that assigns *some* tokens to positions, some to topics, and some to both. Unlike Lin and He's sentiments, our model's positions are associated with the two sides of a debate, and we incorporate topics at the level of questions within debates.

Some studies have specifically analyzed **contrastive viewpoints** or **stances** in general discussion text.Agrawal et al. (2003) used graph mining based method to classify authors in to opposite camps for a given topic. Paul et al. (2010) developed an unsupervised method for summarizing contrastive opinions from customer reviews. Abu-Jbara et al. (2012) and Dasigi et al. (2012) developed techniques to address the problem of automatically detecting subgroups of people holding similar stances in a discussion thread.

Several prior studies have considered **debates**. Cabrio and Villata (2012) developed a system based on argumentation theory which recognizes the entailment and contradiction relationships between two texts. Awadallah et al. (2011) used a debate corpus as a seed for extracting person-opinion-topic tuples from news and other web documents and in later work classified the quotations to specific topics and polarity using language models (Awadallah et al., 2012). Somasundaran and Wiebe (2009) and Anand et al. (2011) were interested in ideological content in debates, relying on discourse structure and leveraging sentiment lexicons to recognize stances.

Closer to the methodology we describe, Lin et al. (2008) presented a statistical model for political discourse that incorporates both topics and ideologies; they used debates on the Israeli-Palestinian conflict. Fortuna et al. (2009) showed that it is possible to isolate a subset of terms from media content that are informative of a news organization's bias towards a particular issue. Ahmed and Xing (2010) introduced multi-level latent Dirichlet allocation, and Eisenstein et al. (2011) introduced sparse additive generative models, both conceived as extensions to well-established probabilistic modeling techniques (Blei et al., 2003); these were applied to debates and political blog datasets. Our approach builds on these models (especially the switching variables of Ahmed and Xing). We go farther in jointly modeling

[16] For more topics, please refer to the supplementary notes.

text across *many* debates evidenced by the structure of Debatepedia, thus grounding our models more solidly in familiar sociopolitical issues, and in making extensive use of existing NLP resources.

6 Conclusion

Using text from Debatepedia, we inferred topics and position term lexicons in the domain of sociopolitical debates. Our approach brings together tools from information extraction and sentiment analysis into a latent-variable topic model and exploits the hierarchical structure of the dataset. Our qualitative and quantitative evaluations show the model's strengths and weaknesses.

Abstract

With the rapid growth of social media, Twitter has become one of the most widely adopted platforms for people to post short and instant message. On the one hand, people tweets about their daily lives, and on the other hand, when major events happen, people also follow and tweet about them. Moreover, people's posting behaviors on events are often closely tied to their personal interests. In this paper, we try to model topics, events and users on Twitter in a unified way. We propose a model which combines an LDA-like topic model and the Recurrent Chinese Restaurant Process to capture topics and events. We further propose a duration-based regularization component to find bursty events. We also propose to use event-topic affinity vectors to model the association between events and topics. Our experiments shows that our model can accurately identify meaningful events and the event-topic affinity vectors are effective for event recommendation and grouping events by topics.

1 Introduction

Twitter is arguably the most popular microblog site where people can post short, instant messages to share with families, friends and the rest of the world. For content analysis on Twitter, two important concepts have been repeatedly visited: (1) **Topics**. These are longstanding themes that many personal tweets revolve around. Example topics range from music and sports to more serious ones like politics and religion. Much work has been done to analyze topics on Twitter (Ramage et al., 2010; Hong and Davison, 2010; Zhao et al., 2011; Lau et al., 2012). (2) **Events**. These are things that take place at a certain time and attract many people's short-term attention in social media. Example events include concerts, sports games, scandals and elections. Event detection on Twitter has been a hot research topic in recent years (Petrović et al., 2010; Weng and Lee, 2011; Becker et al., 2011; Diao et al., 2012; Li et al., 2012).

The concepts of topics and events are orthogonal in that many events fall under certain topics. For example, concerts fall under the topic about music. Furthermore, being *social* media, Twitter users play important roles in forming topics and events on Twitter. Each user has her own topic interests, which influence the content of her tweets. Whether a user publishes a tweet related to an event also largely depends on whether her topic interests match the nature of the event. Modeling the interplay between topics, events and users can deepen our understanding of Twitter content and potentially aid many predication and recommendation tasks. In this paper, we aim to construct a unified model of topics, events and users on Twitter. Although there has been a number of recent studies on event detection on Twitter, to the best of our knowledge, ours is the first that links the topic interests of users to their tweeting behaviors on events.

Specifically, we propose a probabilistic latent variable model that identifies both topics and events on Twitter. To do so, we first separate tweets into *topic tweets* and *event tweets*. The former are related to a user's personal life, such as a tweet complaining about the traffic condition or wishing a friend

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1869–1879,
Seattle, Washington, USA, 18-21 October 2013.

happy birthday. The latter are about some major global event interesting to a large group of people, such as a tweet advertising a concert or commenting on an election result. Although considering only topic tweets and event tweets is a much simplified view of the diverse range of tweets, we find it effective in finding meaningful topics and events. We further use an LDA-like model (Blei et al., 2003) to discover topics and the Recurrent Chinese Restaurant Process (Ahmed and Xing,) to discover events. Details are given in Section 3.1.

Our major contributions lie in two novel modifications to the base model described above. The first is a duration-based regularization component that punishes long-term events (Section 3.2). Because events on Twitter tend to be bursty, this modification presumably can produce more meaningful events. More specifically, we borrow the idea of using pseudo-observed variables to regularize graphical models (Balasubramanyan and Cohen, 2013), and carefully design the pseudo-observed variable in our task to capture the burstiness of events. The second modification is adding event-topic affinity vectors inspired by PMF-based collaborative filtering (Salakhutdinov and Mnih, 2008) (Section 3.3). It uses the latent topics to explain users' preferences of events and subsequently infers the association between topics and events.

We use a real Twitter data set consisting of 500 users to evaluate our model (Section 4). We find that the model can discover meaningful topics and events. Comparison with our base model and with an existing model for event discovery on Twitter shows that the two modifications are both effective. The duration-based regularization helps find more meaningful events; the event-topic affinity vectors improve an event recommendation task and helps produce a meaningful organization of events by topics.

2 Related Work

Study of topics, events and users on Twitter is related to several branches of work. We review the most interesting and relevant work below.

Event detection on Twitter: There have been quite a few studies in this direction in recent years, including both online detection (Sakaki et al., 2010; Petrović et al., 2010; Weng and Lee, 2011; Becker et al., 2011; Li et al., 2012) and offline detection (Diao et al., 2012). Online detection is mostly concerned with early detection of major events, so efficiency of the algorithms is the main focus. These algorithms do not aim to identify *all* relevant tweets, nor do they analyze the association of events with topics. In comparison, our work focuses on modeling topics, events and users as well as their relation. Recently, Petrović et al. (2013) pointed out that Twitter stream does not lead news stream for major news events, but Twitter stream covers a much wider range of events than news stream. Our work helps better understand these additional events on Twitter and their relations with users' topic interests. Our model bears similarity to our earlier work (Diao et al., 2012), but we use a non-parametric model (RCRP) to discover events directly inside the probabilistic model.

Temporal topic modeling: A number of models have been proposed for the temporal aspect of topics (Blei and Lafferty, 2006; Wang and McCallum, 2006; Wang et al., 2007; Hong et al., 2011), but most of them fix the number of topics. The Recurrent Chinese Restaurant Process (Ahmed and Xing,) was proposed to model the life cycles of topics and allows an infinite number of topics. It has later been combined with LDA to model both topics and events in news streams and social media streams (Ahmed et al., 2011; Tang and Yang, 2012). Our work also jointly models topics and events, but different from previous work, we do not assume that every document (tweet in our case) belongs to an event, which is important because Twitter contains many personal posts unrelated to major events.

Collaborative filtering with LDA: Part of our model is inspired by work on collaborative filtering based on probabilistic matrix factorization (PMF) (Salakhutdinov and Mnih, 2008). Recently there has been some work combining LDA with PMF to recommend items with textual content such as news articles and advertisements (Wang and Blei, 2011; Agarwal and Chen, 2010). They use topics to interpret the latent structure of users and items. We borrow their idea but our items are events, which are not known and have to be discovered by our model.

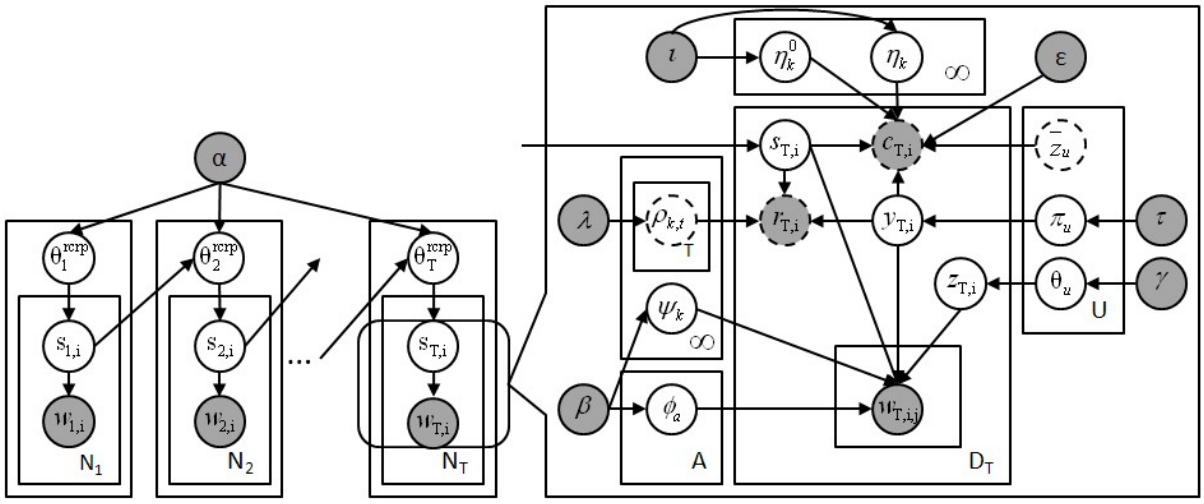

Figure 1: Plate notation for the whole model, in which pseudo-observed variables and distributions based on empirical counts are shown as dotted nodes.

3 Our Model

In this section, we present our model for topics, events and users on Twitter. We assume that we have a stream of tweets which are divided into T epoches. Let $t \in \{1, 2, \ldots, T\}$ be the index of an epoch. Each epoch contains a set of tweets and each tweet is a bag of words. We use $w_{t,i,j} \in \{1, 2, \ldots, V\}$ to denote the j-th word of the i-th tweet in the t-th epoch, where V is the vocabulary size. The author of the i-th tweet in the t-th epoch (i.e. the Twitter user who publishes the tweet) is denoted as $u_{t,i} \in \{1, 2, \ldots, U\}$, where U is the total number of Twitter users we consider.

We first present our base model in Section 3.1. We then introduce a duration-based regularization mechanism to ensure the burstiness of events in Section 3.2. In Section 3.3 we discuss how we model the relation between topics and events using event-topic affinity vectors. Finally we discuss model inference in Section 3.4.

3.1 The Base Model

Recall that our objective is to model topics, events, users and their relations. As in many topic models, our topic is a multinomial distribution over words, denoted as ϕ_a where a is a topic index. Each event is also a multinomial distribution over words, denoted as ψ_k where k is an event index. Because topics are long-standing and stable, we fix the number of topics to be A, where A can be tuned based on historical data. In contrast, events emerge and die along the timeline. We therefore use a non-parametric model called the Recurrent Chinese Restaurant Process (RCRP) (Ahmed and Xing,) to model the birth and death of events. To model the relation between users and topics, we assume each user u has a multinomial distribution over topics, denoted as θ_u.

As we have discussed, we separate tweets into two categories, topic tweets and event tweets. Separation of these two categories is done through a latent variable y sampled from a user-specific Bernoulli distribution π_u. For topic tweets, the topic is sampled from the corresponding user's topic distribution θ_u. For event tweets, the event is sampled according to RCRP. We now briefly review RCRP. Generally speaking, RCRP assumes a Chinese Restaurant Process (CRP) (Blackwell and MacQueen, 1973) for items within an epoch and chains up the CRPs in adjacent epochs along the timeline. Specifically, in our case, the generative process can be described as follows. Tweets come in according to their timestamps. In the t-th epoch, for the i-th tweet, we first flip a biased coin based on probability π_u to decide whether this tweet is event-related. If it is, then we need to decide which event it belongs to. It could be an existing event that has at least one related tweet in the

previous epoch or the current epoch, or it could be a new event. Let $n_{k,t-1}$ denote the number of tweets related to event k at the end of epoch $(t-1)$. Let $n_{k,t}^{(i)}$ denote the number of tweets related to event k in epoch t before the i-th tweet comes. Let N_{t-1} denote the total number of event-related tweets in epoch $(t-1)$ and $N_t^{(i)}$ denote the number of event-related tweets in epoch t before the i-th tweet. Then RCRP assumes that the probability for the i-th tweet to join event k is $\frac{n_{k,t-1}+n_{k,t}^{(i)}}{N_{t-1}+N_t^{(i)}+\alpha}$ and the probability to start a new event is $\frac{\alpha}{N_{t-1}+N_t^{(i)}+\alpha}$, where α is a parameter. As we can see, RCRP naturally captures the "rich-get-richer" phenomenon in social media.

Finally we place Dirichlet and Beta priors on the various parameters in our model. Formally, the generative process of our base model is outlined in Figure 2, excluding the lines in bold and blue. We also show the plate notation in Figure 1, in which the Recurrent Chinese Restaurant Process is represented as an infinite dynamic mixture model (Ahmed and Xing,) and θ_t^{rcrp} means the distribution on an infinite number of events in epoch t. D_t is the total number of tweets (both event-related and topic tweets), while N_t represents the number event-related tweets in epoch t.

3.2 Regularization on Event Durations

As we have pointed out, events on Twitter tend to be bursty, i.e. the duration of an event tends to be short, but this characteristic is not captured by RCRP. While there can be different ways to incorporate this intuition, here we adopt the idea of regularization using pseudo-observed variables proposed recently by Balasubramanyan and Cohen (2013). We introduce a pseudo-observed binary variable $r_{t,i}$ for each tweet, where the value of $r_{t,i}$ is set to 1 for all tweets. We assume that this variable is dependent on the hidden variables y and s. Specifically, if $y_{t,i}$ is 0, i.e. the tweet is topic-related, then $r_{t,i}$ gets a value of 1 with probability 1. If $y_{t,i}$ is 1, then we look at all the tweets that belong to event $s_{t,i}$. Our goal is to make sure that this tweet is temporally close to these other tweets. So we assume that $r_{t,i}$ gets a value of 1 with probability $\exp(-\sum_{t'=1,|t'-t|>1}^{T}\lambda|t-t'|n_{s_{t,i},t'})$, where $n_{s_{t,i},t'}$ is the number of tweets in epoch t' that belong to event $s_{t,i}$ and $\lambda > 0$ is a parameter. We can see that when we factor in the generation of these pseud-observed variables r, we penalize long-term events and favor events whose tweets are concentrated along the timeline. Generation of these variables r is shown in bold and blue in Figure 2.

- For each topic $a = 1, \ldots, A$
  - draw $\phi_a \sim \text{Dirichlet}(\beta)$
- For each user $u = 1, \ldots, U$
  - draw $\theta_u \sim \text{Dirichlet}(\gamma), \pi_u \sim \text{Beta}(\tau)$
- For each epoch t and tweet i
  - draw $y_{t,i} \sim \text{Bernoulli}(\pi_{u_{t,i}})$
  - If $y_{t,i} = 0$
    - draw $z_{t,i} \sim \text{Multinomial}(\theta_{u_{t,i}})$
    - For each j, draw $w_{t,i,j} \sim \text{Multinomial}(\phi_{z_{t,i}})$
  - If $y_{t,i} = 1$
    - draw $s_{t,i}$ from RCRP
    - If $s_{t,i}$ is a new event
      - draw $\psi_{s_{t,i}} \sim \text{Dirichlet}(\beta)$
      - **draw $\eta^0_{s_{t,i}} \sim$ Gaussian$(0, \iota^{-1})$**
      - **draw $\boldsymbol{\eta}_{s_{t,i}} \sim$ Gaussian$(0, \iota^{-1} I_A)$**
    - **draw $r_{t,i} \sim$ Bernoulli$(\rho_{s_{t,i},t})$, where $\rho_{s_{t,i},t} = \exp(-\sum_{t'=1,|t'-t|>1}^{T}\lambda|t'-t|n_{s_{t,i},t'})$**
    - **draw $c_{t,i} \sim$ Gaussian$(\eta^0_{s_{t,i}} + \boldsymbol{\eta}^T_{s_{t,i}} \cdot \bar{\boldsymbol{z}}_{u_{t,i}}, \epsilon^{-1})$**
    - For each j, draw $w_{t,i,j} \sim \text{Multinomial}(\psi_{s_{t,i}})$

Figure 2: The generative process of our model, in which the duration-based regularization (section 3.2) and the event-topic affinity vector (section 3.3) are in blue and bold lines.

3.3 Event-Topic Affinity Vectors

So far in our model topics and events are not related. However, many events are highly related to certain topics. For example, a concert is related to music while a football match is related to sports. We would like to capture these relations between topics and events. One way to do it is to assume that event tweets also have topical words sampled from the event's topic distribution, something similar to the models by Ahmed et al. (2011) and by Tang and Yang (2012). However, our prelimiary experiments show that this idea does not work well on Twitter, mainly because tweets are too short. Here we explore another approach inspired by recommendation methods based on probabilistic matrix factorization (Salakhutdinov and Mnih, 2008). The idea is that when a user posts a tweet about an event, we can treat the event as an item and this posting be-

havior as adoption of the item. If we assume that the adoption behavior is influenced by some latent factors, i.e. the latent topics, then basically we would like the topic distribution of this user to be close to that of the event.

Specifically, we assume that each event k has associated with it an A-dimensional vector $\boldsymbol{\eta}_k$ and a parameter η_k^0. The vector $\boldsymbol{\eta}_k$ represents the event's affinity to topics. η_k^0 is a bias term that represents the inner popularity of an event regardless of its affinity to any topic. We further assume that each tweet has another pseudo-observed variable $c_{t,i}$ that is set to 1. For topic tweets, $c_{t,i}$ gets a value of 1 with probability 1. For event tweets, $c_{t,i}$ is generated by a Gaussian distribution with mean equal to $\eta^0_{s_{t,i}} + \boldsymbol{\eta}_{s_{t,i}} \cdot \bar{\boldsymbol{z}}_{u_{t,i}}$, where $\bar{\boldsymbol{z}}_u$ is an A-dimensional vector denoting the empirical topic distribution of user u's tweets. This treatment follows the practice of fLDA by Agarwal and Chen (2010). Let $\bar{C}_{u,a}$ be the number of tweets by user u assigned to topic a, based on the values of the latent variables y and z. Then

$$\bar{\boldsymbol{z}}_{u,a} = \frac{\bar{C}_{u,a}}{\sum_{a'=1}^{A} \bar{C}_{u,a'}},$$
$$c_{t,i} \sim \text{Gaussian}(\eta^0_{s_{t,i}} + \boldsymbol{\eta}_{s_{t,i}} \cdot \bar{\boldsymbol{z}}_{u_{t,i}}, \epsilon^{-1}),$$

where ϵ is a parameter. We generate $\boldsymbol{\eta}_k$ and η_k^0 using Gaussian priors once event k emerges. The generation of the variables c is shown in bold and blue in Figure 2.

3.4 Inference

We train the model using a stochastic EM sampling scheme. In this scheme, we alternate between Gibbs sampling and gradient descent. In the Gibbs sampling part, we fix the values of η_k^0 and $\boldsymbol{\eta_k}$ for each event k, and then we sample the latent variables $y_{t,i}$,$z_{t,i}$ and $s_{t,i}$ for each tweet. In the gradient descent part, we update the event-topic affinity vectors $\boldsymbol{\eta_k}$ and the bias term η_k^0 of each event k by keeping the assignment of the variables $y_{t,i}$,$z_{t,i}$ and $s_{t,i}$ fixed.

For the Gibbs sampling part, we jointly sample $y_{t,i} = 0, z_{t,i} = a$ (topic tweet) and $y_{t,i} = 1, s_{t,i} = k$ (event tweet) as follows:

Topic tweet:

$$p(y_{t,i} = 0, z_{t,i} = a | \mathbf{y}_{\neg t,i}, \mathbf{z}_{\neg t,i}, \mathbf{w}, \mathbf{r}, \mathbf{c}, u_{t,i})$$
$$\propto \frac{n^{(\pi)}_{u,0} + \tau}{n^{(\pi)}_{u,(.)} + 2\tau} \frac{n^{(\theta)}_{u,a} + \gamma}{n^{(\theta)}_{u,(.)} + A\gamma} \frac{\prod_{v=1}^{V} \prod_{i=0}^{E_{(v)}-1} (n^{(\phi)}_{a,v} + i + \beta)}{\prod_{i=0}^{E_{(.)}-1} (n^{(\phi)}_{a,(.)} + i + V\beta)}$$
$$\prod_{t',i' \in I_u} \frac{\mathcal{N}(c_{t',i'} | \eta^0_{s_{t',i'}} + \boldsymbol{\eta}_{s_{t',i'}} \cdot \bar{\boldsymbol{z}}^*_u, \epsilon^{-1})}{\mathcal{N}(c_{t',i'} | \eta^0_{s_{t',i'}} + \boldsymbol{\eta}_{s_{t',i'}} \cdot \bar{\boldsymbol{z}}_u, \epsilon^{-1})}$$

Event tweet:

$$p(y_{t,i} = 1, s_{t,i} = k | \mathbf{y}_{\neg t,i}, \mathbf{z}_{\neg t,i}, \mathbf{w}, \mathbf{r}, \mathbf{c}, u_{t,i})$$
$$\propto \frac{n^{(\pi)}_{u,1} + \tau}{n^{(\pi)}_{u,(.)} + 2\tau} \frac{1}{\boldsymbol{N}} \Bigg(n^{\text{RCRP}}_{k,t} \mathcal{N}(c_{t,i} | \eta^0_{s_{t,i}} + \boldsymbol{\eta}_{s_{t,i}} \cdot \bar{\boldsymbol{z}}_u, \epsilon^{-1})$$
$$\cdot \exp(- \sum_{\substack{t'=1 \\ |t'-t|>1}}^{T} \lambda |t - t'| n_{k,t'}) \Bigg) \frac{\prod_{v=1}^{V} \prod_{i=0}^{E_{(v)}-1} (n^{(\psi)}_{k,v} + i + \beta)}{\prod_{i=0}^{E_{(.)}-1} (n^{(\psi)}_{k,(.)} + i + V\beta)}$$

in which,

$$n^{\text{RCRP}}_{k,t} = \begin{cases} (n_{k,t-1} + n_{k,t}) & \\ \quad \cdot \frac{n_{k,t} + n_{k,t+1}}{n_{k,t}} & \text{if } n_{k,t-1} > 0, n_{k,t} > 0, \\ n_{k,t-1} & \text{if } n_{k,t-1} > 0, n_{k,t} = 0, \\ n_{k,t+1} & \text{if } n_{k,t+1} > 0, n_{k,t} = 0, \\ \alpha & \text{if } k \text{ is a new event,} \end{cases}$$

where we use u to represent $u_{t,i}$. $n^{(\pi)}_{u,0}$ is the number of topic tweets by user u while $n^{(\pi)}_{u,1}$ is the number of event tweets by user u. They stem from integrating out the user's Bernoulli distribution π_u. $n^{(\pi)}_{u,(.)}$ is the total number of tweets by user u. Similarly, $n^{(\theta)}_{u,a}$ is the number of tweets assigned to topic a for this user, resulting from integrating out the user's topic distribution θ_u. $n^{(\theta)}_{u,(.)}$ is the same as $n^{(\pi)}_{u,0}$. $E_{(v)}$ is the number of times word type v appears in the current tweet, and $E_{(.)}$ is the total number of words in the current tweet. $n^{(\phi)}_{a,v}$ is the number of times word type v is assigned to topic a, and $n^{(\phi)}_{a,(.)}$ is the number of words assigned to topic a. $n^{(\psi)}_{k,v}$ is the number of times word type v is assigned to event k, and $n^{(\psi)}_{k,(.)}$ is the total number of words assigned to event k. These word counters stem form integrating out each event's word distribution and are set to zero when k is a new event. $I_u = \{t', i' | y_{t',i'} = 1, u_{t',i'} = u\}$, which is the set of event tweets published by user u, and u represents $u_{t,i}$ for short. $\bar{\boldsymbol{z}}^*_u$ is the empirical

counting vector which considers the current tweet's topic assignment, while $\bar{\boldsymbol{z}}_u$ and all other counters do not consider the current tweet. Finally, $\boldsymbol{N}$ is a local normalization factor for event tweets, which includes the RCRP, event-topic affinity and regularization on event duration.

With the previous Gibbs sampling step, we can get the assignment of variables $y_{t,i}$,$z_{t,i}$ and $s_{t,i}$. Given the assignment, we use gradient descent to update the values of the bias term η_k^0 and the event-topic affinity vectors $\boldsymbol{\eta}_k$ for each current existing event k. First, we can get the logarithm of the posterior distribution:

$$\begin{aligned}&\ln P(\mathbf{y}, \mathbf{z}, \mathbf{s}, \mathbf{r}, \mathbf{c}|\mathbf{w}, \mathbf{u}, \text{all priors})\\ &= \text{constant} - \sum_{k=1}^{\infty}\{\frac{\iota}{2}({\eta_k^0}^2 + \boldsymbol{\eta}_k \cdot \boldsymbol{\eta}_k)\\ &+ \sum_{u=1}^{U} n_{u,k}\frac{\epsilon}{2}[1 - (\eta_k^0 + \boldsymbol{\eta}_k \cdot \bar{\boldsymbol{z}}_u)]^2\},\end{aligned}$$

where $n_{u,k}$ is the number of event tweets about event k published by user u. The derivative of the logarithm of the posterior distribution with respect to the bias term η_k^0 and the event-topic affinity vector $\boldsymbol{\eta}_k$ are as follows:

$$\begin{aligned}\frac{\partial \ln P}{\partial \eta_k^0} &= -\iota\eta_k^0 + \sum_{u=1}^{U}\epsilon n_{u,k}[1 - (\eta_k^0 + \boldsymbol{\eta}_k \cdot \bar{\boldsymbol{z}}_u)],\\ \frac{\partial \ln P}{\partial \boldsymbol{\eta}_k} &= -\iota\boldsymbol{\eta}_k + \sum_{u=1}^{U}\epsilon n_{u,k}[1 - (\eta_k^0 + \boldsymbol{\eta}_k \cdot \bar{\boldsymbol{z}}_u)]\bar{\boldsymbol{z}}_u.\end{aligned}$$

4 Experiment

4.1 Dataset and Experiment Setup

We evaluate our model on a Twitter dataset that contains 500 users. These users are randomly selected from a much larger pool of around 150K users based in Singapore. Selecting users from the same country/city ensures that we find coherent and meaningful topics and events. We use tweets published between April 1 and June 30, 2012 for our experiments. For preprocessing, we use the CMU Twitter POS Tagger[1] to tag these tweets and remove those non-standard words (i.e. words tagged as punctuation marks, emoticons, urls, at-mentions, pronouns, etc.) and stop words. We also remove tweets with less than three words. After preprocessing, the dataset contains 655,881 tweets in total.

Recall that our model is designed to identify topics, events and their relations with users. We therefore would like to evaluate the quality of the identified topics and events as well as the usefulness of the discovered topic distributions of users and event-topic affinity vectors. Because our topic discovery mechanism is fairly standard and a quick inspection shows that the discovered topics are generally meaningful and comparable to those discovered by standard LDA, here we do not focus on evaluation of topics. In Section 4.2 we evaluate the quality of the discovered events. In Section 4.3 we show how the discovered event-topic affinity vectors can be useful.

For comparison, we consider an existing method called **TimeUserLDA** introduced in our previous work (Diao et al., 2012). TimeUserLDA also models topics and events by separating topic tweets from event tweets. However, it groups event tweets into a *fixed* number of *bursty topics* and then uses a two-state machine in a postprocessing step to identify events from these bursty topics. Thus, events are not directly modeled within the generative process itself. In contrast, events are inherent in our generative model. We do not compare with other event detection methods because our objective is not online event detection.

We also compare our final model with two degenerate versions of it. We refer to the base model described in Section 3.1 as **Base** and the model with the duration-based regularization as **Base+Reg**. Comparison with these two degenerate models allows us to assess the effect of the two modifications we propose. We refer to the final model with both the duration-based regularization and the event-topic affinity vectors as **Base+Reg+Aff**.

For the parameter setting, we empirically set A to 40, γ to $\frac{50}{A}$, τ to 1, β to 0.01, α to 1, ι to 10, ϵ to 1, and the duration regularization parameter λ to 0.01. When a new event k is created, the inner popularity bias term η_k^0 is set to 1, and the factors in event-topic affinity vectors $\boldsymbol{\eta}_k$ are all set to 0. We run the stochastic EM sampling scheme for 300 iterations. After Gibbs sampling assigns each variable a value at the end of each iteration, we update the values of η_k^0 and $\boldsymbol{\eta}_k$ for the existing events using gradient descent.

Event	Top words	Duration	Inner popularity (η_k^0)
debate caused by Manda Swaggie	singapore, bieber, europe, amanda, justin, trending, manda, hates, swaggie, hate	17 June - 19 June	0.9457
Indonesia tsunami	tsunami, earthquake, indonesia, singapore, hit, warning, aceh, 8.9, safe, magnitude	10 April - 12 April	0.9439
SJ encore concert	#ss4encore, cr, #ss4encoreday2, hyuk, 120526, super, leader, changmin, fans, teuk	26 May - 28 May	0.8360
Mother's Day	day, happy, mother's, mothers, love, mom, mum, everyday, mother, moms	11 May - 14 May	0.9370
April Fools' Day	april, fools, day, fool, joke, prank, happy, today, trans, fool's	1 April - 3 April	0.9322

Table 1: The top-5 events identified by Base+Reg+Aff. We show the story name which is manually labeled, top ten ranking words, lasting duration and the inner popularity (η_k^0) for each event.

4.2 Events

First we quantitatively evaluate the quality of the detected events. Our model finds clusters of tweets that represent events. We first assess whether these events are meaningful. We then judge whether the detected event tweets are indeed related to the corresponding event.

Quality of Top Events

Method	P@5	P@10	P@20	P@30
Base+Reg+Aff	**1.000**	**1.000**	**0.950**	**0.900**
Base+Reg	**1.000**	**1.000**	**0.950**	0.867
Base	0.000	0.200	0.250	0.367
TimeUserLDA	**1.000**	0.800	0.750	0.600

Table 2: Precision@K for the various methods.

Usually we are interested in the most popular events on Twitter. We therefore assess whether the top events are meaningful. For each method, we rank the detected events based on the number of tweets assigned to them and then pick the top-30 events for each method. We randomly mix these events and ask two human judges to label them. The judges are given 100 randomly selected tweets for each event (or all tweets if an event contains less than 100 tweets). The judges can use external sources to help them. If an event is meaningful based on the 100 sample tweets, a score of 1 is given. Otherwise it is scored 0. The inter-annotator agreement score is 0.744 using Cohen's kappa, showing substantial agreement. Finally we treat an event as meaningful if both judges have scored it 1.

Table 2 shows the performance in terms of precision@K, and Table 1 shows the top 5 events of our model (i.e., Base+Reg+Aff). We have the following findings from the results: (1) Our base model performs quite poorly for the top events while Base+Reg and Base+Reg+Aff perform much better. This shows that the duration-based regularization is critical in finding meaningful events. A close examination shows that the base model clusters many general topic tweets as events, such as tweets about transportation and music and even foursquare tweets. (2) TimeUserLDA performs well for the very top events (P@5 and P@10) but its performance drops for lower-ranked events (P@20 and P@30), similar to what was reported by Diao et al. (2012). A close examination shows that this method is good at finding major events that do not have strong topic association and thus attract most people's attention, e.g. earthquakes, but not good at finding topic-oriented events such as some concerts and sports games. This is because this method mixes topics and events first and only detects events from bursty topics in a second stage of postprocessing. In contrast, our model performs well for topic-oriented events. (3) The difference between Base+Reg and Base+Reg+Aff is small, suggesting that the event-topic affinity vectors are not crucial for event detection.

Precision of Event Tweets

Next, we evaluate the relevance of the detected event tweets to each event. To make a fair comparison, we select only the common events identified by all the methods. We pick 3 out of 5 common events shared by all methods within top-30 events

Event	TimeUserLDA	Base	Base+Reg	Base+Reg+Aff
Father's Day	0.61	0.63	0.71	**0.72**
debate caused by Manda Swaggie	0.73	0.74	**0.84**	0.80
Indonesia tsunami	0.75	0.75	**0.82**	0.80
Super Junior album release	N/A	0.72	0.78	**0.81**

Table 3: Precision of the event tweets for the 4 common events.

(we pick "Fathers' day" to represent public festivals, and ignore the similar events "Mothers' day" and "April fools"). We also pick one event shared by three RCRP based models. We further ask one of the judges to score the 100 tweets as either 1 or 0 based on their relevance to the event. The precision of the 100 tweets for each event and each method is shown in Table 3. We can see that again Base+Ref and Base+Ref+Aff perform similarly, and both outperform the other two methods. We also take a close look at the tweets and find that the false positives mislabeled by Base is mainly due to the long-duration of the discovered events. For example, for the event "Super Junior album release," Base finds other music-related tweets surrounding the peak period of the event itself.

In summary, our evaluation on event quality shows that (1) Using the non-parametric RCRP model to identify events within the generative model itself is advantageous over TimeUserLDA, which identifies events by postprocessing. (2) The duration-based regularization is crucial for finding more meaningful events.

4.3 Event-Topic Association

Besides event identification, our model also finds the association between events and topics through the event-topic affinity vectors. The discovered event-topic association can potentially be used for various tasks. Here we conduct two experiments to demonstrate its usefulness.

Event Recommendation

Recall that to discover event-topic association, we treat an event as an item and a tweet about the event as indication of the user's adoption of the item. Following this analogy with item recommendation, we define an event recommendation task where the goal is to recommend an event to users who have not posted any tweet about the event but may potentially be interested in the event. Intuitively, if a user's topic distribution is similar to the event-topic affinity vector of the event, then the user is likely to be interested in the event.

Specifically, we use the first two months' data (April and May 2012) as training data to learn all the users' topic distributions. We then use a ransom subset of 250 training users and their tweets in June to identify events in June as well as the event-topic affinity vectors of these events. We pick 8 meaningful events that are ranked high by all methods for testing. For each event, we try to find among the remaining 250 users those who may be interested in the event and compare the results with ground truth obtained by human judgment. Because it is time consuming to obtain the ground truth for all 250 users, we randomly pick 100 of these 250 users for testing purpose. For each test user and each event, we manually inspect the user's tweets around the peak days of the event to judge whether she has commented on the event. This is used as ground truth.

With our complete model Base+Reg+Aff, we can simply rank the 100 test users in decreasing order of $\boldsymbol{\eta}_k \cdot \bar{\boldsymbol{z}}_u$. For the other methods, because we do not have any parameter that directly encodes event-topic association, we cannot rank users based on how similar their topic distributions are to the event's affinity to topics. We instead adopt a collaborative filtering strategy and rank the test users by their similarity with those training users who have tweeted about the event. Specifically, each of these methods produces a topic distribution θ_u for each user. In addition, for each test event these methods identify a list of training users who have tweeted on it. By taking the average topic distribution of these training users and compute its cosine similarity with a test user's topic distribution, we can rank the 100 test users.

Since we have turned the recommendation task into a ranking task, we use Average Precision, a commonly used metric in information retrieval, to compare the performance. Average Precision is the

Event	TimeUserLDA	Base	Base+Reg	Base+Reg+Aff	Inner popularity (η_k^0)
debate caused by Manda Swaggie	0.3533	0.3230	**0.3622**	0.2956	0.943

Table 5: Example topics and their corresponding correlated events.

average of the precision value obtained for the set of top items existing after each relevant item is retrieved (Manning et al., 2008). We also rank the 8 events in decreasing order of their inner popularity η_k^0 learned by our complete model. The results are shown in Table 4. We have the following findings from the table. (1) Our complete method outperforms the other methods for 6 out of the 8 test events, suggesting that with the inferred event-topic affinity vectors we can do better event recommendation. (2) The improvement brought by the event-topic affinity vectors, as reflected in the difference in Average Precision between Base+Reg+Aff and Base (or Base+Reg) is more pronounced for events with lower inner popularity. Recall that the inner popularity of an event shows the inherent popularity of an event regardless of its association with any topic, that is, an event with high inner popularity attracts attention of many people regardless of their topic interests, while an event with low inner popularity tends to attract attention of certain people with similar topic interests. The finding above suggests that the event-topic affinity vectors are especially useful for recommending events that attract only certain people's attention, such as those related to sports, music, etc.

One may wonder for the events with low inner popularity why we could not achieve the same effect by Base or Base+Reg where we consider the topic similarity of test users with training users who have tweeted about the event. Our close examination shows that for these events although Base and Base+Reg may identify relevant event tweets with decent precision, the users they identify who have

tweeted about the event may not share similar topic interests. As a result, when we average these users' topic interests, we cannot obtain a clear skewed topic distribution that explains the event's affinity to different topics. In contrast, Base+Reg+Aff explicitly models the event-topic affinity vector and prefers to assign a tweet to an event if its author's topic distribution is similar to the event's affinity vector. Through the training iterations, the users who have tweeted about an event as identified by Base+Reg+Aff will gradually converge to share similar topic distributions.

Grouping Events by Topics

Finally, we show that the event-topic affinity vectors can also be used to group events by topics. This can potentially be used to better organize and present popular events in social media. In Table 5 we show a few highly related events for a few popular topics in our Twitter data set. Specifically given a topic a we rank the meaningful events that contain at least 70 tweets based on $\eta_{k,a}$. We can see from the table that the events are indeed related to the corresponding topic. The event "LionsXII 9-0 Sabah FA" is particularly interesting in that it is highly related to both the topic on Malay and the topic on soccer. (LionsXII is a soccer team from Singapore and Sabah FA is a soccer team from Malaysia.)

5 Conclusion

In this paper, we propose a unified model to study topics, events and users jointly. The base of our method is a combination of an LDA-like model and the Recurrent Chinese Restaurant Process, which aims to model users' longstanding personal topic interests and events over time simultaneously. The Recurrent Chinese Restaurant Process is appealing in the sense that it provides a principled dynamic nonparametric model in which the number of events is not fixed overtime. We further use a time duration-based regularization to capture the fast emergence and disappearance of events on Twitter, which is effective to produce more meaningful events. Finally, we use an inner popularity bias parameter and event-topic affinity vectors to interpret an event's inherent popularity and its affinity to different topics. Our experiments quantitatively show that our proposed model can effectively identify meaningful events and accurately find relevant tweets for these events. Furthermore, the event-topic association inferred by our model can help an event recommendation task and organize events by topics.

Abstract

Work on authorship attribution has traditionally focused on long texts. In this work, we tackle the question of whether the author of a very short text can be successfully identified. We use Twitter as an experimental testbed. We introduce the concept of an author's unique "signature", and show that such signatures are typical of many authors when writing very short texts. We also present a new authorship attribution feature ("flexible patterns") and demonstrate a significant improvement over our baselines. Our results show that the author of a single tweet can be identified with good accuracy in an array of flavors of the authorship attribution task.

1 Introduction

Research in authorship attribution has developed substantially over the last decade (Stamatatos, 2009). The vast majority of such research has been dedicated towards finding the author of long texts, ranging from single passages to book chapters. In recent years, the growing popularity of social media has created special interest, both theoretical and computational, in short texts. This has led to many recent authorship attribution projects that experimented with web data such as emails (Abbasi and Chen, 2008), web forum messages (Solorio et al., 2011) and blogs (Koppel et al., 2011b). This paper addresses the question to what extent the authors of very short texts can be identified. To answer this question, we experiment with Twitter tweets.

Twitter messages (tweets) are limited to 140 characters. This restriction imposes major difficulties on authorship attribution systems, since authorship attribution methods that work well on long texts are often not as useful when applied to short texts (Burrows, 2002; Sanderson and Guenter, 2006).

Nonetheless, tweets are relatively self-contained and have smaller sentence length variance compared to excerpts from longer texts (see Section 3). These characteristics make Twitter data appealing as a testbed when focusing on short texts. Moreover, an authorship attribution system of tweets may have various applications. Specifically, a range of cybercrimes can be addressed using such a system, including identity fraud and phishing.

In this paper, we introduce the concept of k-*signatures*. We denote the k-*signatures* of an author a as the features that appear in at least $k\%$ of a's training samples, while not appearing in the training set of any other author. When k is large, such signatures capture a unique style used by a. An analysis of our training set reveals that unique k-signatures are typical of many authors. Moreover, a substantial portion of the tweets in our training set contain at least one such signature. These findings suggest that a single tweet, although short and sparse, often contains sufficient information for identifying its author. Our results show that this is indeed the case.

We train an SVM classifier with a set of features that include character n-grams and word n-grams. We use a rigorous experimental setup, with varying number of authors (values between 50-1,000) and various sizes of the training set, ranging from 50 to 1,000 tweets per author. In all our experiments, a single tweet is used as test document. We also use a setting in which the system is allowed to respond *don't know* in cases of uncertainty. Applying this option results in higher precision, at the expense of

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1880–1891,
Seattle, Washington, USA, 18-21 October 2013.

lower recall.

Our results show that the author of a tweet can be successfully identified. For example, when using a dataset of as many as 1,000 authors with 200 training tweets per author, we are able to obtain 30.3% accuracy (as opposed to a random baseline of only 0.1%). Using a dataset of 50 authors with as few as 50 training tweets per author, we obtain 50.7% accuracy. Using a dataset of 50 authors with 1,000 training tweets per author, our results reach as high as 71.2% in the standard classification setting, and exceed 91% accuracy with 60% recall in the *don't know* setting.

We also apply a new set of features, never previously used for this task – flexible patterns. Flexible patterns essentially capture the context in which function words are used. The effectiveness of function words as authorship attribution features (Koppel et al., 2009) suggests using flexible pattern features. The fact that flexible patterns are learned from plain text in a fully unsupervised manner makes them domain and language independent. We demonstrate that using flexible patterns gives significant improvement over our baseline system. Furthermore, using flexible patterns, our system obtains a 6.1% improvement over current state-of-the-art results in authorship attribution on Twitter.

To summarize, the contribution of this paper is threefold.

- We provide the most extensive research to date on authorship attribution of micro-messages, and show that authors of very short texts can be successfully identified.
- We introduce the concept of an author's unique k-signature, and demonstrate that such signatures are used by many authors in their writing of micro-messages.
- We present a new feature for authorship attribution – flexible patterns – and show its significant added value over other methods. Using this feature, our system obtains a 6.1% improvement over the current state-of-the-art.

The rest of the paper is organized as follows. Sections 2 and 3 describe our methods and our experimental testbed (Twitter). Section 4 presents the concept of k-signatures. Sections 5 and 6 present our experiments and results. Flexible patterns are presented in Section 7 and related work is presented in Section 8.

2 Methodology

In the following we briefly describe the main features employed by our system. The features below are binary features.

Character n-grams. Character n-gram features are especially useful for authorship attribution on micro-messages since they are relatively tolerant to typos and non-standard use of punctuation (Stamatatos, 2009). These are common in the non-formal style generally applied in social media services. Consider the example of misspelling "Britney" as "Brittney". The misspelled name shares the 4-grams "Brit" and "tney" with the correct name. As a result, these features provide information about the author's style (or at least her topic of interest), which is not available through lexical features.

Following standard practice, we use 4-grams (Sanderson and Guenter, 2006; Layton et al., 2010; Koppel et al., 2011b). White spaces are considered characters (i.e., a character n-gram may be composed of letters from two different words). A single white-space is appended to the beginning and the end of each tweet. For efficiency, we consider only character n-gram features that appear at least t_{cng} times in the training set of at least one author (see Section 5).

Word n-grams. We hypothesize that word n-gram features would be useful for authorship attribution on micro-messages. We assume that under a strict length restriction, many authors would prefer using short, repeating phrases (word n-grams).

In our experiments, we consider $2 \leq n \leq 5$.[1] We regard sequences of punctuation marks as words. Two special words are added to each tweet to indicate the beginning and the end of the tweet. For efficiency, we consider only word n-gram features that appear at least t_{wng} times in the training set of at least one author (see Section 5).

Model. We use libsvm's Matlab implementation of a multi-class SVM classifier with a linear kernel

[1] We skip unigrams as they are generally captured by the character n-gram features.

(Chang and Lin, 2011). We use ten-fold cross validation on the training set to select the best regularization factor between 0.5 and 0.005.[2]

3 Experimental Testbed

Our main research question in this paper is to determine the extent to which authors of very short texts can be identified. A major issue in working with short texts is selecting the right dataset. One approach is breaking longer texts into shorter chunks (Sanderson and Guenter, 2006). We take a different approach and experiment with micro-messages (specifically, tweets).

Tweets have several properties making them an ideal testbed for authorship attribution of short texts. First, tweets are posted as single units and do not necessarily refer to each other. As a result, they tend to be self contained. Second, tweets have more standardized length distribution compared to other types of web data. We compared the mean and standard deviation of sentence length in our Twitter dataset and in a corpus of English web data (Ferraresi et al., 2008).[3] We found that (a) tweets are shorter than standard web data (14.2 words compared to 20.9), and (b) the standard deviation of the length of tweets is much smaller (6.4 vs. 21.4).

Pre-Processing. We use a Twitter corpus that includes approximately 5×10^8 tweets.[4] All non-English tweets and tweets that contain fewer than 3 words are removed from the dataset. We also remove tweets marked as retweets (using the RT sign, a standard Twitter symbol to indicate that this tweet was written by a different user). As some users retweet without using the RT sign, we also remove tweets that are an exact copy of an existing tweet posted in the previous seven days.

Apart from plain text, some tweets contain references to other Twitter users (in the format of @<user>). Since using reference information makes this task substantially easier (Layton et al., 2010), we replace each user reference with the special meta tag REF. For sparsity reasons, we also replace web addresses with the meta tag URL, numbers with the meta tag NUM, time of day with the meta tag TIME and dates with the meta tag DATE.

[2] In practice, 0.05 or 0.1 are selected in almost all cases.

[3] `http://wacky.sslmit.unibo.it`

[4] These comprise ∼15% of all public tweets created from May 2009 to March 2010.

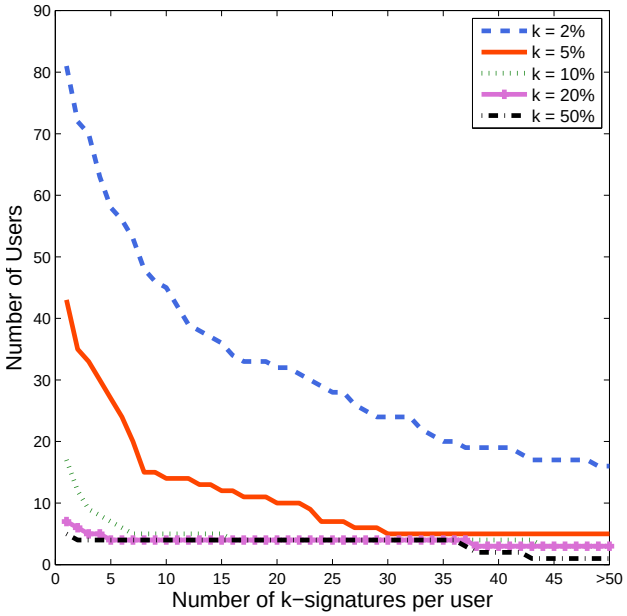

Figure 1: Number of users with at least x k-signatures (100 authors, 180 training tweets per author).

4 k-Signatures

In this section, we show that many authors adopt a unique style when writing micro-messages. This style can be detected by a strong classification algorithm (such as SVM), and be sufficient to correctly identify the author of a single tweet.

We define the concept of the *k-signature* of an author a to be a feature that appears in at least $k\%$ of a's training set, while not appearing in the training set of any other user. Such signatures can be useful for identifying future (unlabeled) tweets written by a.

To validate our hypothesis, we use a dataset of 100 authors with 180 tweets per author. We compute the number of k-signatures used by each of the authors in our dataset. Figure 1 shows our results for a range of k values (2%, 5%, 10%, 20% and 50%). Results demonstrate that 81 users use at least one 2%-signature, 43 users use at least one 5%-signature, and 17 users use at least one 10%-signature. These results indicate that a large portion of the users adopt a unique signature (or set of signatures) when writing short texts. Table 1 provides examples of 10%-signatures.

Signature Type	10%-signature	Examples
Character n-grams	‘ ^_^’	REF oh ok ^_^ Glad you found it!
		Hope everyone is having a good afternoon ^_^
		REF Smirnoff lol keeping the goose in the freezer ^_^
	‘**yew** ’	gurl **yew** serving me tea nooch
		REF about wen **yew** and ronnie see each other
		REF lol so **yew** goin to check out tini’s tonight huh???

		Ludas album is gone be hott**.. lal**
		Dayum refs don’t get injury timeouts**.. lal**.. get him off the field..
	smoochies , e3	I’m just back after takin’ a very long, icy cold shower.....Shivering **smoochies,E3** http://bit.ly/4CzzP9
		A blue stout or two would be nice as well, Purr!Blue smooth **smoochies,E3** http://bit.ly/75D4fO
		That is sooooooooooooooooo unfair!Double **smoochies,E3** http://bit.ly/07sXRGX

Table 1: Examples of 10%-signatures.

Results also show that seven users use one or more 20%-signatures, and five users even use one or more 50%-signatures. Looking carefully at these users, we find that they write very structured messages, and are probably bots, such as news feeds, bidding systems, etc. Table 2 provides examples of tweets posted by such users.[5]

Another interesting question is how many tweets contain at least one k-signature. Figure 2 shows for each user the number of tweets in her training set for which at least one k-signature is found. Results demonstrate that a total of 18.6% of the training tweets contain at least one 2%-signature, 10.3% the training tweets contain at least one 5%-signature and 6.5% of the training tweets contain at least one 10%-signature. These findings validate our assumption that many users use k-signatures in short texts.

These findings also have direct implications on authorship attribution of micro-messages, since k-signatures are reliable classification features. As a result, texts written by authors that tend to use k-signatures are likely to be easily identified by a reasonable classification algorithm. Consequently, k-signatures provide a possible explanation for the high quality results presented in this paper.

In the broader context, the presence (and contribution) of k-signatures is in line with the hypothesis proposed by (Davidov et al., 2010a): while still using an informal and unstructured (grammatical) language, authors tend to use typical and unique structures in order to allow a short message to stand alone without a clear conversational context.

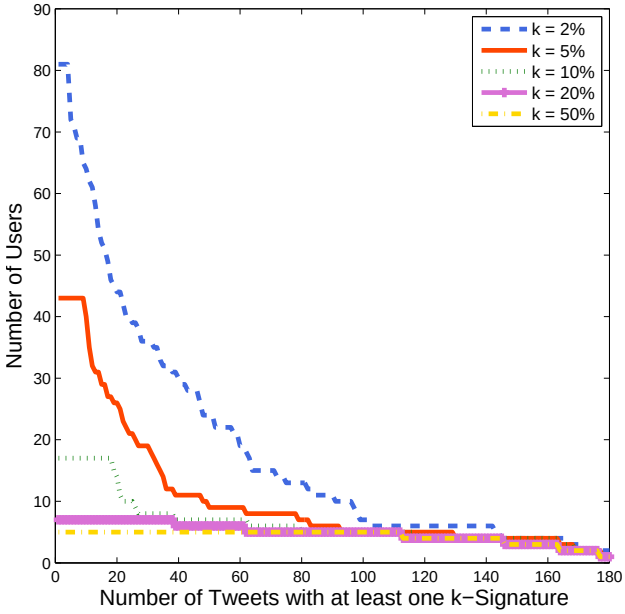

Figure 2: Number of users with at least x training tweets that contain at least one k-signature (100 authors, 180 training tweets per author).

[5]Our k-signature method can actually be useful for automatically identifying such users. We defer this to future work.

Table 2: Examples of tweets published by very structured users, suspected to be bots, along with one of their 20%-signatures.

5 Experiments

We report of three different experimental configurations. In the experiments described below, each dataset is divided into training and test sets using ten-fold cross validation. On the test phase, each document contains a single tweet.

Experimenting with varying Training Set Sizes. In order to test the affect of the training set size, we experiment with an increasingly larger number of tweets per author. Experimenting with a range of training set sizes serves two purposes: (a) to check whether the author of a tweet can be identified using a very small number of (short) training samples, and (b) check how much our system can benefit from training on a larger corpus.

In our experiments we only consider users who posted between 1,000–2,000 tweets[6] (a total of 10,183 users), and randomly select 1,000 tweets per user. From these users, we select 10 groups of 50 users each.[7] We perform a set of classification experiments, selecting for each author an increasingly larger subset of her 1,000 tweets as training set. Subset sizes are (50, 100, 200, 500, 1,000). Threshold values for our features in each setting (see Section 2) are $(2, 2, 4, 10, 20)$ for t_{cng} and $(2, 2, 2, 3, 5)$ for t_{wng}, respectively.

Experimenting with varying Numbers of Authors. In a second set of experiments, we use an increasingly larger number of authors (values between 100-1,000), in order to check whether the author of a very short text can be identified in a "needle in a haystack" type of setting.

Due to complexity issues, we only experiment with 200 tweets per author as training set. We select groups of size 100, 200, 500 and 1,000 users (one group per size). We use the same threshold values as the 200 tweets per author setting previously described (t_{cng} = 4, t_{wng} = 2).

[6] This range is selected since on one hand we want at least 1,000 tweets per author for our experiments, and on the other hand we noticed that users with a larger number of tweets in corpus tend to be spammers or bots that are very easy to identify, so we limit this number to 2,000.

[7] An eleventh group is selected as development set.

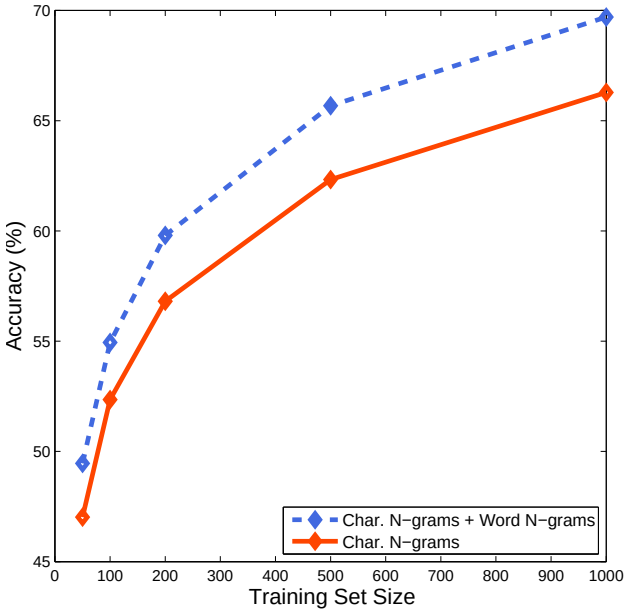

Figure 3: Authorship attribution accuracy for 50 authors with various training set sizes. The values are averaged over 10 groups. The random baseline is 2%.

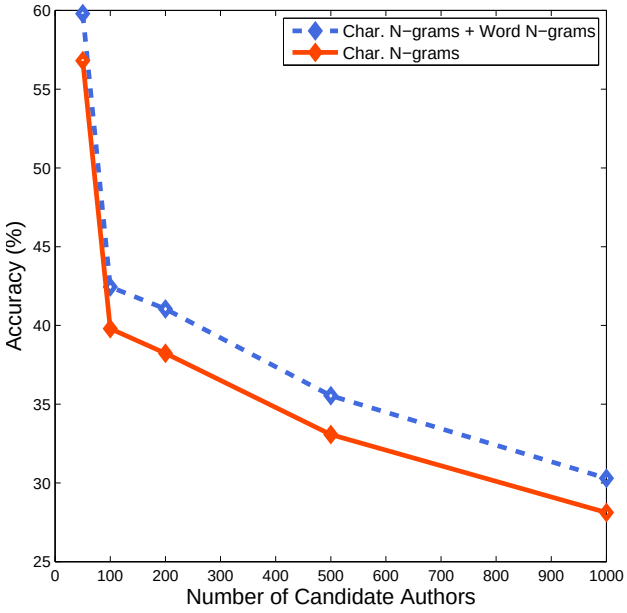

Figure 4: Authorship attribution accuracy with varying number of candidate authors, using 200 training tweets per author. The random baselines for 50[9], 100, 200, 500 and 1,000 authors are 2%, 1%, 0.5%, 0.2% and 0.1%, respectively.

Recall-Precision Tradeoff. Another aspect of our research question is the level of certainty our system has when suggesting an author for a given tweet. In cases of uncertainty, many real life applications would prefer not to get any response instead of getting a response with low certainty. Moreover, in real life applications we are often not even sure that the real author is part of our training set. Consequently, we allow our system to respond "*don't know*" in cases of low confidence (Koppel et al., 2006; Koppel et al., 2011b). This allows our system to obtain higher precision, at the expense of lower recall.

To implement this feature, we use SVM's probability estimates, as implemented in libsvm. These estimates give a score to each potential author. These scores reflect the probability that this author is the correct author, as decided by the prediction model. The selected author is always the one with the highest probability estimate.

As selection criterion, we use a set of increasingly larger thresholds (0.05-0.9) for the probability of the selected author. This means that we do not select test samples for which the selected author has a probability estimate value lower than the threshold.

6 Basic Results

Experimenting with varying Training Set Sizes. Figure 3 shows results for our experiments with 50 authors and various training set sizes. Results demonstrate that authors of very short texts can be successfully identified, even with as few as 50 tweets per author (49.5%). When given more training samples, authors are identified much more accurately (up to 69.7%). Results also show that, according to our hypothesis, word n-gram features substantially improve over character n-grams features only (3% averaged improvement over all settings).

Experimenting with varying Numbers of Authors. Figure 4 shows our results for various numbers of authors, using 200 tweets per author as training set. Results demonstrate that authors of an unknown tweet can be identified to a large extent even when there are as many as 1,000 candidate authors (30.3%, as opposed to a random baseline of only 0.1%). Results further validate that word n-gram features substantially improve over character

[9]Results for 50 authors with 200 tweets per author are taken from Figure 3.

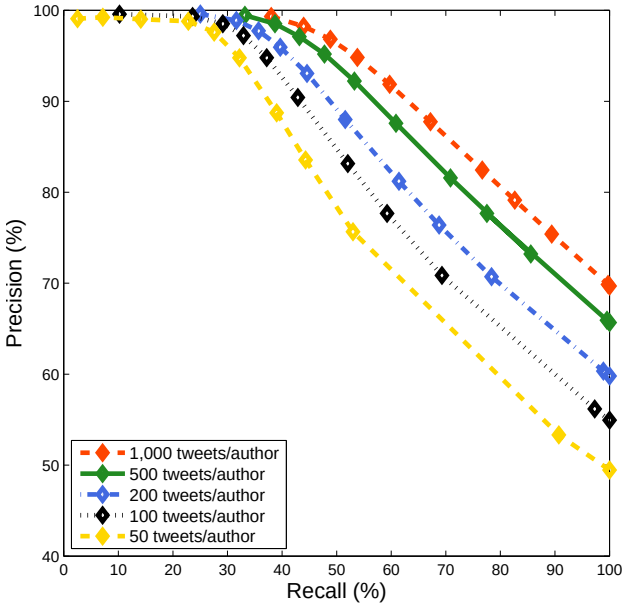

Figure 5: Recall-precision curves for 50 authors with varying training set sizes.

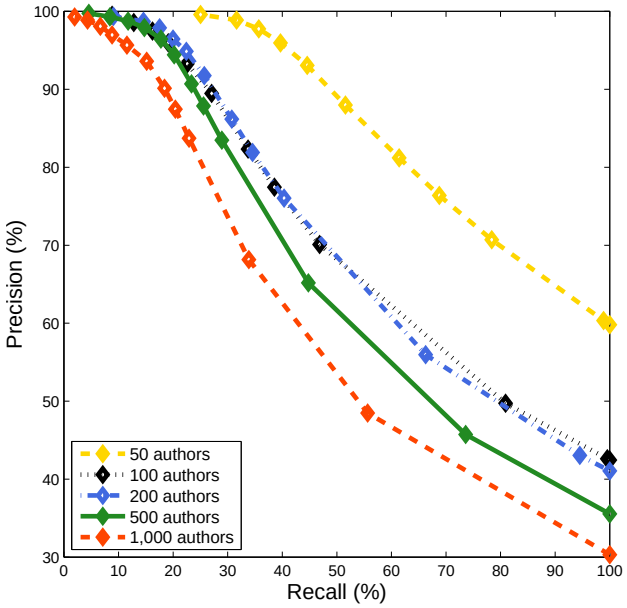

Figure 6: Recall-precision curves for varying number of authors.

n-grams features (2.6% averaged improvement).

Recall-Precision Tradeoff. Figure 5 shows the recall-precision curves for our experiments with 50 authors and varying training set sizes. Results demonstrate that we are able to obtain very high precision (over 90%) while still maintaining a relatively high recall (from ∼35% recall for 50 tweets per author up to $> 60\%$ recall for 1,000 tweets per author).

Figure 6 shows the recall-precision curves for our experiments with varying number of authors. Results demonstrate that even in the 1,000 authors setting, we are able to obtain high precision values (90% and 70%) with reasonable recall values (18% and ∼30%, respectively).

7 Flexible Patterns

In previous sections we provided strong evidence that authors of micro-messages can be successfully identified using standard methods. In this section we present a new feature, never previously used for this task – flexible patterns. We show that flexible patterns can be used to improve classification results.

Flexible patterns are a generalization of word n-grams, in the sense that they capture potentially unseen word n-grams. As a result, flexible patterns can pick up fine-grained differences between authors' styles. Unlike other types of pattern features, flexible patterns are computed automatically from plain text. As such, they can be applied to various tasks, independently of domain and language. We describe them in detail.

Word Frequency. Flexible patterns are composed of high frequency words (HFW) and content words (CW). Every word in the corpus is defined as either HFW or CW. This clustering is performed by counting the number of times each word appears in the corpus of size s. A word that appears more than $10^{-4} \times s$ times in a corpus is considered HFW. A word that appears less than $10^{-3} \times s$ times in a corpus is considered CW. Some words may serve both as HFWs and CWs (see Davidov and Rappoport (2008b) for discussion).

Structure of a Flexible Pattern. Flexible patterns start and end with an HFW. A sequence of zero or more CWs separates consecutive HFWs. At least one CW must appear in every pattern.[10] For efficiency, at most six HFWs (and as a result, five CW sequences) may appear in a flexible pattern. Examples of flexible patterns include

1. "the_{HFW} CW of_{HFW} the_{HFW}"

[10] Omitting this treats word n-grams as flexible patterns.

Flexible Pattern Features. Flexible patterns can serve as binary classification features; a tweet matches a given flexible pattern if it contains the flexible pattern sequence. For example, (1) is matched by (2).

2. "*Go to* $\underline{the_{HFW}\ house_{CW}\ of_{HFW}\ the_{HFW}}$ *rising sun*"

Partial Flexible Patterns. A flexible pattern may appear in a given tweet with additional words not originally found in the flexible pattern, and/or with only a subset of the HFWs (Davidov et al., 2010a). For example, (3) is a partial match of (1), since the word "great" is not part of the original flexible pattern. Similarly, (4) is another partial match of (1), since (a) the word "good" is not part of the original flexible pattern and (b) the second occurrence of the word "the" does not appear in (4) (missing word is marked by ▬).

3. "$\underline{The_{HFW}\ \mathbf{great}_{\mathbf{HFW}}\ king_{CW}\ of_{HFW}\ the_{HFW}}$ *ring*"

4. "$\underline{The_{HFW}\ \mathbf{good}_{\mathbf{HFW}}\ king_{CW}\ of_{HFW}\ \blacksquare}$ *Spain*"

We use such cases as features with lower weight, proportional to the number of found HFWs in the tweet ($w = \frac{0.5 \times n_{found}}{n_{expected}}$). For example, (1) receives a weight of 1 (complete match) against (2). Against (3), it receives a weight of 0.5 ($= \frac{0.5 \times 3}{3}$, partial match with no missing HFWs). Against (4) it receives a weight of $1/3$ ($= \frac{0.5 \times 2}{3}$, partial match with only 2/3 HFWs found).

Experimenting with Flexible Pattern Features. We repeat our experiments with varying training set sizes (see Section 5) with two more systems: one that uses character n-grams and flexible pattern features, and another that uses character n-grams, word n-grams and flexible patterns. High frequency word counts are computed separately for each author using her training set. We only consider flexible pattern features that appear at least t_{fp} times in the training set of at least one author. Values of t_{fp} for training set sizes (50, 100, 200, 500, 1,000) are (2, 3, 7, 7, 8), respectively.

Results. Figure 7 shows our results. Results demonstrate that flexible pattern features have an added value over both character n-grams alone (averaged 2.9% improvement) and over character n-grams and word n-grams together (averaged 1.5% improvement). We perform t-tests on each of our training set sizes to check whether the latter improvement is significant. Results demonstrate that it is highly significant in all settings, with p-values smaller than values between 10^{-3} (for 50 tweets per author) and 10^{-8} (1,000 tweets per author).

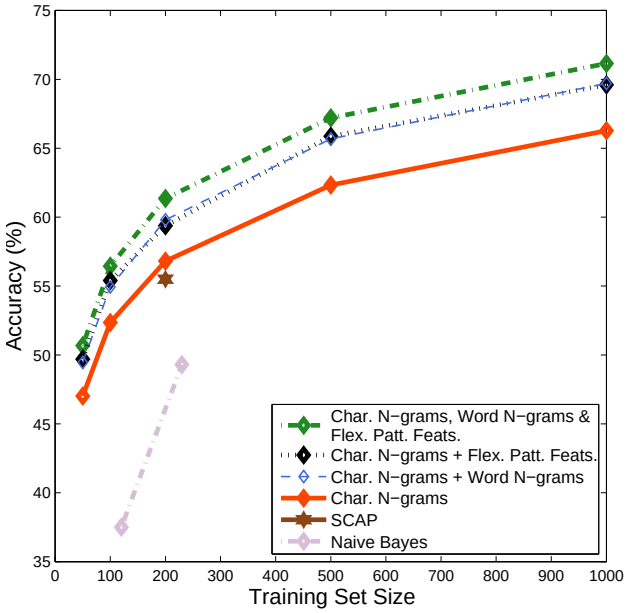

Figure 7: Authorship attribution accuracy for 50 authors with various training set sizes and various feature sets. The values are averaged over 10 groups. The random baseline is 2%.
Comparison to previous work: SCAP – SCAP algorithm results, as reported by (Layton et al., 2010), Naive Bayes – Naive Bayes algorithm results, as reported by (Boutwell, 2011).

Comparison to Previous Works. Figure 7 also shows results for the only two works that experimented in some of the settings we experimented in: Layton et al. (2010) and Boutwell (2011) (see Section 8). Our system substantially outperforms these two systems, by margins of 5.9% to 19%. These margins are explained by the choice of algorithm (SVM and not SCAP/naive Bayes) and our set of features (character n-grams + word n-grams + flexible patterns compared to character n-grams only). In order to rule out the possibility that these margins stem from using different datasets, we tested our system on the dataset used in (Layton et al., 2010). Our system obtains even higher results on this dataset than on our datasets (61.6%, a total im-

provement of 6.1% over (Layton et al., 2010)).

Discussion. To illustrate the additional contribution of flexible patterns over word n-grams, consider the following tweets, written by the same author.

5. "... $\underline{the_{HFW}\ way_{CW}\ I_{HFW}}$ *treated*$_{CW}$ *her*$_{HFW}$"
6. "... *half of* $\underline{the_{HFW}\ things_{CW}\ I_{HFW}}$ *have seen*"
7. "... $\underline{the_{HFW}\ friends_{CW}\ I_{HFW}}$ *have had for years"*
8. "... *in* $\underline{the_{HFW}\ neighborhood_{CW}\ I_{HFW}}$ *grew up in*"

Consider a case where (5) is part of the test set, while (6-8) appear in the training set. As (5) shares no sequence of words with (6-8), no word n-gram feature is able to identify the author's style in (5). However, this style can be successfully identified using the flexible pattern (9), shared by (5-8).

9. the_{HFW} CW I_{HFW}

This demonstrates the added value flexible pattern features have over word n-gram features.

8 Related Work

Authorship attribution dates back to the end of 19th century, when (Mendenhall, 1887) applied sentence length and word length features to plays of Shakespeare. Ever since, many methods have been developed for this task. For recent surveys, see (Koppel et al., 2009; Stamatatos, 2009; Juola, 2012).

Authorship attribution methods can be generally divided into two categories (Stamatatos, 2009). In similarity-based methods, an anonymous text is attributed to some author whose writing style is most similar (by some distance metric). In machine learning methods, which we follow in this paper, anonymous texts are classified, using machine learning algorithms, into different categories (in this case, different authors).

Machine learning papers differ from each other by the features and machine learning algorithm. Examples of features include HFWs (Mosteller and Wallace, 1964; Argamon et al., 2007), character n-gram (Kjell, 1994; Hoorn et al., 1999; Stamatatos, 2008), word n-grams (Peng et al., 2004), part-of-speech n-grams (Koppel and Schler, 2003; Koppel et al., 2005) and vocabulary richness (Abbasi and Chen, 2005).

The various machine learning algorithms used include naive Bayes (Mosteller and Wallace, 1964; Kjell, 1994), neural networks (Matthews and Merriam, 1993; Kjell, 1994), K-nearest neighbors (Kjell et al., 1995; Hoorn et al., 1999) and SVM (De Vel et al., 2001; Diederich et al., 2003; Koppel and Schler, 2003).

Traditionally, authorship attribution systems have mainly been evaluated against long texts such as theater plays (Mendenhall, 1887), essays (Yule, 1939; Mosteller and Wallace, 1964), biblical books (Mealand, 1995; Koppel et al., 2011a) and book chapters (Argamon et al., 2007; Koppel et al., 2007). In recent year, many works focused on web data such as emails (De Vel et al., 2001; Koppel and Schler, 2003; Abbasi and Chen, 2008), web forum messages (Abbasi and Chen, 2005; Solorio et al., 2011), blogs (Koppel et al., 2006; Koppel et al., 2011b) and chat messages (Abbasi and Chen, 2008). Some works focused on SMS messages (Mohan et al., 2010; Ishihara, 2011).

Authorship Attribution on Twitter. The performance of authorship attribution systems on short texts is affected by several factors (Stamatatos, 2009). These factors include the number of candidate authors, the training set size and the size of the test document.

Very few authorship attribution works experimented with Twitter. Unlike our work, all used a single group of authors (group sizes varied between 3-50). Layton et al. (2010) used the SCAP methodology (Frantzeskou et al., 2007) with character n-gram features. They experimented with 50 authors and compared different numbers of tweets per author (values between 20-200). Surprisingly, they showed that their system does not improve when given more training tweets. In our work, we noticed a different trend, and showed that more data can be extremely valuable for authorship attribution systems on micro-messages (see Section 6). Silva et al. (2011) trained an SVM classifier with various features (e.g., punctuation and vocabulary features) on a small dataset of three authors only, with varying training set size. Although their work used a set of Twitter-specific features that we do not explicitly use, our features implicitly cover a large portion of their features (such as punctuation and emoticon

features, which are largely covered by character n-grams).

Boutwell (2011) used a naive Bayes classifier with character n-gram features. She experimented with 50 authors and two training size values (120 and 230). She also provided a set of experiments that studied the effect of joining several tweets into a single document. Mikros and Perifanos (2013) trained an SVM classifier with character n-gram and word n-grams. They experimented with 10 authors of Greek text, and also joined several tweets into a single document. Joining several tweets into a longer document is appealing since it can lead to substantial improvement of the classification results, as demonstrated by the works above. However, this approach requires the test data to contain several tweets that are known a-priori to be written by the same author. This assumption is not always realistic. In our paper, we intentionally focus on a single tweet as document size.

Flexible Patterns. Patterns were introduced by (Hearst, 1992), who used hand crafted patterns to discover hyponyms. Hard coded patterns were used for many tasks, such as discovering meronymy (Berland and Charniak, 1999), noun categories (Widdows and Dorow, 2002), verb relations (Chklovski and Pantel, 2004) and semantic class learning (Kozareva et al., 2008).

Patterns were first extracted in a fully unsupervised manner ("flexible patterns") by (Davidov and Rappoport, 2006), who used flexible patterns in order to establish noun categories, and (Biciçi and Yuret, 2006) who used them for analogy question answering. Ever since, flexible patterns were used as features for various tasks such as extraction of semantic relationships (Davidov et al., 2007; Turney, 2008b; Bollegala et al., 2009), detection of synonyms (Turney, 2008a), disambiguation of nominal compound relations (Davidov and Rappoport, 2008a), sentiment analysis (Davidov et al., 2010b) and detection of sarcasm (Tsur et al., 2010).

9 Conclusion

The main goal of this paper is to measure to what extent authors of micro-messages can be identified. We have shown that authors of very short texts can be successfully identified in an array of authorship attribution settings reported for long documents. This is the first work on micro-messages to address some of these settings. We introduced the concept of *k-signature*. Using this concept, we proposed an interpretation of our results. Last, we presented the first authorship attribution system that uses flexible patterns, and demonstrated that using these features significantly improves over other systems. Our system obtains 6.1% improvement over the current state-of-the-art.

Acknowledgments

We would like to thank Elad Eban and Susan Goodman for their helpful advice, as well as Robert Layton for providing us with his dataset. This research was funded (in part) by the Harry and Sylvia Hoffman leadership and responsibility program (for the first author) and the Intel Collaborative Research Institute for Computational Intelligence (ICRI-CI).

Detection of Product Comparisons – How Far Does an Out-of-the-box Semantic Role Labeling System Take You?

Wiltrud Kessler and **Jonas Kuhn**
Institute for Natural Language Processing
University of Stuttgart
wiltrud.kessler@ims.uni-stuttgart.de

Abstract

This short paper presents a pilot study investigating the training of a standard Semantic Role Labeling (SRL) system on product reviews for the new task of detecting comparisons. An (opinionated) comparison consists of a comparative "predicate" and up to three "arguments": the entity evaluated positively, the entity evaluated negatively, and the aspect under which the comparison is made. In user-generated product reviews, the "predicate" and "arguments" are expressed in highly heterogeneous ways; but since the elements *are* textually annotated in existing datasets, SRL is technically applicable. We address the interesting question how well training an out-of-the-box SRL model works for English data. We observe that even without any feature engineering or other major adaptions to our task, the system outperforms a reasonable heuristic baseline in all steps (predicate identification, argument identification and argument classification) and in three different datasets.

1 Introduction

Sentiment analysis deals with the task of determining the polarity of an opinionated document or a sentence, in product reviews typically with regard to some target product. A common way to express sentiment about some product is by comparing it to a different product. In the corpus data we use, around 10% of sentences contain at least one comparison. Here are some examples of comparison sentences from our corpus:

(1) a. "[This camera]$_{\mathrm{E}+}$ ... its [screen]$_{\mathrm{A}}$ is much **bigger** than the [400D]$_{\mathrm{E}-}$."

b. "[D70]$_{\mathrm{E}+}$ **beats** [EOS 300D]$_{\mathrm{E}-}$ in almost [every category]$_{\mathrm{A}}$, EXCEPT ONE."

c. "[Noise suppression]$_{\mathrm{A}_1\mathrm{A}_2}$ was generally **better**$_1$ than the [D80]$_{\mathrm{E}-_1}$'s and much **better**$_2$ than the [Rebel]$_{\mathrm{E}-_2}$'s."

d. "A striking **difference** between the [EOS 350D]$_{\mathrm{E}-}$ and the new [EOS 400D]$_{\mathrm{E}+}$ concerns the [image sensor]$_{\mathrm{A}}$."

Note that our definition of comparisons is broader than the linguistic category of comparative sentences, which only includes sentences that contain a comparative adjective or adverb. For our work, we consider comparisons expressed by any Part of Speech (POS).

A comparison contains several parts that must be identified in order to get meaningful information. We call the word or phrase that is used to express the comparison ("better", "beats", ...) a *comparative predicate*. A comparison involves two *entities*, one or both of them may be implicit. In our data, most of the entities are products, e.g., the two cameras "D70" and "EOS 300D" in sentence 1b. In graded comparisons, entity+ (E+) is the entity that is being evaluated positively, entity- (E-) the entity evaluated negatively. In many sentences one attribute or part of a product is being compared, like "image sensor" in sentence 1d. We call this the *aspect* (A).

The task we want to solve for a given comparison sentence is to detect the comparative predicate, the entities that are involved and the aspect that is being compared. We borrow our methodology from Semantic Role Labeling (SRL). In SRL, *events* are expressed by predicates and *participants* of these events are expressed by arguments that fill different semantic roles. Adapted to the problem of detecting comparisons, the events we are interested in are comparative predicates and the arguments are the two entities and the aspect that is being compared.

Due to the diversity of possible ways of expressing comparisons, the "predicates" and "arguments"

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1892–1897,
Seattle, Washington, USA, 18-21 October 2013.

in this task are more heterogeneous categories than in standard SRL based on PropBank and NomBank annotations. Moreoever, the existing labeled datasets are based on an annotation methodology which gave the annotators a lot of freedom in deciding on the linguistic anchoring of the "predicate" and "arguments". This adds to the heterogeneity of the observed constructions and makes it even more interesting to ask the question how far an out-of-the-box SRL model can take you.

In this work, we re-train an existing SRL system (Björkelund et al., 2009) on product review data labeled with comparative predicates and arguments. We show that we can get reasonable results without any feature engineering or other major adaptions. This is an encouraging result for a linguistically grounded modeling approach to comparison detection.

2 Related Work

The syntax and semantics of comparative sentences have been the topic of research in linguistics for a long time (Moltmann, 1992; Kennedy, 1999). However, our focus is on computational methods and we also treat comparisons that are not comparative sentences in a linguistic sense.

In sentiment analysis, some studies have been presented to identify comparison sentences. Jindal and Liu (2006a) report good results on English using class sequential rules based on keywords as features for a Naive Bayes classifier. A similar approach for Korean is presented by Yang and Ko (2009; 2011b; 2011a). In our work, we do not address the task of identifying comparison sentences, we assume that we are given a set of such sentences.

The step we are concerned with is the detection of relevant parts of a comparison. To identify entities and aspect, Jindal and Liu (2006b) use an involved pattern mining process to mine label sequential rules from annotated English sentences. A similar approach is again presented by Yang and Ko (2011a) for Korean. In contrast to their complicated processing, we simply use an existing SRL system out of the box. Both approaches consider only nouns and pronouns for entities and aspects, we use all POS and allow for multi-word arguments. Jindal and Liu (2006b) base the recognition of comparative predicates on a list of manually compiled keywords. We use this as our baseline. Our approach is not dependent on a set of keywords and is therefore more easily adaptable to a new domain.

All works label the entities according to their position with respect to the predicate. This requires the identification of the preferred entity in a non-equal comparison as an additional step. Ganapathibhotla and Liu (2008) use hand-crafted rules based on the polarity of the predicate for this task. As we label the entities with their roles from the start, we solve both problems at the same time.

Xu et al. (2011) cast the task as a relation extraction problem. They present an approach that uses conditional random fields to extract relations (*better*, *worse*, *same* and *no_comparison*) between two entitites, an attribute and a predicate phrase.

The approach of Hou and Li (2008) is most related to our approach. They use SRL with standard SRL features to extract comparative relations from Chinese sentences. We confirm that SRL is a viable method also for English. In their experiments they report good results on gold parses, but observe a drop in performance when they use their method on automatic parses. All our experiments are conducted on automatically obtained parses.

3 Approach

The input to our system is a sentence that we assume to contain at least one comparison. The result of our processing are one or more comparative predicates and for each predicate three arguments: The two entities that are being compared, and the aspect they are compared in. More formally speaking, for every sentence we expect to get one or more 4-tupels (predicate, entity+, entity-, aspect). Entity+ is the entity that is being evaluated as better than entity-. Any of the arguments may be empty. Currently, we treat only single words as comparative predicates. Annotated multi-word predicates are mapped to one word. We allow for multi-word arguments, but annotate only the head word of the phrase and treat it as a one word argument for evaluation. We do not place any restrictions on possible POS.

We use a standard pipeline approach from SRL. As a first step, the comparative predicate is identified. The next step in SRL would be predicate

disambiguation to identify the different frames this predicate can express. As we do not have such frame information, predicate disambiguation is not performed in our pipeline.

After we have identified the predicates, the next step is to identify their arguments. The identification step is a binary classification whether a word in the sentence is some argument of the identified predicate. As a final classification step, it is determined for each found argument whether this argument is entity+, entity- or the aspect.

We use an existing SRL system (Björkelund et al., 2009)[1] and the features developed for SRL, based on the output of the MATE dependency parser (Bohnet, 2010). Features use attributes of the predicate itself, its head or its dependents. Additionally, for argument identification and classification there are features that describe the relation of predicate and argument, the argument itself, its leftmost and rightmost dependent and left and right sibling.

For the classification tasks of the pipeline, the SRL system uses regularized linear logistic regression from the LIBLINEAR package (Fan et al., 2008). We set the SRL system to train separate classifiers for predicates of different POS. In preliminary experiments, we have found this to perform slightly better than training one classifier for all kinds of predicates, although the difference is not significant. We do not use the reranker.

4 Experiments

Data. We use the JDPA corpus[2] by J. Kessler et al. (2010) for our experiments. It contains blog posts about cameras and cars. We use the annotation class "Comparison" that has four annotation slots. We convert the "more" slot to entity+, the "less" slot to entity- and the "dimension" slot to the aspect. For now, we ignore the "same" slot which indicates if the two mentions are ranked as equal.

We have also tested our approach on the dataset used in (Jindal and Liu, 2006b)[3]. We use all comparisons annotated as types 1 to 3 (ignoring type 4, non-gradable comparisons). In this dataset (J&L), entities are annotated as entity 1 or entity 2 depending on their position before or after the predicate. We keep this annotation and train our system to assign these labels.

	JDPA		J&L
	cameras	cars	
all sentences	5230	14003	7986
comparison sentences	505	1094	649
predicates	642	1327	695
distinct predicates	147	252	122
preds. occurring once	87	147	61
Entity+ / 1	517	1091	657
Entity- / 2	511	1068	331
Aspect	623	1107	526

Table 1: Statistics about the datasets

We do sentence segmentation and tokenization with the Stanford Core NLP[4]. Annotations are mapped to the extracted tokens. We ignore annotations that do not correspond to complete tokens. In the JDPA corpus, if an annotated argument is outside the current sentence, we follow the coreference chain to find a coreferent annotation in the same sentence. If this is not successful, the argument is ignored. We extract all sentences where we found at least one comparative predicate as our dataset.

Table 1 shows some statistics of the data.

Evaluation Setup. We evaluate on each dataset separately using 5-fold cross-validation. We report precision (P), recall (R), F1-measure (F1), and for argument classification macro averaged F1-measure ($F1_m$) over the three arguments. Bold numbers denote the best result in each column and dataset. We mark a F1-measure result with * if it is significantly higher than all previous lines.[5]

Results on Predicates. We have implemented two baselines based on previous work. The simplest baseline, *BL POS* classifies all tokens with a comparative POS ('JJR', 'JJS', 'RBR', 'RBS') as predicates. A more sophisticated baseline, *BL Keyphrases*, uses a list of about 80 manually com-

Table 4: Results argument classification (gold predicates)

piled comparative keyphrases from (Jindal and Liu, 2006a) in addition to the POS tags.

Table 2 shows the result of our experiments. Our method significantly outperforms both baselines in all datasets. The generally low recall values are mainly a result of the wide variety of predicates that are used to express comparisons (see Discussion).

Results on Arguments. To get results indepent of the errors introduced by the relatively low performance on predicate identification, we use annotated predicates (gold predicates) as a starting point for the argument experiments. All results drop about 10% when system predicates are used.

As a *baseline (BL)* for argument identification and classification, we use some heuristics based on the characteristics of our data. Most entities are (pro)nouns and most predicates are positive, so we classify the first noun or pronoun before the predicate as entity+ (entity 1 for J&L) and the first noun or pronoun after the predicate as a entity- (entity 2). If the predicate is a comparative adjective, we classify the predicate itself as aspect, because this type of annotation is very frequent in the JDPA data. For other predicates except nouns and verbs, we classify the direct head of the predicate as aspect.

Table 3 shows the results for argument identification, the results for argument classification can be seen in Table 4. Our system outperforms the baseline for all datasets. The differences are significant except for the cameras dataset. In general, the numbers are low. We will discuss some reasons for this in the next section.

5 Discussion

Sparseness. There are many ways to express a comparison and the size of the available training data is relatively small. This strongly influences the recall of our system as many predicates and arguments occur only once. As we can see in Table 1, 60% of the predicates in the cameras dataset occur only once. In contrast, only 12 predicates occur ten times or more. The trends are similar in the other datasets. This particularly affects verbs and nouns, where many colloquial expressions are used ("hammers", "pwns", "go head to head with", "put X to the sword", ...).

Argument identification and classification would benefit from generalizing over the many different product identifiers like "EOS 5D" or "D200". We want to try to use a Named Entity Recognition system trained on this type of entities for this purpose.

Sentiment Relevance. The following examples show a problem that is typical for sentiment analysis and responsible for many false positive predicates:

(2) a. "Relatively [**lower**]$_{\mathrm{A}}$ noise at higher ISO ..."
b. "... but [**higher**]$_{\mathrm{A}}$ then [Sony]$_{\mathrm{E+}}$"

Although "higher" often expresses a comparison like in sentence 2b, in sentence 2a it only describes a camera setting and should not be extracted as a comparative predicate. There has been considerable work in the areas of subjectivity classification (Wilson and Wiebe, 2003) and the related sentiment relevance (Scheible and Schütze, 2013) which we will try to use to detect such irrelevant, "descriptive" uses of comparative words.

Linguistic anchoring. In contrast to SRL, the task of comparison detection in reviews is a relatively new task without universally recognized definitions and annotation schemes. The annotators of the corpora had a lot of freedom in their choice of linguistic anchoring of the predicates and arguments. Consider these examples from the cameras dataset:

(3) a. "[**Lighter**]$_{\mathrm{A}}$ in weight compared to the [others]$_{\mathrm{E-}}$."
b. "... [its]$_{\mathrm{E+}}$ [better]$_{\mathrm{A}}$ and faster **compared** vs the [SB800 flash]$_{\mathrm{E-}}$ as well."
c. "... this camera's [screen]$_{\mathrm{E+}}$ is [**smaller**]$_{\mathrm{A}}$ than the [ones]$_{\mathrm{E-}}$ on some competing models ..."

Sentences 3a and 3b show a situation where two words are used to express the same comparison and it is unclear which one to chose as a predicate. The decision is left to the individual annotators.

There is some variety of annotations on arguments as well. In the JDPA data, a comparative adjective is often annotated as aspect, sometimes even when there is an alternative, e.g., "weight" in sentence 3a. Also, for a phrase like "its screen", we find "screen" annotated as the aspect (sentence 1a) or an entity (sentence 3c) – and both have their merit. We want to further study how different linguistic anchorings of comparisons effect classification performance.

Equative comparisons. As we can see from the confusion matrix of our system, the distinction between entity+ and entity- is very difficult to learn. In graded comparisons, the distinction is informative, but sentiment information would be needed for the correct assignment. There are also some problematic cases where the ranking cannot be inferred without the broader context, e.g., sentence 1d.

A more annotation-related problem concerns equative comparisons, i.e., both entities are rated as equal. The difference between entity+ and entity- is meaningless in this case. In the JDPA corpus, entities still have to be annotated as either entity+ or entity- and the annotation guidelines allow the annotator to choose freely. As a result, the data is noisy, for the same predicate sometimes entity- is before the predicate, sometimes entity+. If we eliminate this noise by always assigning the entities in order of surface position, we see a gain in macro averaged F1-measure for all systems of about 2% (cameras) to 4% (cars).

6 Conclusions

We presented a pilot experiment on using an SRL-inspired approach to detect comparisons (comparative predicate, entity+, entity-, aspect) in user generated content. We re-trained an existing SRL system on data that is labeled with comparative predicates and arguments. Even without feature engineering or major adaptions, our approach outperforms the baselines in three datasets in every task. This is an encouraging result for a linguistically grounded modeling approach to comparison detection.

For future work, we plan to include features that have been tailored specifically to the task of detecting product comparisons. To address the inherent diversity of expressions typical for user generated content, we want to employ generalization techniques, e.g., to detect product names. We also want to further study the different possible linguistic anchorings of comparisons and their effect on classification performance. Studies of this kind may also inform future data annotation efforts in that certain ways of anchoring the elements of a comparison linguistically may be more helpful than others. We also believe that the explicit modeling of different types (equative, superlative, non-equal gradable) of comparisons will have a positive effect on performance.

A multi-Teraflop Constituency Parser using GPUs

John Canny **David Hall** **Dan Klein**
UC Berkeley
Berkeley, CA, 94720
canny@berkeley.edu, dlwh,klein@cs.berkeley.edu

Abstract

Constituency parsing with rich grammars remains a computational challenge. Graphics Processing Units (GPUs) have previously been used to accelerate CKY chart evaluation, but gains over CPU parsers were modest. In this paper, we describe a collection of new techniques that enable chart evaluation at close to the GPU's practical maximum speed (a Teraflop), or around a half-trillion rule evaluations per second. Net parser performance on a 4-GPU system is over 1 thousand length-30 sentences/second (1 trillion rules/sec), and 400 general sentences/second for the Berkeley Parser Grammar. The techniques we introduce include grammar compilation, recursive symbol blocking, and cache-sharing.

1 Introduction

Constituency parsing with high accuracy (e.g. latent variable) grammars remains a computational challenge. The $O(Gs^3)$ complexity of full CKY parsing for a grammar with G rules and sentence length s, is daunting. Even with a host of pruning heuristics, the high cost of constituency parsing limits its uses. The most recent Berkeley latent variable grammar for instance, has 1.7 million rules and requires about a billion rule evaluations for inside scoring of a single length-30 sentence. GPUs have previously been used to accelerate CKY evaluation, but gains over CPU parsers were modest. e.g. in Yi et al. (2011) a GPU parser is described for the Berkeley Parser grammar which achieves 5 sentences per second on the first 1000 sentences of Penn Treebank section 22 Marcus et al. (1993), which is comparable with the best CPU parsers Petrov and Klein (2007). Our parser achieves 120 sentences/second per GPU for this sentence set, and over 250 sentences/sec on length ≤ 30 sentences. These results use a Berkeley Grammar approximately twice as big as Yi et al. (2011), an apparent 50x improvement. On a 4-GPU system, we achieve 1000 sentences/sec for length ≤ 30 sentences. This is 2 orders of magnitude faster than CPU implementations that rely heavily on pruning, and 5 orders of magnitude faster than full CKY evaluation on a CPU.

Key to these results is a collection of new techniques that enable GPU parsing at close to the GPU's practical maximum speed (a Teraflop for recent GPUs), or around a half-trillion rule evaluations per second. The techniques are:

1. Grammar compilation, which allows register-to-register code for application of grammar rules. This gives an order of magnitude (10x) speedup over alternative approaches that use shared memory.
2. Symbol/rule blocking of the grammar to respect register, constant and instruction cache limits. This is precondition for 1 above, and the details of the partitioning have a big (> 4x) effect on performance.
3. Sub-block partitioning to distribute rules across the stream processors of the GPU and allow L2 cache acceleration. A factor of 2 improvement.

The code generated by our parser comes close to the theoretical limits of the GPU. 80% of grammar rules

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1898–1907,
Seattle, Washington, USA, 18-21 October 2013.

are evaluated using a single-cycle register-to-register instruction.

2 GPU Design Principles

In this paper, we focus on the architecture of recent NVIDIA® GPUs, though many of the principles we describe here can be applied to other GPUs (e.g. those made by AMD®.) The current NVIDIA® Kepler™ series GPU contains between 2 and 16 "stream processors" or SMX's which share an L2 cache interfacing to the GPUs main memory Anonymous (2013). The SMXs in turn comprise 192 cores which share a memory which is partitioned into "shared memory" and L1 cache. Shared memory supports relatively fast communication between threads in an SMX. Communication between SMXs has to pass through slower main memory.

The execution of instructions within SMXs is virtualized and pipelined - i.e. it is not a simple task to count processors, although there are nominally 192 in the Kepler™ series. Register storage is not attached to cores, instead registers are associated in blocks of 63 or 255 (depending on Kepler™ sub-architecture) with running threads. Because of this, it is usually easier for the programmer to think of the SMXes as 1024 thread processors. These 1024 threads are grouped into 32 groups of 32 threads called *warps*. Each warp of threads shares a program counter and executes code in lock-step. However, execution is not SIMD - all threads do not execute all instructions. When the warp encounters a branching instruction, all branches that are satisfied by some thread will be executed in sequence. Each thread only executes the instructions for its own branch, and idles for the others. NVIDIA® calls this model SIMT (Single Instruction, Multiple Threads). Execution of diverging branches by a warp is called *warp divergence*. While it simplifies programming, warp divergence understandably hurts performance and our first goal is to avoid it.

GPUs are generally optimized for single-precision floating point arithmetic in support of rendering and simulation. Table 1 shows instruction throughput (number of instructions that are executed per cycle on each SMX). The Kepler™ series has two architectural sub-generations (3.0 and 3.5) with significant differences in double-precision support. Data from Anonymous (2012) and NVIDIA (2012).

Instruction type	Architecture	
	3.0	3.5
Shared memory word access	32	32
FP arithmetic +,-,*,FMA	192	192
DP arithmetic +,-,*,FMA	8	64
Integer +,-	160	160
Integer *,FMA	32	32
float sin, exp, log,...	32	32

Table 1: Instructions per cycle per SMX in generation 3.0 and 3.5 Kepler™ devices

In the table, FP is floating point, DP is double precision, and FMA is a single-cycle floating-piont fused multiply-add used in most matrix and vector operations ($A \leftarrow A + B * C$). Note next that floating point (single precision) operations are extremely fast and there is an FPU for each of the 192 processors. Double precision floating point is 3x slower on high-end 3.5 GPUS, and much slower (24x) on the commodity 3.0 machines. While integer addition is fast, integer multiply is much slower. Perhaps most surprising is the speed of single-precision transcendental function evaluation, log, exp, sin, cos, tan, etc., which are as fast as shared memory accesses or integer multiplication, and which amount to a quarter-trillion transcendental evaluations per second on a GTX-680/K10.

PCFG grammar evaluation nominally requires two multiplications and an addition per rule (section 4) which can be written:

$$S_{ij,m} = \sum_{k=1\ldots j;\ n,p\in Q} S_{ik,n} S_{(k+1)j,p} c_{mnp} \qquad (1)$$

i.e. the CKY node scores are sums of products of pairs of scores and a weight. This suggests that at least in principle, it's possible to achieve a trillion rule evaluations per second on a 680 or K10 device, using a * and an FMA operation for each rule. That assumes we are doing register-to-register operations however. If we worked through shared memory (first line of the table), we would be limited to about 80 billion evaluations/sec, 20 times slower. The analysis underscores that high performance for parsing on a GPU is really a challenge of data movement. We next review the different storage types and their

bandwidths, since prudent use of, and movement between storage types is the key to performance.

2.1 Memory Types and Speeds

There are six types of storage on the GPU which matter for us. For each type, we give the capacity and aggregate bandwidth on a typical device (a GTX-680 or K10 running at 1GHz).

Register files These are virtualized and associated with threads rather than processors. 256kB per SMX. Each thread in architecture 3.0 devices can access 63 32-bit registers, or 255 registers for 3.5 devices. Aggregate bandwidth 40 TB/s.

Shared memory/L1 cache is shared by all threads in an SMX. 64kB per SMX partitioned into shared memory and cache functions. Aggregate bandwidth about 1 TB/s.

Constant memory Each SMX has a 48kB read/only cache separate from the L1 cache. It can store grammar constants and has much higher bandwidth than shared memory. Broadast bandwidth 13 TB/s.

Instruction cache is 8 KB per SMX. Aggregate bandwidth 13 TB/s.

L2 cache is 0.5-1.5 MB, shared between all SMXs. Aggregate bandwidth 500 GB/s.

Global memory is 2-6GB typically, and is shared by all SMXs. GPUs use a particularly fast form of SDRAM (compared to CPUs) but it is still much slower than the other memory types above. Aggregate bandwidth about 160 GB/s.

There is one more very important principle: Coalesced main memory access. From the above it can be seen that main memory access is much slower than other memories and can easily bottleneck the calculations. The figure above (160 GB/s) for main memory access assumes such access is *coalesced*. Each thread in the GPU has a thread and a block number which determines where it runs on the hardware. Consecutively-numbered threads should access consecutive main memory locations for fast memory access.

These parameters suggest a set of design principles for peak performance:

1. Maximize use of registers for symbol scores, and minimize use of shared memory (in fact we will not use it at all).
2. Maximize use of constant memory for rule weights, and minimize use of shared memory.
3. Partition the rule set into blocks that respect the limits on number of registers, constant memory (needed for grammar rules probabilities) and instruction cache limits.
4. Minimize main memory access and use L2 cache to speed it up.

Lets look in more detail at how to achieve this.

3 Anatomy of an Efficient GPU Parser

High performance on the GPU requires us to minimize code divergence. This suggests that we do not use a lexicalized grammar or a grammar that is sensitive to the position of a span within the sentence. These kinds of grammars—while highly accurate—have irregular memory access patterns that conflict with SIMD execution. Instead, an unlexicalized approach like that of Johnson (2011) or Klein and Manning (2003), or a latent variable approach like that of Matsuzaki et al. (2005) or Petrov et al. (2006) are more appropriate. We opt for the latter kind: latent variable grammars are fairly small, and their accuracies rival lexicalized approaches.

Our GPU-ized inside algorithm maintains two data structures: parse charts that store scores for each labeled span, as usual, and a "workspace" that is used to actually perform the updates of the inside algorithm. Schematically, this memory layout is represented in Figure 1. A queue is maintained CPU-side that enqueues work items of the form (s, p, l, r), where s is a sentence, and p, l, and r specify the index in the parse chart for parent, left child, and right child, respectively. The outer loop proceeds in increasing span length (or height of parent node scores to be computed). Next the algorithm iterates over the available sentences. Then it iterates over the parent nodes at the current length in that sentences, and finally over all split points for the current parent node. In each case, work items are sent to the queue with that span for all possible split points.

When the queue is full—or when there are no more work items of that length—the queue is flushed

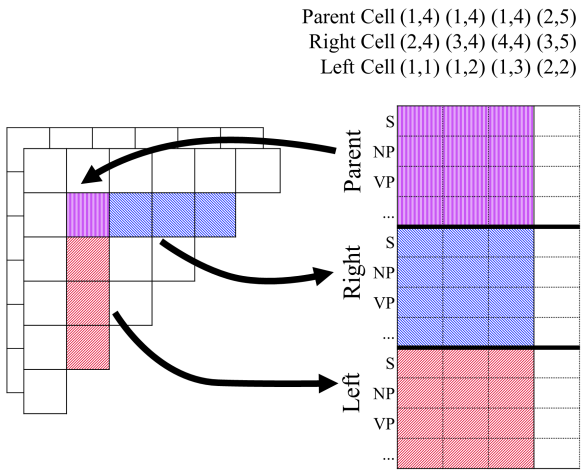

Figure 1: The architecture of the system. Parse charts are stored in triangular arrays laid out consecutively in memory. Scores for left and right children are transposed and copied into the "workspace" array, and the inside updates are calculated for the parent. Scores are then pushed back to the appropriate cell in the parse charts, maxing them with scores that are already there. Transposition ensures that reads and writes are coalesced.

to the GPU, which executes three steps. First, the scores for each left and right child are copied into the corresponding column in the workspace. Then inside updates are applied in parallel for all cells to get parent scores. Then parents are entered back to their appropriate cells in the parse charts. This is typically a many-to one atomic reduction (either a sum for probability scores, or a max for max-sum log probability scores). This process repeats until all span lengths have been processed.

3.1 The Inside Updates

The high-level goal of our parser is to use SIMD parallelism to evaluate the same rule across many spans (1024 threads are currently used to process 8192 spans in each kernel). This approaches allows us to satisfy the GPU performance desiderata from the previous section. As discussed in section 5 each GPU kernel actually processes a small subset of the symbols and rules for the grammar, and kernels are executed in sequence until the entire grammar has been processed. Each thread iterates over the rules in the same order, reading in symbols from the left child and right child arrays in main memory as necessary.

The two-dimensional work arrays must be stored in "symbol-major" order for this to work. That is, the parent VP for one work item is stored next to the parent VP for the next work item, while the VP symbol for the first work item is stored on the next "row" of the work array. The reason the workspace cells are stored in "symbol-major" order is to maximize coalesced access: each thread in the SMX accesses the same symbol for a different work item in parallel, and those work items are in consecutive memory locations.

3.2 The Copy-transpose Operations

Unlike the workspace arrays, the arrays for the parse charts are stored in "span-major" order, transposed from how they are stored in the workspace arrays. That is, for a given span, the NP symbol is next to the same span's VP symbol (for example). This order accelerates both symbol loading and Viterbi search later on. It requires a transpose-copy instead of "non-transposed" copy to move from chart to workspace arrays and back again, but note that a non-transposed copy (or direct access to the chart by the GPU compute kernel) would probably be slower. The reason is that any linear ordering of cells in the triangle table will produce short segments (less than 32 words and often less than 16) of consecutive memory locations. This will lead to many non-coalesced memory accesses. By contrast the span-major representation always uses vectors whose lengths equals the number of symbols (500-1000), and these can be accessed almost entirely with coalesced operations. The copy-transpose operations are quite efficient (the transpose itself is much faster than the I/O), and come close to the 160 GB/s GPU main memory limit.

The reverse copy-transpose (from parent workspace cells to chart) is typically many-to-one, since parent scores derive from multiple splits. They are implemented using atomic reduce operations (either atomic sum or atomic max) to ensure data consistency.

At the heart of our approach is the use of grammar compilation and symbol/rule blocking, described next.

4 Grammar Compilation

Each rule in a probabilistic context-free grammar can be evaluated with an update of the form:

$$S_{ij,m} = \sum_{k=1...j;\ n,p \in Q} S_{ik,n} S_{(k+1)j,p} c_{mnp} \quad (2)$$

where $S_{ij,m}$ is the score for symbol m as a generator of the span of words from position i to j in the input sentence, c_{mnp} is the probability that symbol m generates the binary symbol pair n, p, and Q is the set of symbols. The scores will be stored in a CKY chart indexed by the span ij and the symbol m.

To evaluate (2) as fast as possible, we want to use register variables which are limited in number. The location indices i, j, k can be moved outside the GPU kernel to reduce the variable count. We use symbols P, L and R for respectively the score of the parent, left child and right child in the CKY chart. Then the core relation in (2) can be written as:

$$P_m = \sum_{n,p \in Q} L_n R_p c_{mnp} \quad (3)$$

In the Kepler™ architecture, register arguments are non-indexed, i.e. one cannot access register 3 as an array variable R[i] with i=3[1]. So in order to use register storage for maximum speed, we must open-code the grammar. Symbols like L_3, R_{17} are encoded as variables $L003$ and $R017$, and each rule must appear as a line of C code:

```
P043 += L003*R017*0.023123f;
P019 += L012*R123*6.21354e-7f;
 :        :       :       :
```

Open-coding the grammar likely has a host of performance advantages. It allows both compiler and hardware to "see" what arguments are coming and schedule the operations earlier than a "grammar as data" approach. Note that we show here the sum-product code for computing inner/outer symbol probabilities. For Viterbi parse extraction we replace +,* with max,+ and work on log scores.

L and R variables must be loaded from main memory, while P-values are initialized to zero and then atomically combined (sum or max) with P-values in memory. Loads are performed as late as possible, that is, a load instruction will immediately precede the first use of a symbol:

```
float R031 = right[tid+65*stride];
P001 += L001*R031*1.338202e-001f;
```

where tid is the thread ID plus an offset, and stride is the row dimension of the workspace (typically 8192), and right is the main memory array of right symbol scores. Similarly, atomic updates to P-values occur as early as possible, right after the last update to a value:

```
G020 += L041*R008*6.202160e-001f;
atomicAdd(&par[tid+6*stride],G020);
```

These load/store strategies minimize the active life of each variable and allow reuse of register variables for symbols whose lifetimes do not overlap. This will be critical to successful blocking, described in the next section.

4.1 Common subexpressions

One interesting discovery made by the compiler was that the same L,R pair is repeated in several rules. In hindsight, this is obvious because the symbols in this grammar are splits of base symbols, and so splits of the parent symbol will be involved in rules with each pair of L,R splits. The compiler recognized this by turning the L,R pair into a common subexpression in a register. i.e. the compiler converts

```
P008 += L041*R008*6.200769e-001f;
P009 += L041*R008*6.201930e-001f;
P010 += L041*R008*6.202160e-001f;
```

into

```
float LRtmp = L041*R008;
P008 += LRtmp*6.200769e-001f;
P009 += LRtmp*6.201930e-001f;
P010 += LRtmp*6.202160e-001f;
```

and inspection of the resulting assembly code shows that each rule is compiled into a single fused multiply-add of LRtmp and a value from constant memory into the P symbol register. This allows grammar evaluation to approach the theoretical Gflop limit of the GPU. For this to occur, the rules need to be sorted with matching L,R pairs consecutive. The compiler does not discover this constraint otherwise or reorder instructions to make it possible.

[1] Even if indexing were possible, it is extremely unlikely that such accesses could complete in a single cycle

4.2 Exploiting L2 cache

Finally, we have to generate code to evaluate distinct minor cube rulesets on each of the 8 SMXes concurrently in order to benefit from the L2 cache, as described in the next section. CUDA™ (NVIDIA's GPU programming Platform) does not allow direct control of SMX target, but we can achieve this by running the kernel as 8 thread blocks and then testing the block ID within the kernel and dispatching to one of 8 blocks of rules. The CUDA™ scheduler will execute each thread block on a different SMX which gives the desired distribution of code.

5 Symbol and Rule Blocking

The grammar formula (3) is very sparse. i.e. most productions are impossible and most c_{mnp} are zero. For the Berkeley grammar used here, only 0.2% of potential rules occur. Normally this would be bad news for performance because it suggests low variable re-use. However, the update relation is a *tensor* rather than a matrix product. The re-use rate is determined by the number of rules in which a particular symbol occurs, which is actually very high (more than 1000 on average).

The number of symbols is about 1100 in this grammar, and only a fraction can be stored in a thread's register set at one time (which is either 63 or 255 registers). To compute all productions we will need to break the calculation into smaller groups of variables that can fit in the available register space.

We can visualize this geometrically in figure 2. The vectors of symbols P, L and R form the leading edges of this cube. The cube will be partitioned into smaller subcubes indexed by subsets of those symbols, and containing all the rules that apply between those symbols. The partitioning is chosen so that the symbols in that subset can fit into available register storage. In addition, the partitioning is chosen to induce the same number of rules in each cube - otherwise different code paths in the kernel will run longer than others, and reduce overall performance. This figure is a simplification - in order to balance the number of rules in each subcube, the partitioning is not uniform in number of symbols as the figure suggests.

As can be seen in figure 2, cube partitioning has two levels. The original P-L-R cube is first partitioned into "major" cubes, which are then partitioned into "minor" cubes (2x2x2 in the figure). A major cube holds the symbols and rules that are executed in a single GPU kernel. The minor cubes in a major cube hold the symbols and rules that are executed in a particular SMX. For the GTX-680 or K10 with 8 SMXs, this allows different SMXs to concurrently work on different 2x2x2 subcubes in a major cube. This arrangement substantially reduces main memory bandwidth through the L2 cache (which is shared between SMXes). Each symbol in a major cube will be loaded just once from main memory, but loaded into (up to) 4 different SMXes through the L2 cache. Subcube division for caching in our experiments roughly doubled the kernel's speed.

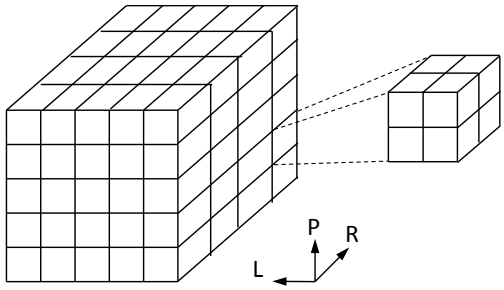

Figure 2: Partition of the cube of symbol combinations into major subcubes (left) and minor subcubes (right).

However, simple partitioning will not work. e.g. if we blocked into groups of 20 P, L, R symbols (in order to fit into 60 registers), we would need 1100/20 = 55 blocks along each edge, and a total of $55^3 \approx 160,000$ cells. Each symbol would need to be loaded $55^2 = 3025$ times, there would be almost no symbol re-use. Throughput would be limited by main memory speed to about 100 Gflops, an order of magnitude slower than our target. Instead, we use a rule partitioning scheme that creates as small a symbol footprint as possible in each cube. We use a spectral method to do this.

Before describing the spectral method we mention an optimization that drops the symbol count by 2. Symbols are either terminal or non-terminal, and in the Berkeley latent variable grammar there are roughly equal numbers of them (503 non-terminals and 631 terminals). All binary rules involve a non-terminal parent. L and R symbols may be either terminal or non-terminal, so there are 4 distinct types

of rules depending on the L, R, types. We handle each of these cases with a different kernel, which rougly halves the number of rules along each edge (it is either 503 or 631 along each edge). Furthermore, these kernels are called in different contexts, and a different number of times. e.g. XX (L, R, both non-terminal) kernels are called $O(s^3)$ times for sentences of length s because both L, R children can occur at every position in the chart. XT and TX kernels (with one terminal and one non-terminal symbol) are called only $O(s^2)$ times since one of L or R must be at the base of the chart. Finally TT kernels (both L and R are terminals) will be called $O(s)$ times. Performance is therefore dominated by the XX kernel.

5.1 Spectral Partitioning

We explored a number of partitioning schemes for both symbol and rule partitioning. In the end we settled on a spectral symbol partitioning scheme. Each symbol is a node in the graph to be partitioned. Each node is assigned a feature vector designed to match it to other nodes with similar symbols occuring in many rules. There was considerable evolution of this feature set to improve partitioning. In the end the vector for a particular P symbol is $a = (a_1, 0.1 * a_2, 0.1 * a_3)$ where a_1 is a vector whose elements are indexed by L, R pairs and whose values represent the number of rules involving both those symbols (and the parent symbol P), a_2 encodes L symbols and counts the number of rules containing that L symbol and P, and a_3 encodes the R symbols and counts rules containing that R symbol and P. This feature vector produces a high similarity between P symbols that exactly share many L,R pairs and lower similarity for shared L and R.

A spectral clustering/partitioning algorithm approximately minimizes the total edge weight of graph cuts. In our case, the total weight of a cut is to first order the product of the number of L,R pairs that occur on each side of the cut, and to second order the count of individual L and R pairs that span the cut. Let S and T be the counts for a particular LR pair or feature, then we are trying to minimize the product S*T while keeping the sum S+T, which is the total occurences of the feature on both sides of the partition, constant. Such a product is minimized when one of S or T is zero. Since many symbols are involved, this typically does not happen to an individual symbol, but this heuristic is successful at making the individual symbol or LR pair distributions across the cuts as unbalanced as possible. i.e. one side of the cut has very few instances of a given symbol. The number of instances of a symbol is an upper bound on the number of subcells in which than symbol occurs, and therefore on the number of times it needs to be loaded from memory. Repeating this operation recursively to produce a 3d cell decomposition also concentrates each symbol in relatively few cells, and so tends to reduce the total register count per cell.

In a bit more detail, from the vectors a above we construct a matrix A whose columns are the feature vectors for each P symbol. Next we construct the symmetric normalized Laplacian L for the adjacency matrix $A^T A$. We then compute the eigendecomposition of L, and extract the eigenvector corresponding to the second-smallest eigenvalue. Each node in the graph is assign a real weight from the corresponding element of this eigenvector. We sort by these weights, and partition the symbols using this sort order. We tried both recursive binary partitioning, and partitioning into k intervals using the original sort order, and obtained better results with the latter.

Partitioning is applied in order P, L, R to generate the major cubes of the rule/symbol partition, and then again to generate minor cubes. This partitioning is far more efficient than a naive partitioning. The XX ruleset for our Berkeley grammar has about 343,000 rules over a 503^3 cube of non-terminal symbols. The optimal PxLxR cube decomposition (optimal in net kernel throughput) for this ruleset was 6x2x2 for major cubes, and then 2x2x2 for minor cubes. This requires 6x2x2=24 GPU kernels, each of which encodes 2x2x2=8 code blocks (recall that each of the 8 SMXs executes a different code block from the same kernel)[2]. Most importantly the reload rate (the mean number of major cells containing a given symbol, or the mean number of times a symbol needs to be reloaded from main memory) drops to about 6 (vs. 3000 for naive partitioning). This is very significant. Each symbol is used on average $343,000/501 \approx 6000$ times overall by the XX ker-

[2]This cube decomposition also respects the constant cache and instruction cache limits

nel. Dropping the reload factor to 6 means that for every 1 main memory load of a symbol, there are approximately 1000 register or L2 cache reuses. A little further calculation shows that L2 cache items are used a little more than twice, so the register reuse rate within kernel code blocks is close to 500 on average. This is what allows teraflop range speeds.

Note that while the maximum number of registers per thread in the GTX-680 or K10 is 63, the average number of variables per minor cube is over 80 for our best-performing kernel, showing a number of variables have non-overlapping lifetimes. Sorting rules lexicographically by (L,R,P) does a good job of minimizing variable lifetime overlap. However the CUDA™ compiler reorders variables anyway with slightly worse performance on average (there seems to be no way around this, other than generating assembly code directly).

6 GPU Viterbi Parse Extraction

In sequential programs for chart generation, it is possible to compute and save a pointer to the best split point and score at each node in the chart. However, here the scores at each node are computed with fine-grained parallelism. The best split point and score cannot be computed until all scores are available. Thus there is a separate Viterbi step after chart scoring.

The gap between GPU and CPU performance is large enough that CPU Viterbi search was a bottleneck, even though it requires asymptotically less work ($O(Gs^2)$ worst case, $O(Gs)$ typical) vs $O(Gs^3)$ to compute the CKY scores. Therefore we wrote a non-recusive GPU-based Viterbi search. Current GPUs support "high-level" recursion, but there is no stack in the SMX. A recursive program must create software stack space in either shared memory or main memory which serious performance impact on small function calls. Instead, we use an iterative version of Viterbi parse extraction which uses pre-allocated array storage to store its output, and such that the partially-complete output array encodes all the information the algorithm needs to proceed - i.e. the output array is also the algorithm's work queue.

Ignoring unaries for the moment, a binary parse tree for a sentence of length n has $2n-1$ nodes, including preterminals, internal nodes, and the root. We can uniquely represent a tree as an array with $2n-1$ elements. In this representation, each index corresponds to a node in prefix (depth-first) order. For example, the root is always at position 0, and the second node will correspond to the root's left child. If this second node has a left child, it will be the third node, otherwise the third node will be the second's right sibling.

We can uniquely identify the topology of the tree by storing the "width" of each node in this array, where the width is the number of words governed by that constituent. For a node at position p, its left child will always be at $p+1$, and its right child will always be at $p + 2 \cdot w_\ell$, where w_ℓ is the width of the left child. The symbol for each node can obviously be stored with the height. For unaries, we require exactly one unary rule per node, with the possibility that it is the identity rule, and so we store two nodes: one for the "pre-unary" symbol, and one for the "post-unary." (Identity unary transitions are removed in post-processing.)

Algorithm 1 Non-recursive Viterbi implementation. The algorithm proceeds left-to-right in depth-first order along the array representing the tree.

```
Input: Sentence length n, parse chart V[i,j]
Output: Array tree of size 2·n−2
  tree[0].preunary ← ROOT
  tree[0].width ← n
  i ← 0                    ▷ Current leftmost position for span
  for p ← 0 to 2·n−2 do
      j ← i + tree[p].width      ▷ Rightmost position
      postu ← BestUnary(V, tree[p].preunary, i, j)
      tree[p].postunary ← parent
      if tree[p].width = 1 then
          i ← i + 1
      else
          lc, rc, k ← BestBinary(V, parent, i, j)
          tree[p + 1].preunary ← lc
          tree[p + 1].width ← k − i
          tree[p + 2·(k−i)].width ← j - k
          tree[p + 2·(k−i)].preunary ← rc
      end if
  end for
```

Armed with this representation, we are ready to describe algorithm 1. The algorithm proceeds in

left-to-right order along the array. First, the symbol of the root is recorded. Then, for each node in the tree, we search for the best unary rule continuing it. If the node is a terminal, then no more nodes can contain the current word, and so we advance the position of the left most child. Otherwise, if the node is a non-terminal, we then find its left and right children, entering their respective symbols and widths into the array representing the tree.

The GPU implementation follows the algorithm outline above although is somewhat technical. Each parse tree is handled by a separate thread block (thread blocks are groups of threads that can communicate through shared memory, and run on a single SMX). Each thread block includes a number of threads which are used to rapidly (in partly parallel fashion) iterate through rulesets and symbol vectors for the BestBinary and BestUnary operations using coalesced memory accesses. Each thread block first loads the complete set of L and R scores for the current split being explored. Recall that these are in consecutive memory locations using the "span-major" ordering, so these loads are coalesced. Then the thread block parallel-iterates through the rules for the current parent symbol, which will be in a contiguous block of memory since the rules are sorted by parent symbol, and again are coalesced. The thread block therefore needs storage for all the L, R symbol scores and in addition working storage proportional to the number of threads (to hold the best child symbol and its score from each thread). The number of threads is chosen to maximize speed: too few will cause each thread to do more work and to run more slowly. Too many will limit the number of thread blocks (since the total threads concurrently running on an SMX is 1024) that can run concurrently. We found 128 to be optimum.

With these techniques, Viterbi search consumes approximately 1% of the parser's running time. Its throughput is around 10 Gflops, and it is 50-100x faster than a CPU reference implementation.

7 Experiments

The parser was tested in an desktop computer with one Intel E5-2650 processor, 64 GB ram, and 2 GTX-690 dual GPUs (effectively 4 GTX-680 GPUs). The high-level parser code is written in a matrix library in the Scala language, which access GPU code through JNI and using the JCUDA wrapper library for CUDA™.

XX-kernel throughput was 900 Gflops per GPU for sum-product calculation (which uses a single FMA for most rules) and 700 Gflops per GPU for max-sum calculations (which requires two instructions for most rules). Net parser throughput including max-sum CKY evaluation, Viterbi scoring traspose-copy etc was between 500 and 600 gigaflops per GPU, or about 2 teraflops total. Parsing max-length-30 sentences from the Penn Treebank test set ran at 250 sentences/sec per GPU, or 1000 sentences/sec total. General sentences were parsed at about half this rate, 120 sentences/sec per GPU, or 480 sentences/sec for the system.

8 Conclusions and Future Work

We described a new approach to GPU constituency parsing with surprisingly fast performance, close to the theoretical limits of the GPU and similar to dense matrix multiplication which achieves the devices highest practical throughput. The resulting parser parses 1000 length-30 sentences per second in a 4-GPU computer. The parser has immediate application to parsing and eventually to parser training. The two highest-priority extensions are:

Addition of pruning: coarse-to-fine score pruning should be applicable to our GPU design as it is to CPU parsers. GPU pruning will not be as granular as CPU pruning and is unlikely to yield as large speedups (4-5 orders of magnitude are common for CPU parser pruning). But on the other hand, we hardly need speedups that large, and 1-2 orders of magnitude would be very useful.

Direct generation of assembly code. Currently our code generator produces ($>$ 1.7 million lines, about same as the number of rules) C source code which must be compiled into GPU binary code. While it takes only 8 seconds to generate the source code, it takes more than an hour to compile it. The compiler evidently applies a number of optimizations that we cannot disable, and this takes time. This is an obstacle to e.g. using this framework to train a parser where there would be frequent updates to the grammar. However, since symbol variables correspond almost one-to-one with registers (modulo

lifetime overlap and reuse, which our code generator is slightly better at than the compiler), there is no reason for our code generator not to generate assembly code directly. Presumably assembly code is much faster to translate into kernel modules than C source, and hopefully this will lead to much faster kernel generation.

8.1 Code Release

The code will be released under a BSD-style open source license once its dependencies are fully integrated. Pre- and Final releases will be here `https://github.com/jcanny/BIDParse`

Fish transporters and miracle homes: How compositional distributional semantics can help NP parsing

Angeliki Lazaridou, Eva Maria Vecchi and **Marco Baroni**

Abstract

In this work, we argue that measures that have been shown to quantify the degree of semantic plausibility of phrases, as obtained from their compositionally-derived distributional semantic representations, can resolve syntactic ambiguities. We exploit this idea to choose the correct parsing of NPs (e.g., (*live fish*) *transporter* rather than *live* (*fish transporter*)). We show that our plausibility cues outperform a strong baseline and significantly improve performance when used in combination with state-of-the-art features.

1 Introduction

Live fish transporter: A transporter of live fish or rather a fish transporter that is not dead? While our intuition, based on the meaning of this phrase, prefers the former interpretation, the Stanford parser, which lacks semantic features, incorrectly predicts the latter as the correct parse.[1] The correct syntactic parsing of sentences is clearly steered by semantic information (as formal syntacticians have pointed out at least since Fillmore (1968)), and consequently the semantic plausibility of alternative parses can provide crucial evidence about their validity.

An emerging line of parsing research capitalizes on the advances of compositional distributional semantics (Baroni and Zamparelli, 2010; Guevara, 2010; Mitchell and Lapata, 2010; Socher et al., 2012). Information related to compositionally-derived distributional representations of phrases is integrated at various stages of the parsing process to improve overall performance.[2] We are aware of two very recent studies exploiting the semantic information provided by distributional models to resolve syntactic ambiguity: Socher et al. (2013) and Le et al. (2013).

Socher et al. (2013) present a recursive neural network architecture which jointly learns semantic representations and syntactic categories of phrases. By annotating syntactic categories with their distributional representation, the method emulates lexicalized approaches (Collins, 2003) and captures similarity more flexibly than solutions based on hard clustering (Klein and Manning, 2003; Petrov et al., 2006). Thus, their approach mainly aims at improving parsing by capturing a richer, data-driven categorial structure.

On the other hand, Le et al. (2013) work with the output of the parser. Their hypothesis is that parses that lead to less semantically plausible interpretations will be penalized by a reranker that looks at the composed semantic representation of the parse. Their method achieves an improvement of 0.2% in F-score. However, as the authors also remark, because of their experimental setup, they cannot conclude that the improvement is truly due to the semantic composition component, a crucial issue that is deferred to further investigation.

This work aims at corroborating the hypothesis that the semantic plausibility of a phrase can indeed determine its correct parsing. We develop a system based on simple and intuitive measures, ex-

tracted from the compositional distributional representations of phrases, that have been shown to correlate with semantic plausibility (Vecchi et al., 2011).

We develop a controlled experimental setup, focusing on a single syntactic category, that is, noun phrases (NP), where our task can be formalized as (left or right) bracketing. Unlike previous work, we compare our compositional semantic component against features based on n-gram statistics, which can arguably also capture some semantic information in terms of frequent occurrences of meaningful phrases. Inspired by previous literature demonstrating the power of metrics based on Pointwise Mutual Information (PMI) in NP bracketing (Nakov and Hearst, 2005; Pitler et al., 2010; Vadas and Curran, 2011), we test an approach exploiting PMI features, and show that plausibility features relying on composed representations can significantly boost accuracy over PMI.

2 Setup

Noun phrase dataset To construct our dataset, we used the Penn TreeBank (Marcus et al., 1993), which we enriched with the annotation provided by Vadas and Curran (2007a), since the original treebank does not distinguish different structures inside the NPs and always marks them as right bracketed, e.g., *local (phone company)* but also *blood (pressure medicine)*. We focus on NPs formed by three elements, where the first can be an adjective (A) or a noun (N), the other two are nouns. Table 1 summarizes the characteristics of the dataset.[3]

Distributional semantic space As our source corpus we use the concatenation of ukWaC, the English Wikipedia (2009 dump) and the BNC, with a total of about 2.8 billion tokens.[4] We collect co-occurrence statistics for the top 8K Ns and 4K As, plus any other word from our NP dataset that was below this rank. Our context elements are composed of the top 10K content words (adjectives, adverbs, nouns and verbs). We use a standard bag-of-words approach, counting within-sentence collocates for every target word. We apply (non-negative) Pointwise Mutual Information as weighting scheme and dimensionality reduction using Non-negative Matrix Factorization, setting the number of reduced-space dimensions to 300.[5]

Composition functions We experiment with various composition functions, chosen among those sensitive to internal structure (Baroni and Zamparelli, 2010; Guevara, 2010; Mitchell and Lapata, 2010), namely dilation (**dil**), weighted additive (**wadd**), lexical function (**lexfunc**) and full additive (**fulladd**).[6] For model implementation and (unsupervised) estimation, we rely on the freely available *DISSECT* toolkit (Dinu et al., 2013).[7] For all methods, vectors were normalized before composing, both in training and in generation. Table 2 presents a summary description of the composition methods we used.

Following previous literature (Mitchell and Lapata, 2010), and the general intuition that adjectival modification is quite a different process from noun combination (Gagné and Spalding, 2009; McNally, 2013), we learn different parameters for noun-noun (NN) and adjective-noun (AN) phrases. As an example of the learned parameters, for the **wadd** model the ratio of parameters w_1 and w_2 is 1:2 for ANs, whereas for NNs it is almost 1:1, confirming the intuition that a non-head noun plays a stronger role in composition than an adjective modifier.

[3]The dataset is available from: `http://clic.cimec.unitn.it/composes`

[4]`http://wacky.sslmit.unibo.it`, `http://en.wikipedia.org`, `http://www.natcorp.ox.ac.uk`

[5]For tuning the parameters of the semantic space, we computed the correlation of cosines produced with a variety of parameter settings (SVD/NMF/no reduction, PMI/Local MI/raw counts/log transform, 150 to 300 dimensions in steps of 50) with the word pair similarity ratings in the MEN dataset: `http://clic.cimec.unitn.it/~elia.bruni/MEN`

[6]We do not consider the popular multiplicative model, as it produces identical representations for NPs irrespective of their internal structure.

[7]`http://clic.cimec.unitn.it/composes/toolkit/`

Model	Composition function	Parameters
wadd	$w_1\vec{u} + w_2\vec{v}$	w_1, w_2
dil	$\|\|\vec{u}\|\|_2^2\vec{v} + (\lambda - 1)\langle\vec{u}, \vec{v}\rangle\vec{u}$	λ
fulladd	$W_1\vec{u} + W_2\vec{v}$	$W_1, W_2 \in \mathbf{R}^{m\times m}$
lexfunc	$A_u\vec{v}$	$A_u \in \mathbf{R}^{m\times m}$

Table 2: Composition functions of inputs (u, v).

Recursive composition In this study we also experiment with recursive composition; to the best of our knowledge, this is the first time that these composition functions have been explicitly used in this manner. For example, given the left bracketed NP *(blood pressure) medicine*, we want to obtain its compositional semantic representation, $\overrightarrow{blood\ pressure\ medicine}$. First, *basic composition* is applied, in which $\overrightarrow{blood}$ and $\overrightarrow{pressure}$ are combined with one of the composition functions. Following that, we apply *recursive composition*; the output of basic composition, i.e., $\overrightarrow{blood\ pressure}$, is fed to the function again to be composed with the representation of $\overrightarrow{medicine}$.

The latter step is straightforward for all composition functions except **lexfunc** applied to left-bracketed NPs, where the first step should return a matrix representing the left constituent (*blood pressure* in the running example). To cope with this nuisance, we apply the **lexfunc** method to *basic composition* only, while recursive representations are derived by summing (e.g., $\overrightarrow{blood\ pressure}$ is obtained by multiplying the *blood* matrix by the *pressure* vector, and it is then summed to $\overrightarrow{medicine}$).

3 Experiments

Semantic plausibility measures We use measures of semantic plausibility computed on composed semantic representations introduced by Vecchi et al. (2011). The rationale is that the correct (wrong) bracketing will lead to semantically more (less) plausible phrases. Thus, a measure able to discriminate semantically plausible from implausible phrases should also indicate the most likely parse. Considering, for example, the alternative parses of *miracle home run*, we observe that *home run* is a more semantically plausible phrase than *miracle home*. Furthermore, we might often refer to a baseball player's miracle home run, but we doubt that even a miracle home can run! Given the composed representation of an AN (or NN), Vecchi et al. (2011) define the following measures:

- *Density*, quantified as the average cosine of a phrase with its (top 10) nearest neighbors, captures the intuition that a deviant phrase should be isolated in the semantic space.
- *Cosine of phrase and head N* aims to capture the fact that the meaning of a deviant AN (or NN) will tend to diverge from the meaning of the head noun.
- *Vector length* should capture anomalous vectors.

Since length, as already observed by Vecchi et al., is strongly affected by independent factors such as input vector normalization and the estimation procedure, we introduce *entropy* as a measure of vector quality. The intuition is that meaningless vectors, whose dimensions contain mostly noise, should have high entropy.

NP Parsing as Classification Parsing NPs consisting of three elements can be treated as binary classification; given *blood pressure medicine*, we predict whether it is left- (*(blood pressure) medicine*) or right-bracketed (*blood (pressure medicine)*).

We conduct experiments using an SVM with Radial Basis Function kernel as implemented in the *scikit-learn* toolkit.[8] Our dataset is split into 10 folds in which the ratio between the two classes is kept constant. We tune the SVM complexity parameter *C* on the first fold and we report accuracy results on the remaining nine folds after cross-validation.

Features Given a composition function $\boldsymbol{f}$, we define the following feature sets, illustrated with the usual *blood pressure medicine* example, which are used to build different classifiers:

- $\boldsymbol{f_{basic}}$ consists of the semantic plausibility measures described above computed for the two-word phrases resulting from alternative bracketings, i.e., 3 measures for each bracketing, evaluated on *blood pressure* and *pressure medicine* respectively, for a total of 6 features.
- $\boldsymbol{f_{rec}}$ contains 6 features computed on the vectors resulting from the recursive compositions

[8] http://scikit-learn.org/

Features	Accuracy
$right$	65.6
pos	77.3
$lexfunc_{basic}$	74.6
$lexfunc_{rec}$	74.0
$lexfunc_{plausibility}$	76.2
$wadd_{basic}$	75.9
$wadd_{rec}$	78.2
$wadd_{plausibility}$	78.7
pmi	81.2
pmi+$lexfunc_{plausibility}$	82.9
pmi+$wadd_{plausibility}$	**85.6**

Table 3: Evaluation of feature sets from Section 3

(blood pressure) medicine and *blood (pressure medicine)*.

- $f_{plausibility}$ concatenates f_{basic} and f_{rec}.
- pmi contains the PMI scores extracted from our corpus for *blood pressure* and *pressure medicine*.[9]
- pmi + $f_{plausibility}$ concatenates pmi and $f_{plausibility}$.

Baseline Model Given the skewed bracketing distribution in our dataset, we implement the following majority baselines: *a*) $right$ classifies all phrases as right-bracketed; *b*) pos classifies NNN as left-bracketed (Lauer, 1995), ANN as right-bracketed.

4 Results and Discussion

Table 3 omits results for **dil** and **fulladd** since they were outperformed by the $right$ baseline. That **wadd**- and **lexfunc**-based plausibility features perform well above this baseline is encouraging, since it represents the typical default behaviour of parsers for NPs, although note that these features perform comparably to the pos baseline, which would be quite simple to embed in a parser (for English, at least). For both models, using both basic and recursive features leads to a boost in performance over basic features alone. Note that recursive features (f_{rec}) achieve at least equal or better performance than basic ones (f_{basic}). We expect indeed that in many cases the asymmetry in plausibility will be sharper when considering the whole NP rather than its sub-parts; a *pressure medicine* is still a conceivable concept, but *blood (pressure medicine)* makes no sense whatsoever. Finally, **wadd** outperforms both the more informative baseline pos and **lexfunc**. The difference between **wadd** and **lexfunc** is significant ($p < 0.05$)[10] only when they are trained with recursive composition features, probably due to our suboptimal adaptation of the latter to recursive composition (see Section 2).

The pmi approach outperforms the best plausibility-based feature set $wadd_{plausibility}$. However, the two make only a small proportion of common errors (29% of the total $wadd_{plausibility}$ errors, 32% for pmi), suggesting that they are complementary. Indeed the pmi + $wadd_{plausibility}$ combination significantly outperforms pmi alone ($p < 0.001$), indicating that plausibility features can improve NP bracketing on top of the powerful PMI-based approach. The same effect can also be observed in the combination of pmi + $lexfunc_{plausibility}$, which again significantly outperforms pmi alone ($p < 0.05$). This behaviour further suggests that the different types of errors are not a result of the parameters or type of composition applied, but rather highlights fundamental differences in the kind of information that PMI and composition models are able to capture.

One hypothesis is that compositional models are more robust for low-frequency NPs, for which PMI estimates will be less accurate; results on those low-frequency trigrams only (20% of the NP dataset, operationalized as those consisting of bigrams with frequency ≤ 100) revealed indeed that $wadd_{plausibility}$ performed 8.1% better in terms of accuracy than pmi.

5 Conclusion

Our pilot study showed that semantic plausibility, as measured on compositional distributional representations, can improve syntactic parsing of NPs. Our results further suggest that state-of-the-art PMI features and the ones extracted from compositional representations are complementary, and thus, when combined, can lead to significantly better results. Besides paving the way to a more general integration

[9] Several approaches to computing PMI for these purposes have been proposed in the literature including the *dependency model* (Lauer, 1995) and the *adjacency model* (Marcus, 1980). We implement the latter since it has been shown to perform better (Vadas and Curran, 2007b) on NPs extracted from Penn TreeBank.

[10] Significance values are based on t-tests.

of compositional distributional semantics in syntactic parsing, the proposed methodology provides a new way to evaluate composition functions.

The relatively simple-minded **wadd** approach outperformed more complex models such as **lexfunc**. We plan to experiment next with more linguistically motivated ways to adapt the latter to recursive composition, including hybrid methods where ANs and NNs are treated differently. We would also like to consider more sophisticated semantic plausibility measures (e.g., supervised ones), and apply them to other ambiguous syntactic constructions.

Abstract

We present a new approach to referring expression generation, casting it as a density estimation problem where the goal is to learn distributions over logical expressions identifying sets of objects in the world. Despite an extremely large space of possible expressions, we demonstrate effective learning of a globally normalized log-linear distribution. This learning is enabled by a new, multi-stage approximate inference technique that uses a pruning model to construct only the most likely logical forms. We train and evaluate the approach on a new corpus of references to sets of visual objects. Experiments show the approach is able to learn accurate models, which generate over 87% of the expressions people used. Additionally, on the previously studied special case of single object reference, we show a 35% relative error reduction over previous state of the art.

1 Introduction

Understanding and generating natural language requires reasoning over a large space of possible meanings; while many statements might achieve the same goal in a certain situation, some are more likely to be used than others. In this paper, we model these preferences by learning distributions over situated meaning use.

We focus on the task of referring expression generation (REG), where the goal is to produce an expression which uniquely identifies a pre-defined object or set of objects in an environment. In practice, many such expressions can be produced. Figure 1 shows referring expressions provided by human subjects for a set of objects (Figure 1a), demonstrating variation in utterances (Figure 1b) and their corresponding meaning representations (Figure 1c). Although nearly a third of the people simply listed the colors of the desired objects, many other strategies were also used and no single option dominated. Learning to model such variation would enable systems to better anticipate what people are likely to say and avoid repetition during generation, by producing appropriately varied utterances themselves. With these goals in mind, we cast REG as a density estimation problem, where the goal is to learn a distribution over logical forms.

Learning such distributions is challenging. For a target set of objects, the number of logical forms that can be used to describe it grows combinatorially with the number of observable properties, such as color and shape. However, only a tiny fraction of these possibilities are ever actually used by people. We must learn to efficiently find these few, and accurately estimate their associated likelihoods.

We demonstrate effective learning of a globally normalized log-linear distribution with features to account for context dependence and communicative goals. We use a stochastic gradient descent algorithm, where the key challenge is the need to compute feature expectations over all possible logical forms. For that purpose, we present a multi-stage inference algorithm, which progressively constructs meaning representations with increasing complexity, and learns a pruning model to retain only those that are likely to lead to high probability expressions. This approach allows us to consider a large

Figure 1: An example scene from our object selection dataset. Figure 1a shows the image shown to subjects on Amazon Mechanical Turk. The target set G is the circled objects. Figure 1b shows the 20 sentences provided as responses. Figure 1c shows the empirical distribution $\hat{P}(z|G,S)$ for this scene, estimated by labeling the sentences in Figure 1b. The correspondence between a sentence in 1b and its labeled logical expression in 1c is indicated by the number in parentheses. Section 5.1 presents a discussion of the space of possible logical forms.

set of possible meanings, while maintaining computational tractability.

To represent meaning we build on previous approaches that use lambda calculus (Carpenter, 1997; Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2013b). We extend these techniques by modeling the types of plurality and coordination that are prominent in expressions which refer to sets.

We also present a new corpus for the task of referring expression generation.[1] While most previous REG data focused on naming single objects, to the best of our knowledge, this is the first corpus with sufficient coverage for learning to name sets of objects. Experiments demonstrate highly accurate learned models, able to generate over 87% of the expressions people used. On the previously studied special case of single object reference, we achieve state-of-the-art performance, with over 35% relative error reduction over previous state of the art (Mitchell et al., 2013).

2 Related Work

Referring expression generation has been extensively studied in the natural language generation

[1]The corpus was collected using Amazon Mechanical Turk and is available on the authors' websites.

community, dating as far back as SHRDLU (Winograd, 1972). Most work has built on variations of the Incremental Algorithm (Dale and Reiter, 1995), a deterministic algorithm for naming single objects that constructs conjunctive logical expressions. REG systems are used in generation pipelines (Dale and Reiter, 2000) and are also commonly designed to be cognitively plausible, for example by following Gricean maxims (Grice, 1975). Krahmer and van Deemter (2012) and van Deemter et al. (2012a) survey recent literature on REG.

Different approaches have been proposed for generating referring expressions for sets of objects. Van Deemter (2002) extended the Incremental Algorithm to allow disjunction and negation, enabling reference to sets. Further work attempted to resolve the unnaturally long expressions which could be generated by this approach (Gardent, 2002; Horacek, 2004; Gatt and van Deemter, 2007). Later, description logic was used to name sets (Areces et al., 2008; Ren et al., 2010). All of these algorithms are manually engineered and deterministic.

In practice, human utterances are surprisingly varied, loosely following the Gricean ideals (van Deemter et al., 2012b). Much recent work in REG has identified the importance of modeling the variation observed in human-generated referring expressions (Viethen and Dale, 2010; Viethen et al., 2013; van Deemter et al., 2012b; Mitchell et al., 2013), and some approaches have applied machine-learning techniques to single-object references (Viethen and Dale, 2010; Mitchell et al., 2011a,b). Recently, Mitchell et al. (2013) introduced a probabilistic approach for conjunctive descriptions of single objects, which will provide a comparison baseline for experiments in Section 8. To the best of our knowledge, this paper presents the first learned probabilistic model for referring expressions defining sets, and is the first effort to treat REG as a density estimation problem.

REG is related to *content selection*, which has been studied for generating text from databases (Konstas and Lapata, 2012), event streams (Chen et al., 2010), images (Berg et al., 2012; Zitnick and Parikh, 2013), and text (Barzilay and Lapata, 2005; Carenini et al., 2006). However, most approaches to this problem output bags of concepts, while we construct full logical expressions, allowing our approach to capture complex relations between attributes.

Finally, our approach to modeling meaning using lambda calculus is related to a number of approaches that used similar logical representation in various domains, including database query interfaces (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005, 2007), natural language instructions (Chen and Mooney, 2011; Matuszek et al., 2012b; Kim and Mooney, 2012; Artzi and Zettlemoyer, 2013b), event streams (Liang et al., 2009; Chen et al., 2010), and visual descriptions (Matuszek et al., 2012a; Krishnamurthy and Kollar, 2013). Our use of logical forms follows this line of work, while extending it to handle plurality and coordination, as described in Section 4.1. In addition, lambda calculus was shown to enable effective natural language generation from logical forms (White and Rajkumar, 2009; Lu and Ng, 2011). If combined with these approaches, our approach would allow the creation of a complete REG pipeline.

3 Technical Overview

Task Let $\mathcal{Z}$ be a set of logical expressions that select a target set of objects G in a world state S, as formally defined in Section 5.1. We aim to learn a probability distribution $P(z \mid S, G)$, with $z \in \mathcal{Z}$.

For example, in the referring expressions domain we work with, the state $S = \{o_1, \ldots, o_n\}$ is a set of n objects o_i. Each o_i has three properties: color, shape and type. The target set $G \subseteq S$ is the subset of objects to be described. Figure 1a shows an example scene. The world state S includes the 11 objects in the image, where each object is assigned color (*yellow, green* ...), shape (*cube, cylinder* ...) and type (*broccoli, apple* ...). The target set G contains the circled objects. Our task is to predict a distribution which closely matches the empirical distribution in Figure 1c.

Model and Inference We model $P(z|S, G)$ as a globally normalized log-linear model, using features of the logical form z, and its execution with respect to S and G. Since enumerating all $z \in \mathcal{Z}$ is intractable, we develop an approximate inference algorithm which constructs a high quality candidate set, using a learned pruning model. Section 5.2 describes the globally scored log-linear model. Sec-

tion 5.3 presents a detailed description of the inference procedure.

Learning We use stochastic gradient descent to learn both the global scoring model and the explicit pruning model, as described in section 6. Our data consists of human-generated referring expressions, gathered from Amazon Mechanical Turk. These sentences are automatically labelled with logical forms with a learned semantic parser, providing a stand-in for manually labeled data (see Section 7).

Evaluation Our goal is to output a distribution that closely matches the distribution that would be produced by humans. We therefore evaluate our model with gold standard labeling of crowd-sourced referring expressions, which are treated as samples from the implicit distribution we are trying to model. The data and evaluation procedure are described in Section 7. The results are presented in Section 8.

4 Modeling Referring Expressions

4.1 Semantic Modeling

Our semantic modeling approach uses simply-typed lambda-calculus following previous work (Carpenter, 1997; Zettlemoyer and Collins, 2005; Artzi and Zettlemoyer, 2013b), extending it in one important way: we treat *sets* of objects as a primitive type, rather than individuals. This allows us to model plurality, cardinality, and coordination for the language observed in our data, and is further motivated by recent cognitive science evidence that sets and their properties are represented as single units in human cognition (Scontras et al., 2012).

Plurals Traditionally, noun phrases are identified with the entity-type $\mathtt{e}$ and pick out individual objects (Carpenter, 1997). This makes it difficult to interpret plural noun-phrases which pick out a set of objects, like "The red cubes". Previous approaches would map this sentence to the same logical expression as the singular "The red cube", ignoring the semantic distinction encoded by the plural.

Instead, we define the primitive entity $\mathtt{e}$ to range over sets of objects. $\langle \mathtt{e}, \mathtt{t} \rangle$-type expressions are therefore functions from sets to a truth-value. These are used in two ways, modeling both *distributive* and *collective* predicates (cf. Stone, 2000):

1. *Distributive* predicates are $\langle \mathtt{e}, \mathtt{t} \rangle$-type expressions which will return $true$ if every individual in the set has a given property. For example, the expression $\lambda x.red(x)$ will be true for all sets which contain only objects for which the value red is *true*.
2. *Collective* predicates are $\langle \mathtt{e}, \mathtt{t} \rangle$-type expressions which indicate a property of the set itself. For example, in the phrase "the two cubes", "two" corresponds to the expression $\lambda x.cardinality_2(x)$ which will return $true$ only for sets which have exactly two members.

We define semantic plurality in terms of two special *collective* predicates: sg for singular and plu for plural. For examples, "cube" is interpreted as $\lambda x.cube(x) \wedge sg(x)$, whereas "cubes" is interpreted as $\lambda x.cube(x) \wedge plu(x)$. The sg predicate returns $true$ only for singleton sets. The plu predicate returns $true$ for sets that contain two or more objects.

We also model three kinds of determiners, functional-type $\langle \langle \mathtt{e}, \mathtt{t} \rangle, \mathtt{e} \rangle$-type expressions which select a single set from the power-set represented by their $\langle \mathtt{e}, \mathtt{t} \rangle$-type argument. The definite determiner "the" is modeled with the predicate ι, which resolves to the maximal set amongst those licensed by its argument. The determiner $Every$ only accepts $\langle \mathtt{e}, \mathtt{t} \rangle$-type arguments that define singleton sets (i.e. the argument includes the sg predicate) and returns a set containing the union of these singletons. For example, although "red cube" is a singular expression, "Every red cube" refers to a set. Finally, the indefinite determiner "a" is modeled with the logical constant $\mathcal{A}$, which picks a singleton set by implicitly introducing an existential quantifier (Artzi and Zettlemoyer, 2013b).[2]

Coordination Two types of coordination are prominent in set descriptions. The first is attribute coordination, which is typically modeled with the boolean operators: $\wedge$ for conjunction and $\vee$ for disjunction. For example, the phrase "the red cubes and green rectangle" involves a disjunction that joins two conjunctive expressions, both within the scope of the definite determiner: $\iota(\lambda x.(red(x) \wedge cube(x) \wedge plu(x)) \vee (green(x) \wedge rectangle(x) \wedge sg(x)))$.

[2] This treatment of the indefinite determiner is related to generalized skolem terms as described by Steedman (2011).

The second kind of coordination, a new addition of this work, occurs when two sets are coordinated. This can either be set union ($\cup$) as in the phrase "The cubes and the rectangle" ($\iota(\lambda x.cube(x) \wedge plu(x)) \cup \iota(\lambda x.rectangle(x) \wedge sg(x))$), or set difference ($\setminus$) as in the phrase "All blocks except the green cube": ($\iota(\lambda x.object(x) \wedge plu(x)) \setminus \iota(\lambda x.green(x) \wedge cube(x) \wedge sg(x))$).

4.2 Visual Domain

Objects in our scenes are labeled with attribute values for four attribute types: `color` (7 values, such as *red*, *green*), `shape` (9 values, such as *cube*, *sphere*), `type` (16 values, such as *broccoli*, *apple*) and a special `object` property, which is *true* for all objects. The special `object` property captures the role of descriptions that are true for all objects, such as "toy" or "item". Each of these 33 attribute values corresponds to an $\langle \mathtt{e}, \mathtt{t} \rangle$-type predicate.

5 Model and Inference

In this section, we describe our approach to modeling the probability $P(z \mid S, G)$ of a logical form $z \in \mathcal{Z}$ that names a set of objects G in a world S, as defined in Section 3. We first define $\mathcal{Z}$ (Section 5.1), and then present the distribution (Section 5.2) and an approximate inference approach that makes use of a learned pruning model (Section 5.3).

5.1 Space of Possible Meanings

The set $\mathcal{Z}$ defines logical expressions that we will consider for picking the target set G in state S. In general, we can construct infinitely many such expressions. For example, every $z \in \mathcal{Z}$ can be trivially extended to form a new candidate z' for $\mathcal{Z}$ by adding a true clause to any conjunct it contains. However, the vast majority of such expressions are overly complex and redundant, and would never be used in practice as a referring expression.

To avoid this explosion, we limit the type and complexity of the logical expressions that are included in $\mathcal{Z}$. We consider only `e`-type expressions, since they name sets, and furthermore only include expressions that name the desired target set G.[3] We also limit the overall complexity of each $z \in \mathcal{Z}$, to contain not more than M logical constants.

To achieve these constraints, we define an inductive procedure for enumerating $\mathcal{Z}$, in order of complexity. We first define $\mathcal{A}_j$ to be the set of all `e`- and $\langle \mathtt{e}, \mathtt{t} \rangle$-type expressions that contain exactly j logical constants. Figure 2 presents five rules that can be used to construct $\mathcal{A}_j$ by induction, for $j = 1, \ldots, \infty$, by repeatedly adding new constants to expressions in $\mathcal{A}_{j'}$ for $j' < j$. Intuitively, $\mathcal{A}_j$ is the set of all complexity j expressions that can be used as subexpressions for higher complexity entires in our final set $\mathcal{Z}$. Next, we define $\mathcal{Z}_j$ to be the `e`-type expressions in $\mathcal{A}_j$ that name the correct set G. And, finally, $\mathcal{Z} = \cup_{j=1 \ldots M} \mathcal{Z}_j$ of all correct expressions up to a maximum complexity of M.

This construction allows for a finite $\mathcal{Z}$ with good

- $p : \langle \langle \mathtt{e}, \mathtt{t} \rangle, \mathtt{e} \rangle, e_1 : \langle \mathtt{e}, \mathtt{t} \rangle \rightarrow p(e_1) : \mathtt{e}$

  e.g.

$p = \iota : \langle \langle \mathtt{e}, \mathtt{t} \rangle, \mathtt{e} \rangle$
$e_1 = \lambda x.cube(x) \wedge sg(x) : \langle \mathtt{e}, \mathtt{t} \rangle$
$\iota(\lambda x.cube(x) \wedge sg(x)) : \mathtt{e}$

- $p : \langle \mathtt{t}, \mathtt{t} \rangle, e_1 : \langle \mathtt{e}, \mathtt{t} \rangle \rightarrow \lambda x.p(e_1(x)) : \langle \mathtt{e}, \mathtt{t} \rangle$

  e.g.

$p = \neg : \langle \mathtt{t}, \mathtt{t} \rangle$
$e_1 = \lambda x.red(x) : \langle \mathtt{e}, \mathtt{t} \rangle$
$\lambda x. \neg(red(x)) : \langle \mathtt{e}, \mathtt{t} \rangle$

- $p : \langle \mathtt{e}, \langle \mathtt{e}, \mathtt{t} \rangle \rangle, e_1 : \mathtt{e} \rightarrow \lambda x.(p(x))(e_1)$

  e.g.

$p = equal : \langle \mathtt{e}, \langle \mathtt{e}, \mathtt{t} \rangle \rangle$
$e_1 = \mathcal{A}(\lambda y.cube(y) \wedge sg(y)) : \mathtt{e}$
$\lambda x.equal(x, \mathcal{A}(\lambda y.cube(y) \wedge sg(y)))$

- $p : \langle \mathtt{e}, \langle \mathtt{e}, \mathtt{e} \rangle \rangle, e_1 : \mathtt{e}, e_2 : \mathtt{e} \rightarrow (p(e_1))(e_2) : \mathtt{e}$

  e.g.

$p = \setminus : \langle \mathtt{e}, \langle \mathtt{e}, \mathtt{e} \rangle \rangle$
$e_1 = \iota(\lambda x.cube(x) \wedge plu(x)) : \mathtt{e}$
$e_2 = Every(\lambda x.object(x) \wedge sg(x)) : \mathtt{e}$
$Every(\lambda x.object(x) \wedge sg(x)) \setminus$ $\iota(\lambda x.cube(x) \wedge plu(x)) : \mathtt{e}$

- $p : \langle \mathtt{t}, \langle \mathtt{t}, \mathtt{t} \rangle \rangle, e_1 : \langle \mathtt{e}, \mathtt{t} \rangle, e_2 \langle \mathtt{e}, \mathtt{t} \rangle \rightarrow$
 $\lambda x.(p(e_1(x)))(e_2(x)) : \langle \mathtt{e}, \mathtt{t} \rangle$

  e.g.

$p = \wedge : \langle \mathtt{t}, \langle \mathtt{t}, \mathtt{t} \rangle \rangle$
$e_1 = \lambda x.red(x) : \langle \mathtt{e}, \mathtt{t} \rangle$
$e_2 = \lambda x.cube(x) : \langle \mathtt{e}, \mathtt{t} \rangle$
$\lambda x.red(x) \wedge cube(x) : \mathtt{e}$

Figure 2: The five rules used during generation. Each rule is a template which takes a predicate $p : t$ of type t and one or two arguments $e_i : t_i$, with type t_i. The output is the logical expression after the arrow $\rightarrow$, constructed using the inputs as shown.

[3] We do not attempt to model underspecified or otherwise incorrect expressions, although our model could handle this by considering all `e`-type expressions.

empirical coverage, as we will see in the experiments in Section 8. However, $\mathcal{Z}$ is still prohibitively large for the maximum complexities used in practise (for example $M = 20$). Section 5.3 presents an approach for learning models to prune $\mathcal{Z}$, while still achieving good empirical coverage.

5.2 Global Model

Given a finite $\mathcal{Z}$, we can now define our desired globally normalized log-linear model, conditioned on the state S and set of target objects G:

$$P_G(z \mid S, G; \theta) = \frac{1}{C} e^{\theta \cdot \phi(z,S,G)} \quad (1)$$

where $\theta \in \mathbb{R}^n$ is a parameter vector, $\phi(z, S, G) \in \mathbb{R}^n$ is a feature function and C is the normalization constant. Section 5.4 defines the features we use.

5.3 Pruning $\mathcal{Z}$

As motivated in Section 5.1, the key challenge for our global model in Equation 1 is that the set $\mathcal{Z}$ is too large to be explicitly enumerated. Instead, we designed an approach for learning to approximate $\mathcal{Z}$ with a subset of the highly likely entries, and use this subset as a proxy for $\mathcal{Z}$ during inference.

More specifically, we define a binary distribution that is used to classify whether each $a \in \mathcal{A}_j$ is likely to be used as a sub-expression in $\mathcal{Z}$, and prune each $\mathcal{A}_j$ to keep only the top k most likely entries. This distribution is a logistic regression model:

$$P_j(a \mid S, G; \pi_j) = \frac{e^{\pi_j \cdot \phi(a,S,G)}}{1 + e^{\pi_j \cdot \phi(a,S,G)}} \quad (2)$$

with features $\phi(a, S, G) \in \mathbb{R}^n$ and parameters $\pi_j \in \mathbb{R}^n$. This distribution uses the same features as the global model presented in Equation 1, which we describe in Section 5.4.

Together, the pruning model and global model define the distribution $\hat{P}(z \mid G, S; \theta, \Pi)$ over $z \in \mathcal{Z}$, conditioned on the world state S and target set G, and parameterized by both the parameters θ of the global model and the parameters $\Pi = \{\pi_1, \ldots, \pi_M\}$ of the pruning models.

5.4 Features

We use three kinds of features: logical expression structure features, situated features and a complexity feature. All features but the complexity feature are shared between the global model in Equation 1 and the pruning model in Equation 2. In order to avoid overly specific features, the attribute value predicates in the logical expressions are replaced with their attribute type (ie. $red \rightarrow color$). In addition, the special constants sg and plu are ignored when computing features.

In the following description of our features, all examples are computed for the logical expression $\iota(\lambda x.red(x) \wedge object(x) \wedge plu(x))$, with respect to the scene and target set in Figure 1a.

Structure Features We use binary features that account for the presence of certain structures in the logical form, allowing the model to learn common usage patterns.

- **Head Predicate** - indicator for use of a logical constant as a head predicate in every subexpression of the expression. A head predicate is the top-level operator of an expression. For example, the head predicate of the expression "$\lambda x.red(x) \wedge object(x)$" is "$\wedge$" and the head of $\lambda x.red(x)$ is red. For our running example, the head features are ι, $\wedge$, $color$, $object$.

- **Head-Predicate Bigrams and Trigrams** - head-predicate bigrams are defined to be the head predicate of a logical form, and the head predicate of one of its children. Trigrams are similarly defined. E.g. bigrams: $[\iota, \wedge]$, $[\wedge, color]$, $[\wedge, object]$, and trigrams: $[\iota, \wedge, red]$, $[\iota, \wedge, object]$.

- **Conjunction Duplicate** - this feature fires if a conjunctive expression contains duplicate subexpressions amongst its children.

- **Coordination Children** - this feature set indicates the presence of a coordination subexpression ($\wedge$, $\vee$, $\cup$ or $\setminus$) and the head expressions of all pairs and triples of its child expressions. E.g. $[\wedge; red, object]$.

Situated Features These features take into account the evaluation of the logical form z with respect to the state S and target set G. They capture common patterns between the target set G and the object groups named by subexpressions of z.

- **Head Predicate and Coverage** - this feature set indicates the head predicate of every sub-expression of the logical form, combined with a comparison between the execution of the sub-expression and the target set G. The possible values for this comparison (which we call the "coverage" of the expression with respect to G) are: EQUAL, SUBSET (SUB), SUPERSET (SPR), DISJOINT, ALL, EMPTY and OTHER. E.g. $[\iota, \texttt{SUB}]$, $[\wedge, \texttt{SUB}]$, $[color, \texttt{SUB}]$, $[object, \texttt{ALL}]$

- **Coordination Child Coverage** - this feature set indicates the head-predicate of a coordination subexpression, combined with the coverage of all pairs and triples of its child expressions. E.g. $[\wedge; \texttt{SUB}, \texttt{ALL}]$.

- **Coordination Child Relative Coverage** - this feature set indicates, for every pair of child subexpressions of coordination expressions in the logical form, the coverage of the child subexpressions relative to each other. The possible relative coverage values are: SUB-SPR, DISJOINT, OTHER. E.g. $[\wedge; \texttt{SUB-SPR}]$.

Complexity Features We use a single real-numbered feature to account for the complexity of the logical form. We define the complexity of a logical form to be the number of logical constants used. Our running example has a complexity of 4. This feature is only used in the global model, since the pruning model always considers logical expressions of fixed complexity.

6 Learning

Figure 3 presents the complete learning algorithm. The algorithm is online, using stochastic gradient descent updates for both the globally scored density estimation model and the learned pruning model. The algorithm assumes a dataset of the form $\{(Z_i, S_i, G_i) : i = 1 \dots n\}$ where each example scene includes a list of logical expressions Z_i, a world state S_i, and a target set of objects, G_i, which will be identified by the resulting logical expressions. The output is learned parameters for both the globally scored density estimation model θ, and for the learned pruning models Π.

Inputs: Training set $\{(Z_i, S_i, G_i) : i = 1 \dots n\}$, where Z_i is a list of logical forms, S_i is a world state, and G_i is a target set of objects. Number of iterations T. Learning rate α_0. Decay parameter c. Complexity threshold M, as described in Section 5.3.

Definitions: Let $\hat{P}(z \mid G_i, S_i; \theta, \Pi)$ be the predicted global probability from Equation 1. Let $\hat{P}_j(z \mid G_i, S_i; \pi_j)$ be the predicted pruning probability from Equation 2. Let $\hat{\mathcal{A}}_j$ be the set of all complexity-M logical expressions, after pruning (see Section 5.1). Let $SUB(j, z)$ be all complexity-j sub-expressions of logical expression z. Let $Q_i(z \mid S_i, G_i)$ be the empirical probability over $z \in \mathcal{Z}$, estimated from Z_i. Finally, let $\phi_i(z)$ be a shorthand for the feature function $\phi(z, S_i, G_i)$ as defined in Section 5.4.

Algorithm:

Initialize $\theta \leftarrow \vec{0}$, $\pi_j \leftarrow \vec{0}$ for $j = 1 \dots M$

For $t = 1 \dots T, i = 1 \dots n$:

Step 1: (Update Global Model)

a. Compute the stochastic gradient:
$\Delta_\theta \leftarrow E_{Q_i(z|S_i,G_i)}[\phi_i(z)] - E_{\hat{P}(z|G_i,S_i;\theta,\Pi)}[\phi_i(z)]$

b. Update the parameters:
$\gamma \leftarrow \frac{\alpha_0}{1+c\times\tau}$ where $\tau = i + t \times n$
$\theta \leftarrow \theta + \gamma\Delta_\theta$

Step 2: (Update Pruning Model)

For $j = 1 \dots M$

a. Construct a set of positive and negative examples:
$\mathcal{D}^+ \leftarrow \bigcup_{z \in Z_i} SUB(j, z)$.
$\mathcal{D}^- \leftarrow \hat{\mathcal{A}}_j \setminus \mathcal{D}^+$

b. Compute mini-batch stochastic gradient, normalizing for data skew:
$\Delta_{\pi_j} \leftarrow \frac{1}{|\mathcal{D}^+|}\sum_{z\in\mathcal{D}^+}(1 - P_j(z \mid S_i, G_i; \pi_j))\phi_i(z)$
$\quad - \frac{1}{|\mathcal{D}^-|}\sum_{z\in\mathcal{D}^-} P_j(z \mid S_i, G; \pi_j)\phi_i(z)$

c. Update complexity-j pruning parameters:
$\pi_j \leftarrow \pi_j + \gamma\Delta_{\pi_j}$

Output: θ and $\Pi = [\pi_1, \dots, \pi_M]$

Figure 3: The learning algorithm.

6.1 Global Model Updates

The parameters θ of the globally scored density estimation model are trained to maximize the log-likelihood of the data:

$$O_i = \log \prod_{z \in Z_i} P_G(z \mid S_i, G_i) \tag{3}$$

Taking the derivative of this objective with respect to θ yields the gradient in Step 1a of Figure 3. The marginals, $E_{\hat{P}(z|G_i,S_i;\theta,\Pi)}(\phi_i(z))$, are computed over the approximate finite subset of $\mathcal{Z}$ constructed with the inference procedure described in Section 5.3.

6.2 Pruning Model Updates

To update each of the M pruning models, we first construct a set of positive and negative examples (Step 2a). The positive examples, $\mathcal{D}^+$, include those sub-expressions which should be in the beam - these are all complexity j sub-expressions of logical expressions in Z_i. The negative examples, $\mathcal{D}^-$, include all complexity-j expressions constructed during beam search, minus those which are in $\mathcal{D}^+$. The gradient (Set 2b) is a binary mini-batch gradient, normalized to correct for data skew.

7 Experimental Setup

Data Collection Our dataset consists of 118 images, taken with a Microsoft Kinect camera. These are the same images used by Matuszek et al. (2012a), but we create multiple prompts for each image by circling different objects, giving 269 scenes in total. These scenes were shown to workers on Amazon Mechanical Turk[4] who were asked to imagine giving instructions to a robot and complete the sentence "Please pick up _____" in reference to the circled objects. Twenty referring expressions were collected for each scene, a total of 5380 expressions.

From this data, 43 scenes (860 expressions) were held-out for use in a test set. Of the remaining scenes, the sentences of 30 were labeled with logical forms. 10 of these scenes (200 expressions) are used as a labeled initialization set, and 20 are used as a development test set (400 expressions). A small number of expressions ($\sim$5%) from the labeled initial set were discarded, either because they did not correctly name the target set, or because they used very rare attributes (such as texture, or location) to name the target objects.

Surrogate Labeling To avoid hand labeling the large majority of the scenes, we label the data with a learned semantic parser (Zettlemoyer and Collins, 2005). We created a hand-made lexicon for the entire training set, which greatly simplifies the learning problem, and learned the parameters of the parsing moder on the 10-scene initialization set. The weights were then further tuned using semi-supervised techniques (Artzi and Zettlemoyer, 2011, 2013b) on the data to be labeled. Testing on the development set shows that this parser achieves roughly 95% precision and 70% recall.

Using this parser, we label the sentences in our training set. We only use scenes where at least 15 sentences were successfully parsed. This gives a training set of 141 scenes (2587 expressions). Combining the automatically labeled training set with the hand-labelled initialization, development and held-out data, our labelled corpus totals 3938 labeled expressions. By contrast, the popular TUNA furniture sub corpus (Gatt et al., 2007) contains 856 descriptions of 20 scenes, and although some of these refer to sets, these sets contain two objects at most.

Framework Our experiments were implemented using the University of Washington Semantic Parsing Framework (Artzi and Zettlemoyer, 2013a).

Hyperparameters Our inference procedure requires two hyperparameters: M, the maximum complexity threshold, and k, the beam size. In practice, we set these to the highest possible values which still allow for training to complete in a reasonable amount of time (under 12 hours). M is set to 20, which is sufficient to cover 99.5% of the observed expressions. The beam-size k is 100 for the first three complexity levels, and 50 thereafter.

For learning, we use the following hyperparameters, which were tuned on the development set: learning rate $\alpha_0 = .25$, decay rate $c = .02$, number of epochs $T = 10$.

Evaluation Metrics Evaluation metrics used in REG research have assumed a system that produces a single output. Our goal is to achieve a distribution over logical forms that closely matches the distribution observed from human subjects. Therefore, we compare our learned model to the labeled test data with mean absolute error:

$$MAE = \frac{1}{2n}\sum_{i=1}^{n}\sum_{z \in \mathcal{Z}} |P(z \mid S_i, G_i) - Q(z \mid S_i, G_i)|$$

where Q is the empirical distribution observed in the training data. MAE measures the total probability mass which is assigned differently in the predicted distribution than in the empirical distribution. We use MAE as opposed to KL divergence or data likelihood as both of these measures are uninformative when the support of the two distributions differ.

–	MAE	$\%_{dup}$	$\%_{uniq}$	Top1
VOA	39.7	98.2	92.5	**72.7**
GenX	**25.8** (5.0)	**100** (0)	**100** (0)	**72.7** (0)

Table 1: Single object referring expression generation results. Our approach (GenX) is compared to the approach from Mitchell et al. (2013) (VOA). Standard deviation over five shuffles of training set is reported in parentheses.

This metric is quite strict; small differences in the estimated probabilities over a large number of logical expressions can result in a large error, even if the relative ordering is quite similar. Therefore, we report the percentage of observed logical expressions which the model produces, either giving credit multiple times for duplicates ($\%_{dup}$) or counting each unique logical expression in a scene once ($\%_{uniq}$). Put another way, $\%_{dup}$ counts logical expression tokens, whereas $\%_{uniq}$ counts types. We also report the proportion of scenes where the most likely logical expression according to the model matched the most common one in the data (Top1).

Single Object Baseline In order to compare our method against the state of the art for generating referring expressions for single objects, we use the subset of our corpus where the target set is a single object. This sub-corpus consists of 44 scenes for training and 11 held out for testing.

For comparison we re-implemented the probabilistic Visual Objects Algorithm (VOA) of Mitchell et al. (2013). We refer the readers to the original paper for details of the approach. The parameters of the model were tuned on the training data: the prior likelihood estimates for each of the four attribute types (α_{att}) were estimated as the relative frequency of each attribute in the data. We pick the ordering of attributes and the length penalty, λ, from the cross-product of all possible $4!$ orderings and all integers on the range of [1,10], choosing the setting which results in the lowest average absolute error (AAE) on the training set. This process resulted in the following parameter settings: $\alpha_{color} = .916$, $\alpha_{shape} = .586$, $\alpha_{type} = .094$, $\alpha_{object} = .506$, AP ordering = $[type, shape, object, color]$, $\lambda = 4$. Inference was done using 10,000 samples per scene.

–	MAE	$\%_{dup}$	$\%_{uniq}$	Top1
Full GenX	**54.3** (4.5)	**87.4** (0.6)	**72.9** (1.1)	**52.6** (8.3)
NoPrune	71.8 (2.5)	42.2 (2.7)	16.1 (1.7)	40.0 (5.0)
NoCOV	87.0 (6.7)	26.0 (3.7)	11.2 (2.1)	14.9 (9.7)
NoSTRUC	60.2 (1.7)	79.6 (0.3)	61.9 (0.5)	44.6 (4.5)
HeadExpOnly	88.8 (6.4)	21.9 (8.6)	9.3 (3.5)	14.0 (7.9)

Table 2: Results on the complete corpus for the complete system (Full GenX), ablating the pruning model (NoPrune) and the different features: without coverage features (NoCOV), without structure features (NoSTRUC) and using only the logical expression HeadExp features (HeadExpOnly). Standard deviation over five runs is shown in parentheses.

8 Results

We report results on both the single-object subset of our data and the full dataset. Since our approach is online, and therefore sensitive to data ordering, we average results over 5 different runs with randomly ordered data, and report variance.

Single Objects Table 1 shows the different metrics for generating referring expression for single objects only. Our approach outperforms VOA (Mitchell et al., 2013) on all metrics, including an average of approximately 35% relative reduction in MAE. In addition, unlike VOA, our system (GenX) produces every logical expression used to refer to single objects in our dataset, including a small number which use negation and equality.

Object Sets Table 2 lists results on the full dataset. Our learned pruning approach produces an average 72.9% of the unique logical expressions used present in our dataset – over 87% when these counts are weighted by their frequency. The globally scored model achieves a mean absolute error of 54.3, and correctly assigns the highest probability to the most likely expression over 52% of the time.

Also shown in Table 2 are results obtained when elements of our approach are ablated. Using the global model for pruning instead of an explicitly trained model causes a large drop in performance, demonstrating that our global model is inappropri-

Figure 4: Example output of our system for the scene on the right. We show the top 10 expressions (z) from the predicted distribution ($\hat{P}$) compared to the empirical distribution estimated from our labeled data (Q). The bottom section shows the predicted probability of the three expressions which were not in the top 10 of the predicted distribution. Although the mean absolute error (MAE) of $\hat{P}$ and Q is 63.8, $\hat{P}$ covers all of the entries in Q in the correct relative order and also fills in many other plausible candidates.

ate for pruning. We also ablate subsets of our features, demonstrating that the coverage and structural features are both crucial for performance.

Qualitatively, we found the learned distributions were often higher quality than the seemingly high mean absolute error would imply. Figure 4 shows an example output where the absolute error of the predicted distribution was 63.8. Much of the error can be attributed to probability mass assigned to logical expressions which, although not observed in our test data, are reasonable referring expressions. This might be due to the fact that our estimate of the empirical distribution comes from a fairly small sample (20), or other factors which we do not model that make these expressions less likely.

9 Conclusion

In this paper, we modeled REG as a density-estimation problem. We demonstrated that we can learn to produce distributions over logical referring expressions using a globally normalized model. Key to the approach was the use of a learned pruning model to define the space of logical expression that are explicitly enumerated during inference. Experiments demonstrate state-of-the-art performance on single object reference and the first results for learning to name sets of objects, correctly recovering over 87% of the observed logical forms.

This approach suggests several directions for future work. Lambda-calculus meaning representations can be designed for many semantic phenomena, such as spatial relations, superlatives, and graded properties, that are not common in our data. Collecting new datasets would allow us to study the extent to which the approach would scale to domains with such phenomena.

Although the focus of this paper is on REG, the approach is also applicable to learning distributions over logical meaning representations for many other tasks. Such learned models could provide a range of possible inputs for systems that map logical expressions to sentences (White and Rajkumar, 2009; Lu and Ng, 2011), and could also provide a valuable prior on the logical forms constructed by semantic parsers in grounded settings (Artzi and Zettlemoyer, 2013b; Matuszek et al., 2012a).

Abstract

The problem to replace a word with a synonym that fits well in its sentential context is known as the lexical substitution task. In this paper, we tackle this task as a supervised ranking problem. Given a dataset of target words, their sentential contexts and the potential substitutions for the target words, the goal is to train a model that accurately ranks the candidate substitutions based on their contextual fitness. As a key contribution, we customize and evaluate several learning-to-rank models to the lexical substitution task, including classification-based and regression-based approaches. On two datasets widely used for lexical substitution, our best models significantly advance the state-of-the-art.

1 Introduction

The task to generate lexical substitutions in context (McCarthy and Navigli, 2007), i.e., to replace words in a sentence without changing its meaning, has become an increasingly popular research topic. This task is used, e.g. to evaluate semantic models with regard to their accuracy in modeling word meaning in context (Erk and Padó, 2010). Moreover, it provides a basis of NLP applications in many fields, including linguistic steganography (Topkara et al., 2006; Chang and Clark, 2010), semantic text similarity (Agirre et al., 2012) and plagiarism detection (Gipp et al., 2011). While closely related to WSD, lexical substitution does not rely on explicitly defined sense inventories (Dagan et al., 2006): the possible substitutions reflect all conceivable senses of the word, and the correct sense has to be ascertained to provide an accurate substitution.

While a few lexical sample datasets (McCarthy and Navigli, 2007; Biemann, 2012) with human-provided substitutions exist and can be used to evaluate different lexical paraphrasing approaches, a practically useful system must also be able to rephrase unseen words, i.e., any word for which a list of synonyms is provided. Correspondingly, unsupervised and knowledge-based approaches that are not directly dependent on any training material, prevailed in the SemEval 2007 shared task on English Lexical Substitution and dominated follow-up work. The only supervised approach is limited to the combination of several knowledge-based lexical substitution models based on different underlying lexicons (Sinha and Mihalcea, 2009).[3]

A recent work by Szarvas et al. (2013) describes a tailor-made supervised system based on delexicalized features that – unlike earlier supervised approaches, and similar to unsupervised and knowledge-based methods proposed for this task – is able to generalize to an open vocabulary. For each target word to paraphrase, they first compute a set of substitution candidates using WordNet: all synonyms from all of the target word's WordNet synsets, together with the words from synsets in *similar to, entailment* and *also see* relation to these synsets are considered as potential substitutions. Each candidate then constitutes a training (or test)

[1]Work was done while working at RGAI of the Hungarian Acad. Sci. and University of Szeged.

[3]Another notable example for supervised lexical substitution is Biemann (2012), but this is a lexical sample system applicable only to the target words of the training datasets.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1926–1932,
Seattle, Washington, USA, 18-21 October 2013.

example, and these instances are characterized using non-lexical features from heterogeneous evidence such as lexical-semantic resources and distributional similarity, n-gram counts and shallow syntactic features computed on large, unannotated background corpora. The goal is then i) to predict how well a particular candidate fits in the original context, and ii) given these predictions for each of the candidates, to correctly order the elements of the candidate set according to their contextual fitness. That is, a model is successful if it prioritizes plausible substitutions ahead of less likely synonyms (given the context). This model is able to generate paraphrases for target words not contained in the training material. This favorable property is achieved using only such features (e.g. local n-gram frequencies in context) that are meaningfully comparable across the different target words and candidate substitutions they are computed from. More importantly, their model also provides superior ranking results compared to state of the art unsupervised and knowledge based approaches and therefore it defines the current state of the art for open vocabulary lexical substitution.

Motivated by the findings of Szarvas et al. (2013), we address lexical substitution as a supervised learning problem, and go beyond their approach from a methodological point of view. Our experiments show that the performance on the lexical substitution task is strongly influenced by the way in which this task is formalized as a machine learning problem (i.e., as binary or multi-class classification or regression) and by the learning method used to solve this problem. As a result, we are able to report the best performances on this task for two standard datasets.

2 Related work

Previous approaches to lexical substitution often seek to automatically generate a set of candidate substitutions for each target word first, and to rank the elements of this set of candidates afterward (Hassan et al., 2007; Giuliano et al., 2007; Martinez et al., 2007; Yuret, 2007). Alternatively, the candidate set can be defined by all human-suggested substitutions for the given target word in all of its contexts; then, the focus is just on the ranking problem (Erk and Padó, 2010; Thater et al., 2010; Dinu and Lapata, 2010; Thater et al., 2011). While only the former approach qualifies as a full-fledged substitution system for arbitrary, previously unseen target words, the latter simplifies the comparison of semantic ranking models, as the ranking step is not burdened with the shortcomings of automatically generated substitution candidates.

As mentioned before, Szarvas et al. (2013) recently formalized the lexical substitution problem as a supervised learning task, using delexicalized features. This non-lexical feature representation makes different target word/substitution pairs in different contexts[4] directly comparable. Thus, it becomes possible to learn an all-words system that is applicable to unseen words, using supervised methods, which provides superior ranking accuracy to unsupervised and knowledge based models.

In this work, we build on the problem formulation and the features proposed by Szarvas et al. (2013) while largely extending their machine learning methodology. We customize and experiment with several different learning-to-rank models, which are better tailored for this task. As our experiments show, this contribution leads to further significant improvements in modeling the semantics of a text and in end-system accuracy.

3 Datasets and experimental setup

Here we introduce the datasets, experimental setup and evaluation measures used in our experiments. Since space restrictions prohibit a comprehensive exposition, we only provide the most essential information and refer to Szarvas et al. (2013), whose experimental setup we adopted, for further details.

Datasets. We use two prominent datasets for lexical substitution. The *LexSub dataset* introduced in the Lexical Substitution task at Semeval 2007 (McCarthy and Navigli, 2007)[5] contains 2002 sentences for a total of 201 target words (from *all parts of speech*), and lexical substitutions assigned (to each target word and sentence pair) by 5 native speaker annotators. The second dataset, *TWSI* (Biemann, 2012)[6], consists of 24,647 sentences for a total of 1,012 target *nouns*, and lexical substitu-

[4] E.g., *bright* substituted with *intelligent* in *"He was bright and independent and proud"* and *side* for *part* in *"Find someone who can compose the biblical side"*.

[5] http://nlp.cs.swarthmore.edu/semeval/tasks/task10/data.shtml

[6] http://www.ukp.tu-darmstadt.de/data/lexical-resources/twsi-lexical-substitutions/

tions for each target word in context resulting from a crowdsourced annotation process.

For each sentence in each dataset, the annotators provided as many substitutions for the target word as they found appropriate in the context. Each substitution is then labeled by the number of annotators who listed that word as a good lexical substitution.

Experimental setup and Evaluation. On both datasets, we conduct experiments using a 10-fold cross validation process, and evaluate all learning algorithms on the same train/test splits. The datasets are randomly split into 10 equal-sized folds on the *target word* level, such that all examples for a particular target word fall into *either the training or the test set, but never both*. This way, we make sure to evaluate the models on target words *not seen during training*, thereby mimicking an open vocabulary paraphrasing system: at testing time, paraphrases are ranked for unseen target words, similarly as the models would rank paraphrases for any words (not necessarily contained in the dataset). For algorithms with tunable parameters, we further divide the training sets into a training and a validation part to find the best parameter settings. For evaluation, we use Generalized Average Precision (GAP) (Kishida, 2005) and Precision at 1 (P@1), i.e., the percentage of correct paraphrases at rank 1.

Features. In all experiments, we used the features described in Szarvas et al. (2013), implemented precisely as proposed by the original work.

Each $(sentence, target\,word, substitution)$ triplet represents an instance, and the feature values are computed from the sentence context, the target word and the substitution word. The features used fall into four major categories.

The most important features describe the syntagmatic coherence of the substitution in context, measured as local n-gram frequencies obtained from web data. The frequency for a 1-5gram context with the substitution word is computed and normalized with respect to either 1) the frequency of the original context (with the target word) or 2) the sum of frequencies observed for all possible substitutions. A third feature computes similar frequencies for the substitution *and* the target word observed in the local context (as part of a conjunctive phrase).

A second group of features describe the (non-positional, i.e. non-local) distributional similarity of the target and its candidate substitution in terms of sentence level co-occurrence statistics collected from newspaper texts: 1) How many words from the sentence appear in the top 1000 salient words listed for the candidate substitution in a distributional thesaurus, 2) how similar the top K salient words lists are for the candidate and the target word, 3) how similar the 2nd order distributional profiles are for candidate and target, etc. All these features are carefully normalized so that values compare well accross different words and contexts.

Another set of features capture the properties of the target and candidate word in WordNet, such as their 1) number of senses, 2) how frequent senses are synonymous and 3) the lowest common ancestor (and all synsets up) for the candidate and target word in the WordNet hierarchy (represented as a nominal feature, by the ID of these synsets).

Lastly a group of features capture shallow syntactic patterns of the target word and its local context in the form of 1) part of speech patterns (trigrams) in a sliding window around the target word using main POS categories, i.e. only the first letter of the Penn Treebank codes, and 2) the detailed POS code of the candidate word assigned by a POS tagger.

We omit a mathematically precise description of these features for space reasons and refer the reader to Szarvas et al. (2013) for a more formal and detailed description of the feature functions. Importantly, these delexicalized features are numerically comparable across the different target words and candidate substitutions they are computed from. This property enables the models to generalize over the words in the datasets and thus enables a supervised, all-words lexical substitution system.

4 Learning-to-Rank methods

Machine learning methods for ranking are traditionally classified into three categories. In the *pointwise* approach, a model is trained that maps instances (in this case candidate substitutions in a context) to scores indicating their relevance or fitness; to this end, one typically applies standard regression techniques, which essentially look at individual instances in isolation (i.e., independent of any other instances in the training or test set). To predict a ranking of a set of query instances, these are simply sorted by their predicted scores (Li et al., 2007).

The *pairwise* approach trains models that are able to compare pairs of instances. By marking such a pair as positive if the first instance is preferred to the second one, and as negative otherwise, the problem can formally be reduced to a binary classification task (Freund et al., 2003). Finally, in the *listwise* approach, tailor-made learning methods are used that directly optimize the ranking performance with respect to a global evaluation metric, i.e., a measure that evaluates the ranking of a complete set of query instances (Valizadegan et al., 2009).

Below we give a brief overview of the methods included in our experiments. We used the implementations provided by the MultiBoost (Benbouzid et al., 2012), RankSVM and RankLib packages.[7] For a detailed description, we refer to the original literature.

4.1 MAXENT

The ranking model proposed by Szarvas et al. (2013) was used as a baseline. This is a pointwise approach based on a maximum entropy classifier, in which the ranking task is cast as a binary classification problem, namely to discriminate good ($label > 0$) from bad substitutions. The actual label values for good substitutions were used for weighting the training examples. The underlying MaxEnt model was trained until convergence, i.e., there was no hyperparameter to be tuned. For a new target/substitution pair, the classifier delivers an estimation of the posterior probability for being a good substitution. The ranking is then produced by sorting the candidates in decreasing order according to this probability.

4.2 EXPENS

EXPENS (Busa-Fekete et al., 2013) is a pointwise method with listwise meta-learning step that exploits an ensemble of multi-class classifiers. It consists of three steps. First, ADABOOST.MH (Schapire and Singer, 1999) classifiers with several different weak learners (Busa-Fekete et al., 2011; Kégl and Busa-Fekete, 2009) are trained to predict the level of relevance (quality) of a substitution (i.e., the number of annotators who proposed the candidate for that particular context). Second, the classifiers are calibrated to obtain an accurate posterior distribution; to this end, several calibration techniques, such as Platt scaling (Platt, 2000), are used to obtain a diverse pool of calibrated classifiers. Note that this step takes advantage of the ordinal structure of the underlying scale of relevance levels, which is an important difference to MAXENT. Third, the posteriors of these calibrated classifiers are additively combined, with the weight of each model being exponentially proportional to its GAP score (on the validation set). This method has two hyperparameters: the number of boosting iterations T and the scaling factor in the exponential weighting scheme c. We select T and c from the intervals $[100, 2000]$ and $[0, 100]$, with step sizes 100 and 10, respectively.

4.3 RANKBOOST

RANKBOOST (Freund et al., 2003) is a pairwise boosting approach. The objective function is the rank loss (as opposed to ADABOOST, which optimizes the exponential loss). In each boosting iteration, the weak classifier is chosen by maximizing the weighted rank loss. For the weak learner, we used the decision stump described in (Freund et al., 2003), which is able to optimize the rank loss in an efficient way. The only hyperparameter of RANKBOOST to be tuned is the number of iterations that we selected from the interval $[1, 1000]$.

4.4 RANKSVM

RANKSVM (Joachims, 2006) is a pairwise method based on support vector machines, which formulates the ranking task as binary classification of pairs of instances. We used a linear kernel, because the optimization using non-linear kernels cannot be done in a reasonable time. The tolerance level of the optimization was set to 0.001 and the regularization parameter was validated in the interval $[10^{-6}, 10^{4}]$ with a logarithmically increasing step size.

4.5 LAMBDAMART

LAMBDAMART (Wu et al., 2010) is a listwise method based on the gradient boosted regression trees by Friedman (1999). The ordinal labels are learned directly by the boosted regression trees whose parameters are tuned by using a gradient-based optimization method. The gradient of parameters is calculated based on the evaluation metric used (in this case GAP). We tuned the number of boosting

[7] RankLib is available at `http://people.cs.umass.edu/~vdang/ranklib.html`. We extended the implementation of the LAMBDAMART algorithm in this package to compute the gradients of and optimize for the GAP measure.

iterations in the interval $[10, 1000]$ and the number of tree leaves in $\{8, 16, 32\}$.

5 Results and discussion

Our results using the above learning methods are summarized in Table 1. As can be seen, the two methods that exploit the cardinal structure of the label set (relevance degrees), namely EXPENS and LAMBDAMART, consistently outperform the baseline taken from Szarvas et al. (2013) – the only exception is the p@1 score for EXPENS on the Semeval Lexical Substitution dataset and the candidate substitutions extracted from WordNet. The improvements are significant (using paired t-test, $p < 0.01$) for 3 out of 4 settings for EXPENS and in all settings for LAMBDAMART. In particular, the results of LAMBDAMART are so far the best scores that have been reported for the best studied setting, i.e. the LexSub dataset using substitution candidates taken from the gold standard (see Table 2).

We suppose that the relatively good results achieved by the LAMBDAMART and EXPENS methods are due to that, first, it seems crucial to properly model and exploit the ordinal nature of the annotations (number of annotators who suggested a given word as a good paraphrase) provided by the datasets. Second, the RANKBOOST and RANKSVM are less complex methods than the EXPENS and LAMBDAMART. The RANKSVM is the least complex method from the pool of learning-to-rank methods we applied, since it is a simple linear model. The RANKBOOST is a boosted decision *stump* where, in each boosting iteration, the stump is found by maximizing the weighted exponential rank loss. On the other hand, both the EXPENS and LAMBDAMART make use of *tree* learners in the ensemble classifier they produce. We believe that overfitting is not an issue in a learning task like the LexSub task: most features are relatively weak predictors on their own, and we can learn from a large number of data points (2000 sentences with an average set size of 20, about 40K data points for the smallest dataset and setting). Rather, as our results show, less complex models tend to underfit the data. Therefore we believe that more complex models can achieve a better performance, of course with an increased computational cost.

6 Conclusion and future work

In this paper, we customized and applied some relatively novel algorithms from the field of learning-to-rank for ranking lexical substitutions in context. In turn, we achieved significant improvements on the two prominent datasets for lexical substitution.

Our results indicate that an exploitation of the ordinal structure of the labels in the datasets can lead to considerable gains in terms of both ranking quality (GAP) and precision at 1 (p@1). This observation is supported both for the theoretically simpler pointwise learning approach and for the most powerful listwise approach. On the other hand, the pairwise methods that cannot naturally exploit this property, did not provide a consistent improvement over the baseline. In the future, we plan to investigate this finding in the context of other, similar ranking problems in Natural Language Processing.

Abstract

Recent work has developed supervised methods for detecting *deceptive opinion spam*—fake reviews written to sound authentic and deliberately mislead readers. And whereas past work has focused on identifying individual fake reviews, this paper aims to identify *offerings* (e.g., hotels) that contain fake reviews. We introduce a semi-supervised manifold ranking algorithm for this task, which relies on a small set of labeled individual reviews for training. Then, in the absence of gold standard labels (at an offering level), we introduce a novel evaluation procedure that ranks artificial instances of real offerings, where each artificial offering contains a known number of injected deceptive reviews. Experiments on a novel dataset of hotel reviews show that the proposed method outperforms state-of-art learning baselines.

1 Introduction

Consumers increasingly rely on user-generated online reviews when making purchase decisions (Cone, 2011; Ipsos, 2012). Unfortunately, the ease of posting content to the Web, potentially anonymously, combined with the public's trust and growing reliance on opinions and other information found online, create opportunities and incentives for unscrupulous businesses to post *deceptive opinion spam*—fraudulent or fictitious reviews that are deliberately written to sound authentic, in order to deceive the reader (Ott et al, 2011).

Unlike other kinds of spam, such as Web (Martinez-Romo and Araujo, 2009; Castillo et al, 2006) and e-mail spam (Chirita et al, 2005), recent work has found that deceptive opinion spam is neither easily ignored nor easily identified by human readers (Ott et al, 2011). Accordingly, there is growing interest in developing automatic, usually learning-based, methods to help users identify deceptive opinion spam (see Section 2). Even in fully-supervised settings, however, automatic methods are imperfect at identifying individual deceptive reviews, and erroneously labeling genuine reviews as deceptive may frustrate and alienate honest reviewers.

An alternative approach, not yet considered in previous work, is to instead identify those product or service offerings where fake reviews appear with high probability. For example, a hotel manager may post fake positive reviews to promote their own hotel, or fake negative reviews to demote a competitor's hotel. In both cases, rather than identifying these deceptive reviews individually, it may be preferable to identify the *manipulated offering* (i.e., the hotel) so that review portal operators, such as TripAdvisor or Yelp, can further investigate the situation without alienating users.[1]

Accordingly, this paper addresses the novel task of *identifying manipulated offerings*, which we frame as a ranking problem, where the goal is to rank offerings by the proportion of their reviews that are believed to be deceptive. We propose a novel three-layer graph model, based on manifold ranking (Zhou et al, 2003a; 2003b), to jointly model deceptive language at the offering-, review- and term-level. In particular, rather than treating reviews within the same offering as independent units, there is a reinforcing relationship between offerings and reviews.

[1] Manipulating online reviews may also have legal consequences. For example, the Federal Trade Commission (FTC) has updated their guidelines on the use of endorsements and testimonials in advertising to suggest that posting deceptive reviews may be unlawful in the United States (FTC, 2009).

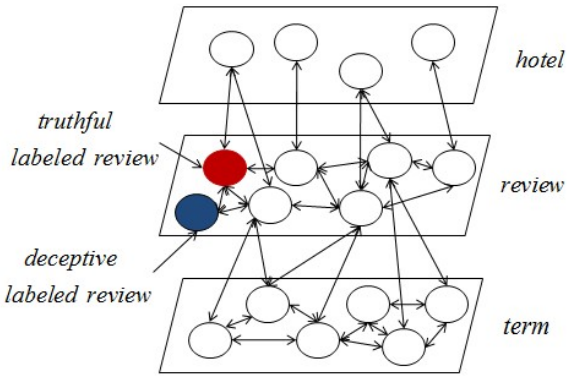

Figure 1: Mutual Reinforcement Graph Model for Hotel Ranking using the Manifold-Ranking Method

Our manifold ranking approach is semi-supervised in that it *requires no supervisory information at the offering level*; rather, it requires only a small amount of labeled data at a review level. Intuitively, and as depicted in Figure 1 for hotel offerings, we represent hotels, reviews and terms as nodes in a graph, where each hotel is connected to its reviews, and each review, in turn, is connected to the terms used within it. The influence of labeled data is propagated along the graph to unlabeled data, such that a hotel is considered more deceptive if it is heavily linked with other deceptive reviews, and a review, in turn, is more deceptive if it is generated by a deceptive hotel.

The success of our semi-supervised approach further depends on the ability to learn patterns of truthful and deceptive reviews that generalize across reviews of different offerings. This is challenging, because reviews often contain offering-specific vocabulary. For example, reviews of hotels in Los Angeles are more likely to include keywords such as "beach", "sea", "sunshine" or "LA", while reviews of Juneau hotels may contain "glacier", "Juneau", "bear" or "aurora borealis." A hotel review might also mention the hotel's restaurant or bar by name.

Unfortunately, it is unclear how important (or detrimental) offering-specific features are when deciding whether a review is fake. Accordingly, we *propose a dimensionality-reduction approach*, based on Latent Dirichlet Allocation (LDA) (Blei et al, 2003), *to obtain a vector representation of reviews for the ranking algorithm that generalizes across reviews of different offerings*. Specifically, we train an LDA-based topic model to view each review as a mixture of aspect-, city-, hotel- and review-specific topics (see Section 6). We then reduce the dimensionality of our data (i.e., labeled and unlabeled reviews) by replacing each review term vector with a vector that corresponds to its term distribution over just its aspect-specific topics, i.e., excluding city-, hotel- and review-specific topics. We find that, compared to models trained either on the full vocabulary, or trained on standard LDA document-topic vectors, this representation allows our models to generalize better across reviews of different offerings.

We evaluate our approach on the task of identifying (ranking) manipulated hotels. In particular, in the absence of gold standard offering-level labels, we introduce a *novel evaluation procedure for this task*, in which we rank numerous *versions* of each hotel, where each hotel version contains a different number of injected, known deceptive reviews. Thus, we expect hotel versions with larger proportions of deceptive reviews to be ranked higher than those with smaller proportions.

For labeled training data, we use the Ott et al. (2011) dataset of 800 *positive* (5-star) reviews of 20 Chicago hotels (400 deceptive and 400 truthful). For evaluation, *we construct a new* FOUR-CITIES *dataset*, containing 40 deceptive and 40 truthful reviews for each of eight hotels in four different cities (640 reviews total), following the procedure outlined in Ott et al. (2011). We find that our manifold ranking approach outperforms several state-of-the-art learning baselines on this task, including transductive Support Vector Regression. We additionally apply our approach to a large-scale collection of real-world reviews from TripAdvisor and explore the resulting ranking.

In the sections below, we discuss related work (Section 2) and describe the datasets used in this work (Section 3), the dimensionality-reduction approach for representing reviews (Section 4), and the semi-supervised manifold ranking approach (Section 5). We then evaluate the methods *quantitatively* (Sections 6 and 7) and *qualitatively* (Section 8).

2 Related Work

A number of recent approaches have focused on identifying individual fake reviews or users who post

fake reviews. For example, Jindal and Liu (2008) train machine learning classifiers to identify duplicate (or near duplicate) reviews. Yoo and Gretzel (2009) gathered 40 truthful and 42 deceptive hotel reviews and manually compare the psychologically relevant linguistic differences between them. Lim et al. (2010) propose an approach based on abnormal user behavior to predict spam users, without using any textual features. Ott et al. (2011) solicit deceptive reviews from workers on Amazon Mechanical Turk, and built a dataset containing 400 deceptive and 400 truthful reviews, which they use to train and evaluate supervised SVM classifiers. Ott et al. (2012) expand upon this work to estimate prevalences of deception in a review community. Mukherjee et al. (2012) study spam produced by groups of fake reviewers. Li et al. (2013) use topic models to detect differences between deceptive and truthful topic-word distributions. In contrast, in this work we aim to identify fake reviews at an offering level.[2]

LDA Topic Models. LDA topic models (Blei et al, 2003) have been employed for many NLP tasks in recent years. Here, we build on earlier work that uses topic models to (a) separate background information from information discussing the various "aspects" of products (e.g., Chemudugunta et al. (2007)) and (b) identify different levels of information (e.g., user-specific, location-specific, time-specific) (Ramage et al., 2009).

Manifold Ranking Algorithm. The manifold-ranking method (Zhou et al, 2003a; Zhou et al, 2003b) is a mutual reinforcement ranking approach initially proposed to rank data points along their underlying manifold structure. It has been widely used in many different ranking applications, such as summarization (Wan et al, 2007; Wan and Yang, 2007).

3 Dataset

In this paper, we train all of our models using the CHICAGO dataset of Ott et al (2011), which contains 20 deceptive and 20 truthful reviews from each of 20 Chicago hotels (800 reviews total). This dataset is unique in that it contains known (*gold standard*) deceptive reviews, solicited through Amazon Mechanical Turk, and is publicly-available.[3]

City	Hotels
Chicago	W Chicago, Palomar Chicago
New York	Hotel Pennsylvania, Waldorf Astoria
Los Angeles	Sheraton Gateway, The Westin Los Angeles Airport
Houston	Magnolia Hotel, Crowne Plaza Houston River Oaks

Table 1: Details of our FOUR-CITIES evaluation data.

Unfortunately, the CHICAGO dataset is limited, both in size (800 reviews) and scope, in that it only contains reviews of hotels in one city: Chicago. Accordingly, in order to perform a more realistic evaluation for our task, we construct a new dataset, FOUR-CITIES, that contains 40 deceptive and 40 truthful reviews from each of eight hotels in four different cities (640 reviews total).

We build the FOUR-CITIES dataset using the same procedure as Ott et al (2011), by creating and dividing 320 Mechanical Turk jobs, called *Human-Intelligence Tasks* (HITs), evenly across eight of the most popular hotels in our four chosen cities (see Table 1). Each HIT presents a worker with the name of a hotel and a link to the hotel's website. Workers are asked to imagine that they work for the marketing department of the hotel and that their boss has asked them to write a fake positive review, as if they were a customer, to be posted on a travel review website. Each worker is allowed to submit a single review, and is paid $1 for an acceptable submission.

Finally, we augment our deceptive FOUR-CITIES reviews with a matching set of truthful reviews from TripAdvisor by randomly sampling 40 positive (5-star) reviews for each of the eight chosen hotels. While we cannot know for sure that the sampled reviews are truthful, previous work has suggested that rates of deception among popular hotels is likely to be low (Jindal and Liu, 2008; Lim et al, 2010).

4 Topic Models for Dimensionality Reduction

As mentioned in the introduction, we want to learn patterns of truthful and deceptive reviews that apply

[2] Approaches for identifying individual fake reviews may be applied to our task, for example, by averaging the review-level predictions for an offering. This averaging approach is one of our baselines in Section 7.

[3] We use the dataset available at: `http://www.cs.cornell.edu/~myleott/op_spam`.

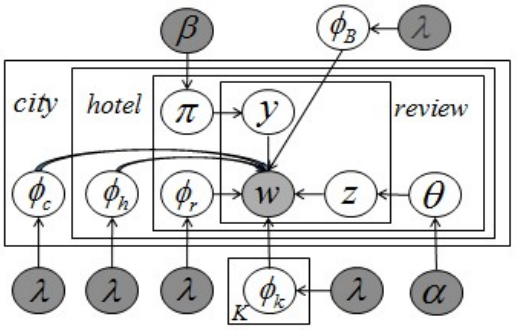

Figure 2: Graphical illustration of the RLDA topic model.

across hotels in different locations. This is challenging, however, because hotel reviews often contain specific information about the hotel or city, and it is unclear whether these features will generalize to reviews of other hotels.

We therefore investigate an LDA-based dimensionality-reduction approach (RLDA) to derive effective vector representations of reviews. Specifically, we model each document as a bag of words, generated from a mixture of: (a) "aspect" topics (that discuss various dimensions of the offering); (b) city-specific topics; (c) hotel-specific topics; (d) review-specific topics;[4] and (e) a background topic. We use this model to reduce the dimensionality of the review representation in our training and test sets, by replacing each review's term vector with a vector corresponding to the distribution over only the aspect-based topics, i.e., we exclude city, hotel and review-specific topics, as well as the background topic.

Below we present specific details of our model (Sections 4.1 and 4.2). The effectiveness of our dimensionality-reduction approach will be directly evaluated in Section 6, by comparing the performance of various classifiers trained either on the full vocabulary, or on our reduced feature representation.

4.1 RLDA Model Details

The plate diagram and generative story for our model are given in Figures 2 and 3, respectively. Our model has a similar general structure to standard LDA, but with additional machinery to handle different levels of information. In particular, in order to model K aspects in a collection of R reviews,

[4]These will be terms used in just a small number of reviews.

- Draw $\phi_B \sim Dir(\lambda)$
- For each aspect $z = 1, 2, ..., K$: draw $\phi^z \sim Dir(\lambda)$
- For each city $c = 1, 2, ..., C$: draw $\phi^c \sim Dir(\lambda)$
- For each hotel $h = 1, 2, ..., H$: draw $\phi^h \sim Dir(\lambda)$
- For each review r:
  - Draw $\pi^r \sim Dir(\beta)$
  - Draw $\phi^r \sim Dir(\lambda)$
  - Draw $\theta^r \sim Dir(\alpha)$
  - For each word w in d:
    - Draw $y_w \sim Multi(\pi_r)$
    - If $y_w = 0$:
      - Draw $z_w \sim Multi(\theta)$
      - Draw $w \sim Multi(\phi^{z_w})$
    - If $y_w = 1$: draw $w \sim Multi(\phi_B)$
    - If $y_w = 2$: draw $w \sim Multi(\phi_d)$
    - If $y_w = 3$: draw $w \sim Multi(\phi_h)$
    - If $y_w = 4$: draw $w \sim Multi(\phi_c)$

Figure 3: Generative story for the RLDA topic model.

of H hotels, in C cities, we first draw multinomial word distributions corresponding to: the background topic, ϕ_B; aspect topics, ϕ_k for $k \in [1, K]$; review-specific topics, ϕ_r for $r \in [1, R]$; hotel-specific topics, ϕ_h for $h \in [1, H]$; and city-specific topics, ϕ_c for $c \in [1, C]$. Then, for each word w in review R, we sample a switch variable, $y \in [0, 4]$, indicating whether w comes from one of the aspect topics ($y = 0$), or the background topic ($y = 1$), review-specific topic ($y = 2$), hotel-specific topic ($y = 3$) or city-specific topic ($y = 4$). If the word comes from one of the aspect topics, then we further sample the specific aspect topic, $z_w \in [1, K]$. Finally, we generate the word, w, from the corresponding ϕ.

4.2 Inference for RLDA

Given the review collection, our goal is to find the most likely assignment y_w (and z_w if $y_w = 0$) for each word, w, in each review. We perform inference using Gibbs sampling. It is relatively straightforward to derive Gibbs sampling equations that allow joint sampling of the z_w and y_w latent variables for each word token w:

$$P(y_w = 0, Z_w = k) = \frac{N^a_{r,-w} + \beta}{N_{r,-w} + 5\beta} \times \frac{C^k_{r,-w} + \alpha}{\sum_k C^k_{r,-w} + K\alpha} \times \frac{E^w_k + \lambda}{\sum_w E^w_k + V\lambda},$$

$$P(y_w = m, m = 1, 2, 3, 4) = \frac{N^m_{r,-w} + \beta}{N_{r,-w} + 5\beta} \times \frac{E^w_m + \lambda}{\sum_w E^w_m + V\lambda},$$

Note that the subscript $-w$ indicates that the count for word token w is excluded. Also, N_r

denotes the number of words in review r and $N^a_{r,-w}, N^1_{r,-w}, N^2_{r,-w}, N^3_{r,-w}, N^4_{r,-w}$ are the number of words in review r assigned to the aspect, background, review-specific, hotel-specific and city-specific topics, respectively, excluding the current word. $C^k_{r,-w}$ denotes the number of words in review r assigned to aspect topic k. $E^w_k, E^w_1, E^w_2, E^w_3, E^w_4$ denote the number of times that the word w is assigned to aspect k, the background topic, review-specific topic r, hotel-specific topic h, and city-specific topic c, respectively. We set hyperparameter α to 1, β to 0.5, λ to 0.01. We run 200 iterations of Gibbs sampling until the topic distribution stabilizes. After each iteration in Gibbs sampling, we obtain:

$$\pi^i_r = \frac{N^i_r + \beta}{\sum_i N^i_r + 5\beta} \quad \theta^k_r = \frac{C^k_r + \alpha}{\sum_k C^k_r + K\alpha}$$
$$\phi^w_z = \frac{E^w_z + \lambda}{\sum_w E^w_z + V\lambda} \quad \phi^w_m = \frac{E^w_m + \lambda}{\sum_w E^w_m + V\lambda} \tag{1}$$

Finally, at the end of Gibbs sampling, we filter out background, document-specific, hotel-specific and city-specific information, by replacing each document's term vector with a $1 \times K$ aspect-topic vector, $\vec{G_r} = \langle \theta^1_r, \theta^2_r, \cdots, \theta^K_r \rangle$.

5 Manifold Ranking for Hotels

In this section, we describe our ranking algorithm — based on manifold ranking (Zhou et al, 2003a; Zhou et al, 2003b) — that tries to jointly model deceptive language at the hotel-, review- and term-level.

5.1 Graph Construction

We use a three-layer (hotel layer, review layer and term layer) mutual reinforcement model (see Figure 1). Formally, we represent our three-layer graph as $G = \langle V_H, V_R, V_T, E_{HR}, E_{RR}, E_{RT}, E_{TT} \rangle$, where $V_H = \{H_i\}_{i=1}^{i=N_H}$, $V_R = \{R\}_{i=1}^{i=H_R}$ and $V_T = \{T_i\}_{i=1}^{i=V}$ correspond to the set of hotels, reviews and terms respectively. E_{HR}, E_{RR} and E_{RT} respectively denote the edges between hotels and reviews, reviews and reviews and reviews and terms. Each edge is associated with a weight that denotes the similarity between two nodes.

Let $sim(H_i, R_j)$, where $H_i \in V_H$ and $R_j \in V_R$, denote the edge weight between hotel H_i and review R_j, calculated as follows:

$$sim(H_i, R_j) = \begin{cases} 1 & if \quad R_i \in H_j \\ 0 & if \quad R_i \notin H_j \end{cases} \tag{2}$$

Then we get row normalized matrices $D_{HR} \in \mathbb{R}^{N_H \times N_R}$ and $D_{RH} \in \mathbb{R}^{N_R \times N_H}$ as follows:

$$D_{HR}(i,j) = \frac{sim(H_i, R_j)}{\sum_{i'} sim(H_{i'}, R_j)}$$
$$D_{RH}(i,j) = \frac{sim(H_i, R_j)}{\sum_{j'} sim(H_i, R_{j'})} \tag{3}$$

As described in Section 4.2, each review is represented with a $1 \times K$ aspect vector G_r after filtering undesired information. The edge weight between two reviews is then the cosine similarity, $sim(R_i, R_j)$, between two reviews and can be calculated as follows:

$$sim(R_i, R_j) = \frac{\sum_{t=1}^{t=K} G^t_i \cdot G^t_j}{\sqrt{\sum_{t=1}^{t=K} G^{t2}_i} \cdot \sqrt{\sum_{t=1}^{t=K} G^{t2}_j}} \tag{4}$$

Since the normalization process will make the review-to-review relation matrix asymmetric, we adopt the following strategy: let P denote the similarity matrix between reviews, where $P(i,j) = sim(R_i, R_j)$ and M denotes the diagonal matrix with (i,i)-element equal to the sum of the i^{th} row of SIM. The normalized matrix between reviews $D_{RR} \in \mathbb{R}^{N_R \times N_R}$ is calculated as follows:

$$D_{RR} = M^{-\frac{1}{2}} \cdot P \cdot M^{-\frac{1}{2}} \tag{5}$$

$sim(R_i, w_j)$ denotes the similarity between review R_i and term w_j and is the conditional probability of word w_j given review R_i. If $w_j \in R_j$, $sim(R_i, w_j)$ is calculated according to Eq. (6) by integrating out latent parameters θ and π. Else if $w_j \notin R_j$, $sim(R_i, w_j) = 0$.

$$\begin{aligned} sim(R_i, w_j) &= \sum_{k=1}^{k=K} p(z=k|r_i) \times p(w_j|z=k) \\ &\quad + \sum_{t \in \{B,h,c,d\}} p(w_j|y_i=t) p(y_i=t|r_i) \\ &= \pi^{(a)}_d \sum_{k=1}^{k=K} \theta^z_d \cdot \phi^{(w_j)}_z + \sum_{t \in \{B,h,c,d\}} \pi^{(t)}_d \phi^{(w_j)}_t \end{aligned} \tag{6}$$

Similar to Eq. (3), we further get the normalized matrix $D_{RT} \in \mathbb{R}^{H_R \times V}$ and $D_{TR} \in \mathbb{R}^{V \times H_R}$.

Similarity between terms $sim(w_i, w_j)$ is given by the WordNet path-similarity,[5] normalized to create the matrix D_{VV}.

[5]Path-similarity is based on the shortest path that connects the senses in the "is-a" (hypernym/hyponym) taxonomy. See `http://nltk.googlecode.com/svn/trunk/doc/howto/wordnet.html`.

Input: The hotel set V_D, review set V_R, term set V_T, normalized transition probability matrix $D_{HR}, D_{RR}, D_{RH}, D_{RT}, D_{TT}, D_{TR}$.
Output: the ranking vectors S_R, S_H, S_T.
Begin:

1. Initialization: set the score labeled reviews to $+1$ or -1 and other unlabeled reviews 0: $S_R^0 = [+1, ..., +1, -1, ..., -1, 0, ..., 0]$. Set S_H^0 and S_T^0 to 0. Normalize the score vector.
2. update S_R^k, S_H^k and S_T^k according to Eq. (7).
3. normalize S_R^k, S_H^k and S_T^k.
4. fix the score of labeled reviews to $+1$ and -1. Go to step (2) until convergence.

Figure 4: Semi-Supervised Reinforcement Ranking.

5.2 Reinforcement Ranking Based on the Manifold Method

Based on the set of labeled reviews, nodes for truthful reviews (positive) are initialized with a high score (1) and nodes for deceptive reviews, a low score (-1). Given the weighted graph, our task is to assign a score to the each hotel, each term, and the remaining unlabeled reviews. Let S_H, S_R and S_T denote the ranking scores of hotels, reviews and terms, which are updated during each iteration as follows until convergence[6]:

$$\begin{cases} S_H^{k+1} = D_{HR} \cdot S_R^k \\ S_R^{k+1} = \epsilon_1 D_{RR} \cdot S_R^k + \epsilon_2 D_{RH} \cdot S_H^k + \epsilon_3 D_{RT} \cdot S_t^k \\ S_T^{k+1} = \epsilon_4 D_{TT} \cdot S_T^k + \epsilon_5 D_{TR} \cdot S_R^k \end{cases} \tag{7}$$

where $\epsilon_1 + \epsilon_2 + \epsilon_3 = 1$ and $\epsilon_4 + \epsilon_5 = 1$. (The score of labeled reviews will be fixed to $+1$ or -1.)

6 Learning Generalizable Classifiers

In Section 4, we introduced RLDA to filter out review-, hotel- and city-specific information from our vector-based review representation. Here, we will directly evaluate the effectiveness of RLDA by comparing the performance of binary deceptive vs. truthful classifiers trained on three feature sets: (a) the full vocabulary, encoded as unigrams and bigrams (N-GRAMS); (b) a reduced-dimensionality feature space, based on standard LDA (Blei et al, 2003); and (c) a reduced-dimensionality feature space, based on our proposed revised LDA approach (RLDA).

We compare two kinds of classifiers, which are trained on only the labeled CHICAGO dataset and tested on the FOUR-CITIES dataset. First, we use SVM^{light} (Joachims, 1999) to train linear SVM classifiers, which have been shown to perform well in related work (Ott et al, 2011). Second, we train a two-layer manifold classifier, which is a simplified version of the model presented in Section 5. In this model, the graph consists of only review and term layers, and the score of a labeled review is fixed to 1 or -1 in each iteration. After convergence, reviews with scores greater than 0 are classified as truthful, and less than 0 as deceptive.

Results and Discussion The results are shown in Table 2 and show the average accuracy and precision/recall w.r.t. the *truthful* (positive) class. We find that SVM and MANIFOLD are comparable in all six conditions, and not surprisingly, perform best when evaluated on reviews from the two Chicago hotels in our FOUR-CITIES data. However, the N-GRAM and LDA feature sets perform much worse than RDLA when evaluation is performed on reviews from the other three (non-Chicago) cities. This confirms that classifiers trained on n-gram features overfit to the training data (CHICAGO) and do not generalize well to reviews from other cities. In addition, the standard LDA-based method for dimensionality reduction is not sufficient for our specific task.

7 Identifying Manipulated Hotels

In this section, we evaluate the performance of our manifold ranking approach (see Section 5) on the task of identifying *manipulated hotels*.

Baselines. We consider several baseline ranking approaches to compare to our manifold ranking approach. Like the manifold ranking approach, the baselines also employ both the CHICAGO dataset (labeled) and FOUR-CITIES dataset (**without** labels).[7] For fair comparison, we use identical processing techniques for each approach. Topic number is set

[6] Convergence is achieved if the difference between ranking scores in two consecutive iterations is less than 0.00001.

[7] While we have not investigated the effects of unlabeled data in detail, providing additional unlabeled data (beyond the test set) boosts the manifold ranking performances reported below by 1-2%.

city	feature set	SVM			Manifold		
		Accuracy	Precision	Recall	Accuracy	Precision	Recall
Chicago	N-GRAMS	0.831	0.844	0.818	0.835	0.844	0.825
	LDA	0.833	0.846	0.819	0.817	0.832	0.802
	RLDA	0.830	0.838	0.822	0.841	0.819	0.863
Non-Chicago	N-GRAMS	0.728	0.744	0.714	0.733	0.738	0.727
	LDA	0.714	0.696	0.732	0.728	0.715	0.741
	RLDA	0.791	0.799	0.780	0.801	0.787	0.815

Table 2: Binary classification results showing that n-gram features overfit to the CHICAGO training data. Results correspond to evaluation on reviews for the two Chicago hotels from FOUR-CITIES and non-Chicago FOUR-CITIES reviews (six hotels).

to five for all topic-model-based approaches. Each baseline makes review-level predictions and then ranks each hotel by the average of those predictions.

- **Review-SVR:** Uses linear Tranductive Support Vector Regression with unigram and bigram features, similar to Ott et al. (2011).
- **Review-SVR+LDA (R):** Similar to REVIEW-SVR but uses our revised LDA (RLDA) topic model for dimensionality reduction **(R)**.
- **Two-Layer Manifold (S):** A simplified version of our model where the hotel-level is removed from the graph. Dimensionality reduction is performed using standard LDA **(S)**.
- **Two-Layer Manifold (R):** Similar to TWO-LAYER MANIFOLD (S) but uses the revised LDA (RLDA) model for dimensionality reduction.
- **Three-layer Manifold (tf-idf):** Our three-layer manifold ranking model, except with each review represented as a TF-IDF term vector. Review similarity is calculated based on the cosine similarity between these vectors.

Evaluation Method. To evaluate ranking performance in the absence of a gold standard set of manipulated hotels, we rearrange the FOUR-CITIES test set of 40 truthful and 40 deceptive reviews for each of eight hotels: we create 41 *versions* of each hotel, where each hotel version contains a different number of injected deceptive reviews, ranging from 0 to 40. For example, the first version of a hotel will have 40 truthful and 0 deceptive reviews, the second version 39 truthful and 1 deceptive, and the 41st version 0 truthful and 40 deceptive. In total, we generate $41 \times 8 = 328$ versions of hotel reviews. We expect versions with larger proportions of deceptive reviews to receive lower scores by the ranking models (i.e., they are ranked higher/more deceptive).

Metrics. To qualitatively evaluate the ranking results, we use the Normalized Discounted Cumulative Gain (NDCG), which is commonly used to evaluate retrieval algorithms with respect to an ideal relevance-based ranking. In particular, NDCG rewards rankings with the most relevant results at the top positions (Liu, 2009), which is also our objective, namely, to rank versions that have higher proportions of deceptive reviews nearer to the top.

Let $R(m)$ denote the relevance score of m^{th} ranked hotel version. Then, NDCG_N is defined as:

$$NDCG_N = \frac{1}{IDCG_N} \sum_{m=1}^{m=N} \frac{2^{R(m)} - 1}{log_2(1+m)} \quad (8)$$

where $IDCG_N$ refers to discounted cumulative gain (DCG) of the ideal ranking of the top N results. We define the ideal ranking according to the proportion of deceptive reviews in different versions, and report NDCG scores for the Nth ranked hotel versions ($N = 8$ to 321), at intervals of 8 (to account for ties among the eight hotels).

Results and Discussion. NDCG results are shown in Figure 5. We observe that our approach (using 2, 5 or 10 topics) generally outperforms the other approaches. In particular, approaches that use our RLDA text representation (OUR APPROACH, TWO-LAYER MANIFOLD (R), and REVIEW-SVR+LDA (R)), which tries to remove city- and hotel-specific information, perform better than those that use the full vocabulary (REVIEW-SVR, TWO-LAYER MANIFOLD (S), and THREE-LAYER MANIFOLD (TF-IDF)). This further confirms that our RLDA dimensionality reduction technique allows models,

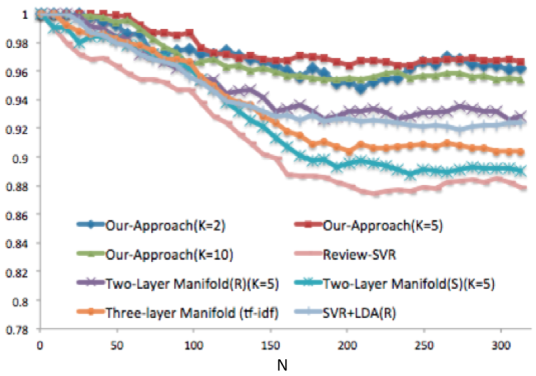

Figure 5: NDCG_N results for different approaches. K indicates the number of topics.

trained on limited data, to generalize to reviews of different hotels and in different locations. We also find that approaches that model a reinforcing relationship between hotels and their reviews are better than approaches that model reviews as independent units, e.g., TWO-LAYER MANIFOLD (R) vs. REVIEW-SVR+LDA and TWO-LAYER MANIFOLD (S) vs. REVIEW-SVR. This confirms our intuition that a hotel is more deceptive if it is connected with many deceptive reviews, and, in turn, a review is more deceptive if from a deceptive hotel.

8 Qualitative Evaluation

We now present qualitative evaluations for the RLDA topic model and the manifold ranking model.

Topic Quality. Table 3 gives the top words for four aspect topics and four city-specific topics in the RLDA topic model; Table 4 gives the highest and lowest ranking term weights in our three-layer manifold model. By comparing the first row of topics in Table 3, corresponding to aspect topics, to the top words in Table 4, we observe that the learned topics relate to truthful and deceptive classes. For example, Topics 1 and 4 share many terms with the top truthful terms in the manifold model, e.g., spatial terms, such as `location`, `floor` and `block`, and punctuation, such as `(`, `)`, and `$`. Similarly, Topics 2 and 7 share many terms with the top deceptive terms in the manifold model, e.g., `hotel`, `husband`, `wife`, `amazing`, `experience` and `recommend`. This makes sense, since topic models have been shown to produce discriminative topics on this data in previous work (Li et al., 2013).

Topic1	**Topic2**	**Topic4**	**Topic7**
location	hotel	(	hotel
$	stay	room	service
walk	staff	)	husband
night	restaurant	park	amazing
block	friendly	bed	will
floor	room	night	weekend
quiet	recommend	shower	friendly
nice	love	view	travel
lobby	excellent	minute	experience
breakfast	wife	pillow	friend
NYC	**Chicago**	**LA**	**Houston**
York	Chicago	los	Houston
ny	Michigan	Angeles	downtown
time	mile	la	Texas
square	tower	lax	cab
nyc	Illinois	shuttling	Westside
street	avenue	hollywood	center
empire	Rogers	plane	Northwest
Chinatown	river	morning	st
station	Burnham	California	museum
Wall	Goodman	downtown	mission

Table 3: Top words in topics extracted from RLDA topic model (see Section 4). The top row presents topic words from four aspect topics ($K = 10$) and the bottom row presents top words from four city-specific topics.

Deceptive		**Truthful**	
term	**score**	**term**	**score**
my	-1.063	$	0.964
visit	-0.944	location	0.922
we	-0.882	(	0.884
hotel	-0.863	)	0.884
husband	-0.828	bathroom	0.842
family	-0.824	floor	0.810
amazing	-0.782	breakfast	0.784
experience	-0.740	bar	0.762
recommend	-0.732	block	0.747
wife	-0.680	small	0.721
relax	-0.678	but	0.720
vacation	-0.651	walk	0.707
will	-0.651	lobby	0.707
friendly	-0.646	quiet	0.684

Table 4: Term scores from our ranking algorithm.

With respect to the second row in Table 4, containing top words from city-specific topics, we observe that each topic does contain primarily city-specific information. This helps to explain why removing terms associated with these topics resulted in a better vector representation for reviews.

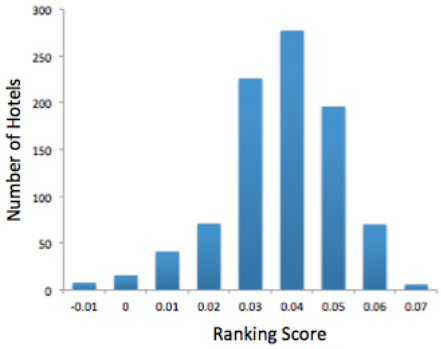

Figure 6: Hotel Ranking Distribution on TripAdvisor

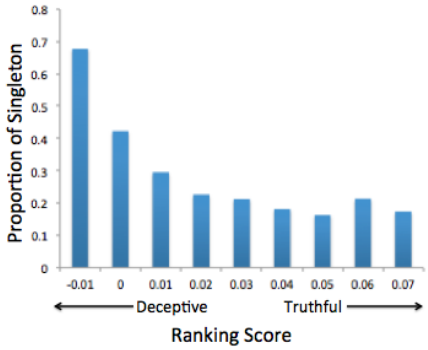

Figure 7: Proportion of Singletons vs. Hotel Ranking.

Real-world Evaluation. Finally, we apply our ranking model to a large-scale collection of real-world reviews from TripAdvisor. We crawl 878,561 reviews from 3,945 hotels in 25 US cities from TripAdvisor excluding all non-5-star reviews and removing hotels with fewer than 100 reviews. In the end, we collect 244,810 reviews from 838 hotels.

We apply our manifold ranking model and rank all 838 hotels. First, we present a histogram of the resulting manifold ranking scores in Figure 6. We observe that the distribution reaches a peak around 0.04, which in our quantitative evaluation (Section 7) corresponded to a hotel with 34 truthful and 6 deceptive reviews. These results suggest that the majority of reviews in TripAdvisor are truthful, in line with previous findings by Ott et al. (2011).

Next, we note that previous work has hypothesized that deceptive reviews are more likely to be posted by first-time review writers, or *singleton* reviewers (Ott et al, 2011; Wu et al, 2011). Accordingly, if this hypothesis were valid, then manipulated hotels would have an above-average proportion of singleton reviews. Figure 7 shows a histogram of the average proportion of singleton reviews, as a function of the ranking scores produced by our model. Noting that lower scores correspond to a higher predicted proportion of deceptive reviews, we observe that hotels that are ranked as being more deceptive by our model have much higher proportions of singleton reviews, on average, compared to hotels ranked as less deceptive.

9 Conclusion

We study the problem of identifying manipulated offerings on review portals and propose a novel three-layer graph model, based on manifold ranking for ranking offerings based on the proportion of reviews expected to be instances of deceptive opinion spam. Experimental results illustrate the effectiveness of our model over several learning-based baselines.

Abstract

Recommendation systems (RS) take advantage of products and users information in order to propose items to consumers. Collaborative, content-based and a few hybrid RS have been developed in the past. In contrast, we propose a new domain-independent semantic RS. By providing textually well-argued recommendations, we aim to give more responsibility to the end user in his decision. The system includes a new similarity measure keeping up both the accuracy of rating predictions and coverage. We propose an innovative way to apply a fast adaptation scheme at a semantic level, providing recommendations and arguments in phase with the very recent past. We have performed several experiments on films data, providing textually well-argued recommendations.

1 Introduction

Recommender systems aim at suggesting appropriate items to users from a large catalog of products. Those systems are individually adapted by using a specific profile for each user and item, derived from the analysis of past ratings. The last decade has shown a historical change in the way we consume products. People are getting used to receive recommendations. Nevertheless, after a few bad recommendations, users will not be convinced anymore by the RS. Moreover, if these suggestions come without explanations, why people should trust it? Numbers and figures cannot talk to people.

To answer these key issues, we have designed a new semantic recommender sytem (SRS) including at least two innovative features:

- Argumentation: each recommendation relies on and comes along with a textual argumentation, providing the reasons that led to that recommendation.
- Fast adaptation: the system is updated in a continuous way, as each new review is posted.

In doing so, the system will be perceived as less intrusive thanks to well-chosen words and its failures will be smoothed over. It is therefore necessary to design a new generation of RS providing textually well-argued recommendations. This way, the end user will have more elements to make a well-informed choice. Moreover, the system parameters have to be dynamically and continuously updated, in order to provide recommendations and arguments in phase with the very recent past. To do so, we have adapted the algorithms we described in Gaillard (Gaillard et al., 2013), by including a semantic level, i.e words, terms and phrases as they are naturally expressed in reviews.

This paper is structured as follows. In the next section, we present the state of the art in recommendation systems and introduce some of the improvements we have made. Then, we present our approach and define the associated methods in section 3. We describe the evaluation protocol and how we have performed some experiments in section 4. Finally we report results including a comparison to a baseline in section 5.

2 Related work and choice of a baseline

We present here some methods used in the literature. Collaborative Filtering (CF) systems use logs

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1943–1947,
Seattle, Washington, USA, 18-21 October 2013.

of users, generally user ratings on items (Burke, 2007; Sarwar et al., 1998). In these systems, the following assumption is made: if user a and user b rate n items similarly, they will rate other items in the same way (Deshpande and Karypis., 2004). This technique has many well-known issues such as the "cold start" problem, i.e when new items or users appear, it is impossible to make a recommendation, due to the absence of rating data (Schein et al., 2002). Other limitations of RS are sparsity, scalability, overspecialization and domain-dependency problems.
In Content Based Filtering (CBF) systems, users are supposed to be independent (Mehta et al., 2008). Hence for a given user, recommendations rely only on items he previously rated.

Some RS incorporate semantic knowledge to improve quality. Generally, they apply a concept-based approach to enhance the user modeling stage and employ standard vocabularies and ontology resources. For instance, ePaper (scientific-paper recommender), computes the matching between the concepts constituting user interests and the concepts describing an item by using hierarchical relationships of domain concepts (Maidel et al., 2008). Codina and Ceccaroni (2010) propose to take advantage of semantics by using an interest-prediction method based on user ratings and browsing events.
However, none of them are actually based on the user opinion as it is expressed in natural language.

2.1 Similarity measures

Similarity measures are the keystone of RS (Herlocker et al., 2005). Resnick (1997) was one of the first to introduce the Pearson correlation coefficient to derive a similarity measure between two entities. Other similarity measures such as Jaccard and Cosine have been proposed (Meyer, 2012). Let S_u be the set of items rated by u, T_i the set of users who have rated item i, $r_{u,i}$ the rating of user u on item i and $\overline{r_x}$ the mean of x (user or item). PEA(i,j) stands for the Pearson similarity between items i and j and is computed as follows:

$$\frac{\sum_{u \in T_i \cap T_j}(r_{u,i} - \overline{r_i})(r_{u,j} - \overline{r_j})}{\sqrt{\sum_{u \in T_i \cap T_j}(r_{u,i} - \overline{r_i})^2 \sum_{u \in T_i \cap T_j}(r_{u,j} - \overline{r_j})^2}} \quad (1)$$

In the remainder, the Pearson similarity measure will be used as a baseline. The Manhattan Weighted and Corrected similarity (MWC), that we introduced in (Gaillard et al., 2013), will be used as a point of comparison as well[1]. Again, for none of them, textual content is taken into account.

2.2 Rating prediction

Let i be a given item and u a given user. We suppose the pair (u, i) is unique. Indeed, most of social networks do not allow multiple ratings by the same user for one item. In this framework, two rating prediction methods have to be defined: one user oriented and the other item oriented. *Sim* stands for some similarity function in the following formula.

$$rating(u,i) = \frac{\sum_{v \in T_i} Sim(u,v) \times r_{v,i}}{\sum_{v \in T_i} |Sim(u,v)|} \quad (2)$$

A symmetrical formula for items $rating(i,u)$ is derived from and combined with (2).

$$\hat{r}_{u,i} = \beta \times rating(u,i) + (1-\beta) \times rating(i,u) \quad (3)$$

3 Methods

In this section, we describe the methods we have used and propose some of the enhancements we have elaborated in our system. In formula (2), Sim can be replaced by several similarity such as Pearson, Cosine or MWC similarity (Tan et al., 2005). All these methods provide a measurement of the likeness between two objects. We then conclude if two users (or items) are "alike" or not. One has to define what "alike" should mean in this case. If two users rate the same movies with equals ratings, then these similarities will be maximal. However, they may have rated identically but for completely different reasons, making them not alike at all. Moreover, none of these similarity measures can express why two users or items are similar. This is due to the fact that they rely on ratings only.

3.1 New similarity based on words

We propose a new similarity method, taking into account words used by users in their past reviews about items. In the remainder, we call it the *Word Based Similarity* (WBS). Each user x (or item) has a vocabulary set V_x and each word w in it is associated

[1] Details on MWC can be found in supplementary material.

with a set of ratings $\mathbf{R}_{w,x}$ and an average usage rating $\overline{r_w}$. In order to balance the contribution of each word, we define a weight function F_w, mixing the well-known Inverse Document Frequency $IDF(w)$ with the variance σ_w^2. Common words and words w associated with very heterogenous ratings $\mathbf{R}_{w,x}$ (i.e a high variance) will have a smaller weight in the similarity. N_w is the number of items in which the word w appears. N_{tot} is the total number of items. D is the maximum difference between two ratings. Note that F_w has to be updated at each iteration.

$$F_w = -log\left(\frac{N_w}{N_{tot}}\right) \times \frac{1}{\sigma_w^2} \tag{4}$$

$$WBS(x,y) = \frac{\sum_{w \in V_x \cap V_y} (D - |\overline{r_{w,x}} - \overline{r_{w,y}}|) F_w}{D \times |V_x \cap V_y| \sum_{w \in V_x \cap V_y} F_w} \tag{5}$$

3.2 Adaptation

An adaptive framework proposed in (Gaillard et al., 2013) allows the system to have a dynamic adaptation along time, overcoming most of the drawbacks due to the cold-start. The authors have designed a dynamic process following the principle that every update (u, i) needs to be instantly taken into account by the system. Consequently, we have to update the σ_w^2 and IDF(w) at each iteration, for every word. Paying attention to avoid a whole re-estimation of these two variables, we derived an iterative relation for the two of them[2]. We thus reduced the complexity by one degree, keeping our system very well-fitted to dynamic adaptation.

3.3 Textual recommendation

The main innovative feature of our proposal is to predict what a user is going to write on an item we recommend. More precisely, we can tell the user why he is expected to like or dislike the recommended item. This is possible thanks to the new similarity measure we have introduced (WBS). Let us consider a user u and an item i. To keep it simple, the system takes into account what u has written on other items in the past and what other users have written on item i, by using WBS. The idea consists in extracting what elements of i have been liked or disliked by other users, and what u generally likes. At the intersection of these two pieces of information, we extract a set of matching words that we sort by relevance using F_w. Then, by taking into account the ratings associated with each word, we define two sub-sets P_w and N_w. P_w contains what user u is probably going to like in i and N_w what u may dislike. Finally, we provide the most relevant arguments contained in both P_w and N_w, and each of them is given in the context they have been used for item i. As an example, some outputs are shown in section 5.2.

[2]More details can be found in the supplementary material.

4 Evaluation criteria

We present here the evaluation protocol we designed. It should be noted that we are not able to make online experiments. Therefore, we can not measure the feedback on our recommendations. However, the cornerstone of recommender system is the accuracy of rating predictions (Herlocker et al., 2004). From this point of view, one could argue that the quality of a recommender engine could be assessed by its capacity to predict ratings. It is thus possible to evaluate our system comparing the prediction $\hat{r}_{u,i}$ for a given pair (u, i), with the actual real rating $r_{u,i}$.

The classical metrics[3] (Bell et al., 2007) *Root Mean Square Error* (RMSE) and *Mean Absolute Error* (MAE) will be used to evaluate our RS.

Last but not least, we make the following assumption: if WBS results are as good as MWC's, the words presented by the system to users as arguments are likely to be relevant.

5 Experiments

This work has been carried out in partnership with the website Vodkaster [4], a Cinema social network. Researchers have used other datasets such as the famous Netflix. Unfortunately, the latter does not include textual reviews. It is therefore strictly impossible to experiment a SRS on such a dataset.

5.1 Corpus

The corpus has been extracted from Vodkaster's database. Users post *micro-reviews* (MR) to express their opinion on a movie and rate it, within a

[3]Details on metrics are given in the supplementary material.

[4]www.vodkaster.com

140 characters Twitter-like length limit. We divided the corpus into three parts, chronologically sorted: training (Tr), development (D) and test (T). Note that in our experiments, the date is taken into account since we also work on dynamic adaptation.

5.2 Results

Figure 1 compares four different methods: the classical Pearson (PEA) method that does not allow quick adaptation, the MWC method with and without quick adaptation MNA and ours (WBS). Within the confidence interval, in terms of accuracy,

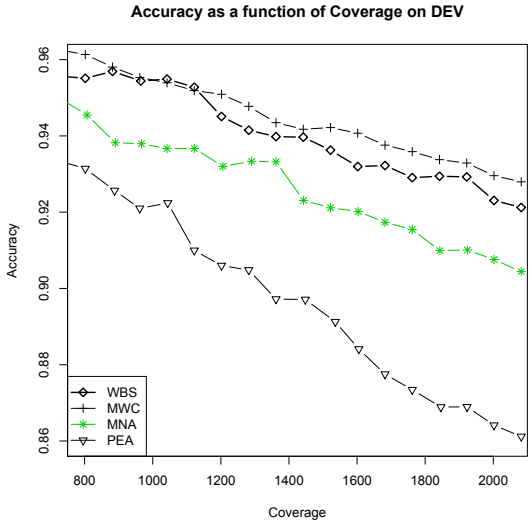

Figure 1: Evolution of accuracy as a function of coverage for PEA, MWC and WBS methods on D corpus.

the same performances are obtained by MWC and WBS. Both outperform[5] PEA and MNA. Our word based approach is thus able to offer the arguments feature without any loss of perfomances with respect to any others RS methods that we know of.

In Table 2, we set a constant coverage (2000 predictions) in order to be able to compare results obtained with different methods.

Corp.	Met.	RMSE	MAE	%Acc.	CI
D	PEA	0.99	0.76	86.41	1.49
E	MNA	0.93	0.72	90.75	1.26
V	MWC	0.89	0.69	92.95	1.12
	WBS	0.89	0.70	92.45	1.16
T	PEA	1.01	0.78	86.02	1.51
E	MNA	0.98	0.75	90.04	1.30
S	MWC	0.92	0.71	91.46	1.22
T	WBS	0.94	0.72	91.15	1.24

Table 2: Results with Pearson (PEA), MWC, MWC without Adaptation (MNA), WBS. CI is the radius confidence interval estimated in % on accuracy (Acc.).

MNA (MWC without adaptation) being better and more easily updated than Pearson (PEA), we have decided to use the adaptive framework only for MWC. Moreover, for Pearson dynamic adaptation, the updating algorithm complexity is increased by one degree.
We want to point out that the results are the same for both MWC and WBS methods, within a confidence interval (CI) radius of 1.16%. From a qualitative point of view, these results can be seen as an assessment of our approach based on words.

Example of outputs: The movie *Apocalypse Now* is recommended to user Theo6 with a rating prediction equal to 4.3. Why he might like: *some brillant moments* (0.99), *among the major masterpiece* (0.91), *Vietnam's hell* (0.8); dislike: *did not understand everything but...* (0.71).

The data we have does not contain the information on the reaction of the user to the recommendation. In particular, we do not know if the textual argumentation would have been sufficient for convincing Theo6 to see the film. But we know that after seeing it, he put a good rating (4.5/5) on this movie.

[5]Note that the key point here is the comparison of results obtained with the baseline and with the method we propose. Both of them have been evaluated with the same protocol: RMSE is computed with respect to rating predictions above some empirical threshold as done in (Gaillard et al., 2013).

6 Conclusion and perspectives

We have presented an innovative proposal for designing a domain-independent SRS relying on a word based similarity function (WBS), providing textually well-argued recommendations to users. Moreover, this system has been developed in a dynamic and adaptive framework. This might be the first step really made towards an anthromorphic and evolutive recommender. As future work, we plan to evaluate how the quality is impacted by the time dimension (adaptation delay, cache reset,etc.).

Abstract

Minimum Error Rate Training (MERT) remains one of the preferred methods for tuning linear parameters in machine translation systems, yet it faces significant issues. First, MERT is an unregularized learner and is therefore prone to overfitting. Second, it is commonly used on a noisy, non-convex loss function that becomes more difficult to optimize as the number of parameters increases. To address these issues, we study the addition of a regularization term to the MERT objective function. Since standard regularizers such as ℓ_2 are inapplicable to MERT due to the scale invariance of its objective function, we turn to two regularizers—ℓ_0 and a modification of ℓ_2—and present methods for efficiently integrating them during search. To improve search in large parameter spaces, we also present a new direction finding algorithm that uses the gradient of expected BLEU to orient MERT's exact line searches. Experiments with up to 3600 features show that these extensions of MERT yield results comparable to PRO, a learner often used with large feature sets.

1 Introduction

Minimum Error Rate Training emerged a decade ago (Och, 2003) as a superior training method for small numbers of linear model parameters of machine translation systems, improving over prior work using maximum likelihood criteria (Och and Ney, 2002). This technique quickly rose to prominence, becoming standard in many research and commercial MT systems. Variants operating over lattices (Macherey et al., 2008) or hypergraphs (Kumar et al., 2009) were subsequently developed, with the benefit of reducing the approximation error from n-best lists.

The primary advantages of MERT are twofold. It directly optimizes the evaluation metric under consideration (e.g., BLEU) instead of some surrogate loss. Secondly, it offers a globally optimal line search. Unfortunately, there are several potential difficulties in scaling MERT to larger numbers of features, due to its non-convex loss function and its lack of regularization. These challenges have prompted some researchers to move away from MERT, in favor of linearly decomposable approximations of the evaluation metric (Chiang et al., 2009; Hopkins and May, 2011; Cherry and Foster, 2012), which correspond to easier optimization problems and which naturally incorporate regularization. In particular, recent work (Chiang et al., 2009) has shown that adding thousands or tens of thousands of features can improve MT quality when weights are optimized using a margin-based approximation. On simulated datasets, Hopkins and May (2011) found that conventional MERT struggles to find reasonable parameter vectors, where a smooth loss function based on Pairwise Ranking Optimization (PRO) performs much better; on real data, this PRO method appears at least as good as MERT on small feature sets, and also scales better as the number of features increases.

In this paper, we seek to preserve the advantages of MERT while addressing its shortcomings in terms of regularization and search. The idea of adding a regularization term to the MERT objective function can be perplexing at first, because the most common regularizers, such as ℓ_1 and ℓ_2, are not directly applicable to MERT. Indeed, these regularizers are *scale sensitive*, while the MERT objective function is not: scaling the weight vector neither changes the predictions of the linear model nor affects the error count. Hence, MERT can hedge any regularization penalty by maximally scaling down linear model weights.

The first contribution of this paper is to analyze various forms of regularization that are not susceptible to this scaling problem. We analyze and experiment with ℓ_0, a form of regularization that is *scale insensitive*. We also present new parameterizations of ℓ_2

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1948–1959,
Seattle, Washington, USA, 18-21 October 2013.

regularization, where we apply ℓ_2 regularization to scale-senstive linear transforms of the original linear model. In addition, we introduce efficient methods of incorporating regularization in Och (2003)'s exact line searches. For all of these regularizers, our methods let us find the true optimum of the regularized objective function along the line.

Finally, we address the issue of searching in a high-dimensional space by using the gradient of expected BLEU (Smith and Eisner, 2006) to find better search directions for our line searches. This direction finder addresses one of the serious concerns raised by Hopkins and May (2011): MERT widely failed to reach the optimum of a synthetic linear objective function. In replicating Hopkins and May's experiments, we confirm that existing search algorithms for MERT—including coordinate ascent, Powell's algorithm (Powell, 1964), and random direction sets (Cer et al., 2008)—perform poorly in this experimental condition. However, when using our gradient-based direction finder, MERT has no problem finding the true optimum even in a 1000-dimensional space.

Our results suggest that the combination of a regularized objective function and a gradient-informed line search algorithm enables MERT to scale well with a large number of features. Experiments with up to 3600 features show that these extensions of MERT yield results comparable to PRO (Hopkins and May, 2011), a parameter tuning method known to be effective with large feature sets.

2 Unregularized MERT

Prior to introducing regularized MERT, we briefly review standard unregularized MERT (Och, 2003). We use $\mathbf{f}_1^S = \{\mathbf{f}_1 \dots \mathbf{f}_S\}$ to denote the S input sentences of a given tuning set. For each sentence $\mathbf{f}_s$, let $\mathbf{C}_s = \{\mathbf{e}_{s,1} \dots \mathbf{e}_{s,M}\}$ denote the list of M-best candidate translations. Each input and output sentence pair $(\mathbf{f}_s, \mathbf{e}_{s,m})$ is weighted using a linear model that applies model parameters $\mathbf{w} = (w_1 \dots w_D) \in \mathbb{R}^D$ to D feature functions $h_1(\mathbf{f}, \mathbf{e}, \sim) \dots h_D(\mathbf{f}, \mathbf{e}, \sim)$, where $\sim$ is the hidden state associated with the derivation from $\mathbf{f}$ to $\mathbf{e}$, such as phrase segmentation and alignment. Furthermore, let $\mathbf{h}_{s,m} \in \mathbb{R}^D$ denote the feature vector representing the translation pair $(\mathbf{f}_s, \mathbf{e}_{s,m})$.

In MERT, the goal is to minimize a loss function $E(\mathbf{r}, \mathbf{e})$ that scores translation hypotheses against a set of reference translations $\mathbf{r}_1^S = \{\mathbf{r}_1 \dots \mathbf{r}_S\}$. This yields the following optimization problem:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left\{ \sum_{s=1}^{S} E(\mathbf{r}_s, \hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w})) \right\} = \arg\min_{\mathbf{w}} \left\{ \sum_{s=1}^{S} \sum_{m=1}^{M} E(\mathbf{r}_s, \mathbf{e}_{s,m}) \delta(\mathbf{e}_{s,m}, \hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w})) \right\} \quad (1)$$

where

$$\hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w}) = \arg\max_{m \in \{1 \dots M\}} \left\{ \mathbf{w}^\intercal \mathbf{h}_{s,m} \right\} \quad (2)$$

While the error surface of Equation 1 is only an approximation of the true error surface of the MT decoder, the quality of this approximation depends on the size of the hypothesis space represented by the M-best list. Therefore, the hypothesis list is grown iteratively: decoding with an initial parameter vector seeds the M-best lists; next, parameter estimation and M-best list gathering alternate until the cumulative M-best list no longer grows, or until changes of $\mathbf{w}$ between two decoding runs are deemed too small. To increase the size of the hypothesis space, subsequent work (Macherey et al., 2008) instead operated on lattices, but this paper focuses on M-best lists.

A crucial observation is that the unsmoothed error count represented in Equation 1 is a piecewise constant function. This enabled Och (2003) to devise a line search algorithm guaranteed to find the optimum point along the line. To extend the search from one to multiple dimensions, MERT applies a sequence of line optimizations along some fixed or variable set of search directions $\{\mathbf{d}_t\}$ until some convergence criteria are met. Considering a given point $\mathbf{w}_t$ and a given direction $\mathbf{d}_t$ at iteration t, finding the most probable translation hypothesis in the set of candidates translations $\mathbf{C}_s = \{\mathbf{e}_{s,1} \dots \mathbf{e}_{s,M}\}$ corresponds to solving the following optimization problem:

$$\hat{\mathbf{e}}(\mathbf{f}_s; \gamma) = \arg\max_{m \in \{1 \dots M\}} \left\{ (\mathbf{w}_t + \gamma \cdot \mathbf{d}_t)^\intercal \mathbf{h}_{s,m} \right\} \quad (3)$$

The function in this equation is piecewise linear (Papineni, 1999), which enables an efficient exhaustive computation. Specifically, this function is optimized by enumerating the up to M hypotheses that form the *upper envelope* of the model score function. The error count, then, is a piecewise constant function

defined by the points $\gamma_1^{\mathbf{f}_s} < \cdots < \gamma_M^{\mathbf{f}_s}$ at which an increase in γ causes a change of optimum in Equation 3. Error counts for the whole corpus are simply the sums of sentence-level piecewise constant functions aggregated over all sentences of the corpus.[1] The optimal γ is finally computed by enumerating all piecewise constant intervals of the corpus-level error function, and by selecting the one that has the lowest error count (or, correspondingly, highest BLEU score). Assuming the optimum is found in the interval $[\gamma_{k-1}, \gamma_k]$, we define $\gamma_{\text{opt}} = (\gamma_{k-1} + \gamma_k)/2$ and change the parameters using the update $\mathbf{w}_{t+1} = \mathbf{w}_t + \gamma_{\text{opt}} \cdot \mathbf{d}_t$.

Finally, this method is turned into a global D-dimensional search using algorithms that repeatedly use the aforementioned exact line search algorithm. Och (2003) first advocated the use of Powell's method (Powell, 1964; Press et al., 2007). Pharaoh (Koehn, 2004) and subsequently Moses (Koehn et al., 2007) instead use coordinate ascent, and more recent work often uses random search directions (Cer et al., 2008; Macherey et al., 2008). In Section 4, we will present a novel direction finder for maximum-BLEU optimization, which uses the gradient of expected BLEU to find directions where the BLEU score is most likely to increase.

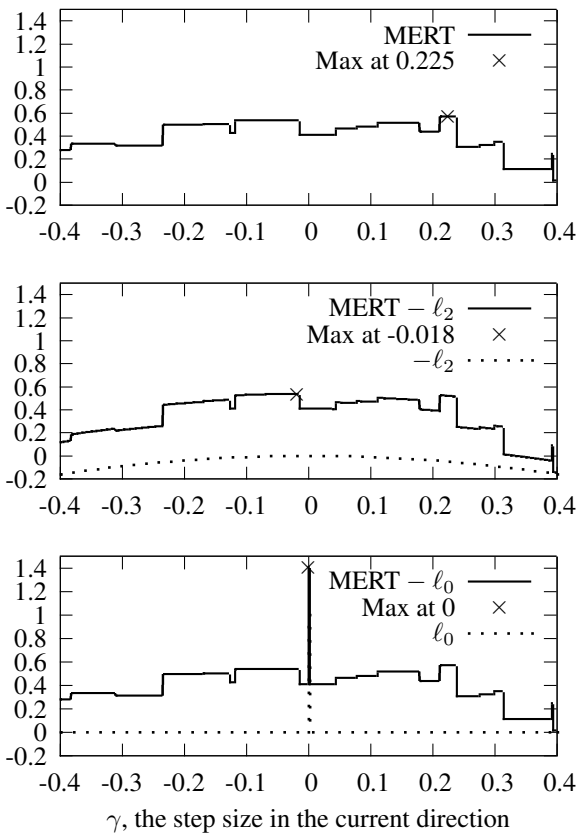

Figure 1: Example MERT values along one coordinate, first unregularized. When regularized with ℓ_2, the piecewise constant function becomes piecewise quadratic. When using ℓ_0, the function remains piecewise constant with a point discontinuity at 0.

3 Regularization for MERT

Because MERT is prone to overfitting when a large number of parameters must be optimized, we study the addition of a regularization term to the objective function. One conventional approach is to regularize the objective function with a penalty based on the Euclidean norm $||\mathbf{w}||_2 = \sqrt{\sum_i w_i^2}$, also known as ℓ_2 regularization. In the case of MERT, this yields the following objective function:[2]

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left\{ \sum_{s=1}^{S} E(\mathbf{r}_s, \hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w})) + \frac{||\mathbf{w}||_2^2}{2\sigma^2} \right\} \quad (4)$$

where the regularization term $1/2\sigma^2$ is a free parameter that controls the strength of the regularization penalty. Similar regularizers have also been used in conjunction with other norms, such as ℓ_1 and ℓ_0 norms. The ℓ_1 norm, defined as $||\mathbf{w}||_1 = \sum_i |w_i|$, applies a constant force toward zero, preferring vectors with fewer non-zero components; ℓ_0, defined as $||\mathbf{w}||_0 = |\{i \mid w_i \neq 0\}|$, simply counts the number of non-zero components of the weight vector, encoding a preference for sparse vectors.

Geometrically, ℓ_2 is a parabola, ℓ_1 is the wedge-shaped absolute value function, and ℓ_0 is an impulse function with a spike at 0. The original formulation (Equation 1) of MERT consists of a piecewise constant representation of the loss, as a function of the step size in a given direction. But with these three reg-

[1] This assumes that the sufficient statistics of the metric under consideration are additively decomposable by sentence, which is the case with most popular evaluation metrics such as BLEU (Papineni et al., 2001).

[2] The ℓ_2 regularizer is often used in conjunction with log-likelihood objectives. The regularization term of Equation 4 could similarly be added to the log of an objective—e.g., log(BLEU) instead of BLEU—but we found that the distinction doesn't have much of an impact in practice.

ularization terms, the function respectively becomes piecewise quadratic, piecewise linear, or piecewise constant with a potential impulse jump for each distinct choice of regularizer. Figure 1 demonstrates this effect graphically.

As discussed in (McAllester and Keshet, 2011), the problem with optimizing Equation 4 directly is that the output of the underlying linear classifier, and therefore the error count, are not sensitive to the scale of $\mathbf{w}$. Moreover, ℓ_2 regularization (as well as ℓ_1 regularization) is scale sensitive, which means any optimizer of this function can drive the regularization term down to zero by scaling down $\mathbf{w}$. As special treatments for ℓ_2, we evaluate three linear transforms of the weight vector, where the vector $\mathbf{w}$ of the regularization term $||\mathbf{w}||_2^2/2\sigma^2$ is replaced with either:

1. an affine transform: $\mathbf{w} - \mathbf{w}_0$
2. a vector with only $(D-1)$ free parameters, e.g., $(1, w'_2, \cdots, w'_D)$
3. an ℓ_1 renormalization: $\mathbf{w}/||\mathbf{w}||_1$

In (1), regularization is biased towards $\mathbf{w}_0$, a weight vector previously optimized using a competitive yet much smaller feature set, such as core features of a phrase-based (Koehn et al., 2007) or hierarchical (Chiang, 2007) system. The requirement that this feature set be small is to prevent overfitting. Otherwise, any regularization toward an overfit parameter vector $\mathbf{w}_0$ would defeat the purpose of introducing a regularization term in the first place.[3] In (2), the transformation is motivated by the observation that the D-parameter linear model of Equation 2 only needs $(D-1)$ degrees of freedom. Fixing one of the components of $\mathbf{w}$ to any non-zero constant and allowing the others to vary, the new linear model retains the same modeling power, but the $(D-1)$ free parameters are no longer scale invariant, i.e., scaling the $(D-1)$-dimensional vector now has an effect on linear model predictions. In (3), the weight vector is normalized as to have an ℓ_1-norm equal to 1. In contrast, the ℓ_0 norm is scale insensitive, thus not affected by this problem.

3.1 Exact line search with regularization

Optimizing with a regularized error surface requires a change in the line search algorithm presented in Section 2, but the other aspects of MERT remain the same, and we can still use global search algorithms such as coordinate ascent, Powell, and random directions exactly the same way as with unregularized MERT. Line search with a regularization term is still as efficient as in (Och, 2003), and it is still guaranteed to find the optimum of the (now regularized) objective function along the line. Considering again a given point $\mathbf{w}_t$ and a given direction $\mathbf{d}_t$ at line search iteration t, finding the optimum γ_{opt} corresponds to finding γ that minimizes:

$$\sum_{s=1}^{S} E(\mathbf{r}_s, \hat{\mathbf{e}}(\mathbf{f}_s; \gamma)) + \frac{||\mathbf{w}_t + \gamma \cdot \mathbf{d}_t||_2^2}{2\sigma^2} \qquad (5)$$

Since regularization does not affect the points at which $\hat{\mathbf{e}}(\mathbf{f}_s; \gamma)$ changes its optimum, the points $\gamma_1^{\mathbf{f}_s} < \cdots < \gamma_M^{\mathbf{f}_s}$ of intersection in the upper envelope remain the same, so the points of discontinuity in the error surface remain the same. The difference now is that the error count on each segment $[\gamma_{i-1}, \gamma_i]$ is no longer constant. This means we need to adjust the final step of line search, which consists of enumerating all $[\gamma_{i-1}, \gamma_i]$, and keeping the optimum of Equation 5 for each segment. $\hat{\mathbf{e}}(\mathbf{f}_s; \gamma)$ remains constant within the segment, so we only need to consider the expression $||\mathbf{w}_t + \gamma \cdot \mathbf{d}_t||_2^2$ to select a segment point. The optimum is either at the left edge, the right edge, or in the middle if the vertex of the parabola happens to lie within that segment.[4] We compute this optimum by finding the value γ for which the derivative of the regularization term is zero. There is an easy closed-form solution:

$$\frac{\mathrm{d}}{\mathrm{d}\gamma}\left[\frac{||\mathbf{w}_t + \gamma \cdot \mathbf{d}_t||_2^2}{2\sigma^2}\right] = 0$$

$$\frac{\mathrm{d}}{\mathrm{d}\gamma}\left[\sum_i (w_{t,i}^2 + 2 \cdot \gamma \cdot w_{t,i} \cdot d_{t,i} + \gamma^2 \cdot d_{t,i}^2)\right] = 0$$

$$\sum_i (2 \cdot w_{t,i} \cdot d_{t,i} + 2 \cdot \gamma \cdot d_{t,i}^2) = 0$$

$$\gamma = -\big(\sum_i w_{t,i} \cdot d_{t,i}\big) / \big(\sum_i d_{t,i}^2\big) = -\frac{\mathbf{w}_t{}^\intercal \mathbf{d}_t}{\mathbf{d}_t{}^\intercal \mathbf{d}_t}$$

This closed-form solution is computed in time proportional to D, which doesn't slow down the com-

[3] (Gimpel and Smith, 2012, footnote 6) briefly mentions the use of such a regularizer with its ramp loss objective function.

[4] When the optimum is either at the left edge γ_{i-1} or right edge γ_i of a segment, we select a point at a small relative distance within the segment ($.999\gamma_{i-1} + .001\gamma_i$, in the former case) to avoid ties in objective values.

putation of Equation 5 for each segment (the construction of each segment of the upper envelope is proportional to D anyway).

We also use ℓ_0 regularization. While minimization of the ℓ_0-norm is known to be NP-hard in general (Hyder and Mahata, 2009), this optimization is relatively trivial in the case of a line search. Indeed, for a given segment, the value in Equation 5 is constant everywhere except where we intersect any of the coordinate hyperplanes, i.e., where one of the coordinates is zero. Thus, our method consists of evaluating Equation 5 at the intersection points between the line and coordinate hyperplanes, returning the optimal point within the given segment. For any segment that doesn't cross any of these hyperplanes, we evaluate the objective function at any point of the segment (since the value is constant across the entire segment).

4 Direction finding

4.1 A Gradient-based direction finder

Perhaps the greatest obstacle in scaling MERT to many dimensions is finding good search directions. In problems of lower dimensions, iterating through all the coordinates is computationally feasible, though not guaranteed to find a global maximum even in the case of a perfect line search. As the number of dimensions increases by orders of magnitude, this coordinate direction approach becomes less and less tractable, and the quality of the search also suffers (Hopkins and May, 2011).

Optimization has traditionally relied on finding the direction of steepest ascent: the gradient. Unfortunately, the objective function optimized by MERT is piecewise constant; while it may admit a subgradient, this direction is generally not very informative. Instead we may consider a smoothed variation of the original approximation. While some variants have been considered (Och, 2003; Flanigan et al., 2013), we use an expected BLEU approximation, assuming hypotheses are drawn from a log-linear distribution according to their parameter values (Smith and Eisner, 2006). That is, we assume the probability of a translation candidate $\mathbf{e}_{s,m}$ is proportional to $(\exp(\mathbf{w}^\intercal \mathbf{h}_{s,m}))^\mu$, where $\mathbf{w}$ are the parameters being optimized, $\mathbf{h}_{s,m}$ is the vector of the features for $\mathbf{e}_{s,m}$, and μ is a scaling parameter. As μ approaches infinity, the distribution places all its weight on the highest scoring candidate.

The log of the BLEU score may be written as:

$$\min\left(1-\frac{R}{C},0\right)+\frac{1}{N}\sum_{n=1}^{N}(\log m_n-\log c_n)$$

where R is the sum of reference lengths across the corpus, C is the sum of candidate lengths, m_n is the number of matched n-grams (potentially clipped), and c_n is the number of n-grams in all candidates.

Given a distribution over candidates, we can use the expected value of the log of the BLEU score. This is a smooth approximation to the BLEU score, which asymptotically approaches the true BLEU score as the scaling parameter μ approaches infinity. While this expectation is difficult to compute exactly, we can compute approximations thereof using Taylor series. Although prior work demonstrates that a second-order Taylor approximation is feasible to compute (Smith and Eisner, 2006), we find that a first-order approximation is faster and very close to the second-order approximation.[5] The first order Taylor approximation is as follows:

$$\min\left(1-\frac{R}{\mathbb{E}[C]},0\right)+\frac{1}{N}\sum_{n=1}^{N}(\log\mathbb{E}[m_n]-\log\mathbb{E}[c_n])$$

where $\mathbb{E}$ is the expectation operator using the probability distribution $P(\mathbf{h};\mathbf{w},\mu)$.

First we note that the gradient $\frac{\partial}{\partial w_i}P(\mathbf{h};\mathbf{w},\mu)$ is

$$P(\mathbf{h};\mathbf{w},\mu)\left(h_i-\sum_{\mathbf{h}'}h_i' P(\mathbf{h}';\mathbf{w},\mu)\right)$$

Using the chain rule, the gradient of the first order approximation to BLEU is as follows:

$$\frac{1}{N}\sum_{n=1}^{N}\Big(\frac{1}{\mathbb{E}[m_n]}\sum_{\mathbf{h}}m_n(\mathbf{h})\frac{\partial P(\mathbf{h};\mathbf{w},\mu)}{\partial w_i} - \frac{1}{\mathbb{E}[c_n]}\sum_{\mathbf{h}}c_n(\mathbf{h})\frac{\partial P(\mathbf{h};\mathbf{w},\mu)}{\partial w_i}\Big)$$

$$+\begin{cases}0 & \text{if } \mathbb{E}[C]>R\\ \frac{R}{\mathbb{E}[C]^2}\sum_{\mathbf{h}}c_1(\mathbf{h})\frac{\partial P(\mathbf{h};\mathbf{w},\mu)}{\partial w_i} & \text{otherwise}\end{cases}$$

[5] Experimentally, we compared our analytical gradient of the first-order Taylor approximation with the finite-difference gradients of the first- and second-order approximations, and we found these three gradients to be very close in terms of cosine similarity (> 0.99). We performed these measurements both at arbitrary points and at points of convergence of MERT.

In the case of ℓ_2-regularized MERT, the final gradient also includes the partial derivative of the regularization penalty of Equation 4, which is w_i/σ^2 for a given component i of the gradient. We do not update the gradient in the case of ℓ_0 regularization since the ℓ_0-norm is not differentiable.

4.2 Search

Our search strategy consists of looking at the directions of steepest increase of expected BLEU, which is similar to that of Smith and Eisner (2006), but with the difference that we do so in the context of MERT. We think this difference provides two benefits. First, while the smooth approximation of BLEU reduces the likelihood of remaining trapped in a local optimum, we avoid approximation error by retaining the original objective function. Second, the benefit of exact line searches in MERT is that there is no need to be concerned about step size, since step size in MERT line searches is guaranteed to be optimal with respect to the direction under consideration.

Finally, our gradient-based search algorithm operates as follows. Considering the current point $\mathbf{w}_t$, we compute the gradient $\mathbf{g}_t$ of the first order Taylor approximation at that point, using the current scaling parameter μ. (We initialize the search with $\mu = 0.01$.) We find the optimum along the line $\mathbf{w}_t + \gamma \cdot \mathbf{g}_t$. Whenever any given line search yields no improvement larger than a small tolerance threshold, we multiply μ by two and perform a new line search. The increase of this parameter μ corresponds to a cooling schedule (Smith and Eisner, 2006), which progressively sharpens the objective function to get a better estimate of BLEU as the search converges to an optimum. We repeatedly perform new line searches until μ exceeds 1000. The inability to improve the current optimum with a sharp approximation ($\mu > 1000$) doesn't mean line searches would fail with smaller values, so we find it helpful to repeat the above procedure until a full pass of updates of μ from 0.01 to 1000 yields no improvement.

4.3 Computational complexity

Computing the gradient increases the computational cost of MERT, though not its asymptotic complexity. The cost of a single exhaustive line search is

$$\mathcal{O}\left(SM(D + \log M + \log S)\right)$$

where S is the number of sentences, each with M possible translations, and D is the number of features. For each sentence, we first identify the model score as a linear function of the step size, requiring two dot products for an overall cost of $\mathcal{O}(SMD)$.[6] Next we construct the upper envelope for each sentence: first the equations are sorted in increasing order of slope, and then they are merged in linear time to form an envelope, with an overall cost of $\mathcal{O}(SM \log M)$. A linear pass through the envelope converts these into piecewise constant (or linear, or quadratic) representations of the (regularized) loss function. Finally the per-sentence envelopes are merged into a global representation of the loss along that direction. Our implementation successively merges adjacent pairs of piecewise smooth loss function representations until a single list remains. These $\log S$ passes lead to a merging runtime of $\mathcal{O}(SM \log S)$.

The time required to compute a gradient is proportional to $\mathcal{O}(SMD)$. For each sentence, we first gather the probability and its gradient, then use this to compute expected n-gram counts and matches as well as those gradients in time $\mathcal{O}(MD)$. A constant number of arithmetic operations suffice to compute the final expected loss value and its gradient. Therefore, computing the gradient does not increase the algorithmic complexity when compared to conventional approaches using coordinate ascent and random directions. Likewise the runtime of a single iteration is competitive with PRO, given that gradient finding is generally the most expensive part of convex optimization. Of course, it is difficult to compare overall runtime of convex optimization with that of MERT, as we know of no way to bound the number of gradient evaluations required for convergence with MERT. Therefore, we resort to empirical comparison later in the paper, and find that the two methods appear to have comparable runtime.

[6] In the special case where the difference between the prior direction and the current direction is sparse, we may update the individual linear functions in time proportional to the number of changed dimensions. Coordinate ascent in particular can update the linear functions in time $\mathcal{O}(SM)$: to the intercept of the equation for each translation, we may add the prior step size multiplied by the feature value in the prior coordinate, and the slope becomes the feature value in the new coordinate. However, this optimization does not appear to be widely adopted, likely because it does not lead to any speedup when random vectors, conjugate directions, or other non-sparse directions are used.

	Language pair	Train	Tune	Dev	Test
GBM	Chinese-English	0.99M	1,797 (mt02+03)	1,000	1,082 (mt05)
	Finnish-English	2.20M	11,935	2,001	4,855
SparseHRM	Chinese-English	3.51M	1,894 (mt05)	1,664 (mt06)	1,357 (mt08)
	Arabic-English	1.49M	1,663 (mt06)	1,360 (mt08)	1,313 (mt09)

Table 1: Datasets for the two experimental conditions.

5 Experimental Design

Following Hopkins and May (2011), our experimental setup utilizes both real and synthetic data. The motivation for using synthetic data is that it is a way of gauging the quality of optimization methods, since the data is constructed knowing the global optimum. Hopkins and May also note that the use of an objective function that is linear in some gold weight vector makes the search much simpler than in a real translation setting, and they suggest that a learner that performs poorly in such a simple scenario has little hope of succeeding in a more complex one.

The setup of our synthetic data experiment is almost the same as that performed by Hopkins and May (2011). We generate feature vectors of dimensionality ranging from 10 to 1000. These features are generated by drawing random numbers uniformly in the interval $[0, 500]$. This synthetic dataset consists of S=1000 source "sentences", and M=500 "translation" hypotheses for each sentence. A pseudo "BLEU" score is then computed for each hypothesis, by computing the dot product between a predefined gold weight vector $\mathbf{w}^*$ and each feature vector $\mathbf{h}_{s,m}$. By this linear construction, $\mathbf{w}^*$ is guaranteed to be a global optimum.[7] The pseudo-BLEU score is normalized for each M-best list, so that the translation with highest model score according to $\mathbf{w}^*$ has a BLEU score of 1, and so that the translation with lowest model score for the sentence gets a BLEU of zero. This normalization has no impact on search, but makes results more interpretable.

For our translation experiments, we use multi-stack phrase-based decoding (Koehn et al., 2007). We report results for two feature sets: non-linear features induced using Gradient Boosting Machines (Toutanova and Ahn, 2013) and sparse lexicalized reordering features (Cherry, 2013). We exploit these feature sets (GBM and SparseHRM, respectively) in two distinct experimental conditions, which we detail in the two next paragraphs. Both GBM and SparseHRM augment baseline features similar to Moses': relative frequency and lexicalized phrase translation scores for both translation directions; one or two language model features, depending on the language pair; distortion penalty; word and phrase count; six lexicalized reordering features. For both experimental conditions, phrase tables have maximum phrase length of 7 words on either side. In reference to Table 1, we used the training set (Train) for extracting phrase tables and language models; the Tune set for optimization with MERT or PRO; the Dev set for selecting hyperparameters of PRO and regularized MERT; and the Test set for reporting final results. In each experimental condition, we first trained weights for the base feature sets, and then decoded the Tune, Dev, and Test datasets, generating 500-best lists for each set. All results report reranking performance on these lists with different feature sets and optimization methods, based on lower-cased BLEU (Papineni et al., 2001).

The GBM feature set (Toutanova and Ahn, 2013) consists of about 230 features automatically induced using decision tree weak learners, which derive features using various word-level, phrase-level, and morphological attributes. For Chinese-English, the training corpus consists of approximately one million sentence pairs from the FBIS and Hong Kong portions of the LDC data for the NIST MT evaluation and the Tune and Test sets are from NIST competitions. A 4-gram language model was trained on the Xinhua portion of the English Gigaword corpus and on the target side of the bitext. For Finnish-English we used a dataset from a technical domain of software manuals. For this language pair we used two language models: one very large model trained on billions of words, and another language model trained from the target side of the parallel training set.

The SparseHRM set (Cherry, 2013) contains 3600 sparse reordering features. For each phrase, the features take the form of indicators describing its orientation in the derivation, and its lexical content in terms of word clusters or frequent words. For both Chinese-English and Arabic-English, systems are trained on data from the NIST 2012 MT evaluation. 4-gram

[7] The objective function remains piecewise constant, and the plateau containing $\mathbf{w}^*$ maps to the optimal *value* of the function.

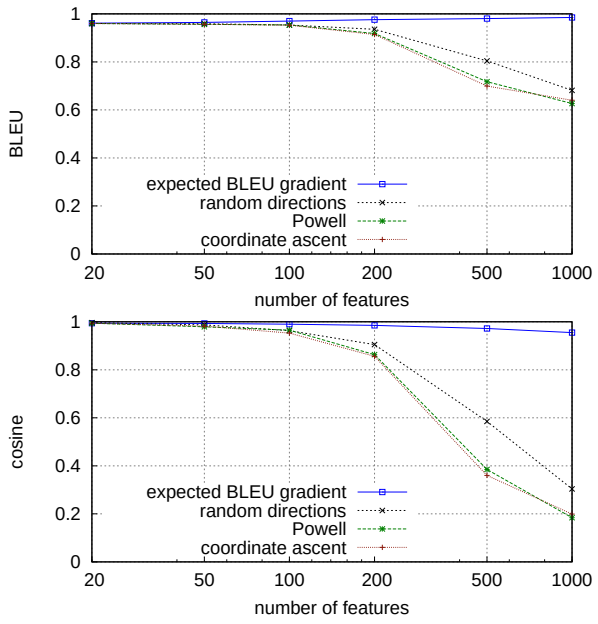

Figure 2: Change in BLEU score and cosine similarity to the gold weight vector $\mathbf{w}^*$ as the number of features increases, using the **noisy** synthetic experiments. The gradient-based direction finding method is barely affected by the noise. The increase of the number of dimensions enables our direction finder to find a slightly better optimum, which moved away from $\mathbf{w}^*$ due to noise.

language models were trained on the target side of the parallel training data for both Arabic and Chinese. The Chinese systems development set is taken from the NIST mt05 evaluation set, augmented with some material reserved from our NIST training corpora in order to better cover newsgroup and weblog domains.

6 Results

We conducted experiments with the synthetic data scenario described in the previous section, as well as with noise added to the data (Hopkins and May, 2011). The purpose of adding noise is to make the optimization task more realistic. Specifically, after computing all pseudo-BLEU scores, we added noise to each feature vector $\mathbf{h}_{s,m}$ by drawing from a zero-mean Gaussian with standard deviation 200. Our results with both noiseless and noisy data yield the same conclusion as Hopkins and May: standard MERT struggles with many dimensions, and fails to recover $\mathbf{w}^*$. However, our experiments with the gradient direction finder of Section 4 are much more positive. This direction finder not only recovers $\mathbf{w}^*$

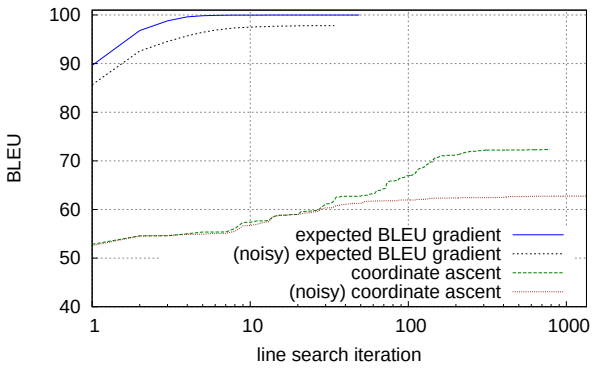

Figure 3: Comparison of rate of convergence between coordinate ascent and our expected BLEU direction finder ($D = 500$). **Noisy** refers to the noisy experimental setting.

(cosine > 0.999) even with 1000 dimensions, but its effectiveness is also visible with noisy data, as seen in Figure 2. The decrease of its cosine is relatively small compared to other search algorithms, and this decrease is not necessarily a sign of search errors since the addition of noise causes the true optimum to be different from $\mathbf{w}^*$. Finally, Figure 3 shows our rate of convergence compared to coordinate ascent.

Our experimental results with the GBM feature set data are shown in Table 2. Each table is divided into three sections corresponding respectively to MERT (Och, 2003) with Koehn-style coordinate ascent (Koehn, 2004), PRO, and our optimizer featuring both regularization and the gradient-based direction finder. All variants of MERT are initialized with a single starting point, which is either uniform weight or $\mathbf{w}_0$. Instead of providing MERT with additional random starting points as in Moses, we use random walks as in (Moore and Quirk, 2008) to attempt to move out of local optima.[8] Since PRO and our optimizer have hyperparameters, we use a held-out set (Dev) for adjusting them. For PRO, we adjust three parameters: a regularization penalty for ℓ_2, the parameter α in the add-α smoothed sentence-level version of BLEU (Lin and Och, 2004), and a parameter for scaling the corpus-level length of the references. The latter scaling parameter is discussed in (He and

[8] In the case of the gradient-based direction finder, we also use the following strategy whenever optimization converges to a (possibly local) optimum. We run one round of coordinate ascent, and continue with the gradient direction finder as soon as the optimum improves. If the none of the coordinate directions helped, we stop the search.

Method	Starting pt.	Chinese-English # feat.	Tune	Dev	Test	Finnish-English # feat.	Tune	Dev	Test
MERT	uniform	14	33.2	19.9	32.9	15	53.0	52.6	54.8
MERT	uniform	224	33.0	19.2	32.1	232	53.2	51.7	53.8
MERT	$\mathbf{w}_0$	224	34.1	20.1	33.0	232	53.9	52.5	54.7
PRO	$\mathbf{w}_0$	224	33.4	20.1	33.3	232	53.3	52.9	55.3
ℓ_2 MERT (v1: $\|\|\mathbf{w} - \mathbf{w}_0\|\|$)	$\mathbf{w}_0$	224	33.2	20.3	33.5	232	53.2	52.7	55.2
ℓ_2 MERT (v2: $D-1$ dimensions)	$\mathbf{w}_0$	224	33.0	20.4	33.2	232	52.9	52.6	55.0
ℓ_2 MERT (v3: ℓ_1-renormalized)	$\mathbf{w}_0$	224	33.1	20.0	33.3	232	53.1	52.5	55.1
ℓ_0 MERT	$\mathbf{w}_0$	224	33.4	20.3	33.2	232	53.2	52.6	55.1

Table 2: BLEU scores for GBM features. Model parameters were optimized on the Tune set. For PRO and regularized MERT, we optimized with different hyperparameters (regularization weight, etc.), and retained for each experimental condition the model that worked best on Dev. The table shows the performance of these retained models.

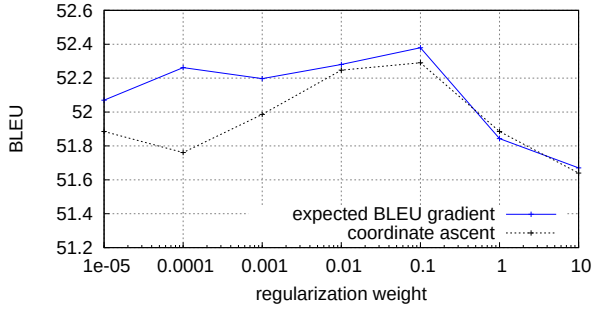

Figure 4: BLEU score on the Finnish Dev set (GBM) with different values for the $1/2\sigma^2$ regularization weight. To enable comparable results, the other hyperparameter (length) is kept fixed.

Deng, 2012; Nakov et al., 2012) and addresses the problem that systems tuned with PRO tend to produce sentences that are too short. On the other hand, regularized MERT only requires one hyperparameter to tune: a regularization penalty for ℓ_2 or ℓ_0. However, since PRO optimizes translation length on the Dev dataset and MERT does so using the Tune set, a comparison of the two systems would yield a discrepancy in length that would be undesirable. Therefore, we add another hyperparameter to regularized MERT to tune length in the same manner using the Dev set.

Table 2 offers several findings. First, unregularized MERT can achieve competitive results with a small set of highly engineered features, but adding a large set of more than 200 features causes MERT to perform poorly, particularly on the test set. However, unregularized MERT can recover much of this drop of performance if it is given a good sparse initializer $\mathbf{w}_0$. Regularized MERT (v1) provides an increase in the order of 0.5 BLEU on the test set compared to the best results with unregularized MERT. Regularized MERT is competitive with PRO, even though the number of features is relatively large. Using the same GBM experimental setting, Figure 4 compares regularized MERT using the gradient direction finder and coordinate ascent. At the best regularization setting, the two algorithms are comparable in terms of BLEU (though coordinate ascent is slower due to its lack of a good direction finder), but our method seems more robust with suboptimal regularization parameters.

Our results with the SparseHRM feature set data are shown in Table 3. As with the GBM feature set, we find again that the version of ℓ_2 MERT regularized towards $||\mathbf{w} - \mathbf{w}_0||$ is competitive with PRO, even though we train MERT with a large set of 3601 features.[9] One remaining question is whether MERT remains practical with large feature sets. As noted in the complexity analysis of Section 4.3, MERT has a dependence on the number of features that is comparable to PRO, i.e., it is linear in both cases. Practically, we find that optimization time is comparable between the two systems. In the case of Chinese-English for the GBM feature set, one run of the PRO optimizer took 26 minutes on average, while regularized MERT with the gradient direction finder took 37 minutes on average, taking into account the time to compute $\mathbf{w}_0$. In the case of Chinese-English for the SparseHRM feature set, average optimization times for PRO and our method were 3.10 hours and 3.84 hours on average, respectively.

[9] We note that the experimental setup of (Cherry, 2013) integrates the Sparse HRM features into the decoder, while we use them in an M-best reranking scenario. The reranking setup of this paper yields smaller improvements for both PRO and MERT than those of (Cherry, 2013).

Method	Starting pt.	Chinese-English # feat.	Tune	Dev	Test	Arabic-English # feat.	Tune	Dev	Test
MERT	uniform	14	25.7	34.0	27.8	14	43.2	42.8	45.5
MERT	uniform	3601	25.4	33.1	27.3	3601	45.7	42.3	44.9
MERT	$\mathbf{w}_0$	3601	27.7	33.5	27.5	3601	46.0	42.4	45.2
PRO	$\mathbf{w}_0$	3601	25.9	34.3	28.1	3601	44.6	43.4	46.1
ℓ_2 MERT (v1: $\|\|\mathbf{w} - \mathbf{w}_0\|\|$)	$\mathbf{w}_0$	3601	26.3	34.3	28.3	3601	45.2	43.2	46.0
ℓ_2 MERT (v2: $D-1$ dimensions)	$\mathbf{w}_0$	3601	26.4	34.1	28.2	3601	45.0	43.4	45.9
ℓ_2 MERT (v3: ℓ_1-renormalized)	$\mathbf{w}_0$	3601	26.1	34.0	27.9	3601	44.9	43.3	45.7
ℓ_0 MERT	$\mathbf{w}_0$	3601	26.5	34.2	28.1	3601	45.4	43.1	46.0

Table 3: BLEU scores for SparseHRM features. Notes in Table 2 also apply here.

Finally, as shown in Table 2, we see that MERT experiments that rely on a good initial starting point $\mathbf{w}_0$ generally perform better than when starting from a uniform vector. While having to compute $\mathbf{w}_0$ in the first place is a bit of a disadvantage compared to standard MERT, the need for good initializer is hardly surprising in the context of non-convex optimization. Other non-convex problems in machine learning, such as deep neural networks (DNN) and word alignment models, commonly require such initializers in order to obtain decent performance. In the case of DNN, extensive research is devoted to the problem of finding good initializers.[10] In the case of word alignment, it is common practice to initialize search in non-convex optimization problems—such as IBM Model 3 and 4 (Brown et al., 1993)—with solutions of simpler models—such as IBM Model 1.

7 Related work

MERT and its extensions have been the target of extensive research (Och, 2003; Macherey et al., 2008; Cer et al., 2008; Moore and Quirk, 2008; Kumar et al., 2009; Galley and Quirk, 2011). More recent work has focused on replacing MERT with a linearly decomposable approximations of the evaluation metric (Smith and Eisner, 2006; Liang et al., 2006; Watanabe et al., 2007; Chiang et al., 2008; Hopkins and May, 2011; Rosti et al., 2011; Gimpel and Smith, 2012; Cherry and Foster, 2012), which generally involve a surrogate loss function incorporating a regularization term such as the ℓ_2-norm. While we are not aware of any previous work adding a penalty on the weights in the context of MERT, (Cer et al., 2008) achieves a related effect. Cer et al.'s goal is to achieve a more regular or smooth objective function, while ours is to obtain a more regular set of parameters. The two approaches may be complementary.

More recently, new research has explored direction finding using a smooth surrogate loss function (Flanigan et al., 2013). Although this method is successful in helping MERT find better directions, it also exacerbates the tendency of MERT to overfit.[11] As an indirect way of controlling overfitting on the tuning set, their line searches are performed over directions estimated over a separate dataset.

8 Conclusion

In this paper, we have shown that MERT can scale to a much larger number of features than previously thought, thanks to regularization and a direction finder that directs the search towards the greatest increase of expected BLEU score. While our best results are comparable to PRO and not significantly better, we think that this paper provides a deeper understanding of why standard MERT can fail when handling an increasingly larger number of features. Furthermore, this paper complements the analysis by Hopkins and May (2011) of the differences between MERT and optimization with a surrogate loss function.

Acknowledgments

We thank the anonymous reviewers for their helpful comments and suggestions.

[10] For example, (Larochelle et al., 2009) presents a pre-trained DNN that outperforms a shallow network, but the performance of the DNN becomes much worse relative to the shallow network once pre-training is turned off.

[11] Indeed, in their Table 3, a comparison between HILS and HOLS suggests tuning set performance improves substantially, while held out performance degrades.

Of words, eyes and brains: Correlating image-based distributional semantic models with neural representations of concepts

Abstract

Traditional distributional semantic models extract word meaning representations from co-occurrence patterns of words in text corpora. Recently, the distributional approach has been extended to models that record the co-occurrence of words with visual features in image collections. These image-based models should be complementary to text-based ones, providing a more cognitively plausible view of meaning grounded in visual perception. In this study, we test whether image-based models capture the semantic patterns that emerge from fMRI recordings of the neural signal. Our results indicate that, indeed, there is a significant correlation between image-based and brain-based semantic similarities, and that image-based models complement text-based ones, so that the best correlations are achieved when the two modalities are combined. Despite some unsatisfactory, but explained outcomes (in particular, failure to detect differential association of models with brain areas), the results show, on the one hand, that image-based distributional semantic models can be a precious new tool to explore semantic representation in the brain, and, on the other, that neural data can be used as the ultimate test set to validate artificial semantic models in terms of their cognitive plausibility.

1 Introduction

Many recent neuroscientific studies have brought support to the view that concepts are represented in terms of patterns of neural activation over broad areas, naturally encoded as vectors in a neural semantic space (Haxby et al., 2001; Huth et al., 2012). Similar representations are also widely used in computational linguistics, and in particular in distributional semantics (Clark, 2012; Erk, 2012; Turney and Pantel, 2010), that captures meaning in terms of vectors recording the patterns of co-occurrence of words in large corpora, under the hypothesis that words that occur in similar contexts are similar in meaning.

Since the seminal work of Mitchell et al. (2008), there has thus being interest in investigating whether corpus-harvested semantic representations can contribute to the study of concepts in the brain. The relation is mutually beneficial: From the point of view of brain activity decoding, a strong correlation between corpus-based and brain-derived conceptual representations would mean that we could use the former (much easier to construct on a very large scale) to make inferences about the second: e.g., using corpus-based representations to reconstruct the likely neural signal associated to words we have no direct brain data for. From the point of view of computational linguistics, neural data provide the ultimate testing ground for models that strive to capture important aspects of human semantic memory (much more so than the commonly used explicit semantic rating benchmarks). If we found that a corpus-based model of meaning can make non-trivial predictions about the structure of the semantic space in the brain, that would make a pretty strong case for the intriguing idea that the model is approximating, in interesting ways, the way in which humans acquire and represent semantic knowledge.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1960–1970,
Seattle, Washington, USA, 18-21 October 2013.

We take as our starting point the extensive experiments reported in Murphy et al. (2012), who showed that purely corpus-based distributional models are at least as good at brain signal prediction tasks as earlier models that made use of manually-generated or controlled knowledge sources (Chang et al., 2011; Palatucci et al., 2009; Pereira et al., 2011), and we evaluate a very recent type of distributional model, namely one that is not extracted from textual data but from *image collections* through automated visual feature extraction techniques. It has been argued that this new generation of image-based distributional models (Bruni et al., 2011; Bruni et al., 2012b; Feng and Lapata, 2010; Leong and Mihalcea, 2011) provides a more realistic view of meaning, since humans obviously acquire a large proportion of their semantic knowledge from perceptual data. The first question that we ask, thus, is whether the more "grounded" image-based models can help us in interpreting conceptual representations in the brain. More specifically, we will compare the performance of different image-based representations, and we will test whether text- and image-based representations are complementary, so that when used together they can better account for patterns in neural data. Finally, we will check for differences between anatomical regions in the degree to which text and/or image models are effective, as one might expect given the well-known functional specializations of different anatomical regions.

2 Brain data

We use the data that were recorded and preprocessed by Mitchell et al. (2008), available for download in their supporting online material.[1] Full details of the experimental protocol, data acquisition and preprocessing can be found in Mitchell et al. (2008) and the supporting material. Key points are that there were nine right-handed adult participants (5 female, age between 18 and 32). The experimental task was to actively think about the properties of sixty objects that were presented visually, each as a line drawing in combination with a text label. The entire set of objects was presented in a random order in six sessions, each object remained on screen for 3 seconds with a seven second fixation gap between presentations.

Mitchell and colleagues examined 12 categories, five objects per category, for a total of 60 concepts (words). Due to coverage limitations, we use 51/60 words representing 11/12 categories. Table 1 contains the full list of 51 words organized by category.

fMRI acquisition and preprocessing Mitchell et al. (2008) acquired functional images on a Siemens Allegra 3.0T scanner using a gradient echo EPI pulse sequence with TR=1000 ms, TE=30 ms and a 60° angle. Seventeen 5-mm thick oblique-axial slices were imaged with a gap of 1-mm between slices. The acquisition matrix was 64×64 with 3.125×3.125×5-mm voxels. They subsequently corrected data for slice timing, motion, linear trend, and performed temporal smoothing with a high-pass filter at 190s cutoff. The data were normalized to the MNI template brain image, spatially normalized into MNI space and resampled to $3\times3\times6$ mm^3 voxels. The voxel-wise percent signal change relative to the fixation condition was computed for each object presentation. The mean of the four images acquired 4s post stimulus presentation was used for analysis.

To create a single representation per object per participant, we took the voxel-wise mean of the six presentations of each word. Likewise to create a single representation per category per participant, we took the voxel-wise mean of all word models per category, per participant.

Anatomical parcellation Analysis was conducted on the whole brain, and to address the question of whether there are differences in models' effectiveness between anatomical regions, brains were further partitioned into frontal, parietal, temporal and occipital lobes. This partitioning is coarse (each lobe is large and serves many diverse functions), but, for an initial test, appropriate, given that each lobe has specialisms that on face value are amenable to interpretation by our different distributional models and the exact nature of specialist processing in localised areas is often subject to debate (so being overly restrictive may be risky). Formulation of the distributional models is described in detail in the Section 3, but for now it is sufficient to know that the Object model is derived from image statistics of the object depicted in images, Context from image statistics of the background scene, Object&Context is a com-

bination of the two, and Window2 is a text-based model.

The *occipital* lobe houses the primary visual processing system and consequently it is reasonable to expect some bias toward image-based semantic models. Furthermore, given that experimental stimuli incorporated line drawings of the object,and the visual cortex has a well-established role in processing low-level visual statistics including edge detection (Bruce et al., 2003), we naturally expected a good performance from Object (formulated from edge orientation histograms of similar objects).

Following Goodale and Milner (1992)'s influential perception-action model (see McIntosh and Schenk (2009) for recent discussion), visual information is channeled from the occipital lobe in two streams: a perceptual stream, serving object identification and recognition; and an action stream, specialist in processing egocentric spatial relationships and ultimately supporting interaction with the world.

The perceptual stream leads to the *temporal lobe*. Here the fusiform gyrus (shared with the occipital lobe) plays a general role in object categorisation (e.g., animals and tools (Chao et al., 1999), faces (Kanwisher and Yovel, 2006), body parts (Peelen and Downing, 2005) and even word form perception (McCandliss et al., 2003)). As the parahippocampus is strongly associated with scene representation (Epstein, 2008), we expect both the Object and Context models to capture variability in the temporal lobe. Of wider relevance to semantic processing, the medial temporal gyrus, inferior temporal gyrus and ventral temporal lobe have generally been implicated to have roles in supramodal integration and concept retrieval (Binder et al., 2009). Given this, we expected that incorporating text would also be valuable and that the Window2&Object&Context combination would be a good model.

The visual action stream leads from the occipital lobe to the *parietal* lobe to support spatial cognition tasks and action control (Sack, 2009). In that there seems to be an egocentric frame of reference, placing actor in environment, it is tempting to speculate that the Context model is more appropriate than the Object model here. As the parietal lobe also contains the angular gyrus, thought to be involved in complex, supra-modal information integration and knowledge retrieval (Binder et al., 2009), we might again forecast that integrating text and image information would boost performance, so Window2&Context was earmarked as a strong candidate.

The *frontal lobe*, is traditionally associated with high-level processing and manipulation of abstract knowledge and rules and controlled behaviour (Miller et al., 2002). Regarding semantics, the dorsomedial prefrontal cortex has been implicated in self-guided retrieval of semantic information (e.g., uncued speech production), the ventromedial prefrontal cortex in motivation and emotional processing, the inferior frontal gyrus in phonological and syntactic processing, (Binder et al., 2009) and integration of lexical information (Hagoort, 2005). Given the association with linguistic processing we anticipated a bias in favour of Window2.

The four lobes were identified and partitioned using Tzourio-Mazoyer et al. (2002)'s automatic anatomical labelling scheme.

Voxel selection The set of 500 most stable voxels, both within the whole brain and from within each region of interest were identified for analysis. The most stable voxels were those showing consistent variation across the different stimuli between scanning sessions. Specifically, and following a similar strategy to Mitchell et al. (2008), for each voxel, the set of 51 words from each unique pair of scanning sessions were correlated using Pearson's correlation (6 sessions and therefore 15 unique pairs), and the mean of the 15 resulting correlation coefficients was taken as the measure of stability. The 500 voxels with highest mean correlations were selected.

3 Distributional models

Distributional semantic models approximate word meaning by keeping track of word co-occurrence statistics from large textual input, relying on the distributional hypothesis: The meaning of a word can be induced by the context in which it occurs (Turney and Pantel, 2010). Despite their great success, these models still rely on verbal input only, while humans base their meaning representation also on perceptual information (Louwerse, 2011).

Thanks to recent developments in computer vision, it is nowadays possible to take the visual perceptual channel into account, and build new computational models of semantics enhanced with visual information (Feng and Lapata, 2010; Bruni et al., 2011; Leong and Mihalcea, 2011; Bergsma and Goebel, 2011; Bruni et al., 2012a). Given a set of target concepts and a collection of images depicting those concepts, it is indeed possible to first encode the image content into low-level features, and subsequently convert it into a higher-level representation based on the bag-of-visual-words method (Grauman and Leibe, 2011). Recently, Bruni et al. (2012b) have shown that better semantic representations can be extracted if we first localize the concept in the image, and then extract distinct higher-level features (visual words) from the box containing the concept and from the surrounding context. We also follow this strategy here.

In our experiments we utilize both traditional text-based models and experimental image-based models, as well as their combination.

3.1 Textual models

Verb We experiment with the original text-based semantic model used to predict fMRI patterns by Mitchell et al. (2008). Each object stimulus word is represented as a 25-dimensional vector, with each value corresponding to the normalized sentence-wide co-occurrence of that word with one of 25 manually-picked sensorimotor verbs (such as *see*, *hear*, *eat*, ...) in a trillion word text corpus.

Window2 To create this model, we collect text co-occurrence statistics from the freely available ukWaC and Wackypedia corpora combined (about 3 billion words in total).[2] As collocates of our distributional model we select a set of 30K words, namely the top 20K most frequent nouns, 5K most frequent adjectives and 5K most frequent verbs.

In the tradition of HAL (Lund and Burgess, 1996), the model is based on co-occurrence statistics with collocates within a fixed-size window of 2 to the left and right of each target word. Despite their simplicity, narrow-window-based models have shown to achieve state-of-the-art results in various standard semantic tasks (Bullinaria and Levy, 2007) and to outperform both document-based and syntax-based models trained on the same corpus (Bruni et al., 2012a). Moreover, in Murphy et al. (2012) a window-based model very similar to ours was not significantly worse than their best model for brain decoding. We tried also a few variations, e.g., using a larger window or different transformations on the raw co-occurrences from those presented below, but with little, insignificant changes in performance. Given that our focus here is on visual information, we only report results for Window2 and its combination with visual models.

3.2 Visual models

Our visual models are inspired by Bruni et al. (2012b), that have explored to what extent extracting features from images where objects are localized results in better semantic representations. They found that extracting visual features separately from the object and its surrounding context leads to better performance than not using localization, and using only object- and, more surprisingly, context-extracted features also results in performant models

[2] http://wacky.sslmit.unibo.it/

(especially when evaluating inter-object similarity, the context in which an object is located can significantly contribute to semantic representation, in certain cases carrying even more information than the depicted object itself).

More in detail, with localization the visual features (visual words) can be extracted from the object bounding box (in our experiments, the **Object** model) or from only outside the object box (the **Context** model). A combined model is obtained by concatenating the two feature vectors (the **Object&Context** model).

Visual model construction pipeline To extract visual co-occurrence statistics, we use images from ImageNet (Deng et al., 2009),[3] a very large image database organized on top of the WordNet hierarchy (Fellbaum, 1998). ImageNet has more than 14 million images, covering 21K WordNet nominal synsets. ImageNet stands out for the high quality of its images, both in terms of resolution and concept annotations. Moreover, for around 3K concepts, annotations of object bounding boxes is provided. This last feature allows us to exploit object localization within our experiments.

To build visual distributional models, we utilize the bag-of-visual-words (BoVW) representation of images (Sivic and Zisserman, 2003; Csurka et al., 2004). Inspired by NLP, BoVW discretizes the image content in terms of a histogram of visual word counts. Differently from NLP, in vision there is not a natural notion of visual words, hence a visual vocabulary has to be built from scratch. The process works as follows. First, a large set of low-level features is extracted from a corpus of images. The low-level feature vectors are subsequently clustered into different regions (visual words). Given then a new image, each of the low-level feature vectors extracted from the patches that compose it is mapped to the nearest visual word (e.g., in terms of Euclidean distance from the cluster centroid) such that the image can be represented with a histogram counting the instances of each visual word in the image.

As low-level features we use SIFT, the Scale Invariant Feature Transform (Lowe, 2004). SIFT features are good at capturing parts of objects and are designed to be invariant to image transformations such as change in scale, rotation and illumination. To construct the visual vocabulary, we cluster the SIFT features into 25K different clusters.[4] We add also spatial information by dividing the image into several subregions, representing each of them in terms of BoVW and then stacking the resulting histograms (Lazebnik et al., 2006). We use in total 8 different regions, obtaining a final vector of 200K dimensions (25K visual words $\times$ 8 regions). Since each concept in our dataset is represented by multiple images, we pool the visual word occurrences across images by summing them up into a single vector.

To perform the entire visual pipeline we use VSEM, an open library for visual semantics (Bruni et al., 2013).[5]

3.3 Model transformations and combination

Once both the textual and the visual models are built, we perform two different transformations on the raw co-occurrence counts. First, we transform them into nonnegative Pointwise Mutual Information (PMI) association scores (Church and Hanks, 1990). As a second transformation, we apply dimensionality reduction to the two matrices. In particular, we adopt the Singular Value Decomposition (SVD), one of the most effective methods to approximate the original data in lower dimensionality space (Schütze, 1997), and reduce the vectors to 50 dimensions.

To combine text- and image-based semantic models in a joint representation, we separately normalize their vectors to unit length, and concatenate them, along the lines of Bruni et al. (2011). More sophisticated combination models have been proposed in the recent literature on multimodal semantics. For example, Bruni et al. (2012a) use SVD as a mixing strategy, given its ability to smooth the matrices and uncover latent dimensions. Another example is Silberer and Lapata (2013), where Canonical Correlation Analysis is used. We reserve the exploration of more advanced combination methods for further studies.

Finally, to represent the 11 categories we experiment with (see Table 1), we average the vectors of the concepts they include.

[3] http://www.image-net.org/

[4] We use *k*-means, the most commonly employed clustering algorithm for this task.

4 Experiments

A question is posed over how to evaluate the relationship between the different distributional models and brain data. Comparing each model's predictive performance using the same strategy as Mitchell et al. (2008) (also followed by Murphy et al. (2012)) is one possibility: they used multiple regression to relate distributional codes to individual voxel activations, thus allowing brain states to be estimated from previously unseen distributional codes. Regression models were trained on 58/60 words and in testing the regression models estimated the brain state associated with the 2 unseen distributional codes. The predicted brain states were compared with the actual fMRI data, and the process repeated for each permutation of left-out words, to build a metric of prediction accuracy. For our purposes, a fair comparison of models using this strategy is complicated by differences in dimensionality between both semantic models and lobes (which we compare to other lobes) in association with the comparatively small number of words in the fMRI data set. Large dimensionality models risk overfitting the data, and it is a nuisance to try to reliably correct for the effects of overfitting in performance comparisons. Not least, to thoroughly evaluate all possible cross-validation permutations is demanding in processing time, and we have many models to compare.

An alternative approach, and that which we have adopted, is representational similarity analysis (Kriegeskorte et al., 2008). Representational similarity analysis circumvents the previous problems by abstracting each fMRI/distributional data source to a common structure capturing the interrelationships between each pair of data items (e.g., words). Specifically, for each model/participant's fMRI data/anatomical region, the similarity structure was evaluated by taking the pairwise correlation (Pearson's correlation coefficient) between all unique category or word combinations. This produced a list of 55 category pair correlations and 121 word pair correlations for each data source. For all brain data, correlation lists were averaged across the nine participants to produce a single list of mean word pair correlations and a single list of mean category pair correlations for each anatomical region and the whole brain. Then to provide a measure of similarity between models and brain data, the correlation lists for respective data sources were themselves correlated using Spearman's rank correlation. Statistical significance was tested using a permutation test: The word-pair (or category-pair) labels were randomly shuffled 10,000 times to estimate a null distribution when the two similarity lists are not correlated. The p-value is calculated as the proportion of random correlation coefficients that are greater than or equal to the observed coefficient.

5 Results

5.1 Category-level analyses

Do image models correlate with brain data? Table 2 displays results of Spearman's correlations between the per-category similarity structure of distributional models and brain data. There is a significant correlation between every purely image-based model and the occipital, parietal and temporal lobes, and also the whole brain ($.38 \leq \rho \geq .51$, all $p \leq .01$). The frontal lobe is less well described. Still, whilst not significant, correlations are only marginally above the conventional $p = .05$ cutoff (all are less than $p = .064$). This strongly suggests that the answer to our first question is yes: *distributional models derived from images can be used to explain concept fMRI data*. Otherwise Window2 significantly correlates with the whole brain and all anatomical regions except for the frontal lobe where ρ=.34, $p = .07$. In contrast Verb (the original, partially hand-crafted model used by Mitchell and colleagues) captures inter-relationships poorly and neither correlates with the whole brain or any lobe.

Do different models correlate with different anatomical regions? 2-way ANOVA without replication was used to test for differences in correlation coefficients between the five pure-modality models (Verb, Window2, Object, Context and Object&Context), and the four brain lobes. This revealed a highly significant difference between models $F(4,12)=45.2$, $p<.001$. Post-hoc 2-tailed t-tests comparing model pairs found that Verb differed significantly from all other models (correlations were lower). There was a clear difference even when Verb (mean$\pm$sd over lobes = .1$\pm$.1) was compared to the second weakest model, Object (mean$\pm$sd=.4$\pm$.09), where t =-7.7, p <.01, df=4. There were no

In each column the first value corresponds to Spearman's rank correlation coefficient and the value in parenthesis is the p-value.

other significant differences between models. However there was a highly significant difference between lobes F(3,12)=13.77, p <.001. Post-hoc 2-tailed t-tests comparing lobe pairs found that the frontal lobe yielded significantly different correlations (lower) than each other lobe. When the frontal lobe (mean±sd over models = .25±.14) was compared to the second weakest anatomical region, the parietal lobe (mean±sd=.38±.19), the difference was highly significant, t =-8, df=3, p <.01. This introduces the question of whether this difference in correlations is the result of differences in neural category organisation and representation, or differences in the quality of the signal, which we address next.

Category-level inter-correlations between lobes were all relatively strong and highly significant. The occipital lobe was found to be the most distinct, being similar to the temporal lobe (ρ=.71, p <.001), but less so to the parietal and frontal lobes (ρ=.53, p <.001 and ρ=.57, p <.001 respectively). The temporal lobe shows roughly similar levels of correlation to each other lobe (all .71≤ ρ ≥.73, all p <.001). The frontal and parietal lobes are related most strongly to each other (ρ=.77, p <.001), to a slightly lesser extent to the temporal lobe (in both cases ρ=.73, p <.001) and least so to the occipital lobe. These strong relationships are consistent with there being a broadly similar category organisation across lobes.

To appraise this assertion in the context of the previously detected difference between the frontal lobe and all other lobes, we examine the raw category pair similarity matrices derived from the occipital lobe and the frontal lobe (Figure 1). All the below observations are qualitative. Although it is difficult to have intuitions about the relative differences between all category pairs (e.g., whether tools or furniture should be more similar to animals), we might reasonably expect some obvious similarities. For instance, for animals to be visually similar to in-

sects and clothing, because all have legs and arms and curves (of course we would not expect a strong relationship between insects and clothes in function or other modalities such as sound), buildings to be similar to building parts and vehicles (hard edges and windows), building parts to be similar to furniture (e.g., from Table 1 we see there is some overlap in category membership between these categories, such as closet and door) and tools to be similar to kitchen utensils. All of these relationships are maintained in the occipital lobe, and many are visible in the frontal lobe (including the similarity between insects and clothes), however there are exceptions that are difficult to explain e.g., within the frontal lobe, building parts are not similar to furniture, kitchen utensils are closer to clothing than to tools and vehicles are more similar to clothing than anything else. As such we conclude that *category-level representations were similar across lobes* with differences likely due to variation in signal quality between lobes.

Are text- and image-based semantic models complementary? Turning to the question of whether text- and image-derived semantic information can be complementary, we observe from Table 2 that there is not a single instance of a joint model with a weaker correlation than its pure-image counterpart. The Window2 model showed a stronger correlation than the Window2&Object model for the frontal and parietal lobes, but was weaker than Window2&Object&Context and Window2&Context in all tests and was also weaker than any joint model in whole-brain comparisons. The mean$\pm$sd correlations for all purely image-based results pooled over lobes (3 models * 4 lobes) was .42$\pm$.08 in comparison to .49$\pm$.08 for the joint models. The relative performance of Object vs. Context vs. Object&Context on the four different lobes is preserved between image-based and joint models: correlating the 12 combinations using Spearman's correlation gives ρ=.85, p <.001. Differences can be statistically quantified by pooling all image related correlation coefficients for each anatomical region (3 models * 4 regions), as for the respective joint models, and comparing with a 2-tailed Wilcoxon signed rank test. Differences were highly significant (W=0, p <.001,n=12). This evidence accumulates to suggest that *text and image-derived semantic information can be complementary* in interpreting concept fMRI data.

Figure 1: Similarity (Pearson correlation) between each category pair in (top) occipital and (bottom) frontal lobes.

5.2 Word-level analyses

Do image models capture word pair similarities? Per-word results generally corroborate the relationships observed in the previous section in the sense that Spearman's correlation between per-word and per-category results for the 40 combinations of models and lobes was ρ=.78, p <.001. There were differences, most obviously a dramatic drop in the strength of correlation coefficients for the per-word results, visible in Table 3. *Subsets*

of per-word image-based models correlated with three lobes and the whole brain. Correlations corresponding to significance values of $p < .05$ were observed in the temporal and parietal lobes, for Context, Object&Context and Window2 whereas Object was correlated with the occipital and temporal lobes ($p < .05$). 2-way ANOVA without replication was used to test for differences between models and lobes. This revealed a significant difference between models (F(4,12)=4.05, $p = .027$). Post-hoc t-tests showed that the Window2 model significantly differed from (was stronger than) the Context (t=3.8, $p = .03$, df=3) and Object&Context models ($t = 4.5$, $p = .02$, df=3). There were no other significant differences between models. There was again a significant difference between lobes (F(3,12)=7.89, $p < .01$), with the frontal lobe showing the weakest correlations. Post-hoc 2-tailed t-tests comparing lobe-pairs found that the frontal lobe differed significantly (correlations were weaker) from the parietal ($t = -9$, $p < .001$, df=4) and temporal lobes ($t = -6.4$, $p < .01$, df=4) but not from the occipital lobe ($t = -2.18$, $p = .09$, df=4). No other significant differences between lobes were observed.

Are there differences between models/lobes? Word-level inter-correlations between lobes were all significant and the pattern of differences in correlation strength largely resembled that of the category-level analyses. The occipital lobe was again most similar to the temporal lobe (ρ=.57, $p < .001$), but less so to the parietal and frontal lobes (ρ=.47, $p < .001$ and ρ=.34, $p < .001$ respectively). The temporal lobe this time showed stronger correlation to the parietal (ρ=.68, $p < .001$) and frontal lobes (ρ=.61, $p < .001$) than the occipital lobe. The frontal and parietal lobes were again strongly related to one another (ρ=.67, $p < .001$). These results echo the category-level findings, that *word-level brain activity is also organised in a similar way across lobes*. Consequently this diminishes our chances of uncovering neat interactions between models and brain areas (where for instance the Window2 model correlates with the frontal lobe and Object model matches the occipital lobe). It is however noteworthy that we can observe some interpretable selectivity in lobe*model combinations. In particular the Context model better matches the parietal lobe than the Object model, which in turn better captures the occipital and temporal lobes (Observations are qualitative). Also as we see next, adding text information boosts performance in both parietal and temporal lobes (see Section 2 on our expectations about information encoded in the lobes).

Does joining text and image models help word-level interpretation? As concerns the benefits of joining Text and Image information, *per-word joint models were generally stronger than the respective image-based models*. There was one exception: adding text to the Object model weakened correlation with the occipital lobe. Joint models were exclusively stronger than Window2 for the temporal and occipital lobes, and were stronger in 1/3 of cases for the frontal and parietal lobes. In an analogous comparison to the per-category analysis, a Wilcoxon signed rank test was used to examine the difference made by adding text information to image models (pooling 3 models over 4 anatomical areas for both image and joint models). The mean$\pm$sd of image models was .1$\pm$.06 whereas for Joint models it was .15$\pm$.07. The difference was highly significant (W=1, $p < .001$, n=12).

6 Conclusion

This study brought together, for the first time, two recent research lines: The exploration of "semantic spaces" in the brain using distributional semantic models extracted from corpora, and the extension of the latter to image-based features. We showed that image-based distributional semantic measures significantly correlate with fMRI-based neural similarity patterns pertaining to categories of concrete concepts as well as concrete basic-level concepts expressed by specific words (although correlations, especially at the basic-concept level, are rather low, which might signify the need to develop still more performant distributional models and/or noise inherent to neural data). Moreover, image-based models complement a state-of-the-art text-based model, with the best performance achieved when the two modalities are combined. This not only presents an optimistic outlook for the future use of image-based models as an interpretative tool to explore issues of cognitive grounding, but also demonstrates that they are capturing useful additional aspects of meaning to

the text models, which are likely relevant for computational semantic tasks.

The weak comparative performance of the original Mitchell et al.'s Verb model is perhaps surprising given its previous success in prediction (Mitchell et al., 2008), but a useful reminder that a good predictor does not necessarily have to capture the internal structure of the data it predicts.

The lack of finding organisational differences between anatomical regions differentially described by the various models is perhaps disappointing, but not uncontroversial, given that the dataset was not originally designed to tease apart visual information from linguistic context. It is however interesting that in the more challenging word-level analysis some meaningful trend was visible. In future experiments it may prove valuable to configure a fMRI stimulus set where text-based and image-based interrelationships are maximally different. Collecting our own fMRI data will also allow us to move beyond exploratory analysis, to test sharper predictions about distributional models and their brain area correlates. There are also many opportunities for focusing analyses on different subsets of brain regions, with the semantic system identified by Binder et al. (2009) in particular presenting one interesting avenue for investigation.

Easy Victories and Uphill Battles in Coreference Resolution

Abstract

Classical coreference systems encode various syntactic, discourse, and semantic phenomena explicitly, using heterogenous features computed from hand-crafted heuristics. In contrast, we present a state-of-the-art coreference system that captures such phenomena implicitly, with a small number of homogeneous feature templates examining shallow properties of mentions. Surprisingly, our features are actually more effective than the corresponding hand-engineered ones at modeling these key linguistic phenomena, allowing us to win "easy victories" without crafted heuristics. These features are successful on syntax and discourse; however, they do not model semantic compatibility well, nor do we see gains from experiments with shallow semantic features from the literature, suggesting that this approach to semantics is an "uphill battle." Nonetheless, our final system[1] outperforms the Stanford system (Lee et al. (2011), the winner of the CoNLL 2011 shared task) by 3.5% absolute on the CoNLL metric and outperforms the IMS system (Björkelund and Farkas (2012), the best publicly available English coreference system) by 1.9% absolute.

1 Introduction

Coreference resolution is a multi-faceted task: humans resolve references by exploiting contextual and grammatical clues, as well as semantic information and world knowledge, so capturing each of these will be necessary for an automatic system to fully solve the problem. Acknowledging this complexity, coreference systems, either learning-based (Bengtson and Roth, 2008; Stoyanov et al., 2010; Haghighi and Klein, 2010; Rahman and Ng, 2011b) or rule-based (Haghighi and Klein, 2009; Lee et al., 2011), draw on diverse information sources and complex heuristics to resolve pronouns, model discourse, determine anaphoricity, and identify semantically compatible mentions. However, this leads to systems with many heterogenous parts that can be difficult to interpret or modify.

We build a learning-based, mention-synchronous coreference system that aims to use the simplest possible set of features to tackle the various aspects of coreference resolution. Though they arise from a small number of simple templates, our features are numerous, which works to our advantage: we can both implicitly model important linguistic effects and capture other patterns in the data that are not easily teased out by hand. As a result, our data-driven, homogeneous feature set is able to achieve high performance despite only using surface-level document characteristics and shallow syntactic information. We win "easy victories" without designing features and heuristics explicitly targeting particular phenomena.

Though our approach is successful at modeling syntax, we find semantics to be a much more challenging aspect of coreference. Our base system uses only two recall-oriented features on nominal and proper mentions: head match and exact string match. Building on these features, we critically evaluate several classes of semantic features which intu-

[1] The Berkeley Coreference Resolution System is available at http://nlp.cs.berkeley.edu.

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1971–1982,
Seattle, Washington, USA, 18-21 October 2013.

itively should prove useful but have had mixed results in the literature, and we observe that they are ineffective for our system. However, these features are beneficial when gold mentions are provided to our system, leading us to conclude that the large number of system mentions extracted by most coreference systems (Lee et al., 2011; Fernandes et al., 2012) means that weak indicators cannot overcome the bias against making coreference links. Capturing semantic information in this shallow way is an "uphill battle" due to this structural property of coreference resolution.

Nevertheless, using a simple architecture and feature set, our final system outperforms the two best publicly available English coreference systems, the Stanford system (Lee et al., 2011) and the IMS system (Björkelund and Farkas, 2012), by wide margins: 3.5% absolute and 1.9% absolute, respectively, on the CoNLL metric.

2 Experimental Setup

Throughout this work, we use the datasets from the CoNLL 2011 shared task[2] (Pradhan et al., 2011), which is derived from the OntoNotes corpus (Hovy et al., 2006). When applicable, we use the standard automatic parses and NER tags for each document. All experiments use system mentions except where otherwise indicated. For each experiment, we report MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF_e (Luo, 2005), as well as their average, the CoNLL metric. All metrics are computed using version 5 of the official CoNLL scorer.[3]

3 A Mention-Synchronous Framework

We first present the basic architecture of our coreference system, independent of a feature set. Unlike binary classification-based coreference systems where independent binary decisions are made about each pair (Soon et al., 2001; Bengtson and Roth, 2008; Versley et al., 2008; Stoyanov et al., 2010), we use a log-linear model to select at most one antecedent for each mention or determine that it begins a new cluster (Denis and Baldridge, 2008). In this mention-ranking or mention-synchronous framework, features examine single mentions to evaluate whether or not they are anaphoric and pairs of mentions to evaluate whether or not they corefer. While other work has used this framework as a starting point for entity-level systems (Luo et al., 2004; Rahman and Ng, 2009; Haghighi and Klein, 2010; Durrett et al., 2013), we will show that a mention-synchronous approach is sufficient to get state-of-the-art performance on its own.

3.1 Mention Detection

Our system first identifies a set of predicted mentions from text annotated with parses and named entity tags. We extract three distinct types of mentions: proper mentions from all named entity chunks except for those labeled as QUANTITY, CARDINAL, or PERCENT, pronominal mentions from single words tagged with PRP or PRP$, and nominal mentions from all other maximal NP projections. These basic rules are similar to those of Lee et al. (2011), except that their system uses an additional set of filtering rules designed to discard instances of pleonastic *it*, partitives, certain quantified noun phrases, and other spurious mentions. In contrast to this highly engineered approach and to systems which use a trained classifier to compute anaphoricity separately (Rahman and Ng, 2009; Björkelund and Farkas, 2012), we aim for the highest possible recall of gold mentions with a low-complexity method, leaving us with a large number of spurious system mentions that we will have to reject later.

3.2 Coreference Model

Figure 1 shows the mention-ranking architecture that serves as the backbone of our coreference system. Assume we have extracted n mentions from a document x, where x denotes the surface properties of a document and any precomputed information. The ith mention in a document has an associated random variable a_i taking values in the set $\{1, \ldots, i-1, \text{NEW}\}$; this variable specifies mention i's selected antecedent or indicates that it begins a new coreference chain. A setting of the a_i, denoted by $a = (a_1, ..., a_n)$, implies a unique set of coreference chains C that serve as our system output.

[2]This dataset is identical to the English portion of the CoNLL 2012 data, except for the absence of a small pivot text.

[3]Note that this version of the scorer implements a modified version of B^3, described in Cai and Strube (2010), that was used for the CoNLL shared tasks. The implementation of CEAF_e is also not exactly as described in Luo et al. (2004), but for completeness we include this metric as well.

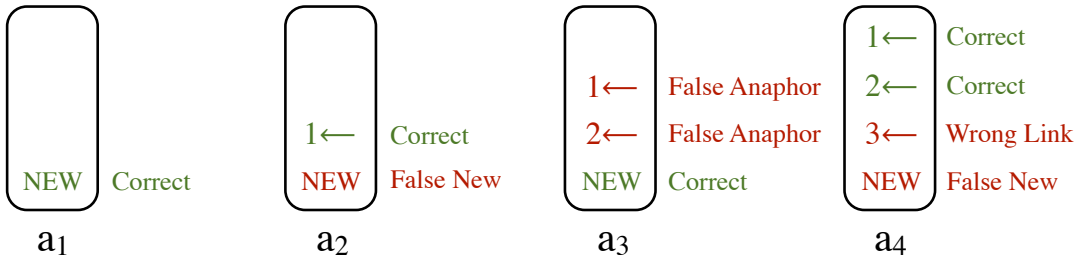

Figure 1: The basic structure of our coreference model. The ith mention in a document has i possible antecedence choices: link to one of the $i-1$ preceding mentions or begin a new cluster. We place a distribution over these choices with a log-linear model. Structurally different kinds of errors are weighted differently to optimize for final coreference loss functions; error types are shown corresponding to the decisions for each mention.

We use a log linear model of the conditional distribution $P(a|x)$ as follows:

$$P(a|x) \propto \exp\left(\sum_{i=1}^{n} \mathbf{w}^\top \mathbf{f}(i, a_i, x)\right)$$

where $\mathbf{f}(i, a_i, x)$ is a feature function that examines the coreference decision a_i for mention i with document context x. When $a_i = \text{NEW}$, the features fired indicate the suitability of the given mention to be anaphoric or not; when $a_i = j$ for some j, the features express aspects of the pairwise linkage, and can examine any relevant attributes of the anaphor i or the antecedent j, since information about each mention is contained in x.

Inference in this model is efficient: because $\log P(a|x)$ decomposes linearly over mentions, we can compute $a_i = \arg\max_{a_i} P(a_i|x)$ separately for each mention and return the set of coreference chains implied by these decisions.

3.3 Learning

During learning, we optimize for conditional log-likelihood augmented with a parameterized loss function (Durrett et al., 2013). The main complicating factor in this process is that the supervision in coreference consists of a gold clustering C^* defined over gold mentions. This is problematic for two reasons: first, because the clustering is defined over gold mentions rather than our system mentions, and second, because a clustering does not specify a full antecedent structure of the sort our model produces. We can address the first of these problems by imputing singleton clusters for mentions that do not appear in the gold standard; our system will then simply learn to put spurious mentions in their own clusters. Singletons are always removed before evaluation because the OntoNotes corpus does not annotate them, so in this way we can neatly dispose of spurious mentions. To address the lack of explicit antecedents in C^*, we simply sum over all possible antecedent structures licensed by the gold clusters.

Formally, we will maximize the conditional log-likelihood of the set $\mathcal{A}(C^*)$ of antecedent vectors a for a document that are *consistent* with the gold annotation.[4] Consistency for an antecedent choice a_i under gold clusters C^* is defined as follows:

1. If $a_i = j$, a_i is consistent iff mentions i and j are present in C^* and are in the same cluster.

2. If $a_i = \text{NEW}$, a_i is consistent off mention i is not present in C^*, or it is present in C^* and has no gold antecedents, or it is present in C^* and none of its gold antecedents are among the set of system predicted mentions.

Given t training examples of the form (x_k, C_k^*), we write the following likelihood function:

$$\ell(\mathbf{w}) = \sum_{k=1}^{t} \log\left(\sum_{a \in \mathcal{A}(C_k^*)} P'(a|x_k)\right) + \lambda\|\mathbf{w}\|_1$$

where $P'(a|x_k) \propto P(a|x_k)\exp(l(a, C_k^*))$ with $l(a, C^*)$ being a real-valued loss function. The loss

[4] Because of this marginalization over latent antecedent choices, our objective is non-convex.

here plays an analogous role to the loss in structured max-margin objectives; incorporating it into a conditional likelihood objective is a technique called softmax-margin (Gimpel and Smith, 2010).

Our loss function $l(a, C^*)$ is a weighted linear combination of three error types, examples of which are shown in Figure 1. A false anaphor (FA) error occurs when a_i is chosen to be anaphoric when it should start a new cluster. A false new (FN) error occurs in the opposite case, when a_i wrongly indicates a new cluster when it should be anaphoric. Finally, a wrong link (WL) error occurs when the antecedent chosen for a_i is the wrong antecedent (but a_i is indeed anaphoric). Our final parameterized loss function is a weighted sum of the counts of these three error types:

$$l(a, C^*) = \alpha_{\text{FA}}\text{FA}(a, C^*) + \alpha_{\text{FN}}\text{FN}(a, C^*) + \alpha_{\text{WL}}\text{WL}(a, C^*)$$

where $\text{FA}(a, C^*)$ gives the number of false anaphor errors in prediction a with gold chains C^* (FN and WL are analogous). By setting α_{FA} low and α_{FN} high relative to α_{WL}, we can counterbalance the high number of singleton mentions and bias the system towards making more coreference linkages. We set $(\alpha_{\text{FA}}, \alpha_{\text{FN}}, \alpha_{\text{WL}}) = (0.1, 3.0, 1.0)$ and $\lambda = 0.001$ and optimize the objective using AdaGrad (Duchi et al., 2011).

4 Easy Victories from Surface Features

Our primary goal with this work is to show that a high-performance coreference system is attainable with a small number of feature templates that use only surface-level information sources. These features will be general-purpose and capture linguistic effects to the point where standard heuristic-driven features are no longer needed in our system.

4.1 SURFACE Features and Conjunctions

Our SURFACE feature set only considers the following properties of mentions and mention pairs:

- Mention type (nominal, proper, or pronominal)
- The complete string of a mention
- The semantic head of a mention
- The first word and last word of each mention
- The word immediately preceding and the word immediately following a mention
- Mention length, in words
- Two distance measures between mentions (number of sentences and number of mentions)

Feature name	Count
Features on the current mention	
[ANAPHORIC] + [HEAD WORD]	41371
[ANAPHORIC] + [FIRST WORD]	18991
[ANAPHORIC] + [LAST WORD]	19184
[ANAPHORIC] + [PRECEDING WORD]	54605
[ANAPHORIC] + [FOLLOWING WORD]	57239
[ANAPHORIC] + [LENGTH]	4304
Features on the antecedent	
[ANTECEDENT HEAD WORD]	57383
[ANTECEDENT FIRST WORD]	24239
[ANTECEDENT LAST WORD]	23819
[ANTECEDENT PRECEDING WORD]	53421
[ANTECEDENT FOLLOWING WORD]	55718
[ANTECEDENT LENGTH]	4620
Features on the pair	
[EXACT STRING MATCH (T/F)]	47
[HEAD MATCH (T/F)]	46
[SENTENCE DISTANCE, CAPPED AT 10]	2037
[MENTION DISTANCE, CAPPED AT 10]	1680

Table 1: Our SURFACE feature set, which exploits a small number of surface-level mention properties. Feature counts for each template are computed over the training set, and include features generated by our conjunction scheme (not explicitly shown in the table; see Figure 2), which yields large numbers of features at varying levels of expressivity.

Table 1 shows the SURFACE feature set. Features that look only at the current mention fire on all decisions ($a_i = j$ or $a_i = \text{NEW}$), whereas features that look at the antecedent in any way (the latter two groups of features) only fire on pairwise linkages ($a_i \neq \text{NEW}$).

Two conjunctions of each feature are also included: first with the "type" of the mention being resolved (either NOMINAL, PROPER, or, if it is pronominal, the citation form of the pronoun), and then additionally with the antecedent type (only if the feature is over a pairwise link). This conjunction process is shown in Figure 2. Note that features that just examine the antecedent will end up with

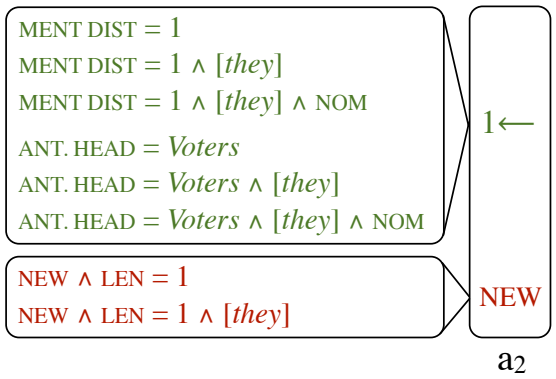

Figure 2: Demonstration of the conjunction scheme we use. Each feature on anaphoricity is conjoined with the type (NOMINAL, PROPER, or the citation form if it is a pronoun) of the mention being resolved. Each feature on a mention pair is additionally conjoined with the types of the current and antecedent mentions.

conjunctions that examine properties of the current mention as well, as shown with the ANT. HEAD feature in the figure.

Finally, we found it beneficial for our lexical indicator features to only fire on words occurring at least 20 times in the training set; for rare words, we use the part of speech of the word instead.

The performance of our system is shown in Table 2. We contrast our performance with that of the Stanford system (Lee et al. (2011), the winner of the CoNLL 2011 shared task) and the IMS system (Björkelund and Farkas (2012), the best publicly available English coreference system). Despite its simplicity, our SURFACE system is sufficient to outperform these sophisticated systems: the Stanford system uses a cascade of ten rule-based sieves each of which has customized heuristics, and the IMS system uses a similarly long pipeline consisting of a learned referentiality classifier followed by multiple resolvers, which are run in sequence and rely on the outputs of the previous resolvers as features.

4.2 Data-Driven versus Heuristic-Driven Features

Why are the SURFACE features sufficient to give high coreference performance, when they do not make apparent reference to important linguistic phenomena? The main reason is that they actually do capture the same phenomena as standard coreference features, just implicitly. For example, rather than having rules targeting person, number, gender, or animacy of mentions, we use conjunctions with pronoun identity, which contains this information. Rather than explicitly writing a feature targeting definiteness, our indicators on the first word of a mention will capture this and other effects. And finally, rather than targeting centering theory (Grosz et al., 1995) with rule-based features identifying syntactic positions (Stoyanov et al., 2010; Haghighi and Klein, 2010), our features on word context can identify configurational clues like whether a mention is preceded or followed by a verb, and therefore whether it is likely in subject or object position.[5]

	MUC	B^3	CEAF_e	Avg.
STANFORD	60.46	65.48	47.07	57.67
IMS	62.15	65.57	46.66	58.13
SURFACE	**64.39**	**66.78**	**49.00**	**60.06**

Table 2: Results for our SURFACE system, the STANFORD system, and the IMS system on the CoNLL 2011 development set. Complete results are shown in Table 7. Despite using limited information sources, our system is able to substantially outperform the other two, the two best publicly-available English coreference systems. Bolded values are significant with $p < 0.05$ according to a bootstrap resampling test.

Not only are data-driven features able to capture the same phenomena as heuristic-driven features, but they do so at a finer level of granularity, and can therefore model more patterns in the data. To contrast these two types of features, we experiment with three ablated versions of our system, where we replace data-driven features with their heuristic-driven counterparts:

1. Instead of using an indicator on the first word of a mention (1STWORD), we instead fire a feature based on that mention's manually-computed definiteness (DEF).

2. Instead of conjoining features on pronominal-pronominal linkages with the citation form of

[5]Heuristic-driven approaches were historically more appropriate, since past coreference corpora such as MUC and ACE were smaller and therefore more prone to overfitting feature-rich models. However, the OntoNotes dataset contains thousands of documents, so having support for features is less of a concern.

	MUC	B^3	CEAF_e	Avg.
SURFACE	64.39	66.78	49.00	60.06
−1STWORD	63.32	66.22	47.89	59.14
+DEF−1STWORD	63.79	66.46	48.35	59.53
−PRONCONJ	59.97	63.46	47.94	57.12
+AGR−PRONCONJ	63.54	66.10	48.72	59.45
−CONTEXT	60.88	64.66	47.60	57.71
+POSN−CONTEXT	62.45	65.44	48.08	58.65
+DEF+AGR+POSN	64.55	66.93	48.94	60.14

Table 3: CoNLL metric scores on the development set, for the three different ablations and replacement features described in Section 4.2. Feature types are described in the text; + indicates inclusion of that feature class, − indicates exclusion. Each individual shallow indicator appears to do as well at capturing its target phenomenon as the hand-engineered features, while capturing other information as well. Moreover, the hand-engineered features give no benefit over the SURFACE system.

each pronoun (PRONCONJ), we only conjoin with a PRONOUN indicator and add features targeting the person, number, gender, and animacy of the two pronouns (AGR).

3. Instead of using our context features on the preceding and following word (CONTEXT), we use manual determinations of when mentions are in subject, direct object, indirect objection, or oblique position (POSN).

All rules for computing person, number, gender, animacy, definiteness, and syntactic position are taken from the system of Lee et al. (2011).

Table 3 shows each of the target ablations, as well as the SURFACE system with the DEF, AGR, and POSN features added. While the heuristic-driven feature always help over the corresponding ablated system, they cannot do the work of the fine-grained data-driven features. Most tellingly, though, none of the heuristic-driven features give statistically significant improvements on top of the data-driven features we have already included, indicating that we are at the point of diminishing returns on modeling those specific phenomena. While this does not preclude further engineering to take better advantage of other syntactic constraints, our simple features represent an "easy victory" on this subtask.

5 Uphill Battles on Semantics

In Section 4, we gave a simple set of features that yielded a high-performance coreference system; this high performance is possible because features targeting only superficial properties in a fine-grained way can actually model complex linguistic constraints. However, while our existing features capture syntactic and discourse-level phenomena surprisingly well, they are not effective at capturing semantic phenomena like type compatibility. We will show that due to structural aspects of the coreference resolution problem, even a combination of several shallow semantic features from the literature fails to adequately model semantics.

5.1 Analysis of the SURFACE System

What can the SURFACE system resolve correctly, and what errors does it still make? To answer this question, we will split mentions into several categories based on their observable properties and the gold standard coreference information, and examine our system's accuracy on each mention subclass in order to more thoroughly characterize its performance.[6] These categories represent important distinctions in terms of the difficulty of mention resolution for our system.

We first split mentions into three categories by their *status* in the gold standard: singleton (unannotated in the OntoNotes corpus), starting a new entity with at least two mentions, or anaphoric. It is important to note that while singletons and mentions starting new entities are outwardly similar in that they have no antecedents, and the prediction should be the same in either case (NEW), we treat them as distinct because the factors that impact the coreference decision differ in the two cases. Mentions that start new clusters are semantically similar to anaphoric mentions, but may be marked by heaviness or by a tendency to be named entities, whereas singletons may be generic or temporal NPs which might be thought of as coreferent in a loose sense, but are not

[6]This method of analysis is similar to that undertaken in Stoyanov et al. (2009) and Rahman and Ng (2011b), though we split our mentions along different axes, and can simply evaluate on accuracy because our decisions do not directly imply multiple links, as they do in binary classification-based systems (Stoyanov et al., 2009) or in entity-mention models (Rahman and Ng, 2011b).

	Nominal/Proper				Pronominal	
	1st w/head		2nd+ w/head			
Singleton	99.7%	18.1K	85.5%	7.3K	66.5%	1.7K
Starts Entity	98.7%	2.1K	78.9%	0.7K	48.5%	0.3K
Anaphoric	7.9%	0.9K	75.5%	3.9K	72.0%	4.4K

Table 4: Analysis of our SURFACE system on the development set. We characterize each predicted mention by its status in the gold standard (singleton, starting a new entity, or anaphoric), its type (pronominal or nominal/proper), and by whether its head has appeared as the head of a previous mention. Each cell shows our system's accuracy on that mention class as well as the size of the class. The biggest weakness of our system appears to be its inability to resolve anaphoric mentions with new heads (bottom-left cell).

included in the OntoNotes dataset due to choices in the annotation standard.

Second, we divide mentions by their type, pronominal versus nominal/proper; we then further subdivide nominals and propers based on whether or not the head word of the mention has appeared as the head of a previous mention in the document.

Table 4 shows the results of our analysis. In each cell, we show the fraction of mentions that we correctly resolve (i.e., for which we make an antecedence decision consistent with the gold standard), as well as the total number of mentions falling into that cell. First, we observe that there are a surprisingly large number of singleton mentions with misleading head matches to previous mentions (often recurring temporal nouns phrases, like *July*). The features in our system targeting anaphoricity are useful for exactly this reason: the more bad head matches we can rule out based on other criteria, the more strongly we can rely on head match to make correct linkages.

Our system is most noticeably poor at resolving anaphoric mentions whose heads have not appeared before. The fact that exact match and head match are our only recall-oriented features on nominals and propers is starkly apparent here: when we cannot rely on head match, as is true for this mention class, we only resolve 7.9% of anaphoric mentions correctly.[7] Many of the mentions in this category can only be correctly resolved by exploiting world knowledge, so we will need to include features that capture this knowledge in some fashion.

5.2 Incorporating Shallow Semantics

As we were able to incorporate syntax with shallow features, so too might we hope to incorporate semantics. However, the semantic information contained even in a coreference corpus of thousands of documents is insufficient to generalize to unseen data,[8] so system designers have turned to external resources such as semantic classes derived from WordNet (Soon et al., 2001), WordNet hypernymy or synonymy (Stoyanov et al., 2010), semantic similarity computed from online resources (Ponzetto and Strube, 2006), named entity type features, gender and number match using the dataset of Bergsma and Lin (2006), and features from unsupervised clusters (Hendrickx and Daelemans, 2007; Durrett et al., 2013). In this section, we consider the following subset of these information sources:

- WordNet hypernymy and synonymy
- Number and gender data for nominals and propers from Bergsma and Lin (2006)
- Named entity types
- Latent clusters computed from English Gigaword (Graff et al., 2007), where a latent cluster label generates each nominal head (excluding pronouns) and a conjunction of its verbal governor and semantic role, if any (Durrett et al., 2013). We use twenty clusters, which include clusters like *president* and *leader* (things which *announce*).

Together, we call these the SEM features. We show results from this expansion of the feature set in Table 5. When using system mentions, the improvements are not statistically significant on every metric, and are quite marginal given that these features add information that is intuitively central to coreference and otherwise unavailable to the system. We explore the reasons behind this in the next section.

[7] There are an additional 346 anaphoric nominal/proper mentions in the 2nd+ category whose heads only appeared previously as part of a different cluster; we only resolve 1.7% of these extremely tricky cases correctly.

[8] We experimented with bilexical features on head pairs, but they did not give statistically significant improvements over the SURFACE features.

	MUC	B^3	CEAF_e	Avg.
SURFACE	64.39	66.78	49.00	60.06
SURFACE+SEM	64.70	**67.27**	**49.28**	**60.42**
SURFACE (G)	82.80	74.10	68.33	75.08
SURFACE+SEM (G)	**84.49**	**75.65**	**69.89**	**76.68**

Table 5: CoNLL metric scores on the development set for our SEM features when added on top of our SURFACE features. We experiment on both system mentions and gold mentions. Surprisingly, despite the fact that absolute performance numbers are much higher on gold mentions and there is less room for improvement, the semantic features help much more than they do on system mentions.

5.3 Analysis of Semantic Features

The main reason that weak semantic cues are not more effective is the small fraction of positive coreference links present in the training data. From Table 4, the number of annotated coreferent spans in the OntoNotes data is about a factor of five smaller than the number of system mentions.[9] This both means that most NPs are not coreferent, and for those that are, choosing the correct links is much more difficult because of the large number of possible antecedents. Even head match, which is generally considered a high-precision indicator (Lee et al., 2011), would introduce many spurious coreference arcs if applied too liberally (see Table 4).

In light of this fact, a system needs very strong evidence to overcome the default hypothesis that a mention is not coreferent, and a weak indicator will have such a high "false positive" rate that it cannot be relied on (given high weight, this feature would do more harm than good, by introducing many false linkages).

To confirm this intuition, we show in the bottom part of Table 5 results when we apply these semantic features on top of our SURFACE system on *gold mentions*, where there are no singletons. In the gold mention setting, we see that the semantic features give a consistent improvement on every metric. Moreover, if we look at a breakdown of errors, the main improvement the semantic features give us is on resolution of anaphoric nominals with no head match: accuracy on the 1601 mentions that fall into this category improves from 28.0% to 37.9%. On predicted mentions, by contrast, this category only improves from 7.9% to 12.2%, a much smaller absolute improvement and one that comes at the expense of performance on most other resolution class. The one class that does not get worse, singleton pronouns, actually improves by a similar 4% margin, indicating that roughly half of the gains we observe are not even necessarily a result of our features doing what they were designed to do.

Our weak cues do yield some small gains, so there is hope that better weak indicators of semantic compatibility could prove more useful. However, while extremely high-precision approaches with carefully engineered features have been shown to be successful (Rahman and Ng, 2011a; Bansal and Klein, 2012; Recasens et al., 2013a), we conclude that capturing semantics in a data-driven, shallow manner remains an uphill battle.

6 FINAL System and Results

While semantic features ended up giving only marginal benefit, we have demonstrated that nevertheless our SURFACE system is a state-of-the-art English coreference system. However, there remain a few natural features that we omitted in order to keep the system as simple as possible, since they were orthogonal to the discussion of data-driven versus heuristic-driven features and do not target world knowledge. Before giving final results, we will present a small set of additional features that consider four additional mention properties beyond those in Section 4.1:

- Whether two mentions are nested
- Ancestry of each mention head: the dependency parent and grandparent POS tags and arc directions (shown in Figure 3)
- The speaker of each mention
- Number and gender of each mention as determined by Bergsma and Lin (2006)

The specific additional features we use are shown in Table 6. Note that unlike in Section 5, we use the number and gender information only on the antecedent. Due to our conjunction scheme, both this

[9] This observation is more general than just our system: the majority of coreference systems, including the winners of the CoNLL shared tasks (Lee et al., 2011; Fernandes et al., 2012), opt for high mention recall and resolve a relatively large number of system mentions.

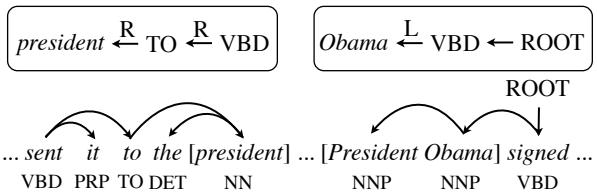

Figure 3: Demonstration of the ancestry extraction process. These features capture more sophisticated configurational information than our context word features do: in this example, *president* is in a characteristic indirect object position based on its dependency parents, and *Obama* is the subject of the main verb of the sentence.

Feature name	Count
Features of the SURFACE system	418704
Features on the current mention	
[ANAPHORIC] + [CURRENT ANCESTRY]	46047
Features on the antecedent	
[ANTECEDENT ANCESTRY]	53874
[ANTECEDENT GENDER]	338
[ANTECEDENT NUMBER]	290
Features on the pair	
[HEAD CONTAINED (T/F)]	136
[EXACT STRING CONTAINED (T/F)]	133
[NESTED (T/F)]	355
[DOC TYPE] + [SAME SPEAKER (T/F)]	437
[CURRENT ANCESTRY] + [ANT. ANCESTRY]	2555359

Table 6: FINAL feature set; note that this includes the SURFACE feature set. As with the features of the SURFACE system, two conjoined variants of each feature are included: first with the type of the current mention (NOMINAL, PROPER, or the citation form of the pronoun), then with the types of both mentions in the pair. These conjunctions allow antecedent features on gender and number to impact pronoun resolution, and they allow speaker match to capture effects like *I* and *you* being coreferent when the speakers differ.

semantic information and the speaker information can apply in a fine-grained way to different pronouns, and can therefore improve pronoun resolution substantially; however, these features generally only improve pronoun resolution.

Full results for our SURFACE and FINAL feature sets are shown in Table 7. Again, we compare to Lee et al. (2011) and Björkelund and Farkas (2012).[10] Despite our system's emphasis on one-pass resolution with as simple a feature set as possible, we are able to outperform even these sophisticated systems by a wide margin.

7 Related Work

Many of the individual features we employ in the FINAL feature set have appeared in other coreference systems (Björkelund and Nugues, 2011; Rahman and Ng, 2011b; Fernandes et al., 2012). However, other authors have often emphasized bilexical features on head pairs, whereas our features are heavily monolexical. For feature conjunctions, other authors have exploited three classes (Lee et al., 2011) or automatically learned conjunction schemes (Fernandes et al., 2012; Lassalle and Denis, 2013), but to our knowledge we are the first to do fine-grained modeling of every pronoun. Inclusion of a hierarchy of features with regularization also means that we organically get distinctions among different mention types without having to choose a level of granularity a priori, unlike the distinct classifiers employed by Denis and Baldridge (2008).

In terms of architecture, many coreference systems operate in a pipelined fashion, making partial decisions about coreference or pruning arcs before full resolution. Some systems use separate rule-based and learning-based passes (Chen and Ng, 2012; Fernandes et al., 2012), a series of learning-based passes (Björkelund and Farkas, 2012), or referentiality classifiers that prune the set of mentions before resolution (Rahman and Ng, 2009; Björkelund and Farkas, 2012; Recasens et al., 2013b). By contrast, our system resolves all mentions in one pass and does not need pruning: the SURFACE system can train in less than two hours without any subsampling of coreference arcs, and rule-based pruning of coreference arcs actually causes our system to perform less well, since our features can learn valuable information from these negative examples.

[10] Discrepancies between scores here and those printed in Pradhan et al. (2012) arise from two sources: improvements to the system of Lee et al. (2011) since the first CoNLL shared task, and a fix to the scoring of B^3 in the official scorer since results of the two CoNLL shared tasks were released. Unfortunately, because of this bug in the scoring program, direct comparison to the printed results of the other highest-scoring English systems, Fernandes et al. (2012) and Martschat et al. (2012), is impossible.

Table 7: CoNLL metric scores for our systems on the CoNLL development and blind test sets, compared to the results of Lee et al. (2011) (STANFORD) and Björkelund and Farkas (2012) (IMS). Starred systems are contributions of this work. Bolded F_1 values represent statistically significant improvements over other systems with $p < 0.05$ using a bootstrap resampling test. Metric values reflect version 5 of the CoNLL scorer.

8 Conclusion

We have presented a coreference system that uses a simple, homogeneous set of features in a discriminative learning framework to achieve high performance. Large numbers of lexicalized, data-driven features implicitly model linguistic phenomena such as definiteness and centering, obviating the need for heuristic-driven rules explicitly targeting these same phenomena. Additional semantic features give only slight benefit beyond head match because they do not provide strong enough signals of coreference to improve performance in the system mention setting; modeling semantic similarity still requires complex outside information and deep heuristics.

Our system, the Berkeley Coreference Resolution System, is publicly available at `http://nlp.cs.berkeley.edu`.

Breaking Out of Local Optima with Count Transforms and Model Recombination: A Study in Grammar Induction

Abstract

Many statistical learning problems in NLP call for local model search methods. But accuracy tends to suffer with current techniques, which often explore either too narrowly or too broadly: hill-climbers can get stuck in local optima, whereas samplers may be inefficient. We propose to arrange individual local optimizers into organized networks. Our building blocks are operators of two types: (i) *transform*, which suggests new places to search, via non-random restarts from already-found local optima; and (ii) *join*, which merges candidate solutions to find better optima. Experiments on grammar induction show that pursuing different transforms (e.g., discarding parts of a learned model or ignoring portions of training data) results in improvements. Groups of locally-optimal solutions can be further perturbed jointly, by constructing mixtures. Using these tools, we designed several modular dependency grammar induction networks of increasing complexity. Our complete system achieves 48.6% accuracy (directed dependency macro-average over all 19 languages in the 2006/7 CoNLL data) — more than 5% higher than the previous state-of-the-art.

1 Introduction

Statistical methods for grammar induction often boil down to solving non-convex optimization problems. Early work attempted to locally maximize the likelihood of a corpus, using EM to estimate probabilities of dependency arcs between word bigrams (Paskin 2001a; 2001b). That parsing model has since been extended to make unsupervised learning more feasible (Klein and Manning, 2004; Headden et al., 2009; Spitkovsky et al., 2012b). But even the latest techniques can be quite error-prone and sensitive to initialization, because of approximate, local search.

In theory, global optima can be found by enumerating all parse forests that derive a corpus, though this is usually prohibitively expensive in practice. A preferable brute force approach is sampling, as in Markov-chain Monte Carlo (MCMC) and random restarts (Hu et al., 1994), which hit exact solutions eventually. Restarts can be giant steps in a parameter space that undo all previous work. At the other extreme, MCMC may cling to a neighborhood, rejecting most proposed moves that would escape a local attractor. Sampling methods thus take unbounded time to solve a problem (and can't certify optimality) but are useful for finding approximate solutions to grammar induction (Cohn et al., 2011; Mareček and Žabokrtský, 2011; Naseem and Barzilay, 2011).

We propose an alternative (deterministic) search heuristic that combines local optimization via EM with *non*-random restarts. Its new starting places are informed by previously found solutions, unlike conventional restarts, but may not resemble their predecessors, unlike typical MCMC moves. We show that one good way to construct such steps in a parameter space is by forgetting some aspects of a learned model. Another is by merging promising solutions, since even simple interpolation (Jelinek and Mercer, 1980) of local optima may be superior to all of the originals. Informed restarts can make it possible to explore a combinatorial search space more rapidly and thoroughly than with traditional methods alone.

2 Abstract Operators

Let C be a collection of counts — the sufficient statistics from which a candidate solution to an optimization problem could be computed, e.g., by smoothing and normalizing to yield probabilities. The counts may be fractional and solutions could take the form of multinomial distributions. A local optimizer L will convert C into $C^* = L_{\mathcal{D}}(C)$ — an updated collection of counts, resulting in a probabilistic model that is no less (and hopefully more) consistent with a data set $\mathcal{D}$ than the original C:

$$C \longrightarrow \boxed{L_{\mathcal{D}}} \longrightarrow C^* \tag{1}$$

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1983–1995,
Seattle, Washington, USA, 18-21 October 2013.

Unless C^* is a global optimum, we should be able to make further improvements. But if L is idempotent (and ran to convergence) then $L(L(C)) = L(C)$. Given only C and $L_{\mathcal{D}}$, the single-node optimization network above would be the minimal search pattern worth considering. However, if we had another optimizer L' — or a fresh starting point C' — then more complicated networks could become useful.

2.1 Transforms (Unary)

New starts could be chosen by perturbing an existing solution, as in MCMC, or independently of previous results, as in random restarts. We focus on intermediate changes to C, without injecting randomness.

All of our transforms involve selective forgetting or filtering. For example, if the probabilistic model that is being estimated decomposes into independent constituents (e.g., several multinomials) then a subset of them can be reset to uniform distributions, by discarding associated counts from C. In text classification, this could correspond to eliminating frequent or rare tokens from bags-of-words. We use circular shapes to represent such model ablation operators:

(2)

An orthogonal approach might separate out various counts in C by their provenance. For instance, if $\mathcal{D}$ consisted of several heterogeneous data sources, then the counts from some of them could be ignored: a classifier might be estimated from just news text. We will use squares to represent data-set filtering:

(3)

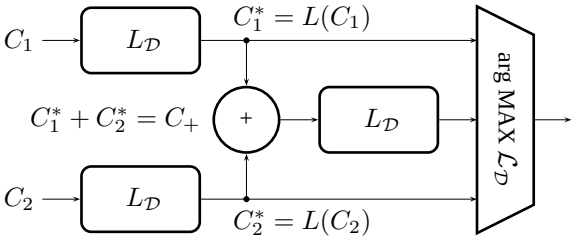
Finally, if C represents a mixture of possible interpretations over $\mathcal{D}$ — e.g., because it captures the output of a "soft" EM algorithm — contributions from less likely, noisier completions could also be suppressed (and their weights redistributed to the more likely ones), as in "hard" EM. Diamonds will represent plain (single) steps of Viterbi training:

(4)

2.2 Joins (Binary)

Starting from different initializers, say C_1 and C_2, it may be possible for L to arrive at distinct local optima, $C_1^* \neq C_2^*$. The better of the two solutions, according to likelihood $\mathcal{L}_{\mathcal{D}}$ of $\mathcal{D}$, could then be selected — as is standard practice when sampling.

Our joining technique could do better than either C_1^* or C_2^*, by entertaining also a third possibility, which combines the two candidates. We construct a mixture model by adding together all counts from C_1^* and C_2^* into $C_+ = C_1^* + C_2^*$. Original initializers C_1, C_2 will, this way, have equal pull on the merged model,[1] regardless of nominal size (because C_1^*, C_2^* will have converged using a shared training set, $\mathcal{D}$). We return the best of C_1^*, C_2^* and $C_+^* = L(C_+)$. This approach may uncover more (and never returns less) likely solutions than choosing among C_1^*, C_2^* alone:



(5)

We will use a short-hand notation to represent the combiner network diagrammed above, less clutter:

(6)

3 The Task and Methodology

We apply transform and join paradigms to grammar induction, an important problem of computational linguistics that involves notoriously difficult objectives (Pereira and Schabes, 1992; de Marcken, 1995; Gimpel and Smith, 2012, *inter alia*). The goal is to induce grammars capable of parsing unseen text. Input, in both training and testing, is a sequence of tokens labeled as: (i) a lexical item and its category, (w, c_w); (ii) a punctuation mark; or (iii) a sentence boundary. Output is unlabeled dependency trees.

3.1 Models and Data

We constrain all parse structures to be projective, via dependency-and-boundary grammars (Spitkovsky et al., 2012a; 2012b): DBMs 0–3 are head-outward generative parsing models (Alshawi, 1996) that distinguish complete sentences from incomplete fragments in a corpus $\mathcal{D}$: $\mathcal{D}_{\text{comp}}$ comprises inputs ending with punctuation; $\mathcal{D}_{\text{frag}} = \mathcal{D} - \mathcal{D}_{\text{comp}}$ is everything

[1] If desired, a scaling factor could be used to bias C_+ towards either C_1^* or C_2^*, for example based on their likelihood ratio.

else. The "complete" subset is further partitioned into simple sentences, $\mathcal{D}_{\text{simp}} \subseteq \mathcal{D}_{\text{comp}}$, with no internal punctuation, and others, which may be complex.

As an example, consider the beginning of an article from (simple) Wikipedia: (i) ***Linguistics*** (ii) *Linguistics (sometimes called philology) is the science that studies language.* (iii) *Scientists who study language are called linguists.* Since the title does not end with punctuation, it would be relegated to $\mathcal{D}_{\text{frag}}$. But two complete sentences would be in $\mathcal{D}_{\text{comp}}$, with the last also filed under $\mathcal{D}_{\text{simp}}$, as it has only a trailing punctuation mark. Spitkovsky et al. suggested two curriculum learning strategies: (i) one in which induction begins with clean, simple data, $\mathcal{D}_{\text{simp}}$, and a basic model, DBM-1 (2012b); and (ii) an alternative bootstrapping approach: starting with still more, simpler data — namely, short inter-punctuation fragments up to length $l = 15$, $\mathcal{D}^l_{\text{split}} \supseteq \mathcal{D}^l_{\text{simp}}$ — and a bare-bones model, DBM-0 (2012a). In our example, $\mathcal{D}_{\text{split}}$ would hold five text snippets: (i) *Linguistics*; (ii) *Linguistics*; (iii) *sometimes called philology*; (iv) *is the science that studies language*; and (v) *Scientists who study language are called linguists.* Only the last piece of text would still be considered complete, isolating its contribution to sentence root and boundary word distributions from those of incomplete fragments. The sparse model, DBM-0, assumes a uniform distribution for roots of incomplete inputs and reduces conditioning contexts of stopping probabilities, which works well with split data. We will exploit both DBM-0 and the full DBM,[2] drawing also on split, simple and raw views of input text.

All experiments prior to final multi-lingual evaluation will use the Penn English Treebank's Wall Street Journal (WSJ) portion (Marcus et al., 1993) as the underlying tokenized and sentence-broken corpus $\mathcal{D}$. Instead of gold parts-of-speech, we plugged in 200 context-sensitive unsupervised tags, from Spitkovsky et al. (2011c),[3] for the word categories.

3.2 Smoothing and Lexicalization

All unlexicalized instances of DBMs will be estimated with "add one" (a.k.a. Laplace) smoothing, using only the word category c_w to represent a token. Fully-lexicalized grammars (L-DBM) are left unsmoothed, and represent each token as both a word and its category, i.e., the whole pair (w, c_w). To evaluate a lexicalized parsing model, we will always obtain a delexicalized-and-smoothed instance first.

3.3 Optimization and Viterbi Decoding

We use "early-switching lateen" EM (Spitkovsky et al., 2011a, §2.4) to train unlexicalized models, alternating between the objectives of ordinary (soft) and hard EM algorithms, until neither can improve its own objective without harming the other's. This approach does not require tuning termination thresholds, allowing optimizers to run to numerical convergence if necessary, and handles only our shorter inputs ($l \leq 15$), starting with soft EM ($L = \text{SL}$, for "soft lateen"). Lexicalized models will cover full data ($l \leq 45$) and employ "early-stopping lateen" EM (2011a, §2.3), re-estimating via hard EM until soft EM's objective suffers. Alternating EMs would be expensive here, since updates take (at least) $O(l^3)$ time, and hard EM's objective ($L = \text{H}$) is the one better suited to long inputs (Spitkovsky et al., 2010).

Our decoders always force an inter-punctuation fragment to derive itself (Spitkovsky et al., 2011b, §2.2).[4] In evaluation, such (*loose*) constraints may help attach *sometimes* and *philology* to *called* (and *the science...* to *is*). In training, stronger (*strict*) constraints also disallow attachment of fragments' heads by non-heads, to connect *Linguistics*, *called* and *is* (assuming each piece got parsed correctly).

3.4 Final Evaluation and Metrics

Evaluation is against held-out CoNLL shared task data (Buchholz and Marsi, 2006; Nivre et al., 2007), spanning 19 languages. We compute performance as directed dependency accuracies (DDA), fractions of correct unlabeled arcs in parsed output (an extrinsic metric).[5] For most WSJ experiments we include also sentence and parse tree cross-entropies (soft and hard EMs' intrinsic metrics), in bits per token (bpt).

[2] We use the short-hand DBM to refer to DBM-3, which is equivalent to DBM-2 if $\mathcal{D}$ has no internally-punctuated sentences ($\mathcal{D}$=$\mathcal{D}_{\text{split}}$), and DBM-1 if all inputs also have trailing punctuation ($\mathcal{D}$=$\mathcal{D}_{\text{simp}}$); DBM_0 is our short-hand for DBM-0.

[3] `http://nlp.stanford.edu/pubs/goldtags-data.tar.bz2`

[4] But these constraints do not impact training with shorter inputs, since there is no internal punctuation in $\mathcal{D}_{\text{split}}$ or $\mathcal{D}_{\text{simp}}$.

[5] We converted gold labeled constituents in WSJ to unlabeled reference dependencies using deterministic "head-percolation" rules (Collins, 1999); sentence root symbols, though not punctuation arcs, contribute to scores, as is standard (Paskin, 2001b).

4 Concrete Operators

We will now instantiate the operators sketched out in §2 specifically for the grammar induction task.

Throughout, we repeatedly employ single steps of Viterbi training to transfer information between subnetworks in a model-independent way: when a module's output is a set of (Viterbi) parse trees, it necessarily contains sufficient information required to estimate an arbitrarily-factored model down-stream.[6]

4.1 Transform #1: A Simple Filter

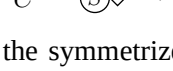
Given a model that was estimated from (and therefore parses) a data set $\mathcal{D}$, the simple filter (F) attempts to extract a cleaner model, based on the simpler complete sentences of $\mathcal{D}_{\text{simp}}$. It is implemented as a single (unlexicalized) step of Viterbi training:

(7)

The idea here is to focus on sentences that are not too complicated yet grammatical. This punctuation-sensitive heuristic may steer a learner towards easy but representative training text and, we showed, aids grammar induction (Spitkovsky et al., 2012b, §7.1).

4.2 Transform #2: A Symmetrizer

The symmetrizer (S) reduces input models to sets of word association scores. It blurs all details of induced parses in a data set $\mathcal{D}$, except the number of times each (ordered) word pair participates in a dependency relation. We implemented symmetrization also as a single unlexicalized Viterbi training step, but now with proposed parse trees' scores, for a sentence in $\mathcal{D}$, proportional to a product over non-root dependency arcs of one plus how often the left and right tokens (are expected to) appear connected:



(8)

The idea behind the symmetrizer is to glean information from skeleton parses. Grammar inducers can sometimes make good progress in resolving undirected parse structures despite being wrong about the polarities of most arcs (Spitkovsky et al., 2009, Figure 3: Uninformed). Symmetrization offers an extra chance to make heads or tails of syntactic relations, after learning which words tend to go together.

At each instance where a word ⓐ attaches ⓩ on (say) the right, our implementation attributes half its weight to the intended construction, ⓐ⁀ⓩ, reserving the other half for the symmetric structure, ⓩ attaching ⓐ to its left: ⓐ⁀ⓩ. For the desired effect, these aggregated counts are left unnormalized, while all other counts (of word fertilities and sentence roots) get discarded. To see why we don't turn word attachment scores into probabilities, consider sentences ⓐ ⓩ and ⓒ ⓩ. The fact that ⓩ co-occurs with ⓐ introduces an asymmetry into ⓩ's relation with ⓒ: $\mathbb{P}(\text{ⓩ} \mid \text{ⓒ}) = 1$ differs from $\mathbb{P}(\text{ⓒ} \mid \text{ⓩ}) = 1/2$. Normalizing might force the interpretation ⓒ⁀ⓩ (and also ⓐ⁀ⓩ), not because there is evidence in the data, but as a side-effect of a model's head-driven nature (i.e., factored with dependents conditioned on heads). Always branching right would be a mistake, however, for example if ⓩ is a noun, since either of ⓐ or ⓒ could be a determiner, with the other a verb.

4.3 Join: A Combiner

The combiner must admit arbitrary inputs, including models not estimated from $\mathcal{D}$, unlike the transforms. Consequently, as a preliminary step, we convert each input C_i into parse trees of $\mathcal{D}$, with counts C_i', via Viterbi-decoding with a smoothed, unlexicalized version of the corresponding incoming model. Actual combination is then performed in a more precise (unsmoothed) fashion: C_i^* are the (lexicalized) solutions starting from C_i'; and C_+^* is initialized with their sum, $\sum_i C_i^*$. Counts of the lexicalized model with lowest cross-entropy on $\mathcal{D}$ become the output:[7]

(9)

5 Basic Networks

We are ready to propose a non-trivial subnetwork for grammar induction, based on the transform and join operators, which we will reuse in larger networks.

5.1 Fork/Join (FJ)

Given a model that parses a base data set $\mathcal{D}_0$, the fork/join subnetwork will output an adaptation of that model for $\mathcal{D}$. It could facilitate a grammar induction process, e.g., by advancing it from smaller

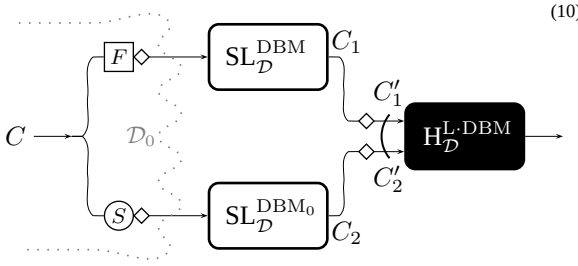
[6] A related approach — initializing EM training with an M-step — was advocated by Klein and Manning (2004, §3).

[7] In our diagrams, lexicalized modules are shaded black.

to larger — or possibly more complex — data sets.

We first fork off two variations of the incoming model based on $\mathcal{D}_0$: (i) a filtered view, which focuses on cleaner, simpler data (transform #1); and (ii) a symmetrized view that backs off to word associations (transform #2). Next is grammar induction over $\mathcal{D}$. We optimize a full DBM instance starting from the first fork, and bootstrap a reduced DBM_0 from the second. Finally, the two new induced sets of parse trees, for $\mathcal{D}$, are merged (lexicalized join):

(10)



The idea here is to prepare for two scenarios: an incoming grammar that is either good or bad for $\mathcal{D}$. If the model is good, DBM should be able to hang on to it and make improvements. But if it is bad, DBM could get stuck fitting noise, whereas DBM_0 might be more likely to ramp up to a good alternative. Since we can't know ahead of time which is the true case, we pursue both optimization paths simultaneously and let a combiner later decide for us.

Note that the forks start (and end) optimizing with soft EM. This is because soft EM integrates previously unseen tokens into new grammars better than hard EM, as evidenced by our failed attempt to reproduce the "baby steps" strategy with Viterbi training (Spitkovsky et al., 2010, Figure 4). A combiner then executes hard EM, and since outputs of transforms are trees, the end-to-end process is a chain of lateen alternations that starts and ends with hard EM.

We will use a "grammar inductor" to represent subnetworks that transition from $\mathcal{D}^l_{\text{split}}$ to $\mathcal{D}^{l+1}_{\text{split}}$, by taking transformed parse trees of inter-punctuation fragments up to length l (base data set, $\mathcal{D}_0$) to initialize training over fragments up to length $l+1$:

$$C \longrightarrow \overset{l+1}{\sim\!\sim\!\sim} \tag{11}$$

The FJ network instantiates a grammar inductor with $l = 14$, thus training on inter-punctuation fragments up to length 15, as in previous work, starting from an empty set of counts, $C = \emptyset$. Smoothing causes initial parse trees to be chosen uniformly at random, as suggested by Cohen and Smith (2010):

$$\emptyset \longrightarrow \overset{15}{\sim\!\sim\!\sim} \tag{12}$$

5.2 Iterated Fork/Join (IFJ)

Our second network daisy-chains grammar inductors, starting from the single-word inter-punctuation fragments in $\mathcal{D}^1_{\text{split}}$, then retraining on $\mathcal{D}^2_{\text{split}}$, and so forth, until finally stopping at $\mathcal{D}^{15}_{\text{split}}$, as before:

$$\overset{1}{\sim\!\sim\!\sim} \bullet \overset{2}{\sim\!\sim\!\sim} \bullet \cdots \bullet \overset{14}{\sim\!\sim\!\sim} \bullet \overset{15}{\sim\!\sim\!\sim} \longrightarrow \tag{13}$$

We diagrammed this system as not taking an input, since the first inductor's output is fully determined by unique parse trees of single-token strings. This iterative approach to optimization is akin to deterministic annealing (Rose, 1998), and is patterned after "baby steps" (Spitkovsky et al., 2009, §4.2).

Unlike the basic FJ, where symmetrization was a no-op (since there were no counts in $C = \emptyset$), IFJ makes use of symmetrizers — e.g., in the third inductor, whose input is based on strings with up to two tokens. Although it should be easy to learn words that go together from very short fragments, extracting correct polarities of their relations could be a challenge: to a large extent, outputs of early inductors may be artifacts of how our generative models factor (see §4.2) or how ties are broken in optimization (Spitkovsky et al., 2012a, Appendix B). We therefore expect symmetrization to be crucial in earlier stages but to weaken any high quality grammars, nearer the end; it will be up to combiners to handle such phase transitions correctly (or gracefully).

5.3 Grounded Iterated Fork/Join (GIFJ)

So far, our networks have been either purely iterative (IFJ) or static (FJ). These two approaches can also be combined, by injecting FJ's solutions into IFJ's more dynamic stream. Our new transition subnetwork will join outputs of grammar inductors that either (i) continue a previous solution (as in IFJ); or (ii) start over from scratch ("grounding" to an FJ):

$$\begin{matrix} C_l \longrightarrow \overset{l+1}{\sim\!\sim\!\sim} \\ \emptyset \longrightarrow \overset{l+1}{\sim\!\sim\!\sim} \end{matrix} \quad \text{H}^{\text{L·DBM}}_{\mathcal{D}^{l+1}_{\text{split}}} \longrightarrow C_{l+1} \tag{14}$$

The full GIFJ network can then be obtained by unrolling the above template from $l = 14$ back to one.

Instance Label	Model	WSJ^{15}_{split} H_{sents}	WSJ^{15}_{split} H_{trees}	WSJ^{15}_{split} DDA	WSJ^{15}_{simp} H_{sents}	WSJ^{15}_{simp} H_{trees}	WSJ^{15}_{simp} DDA	WSJ^{15}_{simp} TA	Description

Table 1: Sentence string and parse tree cross-entropies (in bpt), and accuracies (DDA), on inter-punctuation fragments up to length 15 (WSJ^{15}_{split}) and its subset of simple, complete sentences (WSJ^{15}_{simp}, with exact tree accuracies — TA).

6 Performance of Basic Networks

We compared our three networks' performance on their final training sets, WSJ^{15}_{split} (see Table 1, which also tabulates results for a cleaner subset, WSJ^{15}_{simp}). The first network starts from $C = \emptyset$, helping us establish several straw-man baselines. Its empty initializer corresponds to guessing (projective) parse trees uniformly at random, which has 21.4% accuracy and sentence string cross-entropy of 8.76bpt.

6.1 Fork/Join (FJ)

FJ's symmetrizer yields random parses of WSJ^{14}_{split}, which initialize training of DBM_0. This baseline (B) lowers cross-entropy to 6.18bpt and scores 57.0%. FJ's filter starts from parse trees of WSJ^{14}_{simp} only, and trains up a full DBM. This choice makes a stronger baseline (A), with 5.89bpt cross-entropy, at 62.2%.

The join operator uses counts from A and B, C_1 and C_2, to obtain parse trees whose own counts C'_1 and C'_2 initialize lexicalized training. From each C'_i, an optimizer arrives at C^*_i. Grammars corresponding to these counts have higher cross-entropies, because of vastly larger vocabularies, but also better accuracies: 59.2 and 62.3%. Their mixture C_+ is a simple sum of counts in C^*_1 and C^*_2: it is not expected to be an improvement but happens to be a good move, resulting in a grammar with higher accuracy (64.0%), though not better Viterbi cross-entropy (7.27 falls between 7.08 and 7.30bpt) than both sources. The combiner's third alternative, a locally optimal C^*_+, is then obtained by re-optimizing from C_+. This solution performs slightly better (64.2%) and will be the local optimum returned by FJ's join operator, because it attains the lowest cross-entropy (7.04bpt).

6.2 Iterated Fork/Join (IFJ)

IFJ's iterative approach results in an improvement: 70.5% accuracy and 6.96bpt cross-entropy. To test how much of this performance could be obtained by a simpler iterated network, we experimented with ablated systems that don't fork or join, i.e., our classic "baby steps" schema (chaining together 15 optimizers), using both DBM and DBM_0, with and without a transform in-between. However, all such "linear" networks scored well below 50%. We conclude from these results that an ability to branch out into different promising regions of a solution space, and to merge solutions of varying quality into better models, are important properties of FJ subnetworks.

6.3 Grounded Iterated Fork/Join (GIFJ)

Grounding improves GIFJ's performance further, to 71.4% accuracy and 6.92bpt cross-entropy. This result shows that fresh perspectives from optimizers that start over can make search efforts more fruitful.

7 Enhanced Subnetworks

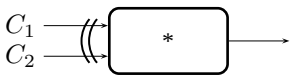
Modularity and abstraction allow for compact representations of complex systems. Another key benefit is that individual components can be understood and improved in isolation, as we will demonstrate next.

7.1 An Iterative Combiner (IC)

Our basic combiner introduced a third option, C^*_+, into a pool of candidate solutions, $\{C^*_1, C^*_2\}$. This new entry may not be a simple mixture of the originals, because of non-linear effects from applying L to $C^*_1 + C^*_2$, but could most likely still be improved.

Rather than stop at C^*_+, when it is better than both originals, we could recombine it with a next best solution, continuing until no further improvement is made. Iterating can't harm a given combiner's cross-entropy (e.g., it lowers FJ's from 7.04 to 7.00bpt), and its advantages can be realized more fully in the larger networks (albeit without any end-to-end guarantees): upgrading all 15 combiners in IFJ would improve performance (slightly) more than grounding (71.5 *vs.* 71.4%), and lower cross-entropy (from 6.96 to 6.93bpt). But this approach is still a bit timid.

A more greedy way is to proceed so long as C^*_+ is not worse than *both* predecessors. We shall now state our most general iterative combiner (IC) algorithm: Start with a solution pool $p = \{C^*_i\}_{i=1}^n$. Next, construct p' by adding $C^*_+ = L(\sum_{i=1}^n C^*_i)$ to p and removing the worst of $n+1$ candidates in the new set. Finally, if $p = p'$, return the best of the solutions in p; otherwise, repeat from $p := p'$. At $n = 2$, one could think of taking $L(C^*_1 + C^*_2)$ as performing a kind of bisection search in some (strange) space. With these new and improved combiners, the IFJ network performs better: 71.9% (up from 70.5 — see Table 1), lowering cross-entropy (down from 6.96 to 6.93bpt). We propose a distinguished notation for the ICs:

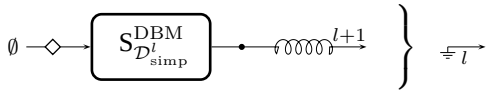


(15)

7.2 A Grammar Transformer (GT)

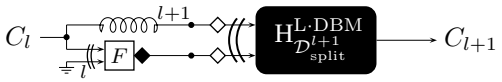
The levels of our systems' performance at grammar induction thus far suggest that the space of possible networks (say, with up to k components) may itself be worth exploring more thoroughly. We leave this exercise to future work, ending with two relatively straight-forward extensions for grounded systems.

Our static bootstrapping mechanism ("ground" of GIFJ) can be improved by pretraining with simple sentences first — as in the curriculum for learning DBM-1 (Spitkovsky et al., 2012b, §7.1), but now with a variable length cut-off l (much lower than the original 45) — instead of starting from $\emptyset$ directly:



(16)

The output of this subnetwork can then be refined, by reconciling it with a previous dynamic solution. We perform a mini-join of a new ground's counts with C_l, using the filter transform (single steps of *lexicalized* Viterbi training on clean, simple data), ahead of the main join (over more training data):

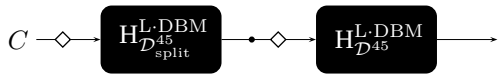


(17)

This template can be unrolled, as before, to obtain our last network (GT), which achieves 72.9% accuracy and 6.83bpt cross-entropy (slightly less accurate with basic combiners, at 72.3% — see Table 1).

8 Full Training and System Combination

All systems that we described so far stop training at $\mathcal{D}^{15}_{\mathrm{split}}$. We will use a two-stage adaptor network to transition their grammars to a full data set, $\mathcal{D}^{45}$:



(18)

The first stage exposes grammar inducers to longer inputs (inter-punctuation fragments with up to 45 tokens); the second stage, at last, reassembles text snippets into actual sentences (also up to $l = 45$).[8]

After full training, our IFJ and GT systems parse Section 23 of WSJ at 62.7 and 63.4% accuracy, better than the previous state-of-the-art (61.2% — see Table 2). To test the generalized IC algorithm, we merged our implementations of these three strong grammar induction pipelines into a combined system (CS). It scored highest: 64.4%.

(19)

The quality of bracketings corresponding to (non-trivial) spans derived by heads of our dependency structures is competitive with the state-of-the-art in unsupervised *constituent* parsing. On the WSJ sentences up to length 40 in Section 23, CS attains similar F_1-measure (54.2 *vs.* 54.6, with higher recall) to

[8] Note that smoothing in the final (unlexicalized) Viterbi step masks the fact that model parts that could not be properly estimated in the first stage (e.g., probabilities of punctuation-crossing arcs) are being initialized to uniform multinomials.

PRLG (Ponvert et al., 2011), which is the strongest system of which we are aware (see Table 3).[9]

9 Multi-Lingual Evaluation

Last, we checked how our algorithms generalize outside English WSJ, by testing in 23 more set-ups: all 2006/7 CoNLL test sets (Buchholz and Marsi, 2006; Nivre et al., 2007), spanning 19 languages. Most recent work evaluates against this multi-lingual data, with the unrealistic assumption of part-of-speech tags. But since inducing high quality word clusters for many languages would be beyond the scope of our paper, here we too plugged in gold tags for word categories (instead of unsupervised tags, as in §3–8).

We compared to the two strongest systems we knew:[10] MZ (Mareček and Žabokrtský, 2012) and SAJ (Spitkovsky et al., 2012b), which report average accuracies of 40.0 and 42.9% for CoNLL data (see Table 4). Our fully-trained IFJ and GT systems score 40.0 and 47.6%. As before, combining these networks with our own implementation of the best previous state-of-the-art system (SAJ) yields a further improvement, increasing final accuracy to 48.6%.

[9] These numbers differ from Ponvert et al.'s (2011, Table 6) for the full Section 23 because we restricted their `eval-ps.py` script to a maximum length of 40 words, in our evaluation, to match other previous work: Golland et al.'s (2012, Figure 1) for CCM and LLCCM; Huang et al.'s (2012, Table 2) for the rest.

[10] During review, another strong system (Mareček and Straka, 2013, scoring 48.7%) of possible interest to the reader came out, exploiting prior knowledge of stopping probabilities (estimated from large POS-tagged corpora, via reducibility principles).

10 Discussion

CoNLL training sets were intended for comparing supervised systems, and aren't all suitable for unsupervised learning: 12 languages have under 10,000 sentences (with Arabic, Basque, Danish, Greek, Italian, Slovenian, Spanish and Turkish particularly small), compared to WSJ's nearly 50,000. In some treebanks sentences are very short (e.g., Chinese and Japanese, which appear to have been split on punctuation), and in others extremely long (e.g., Arabic). Even gold tags aren't always helpful, as their number is rarely ideal for grammar induction (e.g., 42 *vs.* 200 for English). These factors contribute to high variances of our (and previous) results (see Table 4).

Nevertheless, if we look at the more stable average accuracies, we see a positive trend as we move from a simpler fully-trained system (IFJ, 40.0%), to a more complex system (GT, 47.6%), to system combination (CS, 48.6%). Grounding seems to be more important for the CoNLL sets, possibly because of data sparsity or availability of gold tags.

11 Related Work

The surest way to avoid local optima is to craft an objective that doesn't have them. For example, Wang et al. (2008) demonstrated a convex training method for semi-supervised dependency parsing; Lashkari and Golland (2008) introduced a convex reformulation of likelihood functions for clustering tasks; and Corlett and Penn (2010) designed

Table 4: Blind evaluation on 2006/7 CoNLL test sets (all sentences) for our full networks (IFJ and GT), previous state-of-the-art systems of Spitkovsky et al. (2012b) and Mareček and Žabokrtský (2012), and three-way combination with SAJ (CS, including results up to length ten).

a search algorithm for encoding decipherment problems that guarantees to quickly converge on optimal solutions. Convexity can be ideal for comparative analyses, by eliminating dependence on initial conditions. But for many NLP tasks, including grammar induction, the most relevant known objective functions are still riddled with local optima. Renewed efforts to find exact solutions (Eisner, 2012; Gormley and Eisner, 2013) may be a good fit for the smaller and simpler, earlier stages of our iterative networks.

Multi-start methods (Solis and Wets, 1981) can recover certain global extrema almost surely (i.e., with probability approaching one). Moreover, random restarts via uniform probability measures can be optimal, in a worst-case-analysis sense, with parallel processing sometimes leading to exponential speed-ups (Hu et al., 1994). This approach is rarely emphasized in NLP literature. For instance, Moore and Quirk (2008) demonstrated consistent, substantial gains from random restarts in statistical machine translation (but also suggested better and faster replacements — see below); Ravi and Knight (2009, §5, Figure 8) found random restarts for EM to be crucial in parts-of-speech disambiguation. However, other reviews are few and generally negative (Kim and Mooney, 2010; Martin-Brualla et al., 2010).

Iterated local search methods (Hoos and Stützle, 2004; Johnson et al., 1988, *inter alia*) escape local basins of attraction by perturbing candidate solutions, without undoing all previous work. “Large-step” moves can come from jittering (Hinton and Roweis, 2003), dithering (Price et al., 2005, Ch. 2) or smoothing (Bhargava and Kondrak, 2009). Non-improving “sideways” moves offer substantial help with hard satisfiability problems (Selman et al., 1992); and injecting non-random noise (Selman et al., 1994), by introducing “uphill” moves via mixtures of random walks and greedy search strategies, does better than random noise alone or simulated annealing (Kirkpatrick et al., 1983). In NLP, Moore and Quirk’s (2008) random walks from previous local optima were faster than uniform sampling and also increased BLEU scores; Elsner and Schudy (2009) showed that local search can outperform greedy solutions for document clustering and chat disentanglement tasks; and Mei et al. (2001) incorporated tabu search (Glover, 1989; Glover and Laguna, 1993, Ch. 3) into HMM training for ASR.

Genetic algorithms are a fusion of what’s best in local search and multi-start methods (Houck et al., 1996), exploiting a problem’s structure to combine valid parts of any partial solutions (Holland, 1975; Goldberg, 1989). Evolutionary heuristics proved useful in the induction of phonotactics (Belz, 1998), text planning (Mellish et al., 1998), factored modeling of morphologically-rich languages (Duh and Kirchhoff, 2004) and plot induction for story generation (McIntyre and Lapata, 2010). Multi-objective genetic algorithms (Fonseca and Fleming, 1993) can handle problems with equally important but conflicting criteria (Stadler, 1988), using Pareto-optimal ensembles. They are especially well-suited to language, which evolves under pressures from competing (e.g., speaker, listener and learner) constraints, and have been used to model configurations of vowels and tone systems (Ke et al., 2003). Our transform and join mechanisms also exhibit some features of genetic search, and make use of competing objec-

tives: good sets of parse trees must make sense both lexicalized and with word categories, to rich and impoverished models of grammar, and for both long, complex sentences and short, simple text fragments.

This selection of text filters is a specialized case of more general "data perturbation" techniques — even cycling over randomly chosen mini-batches that partition a data set helps avoid some local optima (Liang and Klein, 2009). Elidan et al. (2002) suggested how example-reweighing could cause "informed" changes, rather than arbitrary damage, to a hypothesis. Their (adversarial) training scheme guided learning toward improved generalizations, robust against input fluctuations. Language learning has a rich history of reweighing data via (cooperative) "starting small" strategies (Elman, 1993), beginning from simpler or more certain cases. This family of techniques has met with success in semi-supervised named entity classification (Collins and Singer, 1999; Yarowsky, 1995),[11] parts-of-speech induction (Clark, 2000; 2003), and language modeling (Krueger and Dayan, 2009; Bengio et al., 2009), in addition to unsupervised parsing (Spitkovsky et al., 2009; Tu and Honavar, 2011; Cohn et al., 2011).

12 Conclusion

We proposed several simple algorithms for combining grammars and showed their usefulness in merging the outputs of iterative and static grammar induction systems. Unlike conventional system combination methods, e.g., in machine translation (Xiao et al., 2010), ours do not require incoming models to be of similar quality to make improvements. We exploited these properties of the combiners to reconcile grammars induced by different views of data (Blum and Mitchell, 1998). One such view retains just the simple sentences, making it easier to recognize root words. Another splits text into many inter-punctuation fragments, helping learn word associations. The induced dependency trees can themselves also be viewed not only as directed structures but also as skeleton parses, facilitating the recovery of correct polarities for unlabeled dependency arcs.

By reusing templates, as in dynamic Bayesian network (DBN) frameworks (Koller and Friedman, 2009, §6.2.2), we managed to specify relatively "deep" learning architectures without sacrificing (too much) clarity or simplicity. On a still more speculative note, we see two (admittedly, tenuous) connections to human cognition. First, the benefits of not normalizing probabilities, when symmetrizing, might be related to human language processing through the base-rate fallacy (Bar-Hillel, 1980; Kahneman and Tversky, 1982) and the availability heuristic (Chapman, 1967; Tversky and Kahneman, 1973), since people are notoriously bad at probability (Attneave, 1953; Kahneman and Tversky, 1972; Kahneman and Tversky, 1973). And second, intermittent "unlearning" — though perhaps not of the kind that takes place inside of our transforms — is an adaptation that can be essential to cognitive development in general, as evidenced by neuronal pruning in mammals (Craik and Bialystok, 2006; Low and Cheng, 2006). "Forgetful EM" strategies that reset subsets of parameters may thus, possibly, be no less relevant to unsupervised learning than is "partial EM," which only suppresses updates, other EM variants (Neal and Hinton, 1999), or "dropout training" (Hinton et al., 2012; Wang and Manning, 2013), which is important in supervised settings.

Future parsing models, in grammar induction, may benefit by modeling head-dependent relations separately from direction. As frequently employed in tasks like semantic role labeling (Carreras and Màrquez, 2005) and relation extraction (Sun et al., 2011), it may be easier to first establish existence, before trying to understand its nature. Other key next steps may include exploring more intelligent ways of combining systems (Surdeanu and Manning, 2010; Petrov, 2010) and automating the operator discovery process. Furthermore, we are optimistic that both count transforms and model recombination could be usefully incorporated into sampling methods: although symmetrized models may have higher cross-entropies, hence prone to rejection in vanilla MCMC, they could work well as seeds in multi-chain designs; existing algorithms, such as MCMCMC (Geyer, 1991), which switch contents of adjacent chains running at different temperatures, may also benefit from introducing the option to combine solutions, in addition to just swapping them.

Abstract

We present a framework for cross-lingual transfer of sequence information from a resource-rich source language to a resource-impoverished target language that incorporates soft constraints via posterior regularization. To this end, we use automatically word aligned bitext between the source and target language pair, and learn a discriminative conditional random field model on the target side. Our posterior regularization constraints are derived from simple intuitions about the task at hand and from cross-lingual alignment information. We show improvements over strong baselines for two tasks: part-of-speech tagging and named-entity segmentation.

1 Introduction

Supervised systems for NLP tasks are available for a handful of languages. These systems achieve high accuracy for many applications; a variety of robust algorithms to train them from labeled data have been developed. Here, we focus on learning sequence models for the languages that lack annotated resources. For a given resource-poor target language of interest, we assume that parallel data with a resource-rich source language exists. With the help of this bitext and a supervised system in the source language, we infer constraints over the label distribution in the target language, and train a discriminative model using posterior regularization (Ganchev et al., 2010).

Cross-lingual learning of structured prediction models via parallel data has been applied for several natural language processing problems, including part-of-speech (POS) tagging (Yarowsky and Ngai, 2001), syntactic parsing (Hwa et al., 2005) and named-entity recognition (Kim et al., 2012). These methods are useful in several ways. First, they help in fast prototyping of natural language systems for new languages that do not boast human annotations. Second, the output of such systems could be used to bootstrap more extensive human annotation projects (Vlachos, 2006). Finally, they are significantly more accurate than purely unsupervised systems (McDonald et al., 2011; Das and Petrov, 2011).

Recently, Täckström et al. (2013) presented a technique for coupling token constraints derived from projected cross-lingual information and type constraints derived from noisy tag dictionaries to learn POS taggers. Although this technique resulted in state-of-the-art weakly supervised taggers, the authors used a heuristic to combine the aforementioned two sources of constraints: the dictionary constraints pruned the tagger's search space, and the intersected token-level projections were treated as hard observations. On the other hand, Ganchev et al. (2009) presented a framework for learning weakly-supervised systems (in their case, dependency parsers) that incorporated alignment-based information too, but used the cross-lingual information only as soft constraints, via posterior regularization. The advantage of this framework lay in the fact that the projections were only trusted to a certain degree, determined by a strength hyperparameter, which unfortunately the authors did not have an elegant way to tune. In this paper, we exploit the better aspects of these two lines of work: first, we extend the framework of Täckström et al. by treating the alignment-based projections only as soft constraints (see §3.4); second, we choose the constraint strength by utilizing the tag ambiguity of tokens for a given resource-poor language (see §6.1).

Other than validating our framework on part-of-speech tagging, we experiment on named-entity segmentation in a cross-lingual framework. For this

Proceedings of the 2013 Conference on Empirical Methods in Natural Language Processing, pages 1996–2006,
Seattle, Washington, USA, 18-21 October 2013.

task, we present a novel method to perform high-precision phrase-level entity transfer (§5.2.2); we also provide ways to balance precision and recall with posterior regularization (§6.2) by incorporating intuitive soft constraints during learning. We measure performance on standard benchmark datasets for both of these tasks, and report improvements over state-of-the-art baselines.

2 Prior Work

Cross-lingual projection methods can be classified by their use of two very broad ideas. The first idea utilizes parallel data to create full or partial annotations in the low-resource language and trains from this data. This was popularized by Yarowsky and Ngai (2001) who applied this to POS tagging and shallow parsing. It was later applied to parsing (Hwa et al., 2005) and named entity recognition (Kim et al., 2012). The second idea, first proposed by Zeman and Resnik (2008) and applied more broadly by McDonald et al. (2011), is to train a model on a resource-rich language and apply it to a resource-poor language directly. The disparity between the languages is mitigated by the choice of features. In addition to cross-lingual projection, purely unsupervised methods have been explored but with limited success (Christodoulopoulos et al., 2010). Here, we resort to cross-lingual projection and incorporate the first idea; we also follow Li et al. (2012) and use Wiktionary to further constrain the POS tagging task.

Our learning setup is similar to that of Ganchev et al. (2009), who also use posterior regularization but focus on dependency parsing alone. Our work differs with respect to the tasks, the learning algorithm and also in that we use corpus-wide constraints, while Ganchev et al. use one constraint per sentence. For the part-of-speech tagging task, our approach is similar to that of Täckström et al. (2013), who use an almost identical learning setup but only make use of hard constraints. By relaxing these constraints, we allow the model to identify and ignore inconsistently labeled parts of sentences, and achieve better results using identical training and test data.

3 Approach

We give an overview of our approach, and present the details of our model used for cross-lingual learning.

Algorithm 1 Cross-Lingual Learning with Posterior Regularization

Require: Parallel source and target language data $\mathcal{D}^e$ and $\mathcal{D}^f$, source language model $(M)^e$, task-specific target language constraints $\mathcal{C}$.
Ensure: Θ^f, a set of target language parameters.
1: $\mathcal{D}^{e \leftrightarrow f} \leftarrow$ word-align-bitext$(\mathcal{D}^e, \mathcal{D}^f)$
2: $\widehat{\mathcal{D}^e} \leftarrow$ label-supervised$(\mathcal{D}^e)$
3: $\widehat{\mathcal{D}^f} \leftarrow$ project-and-filter-labels$(\mathcal{D}^{e \leftrightarrow f}, \widehat{\mathcal{D}^e})$
4: $\Theta^f \leftarrow$ learn-posterior-constrained$(\widehat{\mathcal{D}^f}, \mathcal{C})$
5: Return Θ^f

3.1 General Overview

The general overview of our framework is provided in Algorithm 1. The process of learning parameters for a target language for a given task involves four subtasks. First, we run word alignment over a large corpus of parallel data between the resource-rich source language and the resource-impoverished target language (see §4.3). In the second step, we use a supervised model to label the source side of the parallel data (see §5.1.1 and §5.2.1). The third step involves a task-specific word-alignment filtering step; this step involves heuristics for which we use cues from prior state-of-the-art (Das and Petrov, 2011; Täckström et al., 2013, see §5.1.2) and also introduce some novel ones for the NE segmentation problem (see §5.2.2). In the fourth step, we train a linear chain conditional random field (Lafferty et al., 2001, CRF henceforth) using posterior regularization. In the next subsection, we turn to a brief summary of this final step of estimating parameters of a discriminative model with posterior regularization.

3.2 Learning with Posterior Regularization

In this work, we utilize discriminative CRF models, and use posterior regularization (PR) to optimize their parameters. As a framework, posterior regularization is described in detail by Ganchev et al. (2010). However in our work, we adopt a different optimization technique; in what follows, we summarize the optimization algorithm in the context of CRF models.

Let $\mathbf{x}$ be an input sentence with a set of possible labelings $\mathcal{Y}(\mathbf{x})$ and let $\mathbf{y} \in \mathcal{Y}(\mathbf{x})$ be a particular labeling for sentence $\mathbf{x}$. We use bold capital letters $\mathbf{X} = \{\mathbf{x}_1 \dots \mathbf{x}_n\}$ and $\mathbf{Y} = \{\mathbf{y}_1 \dots \mathbf{y}_n\}$ to denote

a corpus of sentences and labelings for the corpus respectively. A CRF models the probability distribution over possible labels for a sentence $p_\theta(\mathbf{y}|\mathbf{x})$ as:

$$p_\theta(\mathbf{y} \mid \mathbf{x}) \propto \exp(\theta \cdot \mathbf{f}(\mathbf{x}, \mathbf{y})) \quad (1)$$

where θ are the model parameters and $\mathbf{f}(.)$ is a feature function. The model examines sentences in isolation, and the probability of a particular labeling for a corpus is defined as a product over the individual sentences:

$$p_\theta(\mathbf{Y} \mid \mathbf{X}) = \prod_{(\mathbf{x},\mathbf{y})\in(\mathbf{X},\mathbf{Y})} p_\theta(\mathbf{y} \mid \mathbf{x}). \quad (2)$$

Traditionally, CRF models have been trained to optimize the regularized log-likelihood of the training data

$$\max_\theta \ \mathcal{L}(\theta) = \max_\theta \ \log(p_\theta(\mathbf{Y} \mid \mathbf{X})) - \gamma \, ||\theta|| \quad (3)$$

In our setting, we do not have a fully labeled corpus, but we have constraints on the distribution of labels. For example, we may know that a particular token could be labeled only by a label inventory licensed by a dictionary, or that a labeling projected from a source language is usually (but not always) correct. We define these constraints in terms of feature expectations. Let $q(\mathbf{Y})$ be a distribution over all possible labelings of our corpus $\mathcal{Y}(\mathbf{X})$. Let $\mathcal{Q}$ be a set of distributions defined by:

$$\mathcal{Q} = \{q(\mathbf{Y}) : \mathbf{E}_q[\phi(\mathbf{X}, \mathbf{Y})] \leq \mathbf{b}\}, \quad (4)$$

where ϕ is a *constraint* feature function and $\mathbf{b}$ is a vector of non-negative values that serve as upper bounds to the expectations of every constraint feature. The vector $\mathbf{b}$ is used to encode our prior knowledge about desirable distributions $q(\mathbf{Y})$. Note that the constraint features ϕ are not related to the model features $\mathbf{f}$. The model features, together with the model parameters θ define the CRF model; the model features need to be computed at inference time for prediction. By contrast, the constraint features and their corresponding constraint values are used to define our training objective function (and are only used during learning). The PR objective with no labeled data is defined with respect to $\mathcal{Q}$ as:

$$\textbf{PR: } \max_\theta \ \mathcal{J}_\mathcal{Q}(\theta) = \max_\theta \ -\mathbf{KL}(\mathcal{Q}||p_\theta(\mathbf{Y} \mid \mathbf{X})) - \gamma \, ||\theta|| \quad (5)$$

where $\mathbf{KL}(\mathcal{Q}||p) = \min_{q\in\mathcal{Q}} \mathbf{KL}(q||p)$ is the KL-divergence (Kullback and Leibler, 1951) from a set to a point. Note that as we add more constraints, $\mathcal{Q}$ becomes a smaller set. In the limit, $\mathcal{Q} = \{q(\mathbf{Y}) : q(\hat{\mathbf{Y}}) = 1\}$ contains just one distribution concentrated on a single labeling $\hat{\mathbf{Y}}$. In this limit, posterior regularization degenerates into the convex log-likelihood objective normally used for supervised data $\mathcal{J}_\mathcal{Q}(\theta) = \mathcal{L}(\theta)$. However, in the general case, the PR objective $\mathcal{J}_\mathcal{Q}$ is not necessarily convex. Prior work, including that of Ganchev et al. propose an algorithm similar to Expectation-Maximization (Dempster et al., 1977, EM henceforth) to optimize $\mathcal{J}_\mathcal{Q}$, but we follow Liang et al. (2009) in using a schochastic update-based algorithm described below.

Note: To make it easier to reason about constraint values $\mathbf{b}$, we scale constraint features $\phi(\mathbf{X}, \mathbf{Y})$ to lie in $[0, 1]$ by computing $\max_\mathbf{Y} \phi(\mathbf{X}, \mathbf{Y})$ for the corpus to which ϕ is applied.

3.3 Optimization

The optimization procedure proposed by Ganchev et al. is similar to the EM algorithm, and computes the minimization $\min_{q\in\mathcal{Q}} \mathbf{KL}(q||p)$ at each step, using its dual form; this minimization is convex, so there is no duality gap. They show that the optimal primal variables $q^*(\mathbf{Y})$ are related to the optimal dual variables λ^* by:

$$q^*(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{X})e^{-\lambda^*\cdot\phi(\mathbf{X},\mathbf{Y})}}{Z(\lambda^*)}. \quad (6)$$

where $Z(\lambda^*)$ is the normalizer. The dual problem is given by:

$$\max_{\lambda\geq 0} -\mathbf{b}\cdot\lambda - \log Z(\lambda). \quad (7)$$

Substituting Eq. 7 into the objective in Eq. 5, we get the saddle-point problem:

$$\max_\theta \ \min_{\lambda\geq 0} \ \mathbf{b}\cdot\lambda + \log \sum_\mathbf{Y} p_\theta(\mathbf{Y}|\mathbf{X})e^{-\lambda^*\cdot\phi(\mathbf{X},\mathbf{Y})} - \gamma \, ||\theta|| \, . \quad (8)$$

To optimize the above objective function, we need to compute partial derivatives with respect to both θ and λ. First, to compute the partial derivatives of Eq. 8

with respect to θ, we need to find expectations of the model features $\mathbf{f}$ given the current distribution p_θ and the constraint distribution q. To perform tractable inference, a linear-chain CRF model assumes that the feature function factorizes according to smaller parts; in particular the factorization uses the following structure:

$$\mathbf{f}(\mathbf{x}, \mathbf{y}) = \sum_i \mathbf{f}(\mathbf{x}, y_i, y_{i-1}) \quad (9)$$

where i ranges over the tokens in the sentence. This factorization allows us to efficiently compute expectations over the labels y_i and label-pairs (y_i, y_{i+1}). To compute the partial gradient of Eq. 8 with respect to λ, we need to find the expectations of the constraint features ϕ. In order to be tractable here too, we ensure that ϕ also factorize according to the same structure as $\mathbf{f}$. Therefore, the gradient computation w.r.t. λ turns out to be straightforward.

For all the experiments in this paper, we optimize Eq. 8 using stochastic projected gradient. For each training sentence, we compute the gradient of θ and λ with respect to Eq. 8, take a gradient step in each one, and truncate the negative entries in λ to zero. We use a step size of 1 for all experiments.[1]

3.4 Relationship with Täckström et al. (2013)

In this subsection, we focus briefly on the relationship between this work and the work of Täckström et al. (2013), who focused on constrained learning of POS taggers. Täckström et al. define constrained lattices and train by optimizing marginal conditional log-likelihood. In our notation, they define their objective as:

$$\max_\theta \log \sum_{\mathbf{Y} \in \widehat{\mathcal{Y}}(\mathbf{X})} p_\theta(\mathbf{Y}|\mathbf{X}) - \gamma\|\theta\| \quad (10)$$

where $\widehat{\mathcal{Y}}(\mathbf{X})$ are the constrained lattices of label sequences that agree with both a dictionary and cross-lingually projected POS tags for each sentence of the training corpus. Let us define a constraint feature $\phi(\mathbf{X}, \mathbf{Y})$ which counts the number of tags in $\mathbf{Y}$ which are outside the constraint set $\widehat{\mathcal{Y}}(\mathbf{X})$ and require $\phi(\mathbf{X}, \mathbf{Y}) \leq 0$. Note that,

$$\arg\min_q \mathbf{KL}(q||p_\theta(\mathbf{Y}|\mathbf{X})) \text{ s.t. } \phi(\mathbf{X}, \mathbf{Y}) \leq 0$$

gives the same distribution as Eq. 10. Given this equivalence, it is easy to see that the gradient of Eq. 5 with respect to θ is the same as that of Eq. 10. By using such constrained lattices, Täckström et al. avoid maintaining a parameter for the constraint, but lose the ability to relax the constraint value and allow some probability mass outside the pruned lattice. Their paper also differs from ours in that they use L-BFGS (Liu and Nocedal, 1989), while we use an online optimization procedure. Since the objectives are non-convex, the two optimization techniques could lead to different local optima even when the constraint is not relaxed ($\mathbf{b} = 0$).

4 Tasks and Data

In this section, we focus on the nature of the two tasks that we attempt to solve, describe the source language datasets we use to train our supervised models for transfer, the target language datasets on which we evaluate our models and the parallel data we use for cross-lingual transfer.

4.1 Part-of-Speech Tagging

First, we focus on the task of part-of-speech tagging. Following previous work on cross-lingual POS tagging (Das and Petrov, 2011; Täckström et al., 2013), we adopt the POS tags of Petrov et al. (2012), version 1.03;[2] we use the October 2012 version of Wiktionary[3] as our tag dictionary.

After pruning the search space with the dictionary, we place soft constraints derived by projecting POS tags across word alignments. The alignments are filtered for confidence (see §5.1.2), but we also filter any projected tags that are not licensed by the dictionary. The example in Figure 1 illustrates why this dictionary filtering step is important. Consider the English-Spanish phrase pair from Figure 1, which we observed in our training data. Our supervised tagger correctly tags *Asian* with the ADJ tag as shown in the figure. *Asian* is aligned to the Spanish word *Asia*, which should be tagged NOUN. Because the Spanish Wiktionary only allows the NOUN tag for *Asia*, we do not project the ADJ tag from the English word *Asian*. By contrast, we do project the NOUN tag from the English word *sponges* to the Spanish

[1] Note that we did not implement regularization of θ in the stochastic optimizer, hence our PR objective (Eq. 8) was unregularized; however, the baseline models use ℓ_2 regularization.

[2] http://code.google.com/p/universal-pos-tags

[3] http://meta.wikimedia.org/wiki/Wiktionary

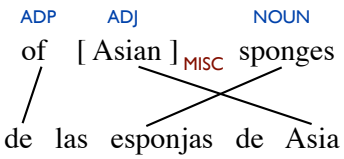

Figure 1: An English (top) – Spanish (bottom) phrase pair from our parallel data. The correct POS tags and NER annotations are shown for the English phrase. Word alignments are shown as links between English and Spanish words.

word *esponjas* because this tag is in our dictionary for the latter word.

For all our POS experiments, we evaluate on seventeen target languages. Fifteen of these languages were part of the experiments conducted by Täckström et al. (2013); we add Arabic and Hungarian to the set. The first column of Table 1 lists all seventeen languages using their two-letter abbreviation codes from the ISO 639-1 standard. The evaluation datasets correspond to the test sets from the CoNLL shared tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). For French we use the treebank of Abeillé et al. (2003). English serves as our source language and we use the Penn Treebank (Marcus et al., 1993, with tags mapped to the universal tags) to train our supervised source-side model.

4.2 Named-Entity Segmentation

Second, we investigate the task of named-entity segmentation. The goal of this task is to identify the boundaries of named-entities for a given language without classifying them by type. This is the *unlabeled* version of named-entity recognition, and is more amenable to cross-lingual supervision. To understand why that is, consider again the example from Figure 1. The English supervised NE tagger correctly identifies *Asian* as a named entity of type MISC (miscellaneous). The word-alignments suggest we should transfer this annotation to the Spanish word *Asia* which is also an entity. However, this should be labeled LOC (location) according to the CoNLL annotation guidelines (Tjong Kim Sang and De Meulder, 2003). Because syntactic variations of this kind are common, it makes cross-lingual detection of NE boundaries as well as types hard.[4] In this paper, we focus on named-entity segmentation alone, consider the full NER task out of scope. We use English as a source language and train a supervised English named-entity tagger with the labels in place, using the CoNLL 2003 shared task data (Tjong Kim Sang and De Meulder, 2003). We project the spans using the maximal-span heuristic (Yarowsky and Ngai, 2001). We project into Dutch, German and Spanish and evaluate on the standard CoNLL 2002 and 2003 shared task data sets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003).

4.3 Parallel Data

For both tasks we use parallel data gathered automatically from the web using the method of Uszkoreit et al. (2010), as well as data from Europarl (Koehn, 2005) and the UN parallel corpus (UN, 2006), for languages covered by the latter two corpora. The parallel sentences are word aligned with the aligner of DeNero and Macherey (2011). The size of the parallel corpus is larger than we need for our tasks, so we follow Täckström et al. (2013) in sampling 500k tokens for POS tagging and 10k sentences for named-entity segmentation (see §5.1.2 and §5.2.2).

5 Experimental Details

In this section, we provide details about task-specific implementations of the supervised source-side model and the word-alignment filtering techniques (steps 2 and 3 in Algorithm 1 respectively); we also briefly describe the setup of the cross-lingual experiments for each task.

5.1 Part-of-Speech Tagging

We first focus on the experimental setup for the POS tagging task. When describing feature sets we refer to features conjoined with just a single tag as *emission features* and with consecutive tag pairs as *transition features*.

[4] We tried using English and German gazetteers from the CoNLL 2002 and 2003 shared tasks as a label dictionary similar to the way we use Wiktionary for POS tagging. This did not work well because the CoNLL gazetteers do not have good coverage on our parallel datasets, which we use for training.

5.1.1 Supervised Source-Side Model

We tag the English side of our parallel data with a supervised first-order linear-chain CRF POS tagger. We use standard features for tagging. Our emission features are a bias feature, the current word, its suffixes up to length 3, its capitalization shape, whether it contains a hyphen, digit or punctuation and its cluster identity. Our transition features are a bias feature and the cluster identities of each word in the transition. For the cluster-based features, we use monolingual word clusters induced with the exchange algorithm of Uszkoreit and Brants (2008), which implements the same objective as Brown et al. (1992); these clusters have shown improvements for sequence labeling tasks (Turian et al., 2010; Täckström et al., 2012). We set the number of clusters to 256 for both the source side tagger and all the other languages. On Section 23 of the WSJ section of the Penn Treebank, the source side tagger achieves an accuracy of 96.2%.

5.1.2 Word Alignment Filtering

Following Täckström et al. (2013), we tag the English side of our parallel data using the source-side POS tagger, intersect the word alignments and filter alignments with confidence below 0.95. We sample 500,000 tokens of target side sentences for each language, and use this as training data for learning weakly-supervised taggers.

5.1.3 Setup for Cross-Lingual Experiments

Following Täckström et al. (2013) we use a reduced feature set for the cross-lingual models. The emission features are the same as the supervised model but without the punctuation feature,[5] and we use only the bias transition feature. Because this limits the ability of the model to use context, we also experiment with an extended feature set that has transition features for the clusters of each word in the transition, and their suffixes up to length 3. We refer to the extended-feature models as "BASE+" and "PR+" to distinguish them from the models with fewer features, labeled "BASE" and "PR".

We train BASE and BASE+ using L-BFGS with an ℓ_2 regularization weight of 1 for 100 iterations to reproduce the setup used by Täckström et al. (2013). We have only one constraint feature in our posterior regularization models that fires for the unpruned projected tags on words x_i. This feature controls how often our model trusts a projected tag; we explain how its strength is chosen in §6.1. The PR and PR+ models are trained using the stochastic gradient method described in §3.3.

[5]The dictionary licenses punctuations, only by the '.' tag.

5.2 Named-Entity Segmentation

In this subsection, we turn to the experimental details of the named-entity segmentation system.

5.2.1 Supervised Source-Side Model

To train our supervised source-side NER model, we implemented a linear-chain first order CRF model. Our feature set was inspired by the model of Kazama and Torisawa (2007, §6.1); we used all the local features from their model except the gazetteer features, and added cluster emission features for offsets in the range [-2, 2] and transition features for offsets in the range [-1, 1] as well as a sentence-start feature. We use automatic POS tags for all the experiments.

We use a BIO encoding of the four NER labels (PER, LOC, ORG and MISC). We also experimented with omitting the NE labels from the tagger, still with a BIO encoding for segments, but the results were worse on average than what we report in Table 2. We train the source-side model on the CoNLL 2003 English training set with log-loss using L-BFGS for 100 iterations with ℓ_2 regularization weight of 0.1. The model gets 90.9% and 87.5% labeled F_1 on the CoNLL development and test sets respectively.[6]

5.2.2 Word-Alignment Filtering

Projecting named entities across languages can be error prone for several reasons. Mistakes introduced by the automatic word aligner is one of them. Word alignment errors are particularly problematic for entity mentions because of the garbage collector effect (Brown et al., 1993); due to differences in the word order between languages, a few alignment errors can result in many errors in the other language. Additionally, entities can occur on just one side of the bitext.[7] Another source of error is the automatic

[6]These performance values would place us among the top three competitors of the CoNLL 2003 shared task.

[7]For example, "*It's all Greek to me.*" in one language and "*I don't understand it.*" in another.

labeling on the source side, which is inaccurate if the parallel corpus is out of domain. To mitigate these errors, we aggressively filter the training data for this task. We discard sentence pairs where more than 30% of the source language tokens are unaligned, where any source entities are unaligned or where any source entities are more than 4 tokens long. We also compute a confidence score over entity annotations as the minimum posterior over the tags that comprise the entity and discard sentence pairs that have an entity with confidence below 0.9. Finally, we discard any sentences that contain no projected entities. These filtering steps allow us to keep 7.4%, 9.7% and 10.4% of the aligned sentence pairs for German, Spanish and Dutch, respectively, resulting in very high-precision named-entity projections (see Table 2). For comparison, we also perform experiments without this filtering step.

5.2.3 Setup for Cross-Lingual Experiments

We use a CRF with the same feature set and BIO encoding for the cross-lingual models as the source-side NER model. We compare our approach ("PR" in Table 2) to a baseline ("BASE" in Table 2) which treats the projected annotations as fully observed. The PR model treats the projected NE spans of a sentence as observed, and allows all labels on the remaining tokens. Since the "O" tag is never seen, an unconstrained model would learn to never predict it. We add two features that fire when the current word is tagged "O": a bias feature and a feature that fires when the automatic POS tag is a proper noun. We set up $\mathcal{Q}$ so the desired expectations are at least 0.98 and at most 0.1 for these constraint features respectively.

6 Results

In this section, we turn to our experimental results; first, we focus on POS tagging and then turn to the NE segmentation task.

6.1 Part-of-Speech Tagging

Constraint Strength: As discussed in §4.1, it is important to filter out projected annotations not licensed by Wiktionary. Thus, the quality of weakly-supervised POS taggers learned from projections is closely correlated with the coverage of the Wiktionary. To quantify the effect of Wiktionary coverage, we counted the expected number of possible tags per token (TpT) for our unlabeled corpora. Specifically, for each token, we counted the number of tags licensed by the dictionary, or all tags for word forms not in the dictionary. For each language, we also ran our system with constraint strengths in {0.7, 0.75, 0.8, 0.85, 0.9, 0.92, 0.95, 0.98, 1.00}, and computed the optimal constraint strength from this set. We found that the best constraint strength is closely correlated with the average number of tags available for each token. Figure 2 shows the best constraint strength as a function of the inverse of the number of unpruned tags per token. As observed in the figure, the relationship between the optimal strength and 1/TpT is roughly linear. Figure 2 also shows a linear approximation to the data plotted. When applying this technique to a new language, we would not be able to estimate the optimal constraint strength, but we could use the linear approximation and knowledge of 1/TpT to estimate it. For our experiments below, we perform this estimation for each language using the linear approximation computed from the remaining languages.

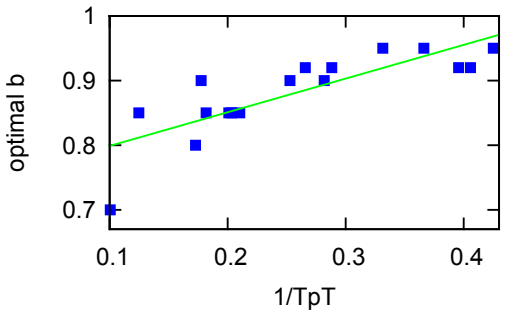

Figure 2: Correlation between optimal constraint value $\mathbf{b}$ and dictionary pruning efficiency. Each blue square is a language, the green line is a linear approximation of the data.

Results: The results for our part-of-speech tagging experiments are in Table 1. We compare our results to BASE, which corresponds to reruns of the best model of Täckström et al. (2013, Column 9 of Table 2), and closely aligns with the numbers reported by the authors. We see in Table 1 that for both feature sets (i.e., with and without the '+' extension), our estimated constraint strength is usually better than using a constraint strength of 1. The results in the column labeled PR are better than BASE for 12 out of 17 languages, and the results for PR+ are

Table 1: POS tagging results. BASE represents the best model of Täckström et al. (2013). PR is a system with the same features but with relaxed constraints. BASE+ and PR+ add additional model features (see §5.2.3). * indicates improvements over the previous state of the art (BASE), and bold values indicate the best score for a language. "Avg" indicates averaged results for all 17 languages, while "-zh-ar" shows averaged results without Chinese and Arabic.

better than BASE+ for 13 out of 17 languages. Additionally, adding features does not tend to help the baseline model to a large extent (the wins are for 6 languages), but does tend to help the PR model (for 11 languages); however, there is a large drop in performance for Chinese.

Error Analysis: Here, we analyze the nature of improvements that the PR models get. For the languages where PR results in large improvements, it stems from the ability to allow the sentential context to sometimes override the tag projected via the parallel data. For example, the Czech word *se* can either be a reflexive pronoun (such as *ourselves* in English) or translate to the preposition *with*. The pronominal sense comprises about 95% of occurrences in the Czech annotations, but it would not appear in an English translation. For example, the phrase "*podívali jsme se*" translates to "*we looked*", and the word *jsme* would typically be aligned to *we*; *se*, which serves as a reflexive pronoun here, remains unaligned. Consequently, in our data, over 7000 occurrences of *se* appear, but only 17 instances have a tag projection that is not filtered by Wiktionary. Since the remaining are tagged with the preposition tag, the hard-constrained baseline always tags *se* as a preposition. By contrast, the soft-constrained PR model predicts the pronominal sense in cases where the context is most indicative of a pronoun – 38% of the time. It still mistags many of the pronominal cases where the contextual evidence is not strong enough. We get very similar behavior with the Hungarian word *hogy* which can translate to the conjunction *that* (as in "*I see that you are here*") or the adverb *how*.

We found that the drastic drop in performance for Chinese under the PR+ model is due to the possessive marker "的" which serves exclusively as a particle in the test data. Wiktionary also allows the noun and adverb tags. The adverbial use is actually a different token (的确 ↔ *really, truly*) containing the same character. Because the cross-lingual training data is based on machine-learned alignments, 99.4% of the training examples of 的 have no annotations, and only 0.6% have the particle annotation projected from the English *'s* possessive marker. If we remove the noun and adverb senses from the Wiktionary performance of PR+ improves to 72.87%. Alternatively, we could add another constraint to prefer closed-class words over open-class words when both are licensed by the dictionary. When we add such a constraint to Chinese with a constraint value of 0.95, we recover most of the loss (68.43 → 72.94); however, we do not report this specific change to the Chinese experimental setup in Table 1 to maintain generality.

6.2 Named-Entity Segmentation

Results: Table 2 shows the results for the named entity segmentation experiments. First, we observe that the word alignment filtering step (§5.2.2) improves results for all three languages by significant margins, for both the BASE and PR models. Both with and without filtering, we observe that the baseline models are very strongly biased towards precision. The filtering step tends to help with recall more than precison for both models. By having a soft constraint via PR and allowing some segmentations to fall outside of the transferred one, we get an increase in recall,

		No Filtering		Filtering (§5.2.2)

Table 2: Result for the named-entity segmentation experiments. The highest score in each category is shown in bold. Note that "No Filtering" still discards sentences with no projected entities.

and in turn an improved F_1 score. On average the PR model improves F-score by 3.6% on the development set and 4.6% on the test set over the baseline (when filtering is used). Note that because we focus on named entity segmentation, our results are not directly comparable to those of Täckström (2012), who train a de-lexicalized named entity recognizer on one language and apply it to other languages.

Error Analysis: In order to get a sense for the types of errors made by the baseline which are corrected by the PR model, we collected statistics about the most frequent errors in the segments extracted by the baseline and by our model. We divided the errors into missing segments, extraneous segments and overlapping segments.

From Table 2, it is clear that the most common errors for the baseline models are missing entities. From our analysis of the CoNLL development data, we found that the entities that occur with little context (such as the location and publisher of an item) at the onset of news articles are most frequently missed. For German, *dpa* (Deutsche Presse-Agentur) and *Reuter* are the two most common missing segmentations; the Spanish counterparts are *Gobierno* (Government) and *Barcelona*, while for Dutch they are *De Morgen* and *Brussel*. While filtering parallel sentences and using a soft constraint both increase recall, even our strongest model does not get enough information to predict these entities, and they continue to be major sources of error. By contrast, the names mentioned in context are the ones that are most frequently added to the analysis when PR is used. In a sense this is desirable, since a machine-learned named-entity segmentation system is most useful for the long tail of entity mentions.

If we filter the training data and use the PR model to further increase recall, precision errors tend to become relatively more frequent (this trend is observable in Table 2). For German, the most frequent precision error is *Mark* referring to the *Deutsche Mark*. For Spanish, the most frequent precision errors are due to boundary errors. The Spanish annotation guidelines include enclosing quotes as part of the entity name, and failing to include them accounts for just under 1% of the precision errors of the PR system that uses filtering. The second most frequent error is failing to segment *Inter de Milán*. The model segments out either *Inter* or *Milán* or both by themselves depending on context.

7 Conclusions

In this paper, we presented a framework for cross-lingual transfer of sequence information from a resource-rich source language to a resource-poor target language. Our framework incorporates soft constraints while training with projected information via posterior regularization. We presented the efficacy of our framework on two very useful natural language tasks: POS tagging and named-entity segmentation. The soft constraints used in our work model intuitions about a given task. For the POS tagging problem, we designed constraints that also incorporate projected token-level information, and presented a principled method for choosing the extent to which this information should be trusted within the PR framework. This approach generalizes the state of the art in cross-lingual projection work in the context of POS tagging, and improves upon it.

Across seventeen languages, our models outperform the previous state of the art by an average of 0.8% (greater than 4% error reduction), and outperforms it on twelve out of seventeen languages. For named-entity segmentation, our model results in 3.6% and 4.6% absolute improvements in F_1-score on our development and test sets respectively, when averaged across three languages.

Acknowledgments

We would like to thank Ryan McDonald, Fernando Pereira, Slav Petrov and Oscar Täckström for numerous discussions on this topic and providing detailed feedback on early drafts of this paper. We are also grateful to the four anonymous reviewers for their valuable comments.
