Pettersson et al. (2014) find that a CSMT system often performs best in a comparison with a filtering method and a distance-based approach on five different languages. Schneider et al. (2017) compare VARD 2 to CSMT on English and find that VARD 2 performs slightly better. Domingo and Casacuberta (2018) evaluate both word-based and character-based models and find that SMT outperforms a neural network model.

2.5 Neural Models

Neural network architectures have become popular for a variety of NLP tasks, and historical normalization is no exception. *Character-based neural machine translation (CNMT)* is the logical neural equivalent to the CSMT approach, and has first been used for normalization of historical German (Bollmann et al., 2017; Korchagina, 2017) using encoder–decoder models with long short-term memory (LSTM) units. Robertson and Goldwater (2018) present a more detailed evaluation of this architecture on five different languages. Hämäläinen et al. (2018) evaluate SMT, NMT, an edit-distance approach, and a rule-based finite-state transducer, and advocate for a combination of these approaches to make use of their individual strengths; however, they restrict their evaluation to English.

Other neural architectures have rarely been used for normalization so far. Al Azawi et al. (2013) and Bollmann and Søgaard (2016) frame the normalization task as a sequence labelling problem, labelling each character in the historical word form with its normalized equivalent. Kestemont et al. (2016) use convolutional networks for lemmatization of historical Dutch. Overall, though, the encoder–decoder model with recurrent layers is the dominant approach.

2.6 Beyond Token-Level Normalization

The presented literature almost exclusively focuses on models where the input is a single token. In theory, it would be desirable to include context from the surrounding tokens, as some historical spellings can have more than one modern equivalent depending on the context in which they are used (e.g., historical *ther* could represent *their* or *there*). Remarkably few studies have attempted this so far: Jurish (2010b) uses hidden Markov models to select between normalization candidates; Mitankin et al. (2014) use a language model in a similar vein; Ljubešić et al. (2016) experiment with "segment-level" input, i.e., a string of several historical tokens as input to a normalizer. Since this area is currently very underexplored, it warrants a deeper investigation that goes beyond the scope of this paper.

3 Experimental Setup

Systems The selection of normalization systems follows two goals: (i) to include at least one system for each major category as identified in Sec. 2; and (ii) to use only freely available tools in order to facilitate reproduction and application of the described methods. To that effect, this study compares the following approaches:

- **Norma**[3] (Bollmann, 2012), which combines substitution lists, a rule-based normalizer, and a distance-based algorithm, with the option of running them separately or combined. Importantly, it implements supervised learning algorithms for all of these components and is not restricted to a particular language.
- **cSMTiser**[4] (Ljubešić et al., 2016; Scherrer and Ljubešić, 2016), which implements a normalization pipeline using character-based statistical machine translation (CSMT) using the Moses toolkit (Koehn et al., 2007).
- **Neural machine translation (NMT)**, in the form of two publicly available implementations: (i) the model by Bollmann (2018), also used in Bollmann et al. (2018);[5] and (ii) the model by Tang et al. (2018).[6]

Two systems were chosen for the NMT approach as they use very different hyperparameters, despite both using comparable neural encoder–decoder models: Bollmann (2018) uses a single LSTM layer with dimensionality 300 in the encoder and decoder, while Tang et al. (2018) use six vanilla RNN cells with dimensionality 1024.

Table 1: Historical datasets used in the experiments

Datasets Table 1 gives an overview of the historical datasets. They are taken from Bollmann (2018) and represent the largest and most varied collection of datasets used for historical text normalization so far, covering eight languages from different language families—English, German, Hungarian, Icelandic, Spanish, Portuguese, Slovene, and Swedish—as well as different text genres and time periods. Furthermore, most of these have also been used in previous work, such as the English, Hungarian, Icelandic, and Swedish datasets (e.g., Pettersson et al., 2014; Pettersson, 2016; Robertson and Goldwater, 2018; Tang et al., 2018) and the Slovene datasets (e.g., Ljubešić et al., 2016; Scherrer and Erjavec, 2016; Etxeberria et al., 2016; Domingo and Casacuberta, 2018).

Additionally, contemporary datasets are required for the rule-based and distance-based components of Norma, as they expect a list of valid target word forms to function properly. For this, we want to choose resources that are readily available for many languages and are reliable, i.e., consist of carefully edited text. Here, I choose a combination of three sources:[7] (i) the normalizations in the training sets, (ii) the Europarl corpus (Koehn, 2005), and (iii) the parallel Bible corpus by Christodouloupoulos and Steedman (2015). The only exception is Icelandic, which is not covered by Europarl; here, we can follow Pettersson (2016) instead by using data from two specialized resources, the BÍN database (Bjarnadóttir, 2012) and the MÍM corpus (Helgadóttir et al., 2012). This way, we obtain full-form lexica of 12k–64k word types from the Bible corpus, 55k–268k types from Europarl, and 2.8M types from the Icelandic resources.

Preprocessing The most important preprocessing decisions[8] are (i) to lowercase all characters and (ii) to remove all punctuation-only tokens. Both capitalization and punctuation often cannot be handled correctly without considering token context, which all current normalization models do not do. Furthermore, their usage can be very erratic in historical texts, potentially distorting the evaluation; e.g., when a text uses punctuation marks according to modern conventions, their normalization is usually trivial, resulting in artificial gains in normalization accuracy that other texts do not get. At the same time, most previous work has not followed these same preprocessing guidelines, making a direct comparison more difficult. This work tries to make up for this by evaluating many different systems, effectively reproducing some of these previous results instead.

4 Evaluation

All models are trained and evaluated separately for each dataset by calculating word accuracy over all tokens. In particular, there is no step to discriminate between tokens that require normalization and those that do not; all word forms in the datasets are treated equally.

For Norma, all components are evaluated both separately and combined, as the former gives us insight into the performance of each individual

---

[7] Detailed descriptions of the data extraction procedure can be found in the Supplementary Material.

[8] The full preprocessing steps can be found in the Supplementary Material.

Table 2: Word accuracy of different normalization methods on the test sets of the historical datasets, in percent; best result for each dataset in bold; results marked with an asterisk (*) are not significantly different from the best result using McNemar's test at $p < 0.05$. † indicates scores that were not (re)produced here, but reported in previous work; they might not be strictly comparable due to differences in data preprocessing (cf. Sec. 3). Additionally, *Identity* shows the accuracy when leaving all word forms unchanged, while *Maximum* gives the theoretical maximum accuracy with purely token-level methods.

component, while the latter is reported to produce the best results (Bollmann, 2012). For cSMTiser, the authors suggest using additional monolingual data to improve the language model; the contemporary datasets are used for this purpose and the model is trained both without and with this additional data; the latter is denoted cSMTiser$_{\text{+LM}}$. For NMT, the model by Bollmann (2018) is evaluated using an ensemble of five models; the model by Tang et al. (2018) is trained on character-level input using the default settings provided by their implementation.[9]

To illustrate how challenging the normalization task is on different datasets, we can additionally look at the *identity baseline*—i.e., the percentage of tokens that do *not* need to be normalized—as well as the *maximum accuracy* obtainable if each word type was mapped to its most frequently occurring normalization. The latter gives an indication of the extent of ambiguity in the datasets and the disadvantage of not considering token context (cf. Sec. 2.6).

Results Table 2 shows the results of this evaluation. The extent of spelling variation varies greatly between datasets, with less than 15% of tokens requiring normalization (SL_G) to more than 80% (HU). The maximum accuracy is above 97% for most datasets, suggesting that we can obtain high normalization accuracy in principle even without considering token context.

For the normalization systems, we observe significantly better word accuracy with SMT than NMT on four of the datasets, and non-significant differences on five others. There is only one dataset (DE_A) where the NMT system by Tang et al. (2018) gets significantly better word accuracy than other systems. This somewhat contradicts the results from Tang et al. (2018), who find NMT to usually outperform the SMT baseline by Pettersson et al. (2014). However, note that the results for the cSMTiser system are often significantly better than reported in previous work: e.g., on Hungarian, cSMTiser obtains 91.7% accuracy, but only 80.1% with the SMT system from Pettersson et al. (2014).

Overall, the deep NMT model by Tang et al. (2018) consistently outperforms the shallow one by Bollmann (2018). cSMTiser seems to benefit from the added contemporary data for language modelling, though the effect is not significant on any individual dataset. Finally, while Norma does produce competitive results on sev-

---

[9] This is the "Att-RNN" setting reported in their paper; due to the high computational demands of the model, it was not feasible to run experiments with multiple configurations.

(b) Stemming accuracy: percentage of incorrect normalizations with correct word stems (higher is better)

Table 3: Evaluations on the subset of incorrect normalizations only; best results for each dataset in bold. Note that this subset is different for each system, so for comparisons between systems, these numbers should be considered in conjunction with word accuracy scores from Table 2.

eral datasets (particularly in the "combined" setting), it is generally significantly behind the SMT and NMT methods.

5 Analysis

5.1 Measuring Normalization Quality

While word accuracy is easily interpretable, it is also a very crude measure, as it classifies predictions as correct/incorrect without considering the type of error(s) made by the model. *Character error rate (CER)* has sometimes been suggested as a complement to address this issue, but I believe this is not very insightful: For any normalization system that achieves a reasonably high word accuracy, CER will highly correlate with accuracy simply because CER equals zero for any word that is accurately normalized.[10] At the same time, there is a need for a more fine-grained way to assess the normalization quality. Consider the following example from the Hungarian dataset with its predicted normalization from the NMT system by Bollmann (2018):

(1) ORIG yduewzewlendewk
GOLD üdvözülendőek
PRED üdvözülendők

Here, the prediction matches the correct target form almost perfectly, but would be counted as incorrect since it misses an insertion of the letter ⟨*e*⟩ towards the end. In this vein, it will be treated the same by the word accuracy measure as a prediction that, e.g., had left the original form unchanged.

CER$_\text{I}$ One alternative is to consider character error rate *on the subset of incorrect normalizations only.* This way, CER becomes a true complement to word accuracy by assessing the *magnitude of error* that a normalization model makes when it is not perfectly accurate. The results of this measure, denoted CER$_\text{I}$, are shown in Table 3a. The lowest CER$_\text{I}$ score is often achieved

---

[10] When comparing word accuracy scores in Table 2 with the same configurations evaluated using CER, they correlate with Pearson's $r \approx -0.96$.

by Norma's lookup module, which leaves historical word forms unchanged if they are not in its lookup wordlist learned during training. This suggests that the incorrect predictions made by other systems are often *worse* than just leaving the historical spelling unchanged.

Stemming Another problem of CER is that all types of errors are treated the same: a one-letter difference in inflection, such as *king – kings* or *came – come*, would be treated identically to an error that changes the meaning of the word (*bids – beds*) or results in a non-word (*creature – cryature*). I propose an approach that, to the best of my knowledge, has not been used in normalization evaluation before: measure accuracy on *word stems,* i.e., process both the reference normalization and the prediction with an automatic stemming algorithm and check if both stems match. For this evaluation, I choose the Snowball stemmer (Porter, 2001) as it contains stemming algorithms for many languages (including the ones represented here except for Icelandic and Slovene) and is publicly available.[11]

Table 3b shows the accuracy on word stems, again only evaluated on the subset of incorrect normalizations, as this better highlights the differences between settings. This evaluation reveals some notable differences between *datasets*: For example, while the English and Spanish datasets have very comparable accuracy scores overall (cf. Tab. 2), they show very different characteristics in the stemming evaluation; for English, only up to 9.86% of incorrect predictions show the correct word stem, while for Spanish the number is up to 43.82%. Examining predictions on the dev set, many of the incorrectly predicted cases in Spanish result from mistakes in placement of diacritics, such as *ésta – está* or *envíe – envié*; the stemming algorithm removes diacritics and can therefore match these instances. Overall, this gives an indication that the errors made on the Spanish dataset are less severe than those on English, despite comparable word accuracy scores and a usually higher CER_I for Spanish.

This case study shows that stemming can be a useful tool for error analysis in normalization models and reveal characteristics that neither word accuracy nor CER alone can show.

5.2 Effect of Training Data Quantity

Supervised methods for historical text normalization have been evaluated with highly varying amounts of training data: e.g., Domingo and Casacuberta (2018) train a normalizer for 17th century Spanish on 436k tokens; Etxeberria et al. (2016) use only 8k tokens to train a normalizer for Basque. Even in the evaluation in Sec. 4, training set sizes varied between 24k and 234k tokens, depending on the dataset. Furthermore, many research projects seeking to use automatic normalization techniques cannot afford to produce training data in high quantity. All of this raises the question how different normalization systems perform with varying amounts of training data, and whether reasonable normalization results can be achieved in a low-resource scenario.

Methodology All models are retrained on varying subsets of the training data, with sizes ranging from 100 tokens to 50,000 tokens. However, the lower the training set size is, the higher the potential variance when training on it, since random factors such as the covered spelling variants or vocabulary are more likely to impact the results. Therefore, I choose the following approach: For each dataset and training size, up to ten different training splits are extracted,[12] and a separate model is trained on each one. Each model is then evaluated on the respective development dataset, and only the average accuracy across all splits is considered.

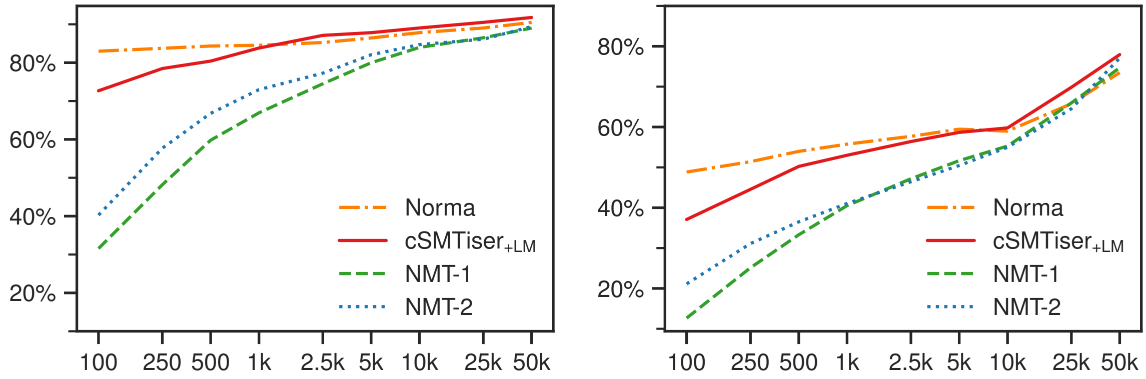
Results Figure 2 shows two learning curves that are representative for most of the datasets.[13] They reveal that Norma (in the "combined" setting) performs best in extremely low-resource scenarios, but is overtaken by the SMT approach as more training data becomes available; usually already around 500–1000 tokens. The NMT models have a steeper learning curve, needing more training data to become competitive. Extrapolating this trend, it is conceivable that the NMT models would simply need more training data than our current datasets provide in order to consistently outperform the SMT approach. On the other hand, there appears to be no correlation between the size of the training set (cf. Tab. 1) and the relative per-

---

[11] `http://snowballstem.org/`

[12] The ten training splits consist of chunks of n tokens that are spaced equidistantly across the full training set; for larger n, the number of chunks is reduced so that no splits overlap to more than 50%.

[13] Plots for all datasets can be found in the Appendix.



(a) English

(b) Hungarian

Figure 2: Word accuracy on the development sets for different amounts of training data (note that the x-axis is log-scaled); NMT-1 is the model by Bollmann (2018), NMT-2 is the model by Tang et al. (2018).

formance of NMT vs. SMT (cf. Tab. 2) in the experiments. Since I am not aware of larger datasets for the historical normalization task, this remains an open question for now.

A remarkable result is that very small amounts of training data can already be helpful for the normalization task. The English dataset has comparatively little spelling variation to begin with: leaving all words unnormalized already results in an accuracy of 75.5%. Still, with as little as 100 tokens for training, applying the Norma tool raises the accuracy above 83%. For Hungarian, the same amount of training data raises the accuracy from 17.8% (unnormalized) to around 50%. It would be interesting to further compare these results with fully unsupervised methods.

5.3 Out-of-Vocabulary Words

Robertson and Goldwater (2018) highlight the importance of evaluating separately on seen vs. unseen tokens, i.e., tokens that have also been in the training set (in-vocabulary) and those that have not (out-of-vocabulary), as well as comparing to a naive memorization baseline. These numbers are presented in Table 4. For unseen tokens (Tab. 4b), the accuracy scores follow generally the same trend as in the full evaluation of Tab. 2; i.e., SMT performs best in most cases. For seen tokens (Tab. 4a), however, Norma's lookup component—which implements naive memorization—obtains the highest score on nine datasets.

These observations suggest a new normalization strategy: apply the naive lookup on the subset of in-vocabulary tokens and the SMT/NMT models on the subset of out-of-vocabulary tokens only. Table 5 shows the results of this strategy.[14] On nine datasets, it performs better than always using the learned models (as in Tab. 2), and this difference is statistically significant on five of them. These results support the claim from Robertson and Goldwater (2018) that "learned models should typically only be applied to *unseen* tokens."

6 Conclusion

This paper presented a large study of historical text normalization. Starting with a systematic survey of the existing literature, four different systems (based on supervised learning) were evaluated and compared on datasets from eight different languages. On the basis of these results, we can extract some practical recommendations for projects seeking to employ normalization techniques:

1. to use the Norma tool when only little training data (<500 tokens) is available;

2. to use cSMTiser otherwise, ideally with additional data for language modelling; and

3. to make use of the naive memorization/lookup technique for in-vocabulary tokens when possible.

Furthermore, the qualitative analysis (in Sec. 5.1) should encourage authors evaluating normalization systems to use task-motivated approaches, such as evaluation on word stems, to provide

---

[14] The non-lookup components of Norma are not included in this evaluation since "Norma (Combined)" effectively implements such a strategy already.

Table 5: Word accuracy for the "lookup on *seen* tokens, learned models on *unseen* tokens" strategy, following Robertson and Goldwater (2018) (cf. Sec. 5.3), compared to the best result without this strategy (according to Table 2). Best result for each dataset in bold; results marked with an asterisk (*) are not significantly different from the best result using McNemar's test at $p < 0.05$.

deeper insight into the properties of their models and datasets.

Detailed information on how to train and apply all of the evaluated techniques is made available online at `https://github.com/coastalcph/histnorm`.

Acknowledgments

I would like to thank my PhD supervisor, Stefanie Dipper, for her continuous support over many years that culminated in the doctoral thesis on which this paper is based; the acknowledgments in that thesis largely extend to this paper as well. Many thanks to Anders Søgaard for many helpful discussions and for supporting the follow-up experiments conducted for this paper. Further thanks go to the anonymous reviewers whose helpful suggestions have largely been incorporated here.

I gratefully acknowledge the donation of a Titan Xp GPU by the NVIDIA Corporation that was used for a substantial part of this research.

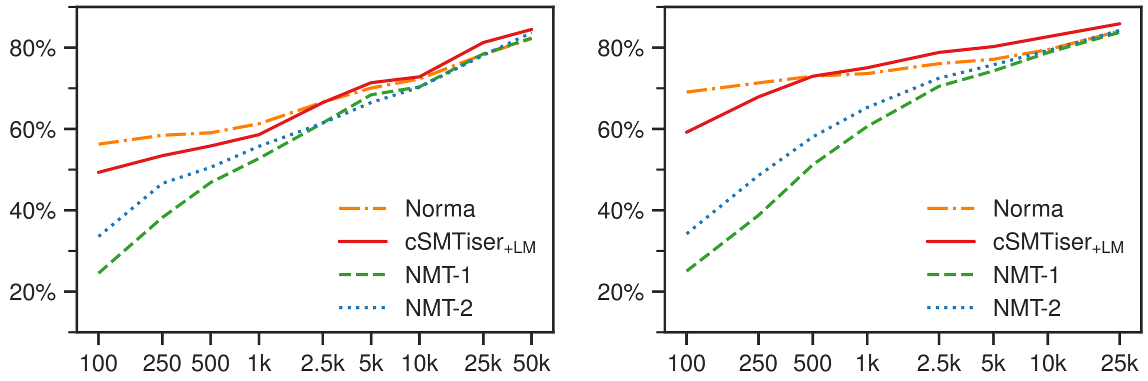
A Appendix

Figures 3 and 4 show plots of the learning curves for all of the datasets.

A.1 Preprocessing

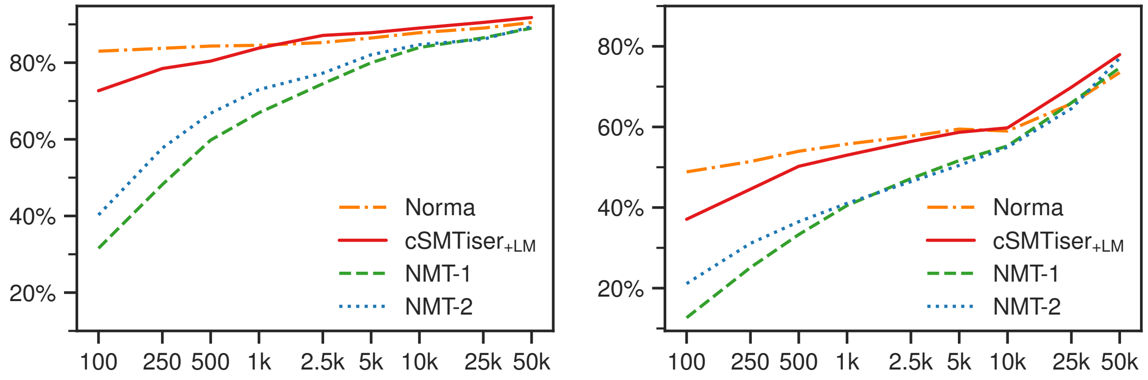
The full preprocessing steps of all datasets (both historical and contemporary) comprise of:

1. lowercasing all tokens;
2. filtering out pairs where either the historical token or the reference normalization is empty;
3. filtering out pairs where either the historical token or the reference normalization consists *only* of punctuation marks, defined as characters that belong to one of the Unicode "Punctuation" categories;



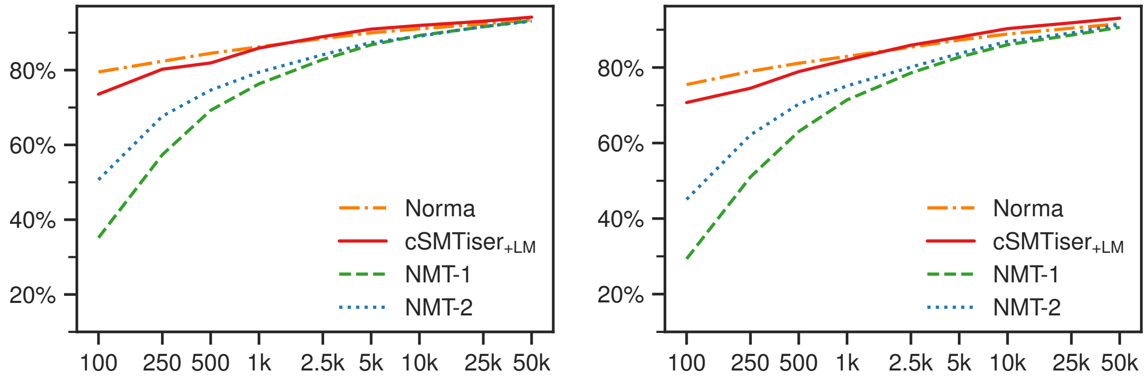
(a) German (Anselm)

(b) German (RIDGES)



(c) English

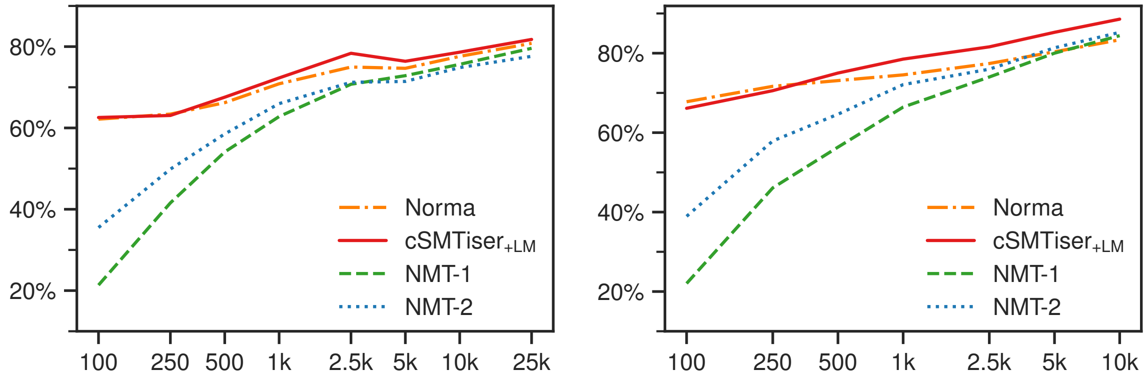
(d) Hungarian



(e) Spanish

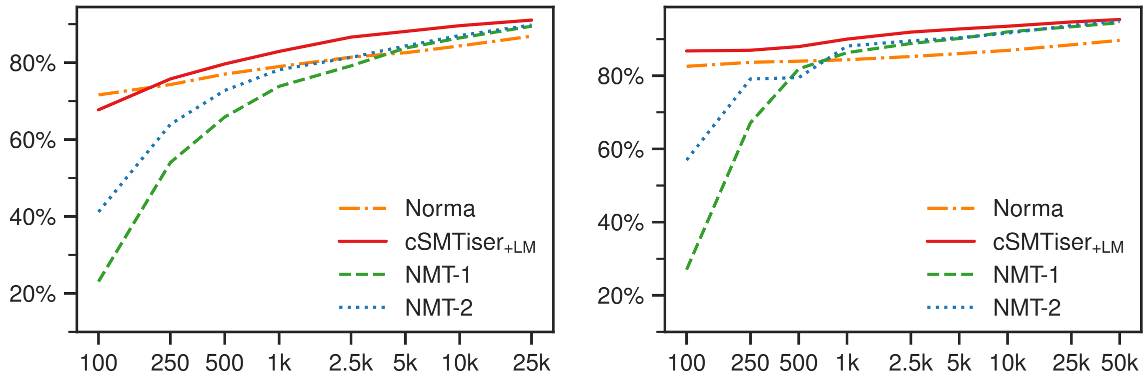
(f) Portuguese

Figure 3: Word accuracy on the development sets for different amounts of training data (note that the x-axis is log-scaled); NMT-1 is the model by Bollmann (2018), NMT-2 is the model by Tang et al. (2018).



(a) Icelandic

(b) Swedish



(c) Slovene (Bohorič)

(d) Slovene (Gaj)

Figure 4: Word accuracy on the development sets (continued); NMT-1 is the model by Bollmann (2018), NMT-2 is the model by Tang et al. (2018).

4. replacing all digits with zeroes *iff* the digits in the historical token and the reference normalization match;

5. replacing actual space characters in either the historical token or the reference normalization with a special symbol that does not otherwise occur in the dataset; and

6. performing Unicode normalization according to the NFC standard.

Additionally, the preprocessing script can also be found in the Supplementary Material or at `https://github.com/coastalcph/histnorm`.

Combining Discourse Markers and Cross-lingual Embeddings for Synonym–Antonym Classification

Michael Roth[1], **Shyam Upadhyay**[2]
[1]Institute for Natural Language Processing, University of Stuttgart
[2]Department of Computer and Information Science, University of Pennsylvania
`rothml@ims.uni-stuttgart.de`, `shyamupa@seas.upenn.edu`

Abstract

It is well-known that distributional semantic approaches have difficulty in distinguishing between synonyms and antonyms (Grefenstette, 1992; Padó and Lapata, 2003). Recent work has shown that supervision available in English for this task (e.g., lexical resources) can be transferred to other languages via cross-lingual word embeddings. However, this kind of transfer misses monolingual distributional information available in a target language, such as contrast relations that are indicative of antonymy (e.g., *hot*...*while*...*cold*). In this work, we improve the transfer by exploiting monolingual information, expressed in the form of co-occurrences with discourse markers that convey contrast. Our approach makes use of less than a dozen markers, which can easily be obtained for many languages. Compared to a baseline using only cross-lingual embeddings, we show absolute improvements of 4–10% F_1-score in Vietnamese and Hindi.

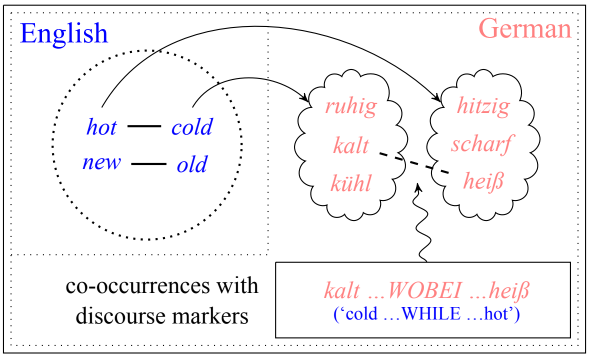


Figure 1: Supervision for distinguishing antonyms from synonyms can be derived using discourse markers. Here, antonyms available in English (denoted by solid edge between *hot* and *cold*) are translated to German via cross-lingual word embeddings. Using co-occurrences with discourse markers indicative of antonymy (shown in box), we can identify pairs of words in the n-best translations (clouds) that are also antonymous (e.g., dashed edge between *kalt* and *heiß*).

1 Introduction

Recent work has shown that monolingual word embeddings in different languages can be aligned in an unsupervised manner (Artetxe et al., 2018; Kementchedjhieva et al., 2018). The resulting *cross-lingual embeddings* can be used to share supervision for lexical classification tasks across languages, when annotated data is not available in one language. For instance, a model for distinguishing lexical relations such as hypernymy and meronymy can be transferred to other languages (Glavaš and Vulić, 2018). However, this kind of transfer, using only cross-lingual embeddings, misses useful monolingual information available in the target language.

In this paper, we consider one lexical classification task, namely the distinction between synonyms and antonyms, which is important for downstream applications such as contradiction detection (Harabagiu et al., 2006; Marneffe et al., 2008; Voorhees, 2008) and machine translation (Marton et al., 2011). To facilitate better transfer, we propose to use monolingual information in the form of word co-occurrences in contrast relations, in addition to cross-lingual embeddings (see Figure 1). In particular, we utilize the fact that discourse markers conveying contrast are more likely to be surrounded by antonyms than synonyms (e.g., *hot*...*while*...*cold*), as shown by Roth and Schulte im Walde (2014).

Our analysis reveals that (1) fine-grained semantic information that is required to distinguish synonyms from antonyms is insufficiently preserved cross-lingually in word embeddings, but (2) such information can be recovered (at least partially) by relying on linguistic intuitions about contrast relations in discourse.

2 Related Work

The identification of paradigmatic relations such as synonymy and antonymy has been a task of interest for more than a decade. Early work focused on the identification of instances of a single relation: for example, Charles and Miller (1989) investigated co-occurrences as an indicator for antonymy, Hearst (1992) introduced a pattern-based approach to identify hypernymy, and Edmonds and Hirst (2002) applied distributional statistics to identify synonymy.

Beyond the *identification* of instances of a particular relation, more recent approaches attempt to *distinguish* relations such as synonymy and antonymy, based on lexico-syntactic patterns, distributional information, or combinations of both (Lin et al., 2003; Shwartz and Dagan, 2016). As supervision for weighting different features, most recent work makes use of lexical resources and/or lists of affix patterns that indicate contrast morphologically (Yih et al., 2012; Mohammad et al., 2013; Ono et al., 2015).

Supervision for lexical classification tasks is not available in all languages. To overcome this difficulty, some approaches (Mrkšić et al., 2017; Glavaš and Vulić, 2018) combine resources for English and cross-lingual word embeddings to distinguish lexical relations in other languages. That is, they train and test one model *across* different languages. In contrast, we propose to first use unsupervised translation techniques to *transfer supervision* into a target language, given resources available in English. More specifically, our approach transfers supervision using a combination of unsupervised cross-lingual embeddings (Artetxe et al., 2018) and word co-occurrences with discourse markers that indicate contrast. In doing so, our approach generalizes the discourse-marker based model for relation classification by Roth and Schulte im Walde (2014) to a cross-lingual setting.

3 Our Approach

In this work, we address the task of distinguishing synonyms and antonyms cross-lingually: given a word pair (a, b) in a target language, a model trained in a different source language determines whether this constitutes a synonym or an antonym pair. Our approach consists of two main ingredients: a *translation module* that creates training data in a target language (see Figure 2), and a *classification module* that uses this data in a supervised fashion. Our focus is on the first part, which we describe in more detail below. For classification, we re-use the LexNet model by Shwartz and Dagan (2016), which is a feed-forward network that uses distributional word representations as input.

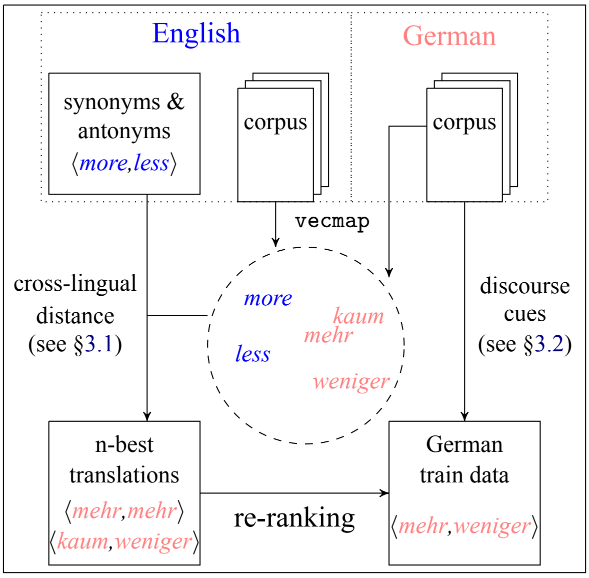

Figure 2: In our approach, we create training data in multiple languages by translating English data via cross-lingual word embeddings and discourse cues.

3.1 Cross-lingual Embeddings for Translation

Our transfer approach addresses a general setting that only assumes availability of monolingual data. Accordingly, we induce a translation dictionary of synonyms and antonyms in an unsupervised way, instead of relying on manually crafted dictionaries. We achieve this by finding n-best translations of English words in a cross-lingual word embedding space. We create this space using `vecmap`, a method that aligns and maps embedding spaces in two languages (Artetxe et al., 2018). Formally, we define the n^{th} best translation $w_t^{(n)}$ of a source word w_s to be the n^{th} nearest neighbor in the joint semantic space (based on cosine similarity).

3.2 Re-ranking n-best Translations

While 1$^{\text{st}}$ best translations are often accurate, erroneous translations occur for example when two related words in a source language are close to the same words in the target language (e.g., *less* and *more* share the same nearest neighbor in Figure 2: *mehr* 'more'). In such cases, we aim to use monolingual information about lexical relations in the form of discourse cues. Specifically, given two antonymous words a_s and b_s (henceforth $a_s \perp b_s$)

Language	Corpus size (in words)	Data size (in pairs)	Ratio (#syn:#ant)
English (train)	2.1 B	10 932	50:50
German (dev)	0.7 B	811	52:48
Hindi	0.5 B	1 000	50:50
Vietnamese	0.2 B	353	45:55

Table 1: Data statistics of the classification datasets as well as the corpora used to create word representations. Note that the data used here consist of only synonyms and antonyms (approximately in equal proportions).

in the source language, we want to choose translations $a_t^{(i)}$ and $b_t^{(j)}$ that are most likely antonymous as well. We achieve this by re-ranking translations $a_t^{(i)}$ and $b_t^{(j)}$ such that the probability $\Pr(a_t^{(i)} \perp b_t^{(j)})$ of them appearing in contrast relations is maximized. We only assume a set of discourse markers M that indicate contrast as knowledge about the target language. We approximate $\Pr(a_t^{(i)} \perp b_t^{(j)})$ by computing the pointwise mutual information (PMI) between two terms, conditioned on co-occurrence *around* a discourse marker $m \in M$:

$$\Pr(a_t^{(i)} \perp b_t^{(j)}) \sim \min_{m \in M} \log \frac{N(m)\, n(a_t^{(i)}, b_t^{(j)}|m)}{n(a_t^{(i)}|m)\, n(b_t^{(j)}|m)}$$

where $N(m)$ is the frequency of discourse marker m in the corpus, $n(w|m)$ is the number of times term w occurs with m, and $n(w_1, w_2|m)$ is the number of co-occurrences $w_1 ... m ... w_2$. For simplicity, we count all joint occurrences within a sentence, regardless of sentence length and distance between words. In practice, the set M is constructed by manually translating eight discourse markers that frequently indicate contrast relations according to the Penn Discourse Treebank 2.0 (Prasad et al., 2007): *although*, *by comparison*, *by contrast*, *however*, *nevertheless*, *nonetheless*, *though*, and *thus*.

4 Experiments

Our experiments test the performance of an off-the-shelf system for lexical relation classification under different cross-lingual settings. In particular, we evaluate the performance of unsupervised cross-lingual word embeddings and assess the benefits of translation and re-ranking, taking into account word co-occurrences in contrast relations.

Experimental setup. For our experiments, we use four languages: English, German, Hindi and Vietnamese. The antonymy and synonymy dataset by Nguyen et al. (2017) is used for training and estimating an upper bound in English. For cross-lingual development and hyper-parameter selection, we use the German dataset by Glavaš and Vulić (2018). Specifically, we select the number of hidden layers $\{0, \underline{1}\}$, learning rate $\{\underline{0.001}, \ldots, 0.1\}$, dropout rate $\{0.0, \underline{0.5}\}$, and whether to include information on paths between words {yes, $\underline{\text{no}}$}.[1] As examples of under-resourced languages, we evaluate on the Vietnamese dataset ViCon by Nguyen et al. (2018) and on a new Hindi dataset, which we crawled from `hindi2dictionary.com`.[2] Note that annotated data in these languages is held out exclusively for testing.

The task addressed here is to distinguish synonymous from antonymous words. Accordingly, we consider only word pairs for training and testing that are marked as antonyms or synonyms, even if the original dataset also contains unrelated words or other relations. Statistics of all considered word pairs, the ratio between synonyms and antonyms, as well as sizes of the text corpora used in our experiments are given in Table 1.

Models. We test our proposed approach against two baselines: **NoTrans** and **BestTrans**. **NoTrans** simply uses the training data in English and allows us to test in how far semantic properties related to the distinction between synonymy and antonymy are preserved cross-lingually. **BestTrans** uses 1st best translations of the English training data in a target language, as described in Section 3.1.

Our own approach, henceforth called **LingTrans**, is based on n-best translations and exploits word co-occurrences in contrast relations for re-ranking, as described in Section 3.2.

All three models take cross-lingual word embeddings as input. We created these as follows. First, the unsupervised morphological analyzer of Xu et al. (2018) is used to lemmatize the monolingual corpora for the respective languages—the German Wikipedia, the Vietnamese portion of the LORELEI pack (Strassel and Tracey, 2016), and the HindEnCorp corpus (Bojar et al., 2014). This step ensures that we can compare the (stems of)

---

[1] Since we do not assume access to syntactic paths in the target languages, we only experimented with lexical surface paths and found them to consistently degrade performance.

[2] To verify the correctness of the crawled data, we asked a native speaker to validate all instances. Since synonym/antonym labels were derived automatically, validation was only performed to remove noisy instances.

LexNet-crosslingual	de (dev)	hi	vi
NoTrans	59.9	54.6	42.2
BestTrans	62.2	59.2	46.9
LingTrans	**64.2***	**63.5***	**56.8****
LexNet-monolingual (en)		70.1	
+ path embeddings		**74.3**	

Table 2: Macro-averaged F_1-scores for crosslingual synonymy/antonymy distinction in German (de), Hindi (hi), and Vietnamese (vi). Significant differences from NoTrans are marked by asterisk(s) (*$p<0.1$, **$p<0.01$). Monolingual results in English (en) are only shown for comparison.

word tokens in text to those of the word forms that actually appear in the synonymy/antonymy datasets. Note that, while we use an unsupervised morphological analyzer, a stemmer can also be used, if available for that language. Next, we created monolingual embeddings for each language using fastText (Bojanowski et al., 2017). Finally, we applied the unsupervised variant of `vecmap` (Artetxe et al., 2018) to compute alignments and cross-lingual mappings.

The word and discourse marker co-occurrence counts required for our approach are computed on the same monolingual corpora used for training monolingual embeddings.

Results. Table 2 shows macro-averaged F_1-scores for crosslingual synonymy/antonymy distinction (top part) as well as monolingual results in English for comparison (bottom part). The monolingual results show that word embeddings provide appropriate information for classification in most instances, achieving an F_1-score of 70.1. The comparatively low cross-lingual results by **NoTrans** indicate that aligning and mapping embedding spaces does not preserve all semantic properties relevant to the distinction between synonymy and antonymy. The use of first-best translations in **BestTrans** alleviates this issue partially and improves F_1 by up to 4.6 points. Our intuition regarding discourse cues in **LingTrans** leads to further improvements of up to 9.9 additional points in F_1 and considerably closes the gap between monolingual and cross-lingual results (56.8−64.2 vs. 70.1 F_1). Based on an approximate randomization test over the respective test items (Yeh, 2000), we find the improvements of our proposed approach **LingTrans** over **NoTrans** to be significant in Vietnamese ($p<0.01$), German and Hindi ($p<0.1$). In contrast, there is no significant difference in performance between **BestTrans** and **NoTrans**, confirming that both translation *and* reranking are required to achieve consistent gains.

5 Analysis

We examine how far our proposed approach affects performance on the task of synonymy–antonymy distinction and discuss remaining shortcomings.

A first observation concerns the general variance of results across languages. In addition to differences in terms of available corpus sizes, we observe different challenges in each language and dataset. Notably, each dataset is created with its own linguistically motivated definitions of antonymy and synonymy, some of which are more relaxed than others. For example, Nguyen et al. (2018) consider "words which are strongly associated but highly dissimilar to each other" as antonyms and "words that are highly similar in meaning" as synonyms.

The performance of our baseline **NoTrans** suggests that the distinction between synonyms and antonyms in the crosslingual space is harder for Vietnamese than for the other languages. At least partially, this is due to errors and noise from preprocessing (i.e., lemmatization). Also, Vietnamese belongs to a different language family than English. Consequently, information relevant to the synonymy–antonymy distinction may be distributed differently in the target language space than in the source language. In Hindi, some errors specific to the data involve synonyms that denote the same mythological deity (e.g., हनुमान / बजरंगबली 'Hanuman/Bajrangbali') and thus require factual knowledge for classification.

Even for our development language German, results suggest that there is room for improvement. We examine the improvements achieved and remaining errors in German in more detail below.

Classification improvements. The main improvement of our **LingTrans** approach over **BestTrans** is reflected in an increased number of correctly classified antonyms, mostly including antonymous adjectives (e.g., *ständig* 'steadily' vs. *sporadisch* 'sporadically') but also mutually exclusive nouns (e.g., *Privatgelände* 'private grounds' vs. *Öffentlichkeit* 'public'). Compared to the **NoTrans** baseline, we find **BestTrans** to substantially increase the number of correctly classified synonyms (by almost 20%). In particular, this affects words derived from the same stem (*unzählig/zahllos* 'countless'), synonymous verbs (*pfuschen/schummeln* 'cheat') as well as (near-)synonymous adjectives (*verfügbar/verwendbar* 'available/usable').

Translation improvements. The observed quantitative improvements are in line with qualitative improvements that we see in the automatically generated training data. For example, *more* and *less* have the same 1st-best translation in German according to the cross-lingual space (*mehr* 'more'); as illustrated in Figure 2, reranking is required to find the correct translation for the latter word (i.e., *weniger* 'less'). To quantify translation improvements of our proposed reranking method, we count the number of words overlapping between the automatically translated data and data available in the target languages. Compared to the **BestTrans** baseline, we find our **LingTrans** approach to improve overlap for German, Hindi, and Vietnamese by 2%, 5% and 5%, respectively. Despite the increase in word overlap, it is worth noting that the overlap between training and testing in terms of actual data instances (i.e., pairs of words) remains constant between 0% and 1%. A partial explanation for the improved results could thus be that our reranking approach lets us find translations that are *generally* more likely to have an antonym (or synonym)—regardless of which other word they are presented with. A similar observation was made by Levy et al. (2015) regarding hypernymy classification, in which they found some words to be generally more likely to be "category words". Whether similar biases exist in synonymy–antonymy classification will be subject of future work.

Remaining errors. We categorized a randomly selected subset of 30 mis-classifications. We found 30% of the errors to be related to sparsity. In these cases, at least one word was infrequent or the word pair never co-occurred in the corpus (e.g., *unversöhnbar/unvereinbar* 'unforgiving/irreconcilable'). 27% of the errors can be attributed to problems with the test data because it contains "synonyms" that are only indirectly related (e.g., *parieren/ausweichen* 'parry/dodge').

The 42% remaining cases involve a number of challenging antonyms and synonyms, but also a few remarkably easy cases. The latter include morphologically marked antonyms (e.g., *Richtigkeit* 'correctness' vs. *Unrichtigkeit* 'incorrectness') and instances of synonyms that involve two identical words (e.g., *Verwandtschaft/Verwandtschaft* 'kinship'), which presumably is an artifact of the automatic translation step used in creating the German dataset (see Glavaš and Vulić (2018)). Both types of errors could be identified by simple heuristics but are incorrectly classified by the model. On the other hand, hard cases involve words of different linguistic register, which are expected to be distributed differently and therefore hard to capture by distributional methods (e.g., *mittellos/verarmt* 'penniless/impoverished').

In summary, we find substantial improvement through our transfer method, compared to the baselines. However, further improvements could be achieved, for example, taking into account register (e.g., formal vs. colloquial) and morphological marking (e.g., negation affixes).

6 Conclusion

We proposed to combine unsupervised cross-lingual embeddings and discourse cues to generate supervision for distinguishing synonyms and antonyms in under-resourced languages. Compared to a baseline that uses only cross-lingual embeddings, we showed that the use of a small set of discourse markers indicating contrast can yield absolute improvements of up to 10% F_1-score. The simplicity of our approach allows to easily incorporate other features (e.g., morphological marking) and it can be extended to further languages or lexical relations. For example, discourse markers that indicate specification and instantiation relations (e.g. *specifically*, *for instance*) could be used to detect hypernymy (cf. Roth and Schulte im Walde (2014)). Beyond classification, another direction for future work is to extend our approach to distinguish synonyms and antonyms from unrelated word pairs. An interesting direction to pursue would be to use multiple related languages, to aid lexical relation classification in an under-resourced language, instead of transferring supervision from a single language (English).

Abstract

Cross-lingual word vectors are typically obtained by fitting an orthogonal matrix that maps the entries of a bilingual dictionary from a source to a target vector space. Word vectors, however, are most commonly used for sentence or document-level representations that are calculated as the weighted average of word embeddings. In this paper, we propose an alternative to word-level mapping that better reflects sentence-level cross-lingual similarity. We incorporate context in the transformation matrix by directly mapping the averaged embeddings of aligned sentences in a parallel corpus. We also implement cross-lingual mapping of deep contextualized word embeddings using parallel sentences with word alignments. In our experiments, both approaches resulted in cross-lingual sentence embeddings that outperformed context-independent word mapping in sentence translation retrieval. Furthermore, the sentence-level transformation could be used for word-level mapping without loss in word translation quality.

1 Introduction

Cross-lingual word vector models aim to embed words from multiple languages into a shared vector space to enable cross-lingual transfer and dictionary expansion (Upadhyay et al., 2016). One of the most common and effective approaches for obtaining bilingual word embeddings is by fitting a linear transformation matrix on the entries of a bilingual seed dictionary (Mikolov et al., 2013). This approach is versatile and scalable: multilingual embeddings can be obtained by mapping the vector spaces of multiple languages into a shared target language, typically English. In addition, imposing an orthogonality constraint on the mapping ensures that the original pair-wise distances are preserved after the transformation and results in better word translation retrieval (Artetxe et al., 2016; Smith et al., 2017).

While word vector spaces tend to be globally consistent across language variations (Aldarmaki et al., 2018), individual words like homographs with unrelated senses (e.g. 'bank', 'coast') and phrasal verbs ('stand up', 'stand out') are likely to behave less consistently in multilingual vector spaces due to their different usage distributions. Consequently, using such words in the alignment dictionary may result in suboptimal overall mapping. We propose two approaches to counteract this effect by incorporating sentential context in the mapping process without explicit word sense disambiguation or additional linguistic resources. The first approach is based on the recently proposed contextualized embeddings from language models, ELMo (Peters et al., 2018). Using a parallel corpus with word-alignments, we extract contextualized embeddings to construct a context-aware dictionary for mapping. The second approach is to learn a transformation between sentence embeddings rather than individual word embeddings. Since these embeddings include context that spans full sentences, we surmise that a mapping learned at this level would be more robust to individual word misalignments.

We used a constrained set of parallel sentences ranging from one hundred to a million sentences for alignment. We then evaluated the resultant mappings on sentence translation retrieval among English, Spanish, and German as test languages. Our results show that context-aware mappings significantly outperform context-independent cross-lingual word mappings using reasonably-sized parallel corpora, particularly when using contextualized word embeddings. In addition, when averaging static word embeddings, the sentence-level mapping can still be used for word-level mapping without loss in word translation quality.

Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related Work

For cross-lingual alignment, we follow the popular approach of fitting a linear transformation matrix between word vector spaces that are independently trained for each language. Aligning monolingual word vector spaces using a seed dictionary was originally proposed in Mikolov et al. (2013). In Artetxe et al. (2016) and Smith et al. (2017), it was shown that imposing an orthogonality constraint on the transformation leads to better word translation quality. Recently, contextualized word embeddings were proposed, where a sequential neural network is trained as a language model and then used to extract context-sensitive word representations from the hidden states (Peters et al., 2018). We use parallel text in order to align independently-trained contextualized embeddings across languages. Schuster et al. (2019) independently proposed a cross-lingual alignment approach for contextualized embeddings without the use of parallel text.

3 Approach

3.1 Orthogonal Bilingual Mapping

Given a dictionary of source to target pairs $\langle x, y \rangle$ and matrix representations X and Y whose columns are vector representations of the corresponding dictionary items, we seek to find an orthogonal transformation matrix R that minimizes the distances between the transformed vectors in RX and Y. Formally,

$$R = \arg\min_{\hat{R}} \|\hat{R}X - Y\| \quad \text{s. t.} \quad \hat{R}^T \hat{R} = I \qquad (1)$$

where $\|.\|$ denotes the Frobenius norm. The orthogonality constraint ensures that pair-wise distances in the original source vector space are preserved after the transformation. As shown in (Schönemann, 1966), the solution can be found by singular value decomposition of YX^T

$$YX^T = U\Sigma V^T$$

Then,

$$R = UV^T \qquad (2)$$

The resultant transformation, R, can then be used to transform additional vectors in the source vector space. The quality of the transformation depends on the size and accuracy of the initial dictionary, and it is typically evaluated on word translation precision using nearest neighbor search (Smith et al., 2017).

3.2 Mapping of Contextualized Embeddings

Word embeddings in a given language tend to have similar structures as their translations in a target language (Aldarmaki et al., 2018), which enables orthogonal mappings of word vector spaces to generalize well across various languages. However, items in bilingual dictionaries typically refer to specific word senses. In a given dictionary pair, the source word may have multiple senses that are not consistent with its aligned target translation (and vise versa), which could result in suboptimal global mappings. Intuitively, better mappings could be obtained using sense-disambiguated word embeddings, which could be approximated from context. ELMo (Embeddings from Language Models) is a recently-proposed deep model for obtaining contextualized word embeddings, which are calculated as the hidden states of a bi-LSTM network trained as a language model (Peters et al., 2018). The network can be used in lieu of static word embeddings within other models, which yields better performance in a range of tasks, including word sense disambiguation. Sentence embeddings can be obtained from ELMo by averaging the contextualized word embeddings (Perone et al., 2018).

Since ELMo generates dynamic, context-dependent vectors, we cannot use a simple word-level dictionary to map the model across languages. Instead, we use a parallel corpus with word alignments, i.e using an IBM Model (Brown et al., 1993), to extract a dynamic dictionary of aligned contextualized word embeddings. Depending on the size of the parallel corpus, a large dictionary can be extracted to learn an orthogonal mapping as described in Section 3.1, which is then applied post-hoc on newly generated contextualized embeddings.

3.3 Sentence-Level Mapping

An alternative general approach for obtaining a context-aware mapping is to learn sentence-level transformations. Intuitively, a sentence is less ambiguous than stand-alone words since the words are interpreted within a specific context, so a mapping learned at the sentence-level is likely to be less sensitive to individual word inconsistencies. Therefore, we learn the mapping as described in

Section 3.1 using a dictionary of aligned sentence embeddings. Over a large parallel corpus, the aggregate mapping can yield a more optimal global solution compared to word-level mapping. This approach can be applied using any model capable of generating monolingual sentence embeddings. In this work, we use the average of word vectors in each sentence, where the word vectors are either static or contextualized. For inference, monolingual sentence embeddings are generated first, then mapped to the target space using the sentence-level transformation matrix.[1]

4 Experiments

We used skip-gram with subword information, i.e FastText (Bojanowski et al., 2017), for the static word embeddings, and ELMo for contextualized word embeddings. Sentence embeddings were calculated from ELMo as the arithmetic average of the contextualized embeddings [2]. For FastText, we applied weighted averaging using smooth inverse frequency (Arora et al., 2017), which works better for sentence similarity compared to other averaging schemes (Aldarmaki and Diab, 2018).

4.1 Data and Processing

We trained and aligned all models using the same monolingual and parallel datasets. For monolingual training, we used the 1 Billion Word benchmark (Chelba et al., 2014) for English, and equivalent subsets of $\sim$400 million tokens from WMT'13 (Bojar et al., 2013) news crawl data. We trained monolingual ELMo and FastText with default parameters. We used the WMT'13 common-crawl data for cross-lingual mapping, and the WMT'13 test sets for evaluating sentence translation retrieval. For all datasets, the only preprocessing we performed was tokenization.

4.2 Evaluation Framework

We evaluated the cross-lingual mapping approaches on sentence translation retrieval, where we calculate the accuracy of retrieving the correct translation from the target side of a test parallel corpus using nearest neighbor search with cosine similarity. To assess the minimum bilingual data requirements of each approach and measure how the various models respond to additional data, we split the training parallel corpus into smaller subsets of increasing sizes, starting from 100 to a million sentences (we double the size at each step). Data splits and evaluation scripts are available at `https://github.com/h-aldarmaki/sent_translation_retrieval`.

4.3 Alignment Schemes

For ELMo, word embeddings need to be calculated from context, so we extracted a dictionary of contextualized words from the parallel corpora by first applying word-level alignments using Fast_Align (Dyer et al., 2013). We then calculated the contextualized embeddings for source and target sentences, and extracted a dictionary from the aligned words that have a one-to-one alignment (i.e. we excluded phrasal alignments). Since this can result in a very large dictionary, we capped the number of dictionary words at 1M for efficiency. For a fair comparison with FastText word-level mapping, we extracted a dictionary from word alignment probabilities using the same parallel sets. For each word in the source language, we extracted its translation as the word with the maximum alignment probability if the maximum was unique[3]. As a baseline, we used static dictionaries from (Conneau et al., 2017) to obtain word-level mappings (`dict`). All alignments were performed from the source languages to English.

4.3.1 Results

Sentence translation retrieval results in all language directions are shown in Figure 1 (note the x-axis denotes the size of the alignment corpus in log scale). The arrows indicate the translation direction from source to target, with en for English, es for Spanish, and de for German. For clarity, the legend shows the average accuracies in the final step (1M).

Overall, ELMo word alignment resulted in the highest sentence translation retrieval accuracies, even with small amounts of training data; it exceeded the static dictionary baseline at around 2K parallel sentences. Sentence-level mapping outperformed word-level mapping only when additional parallel data were used (over 50K sentences).

---

[1] Since we use vector averaging, it doesn't matter whether we apply the learned transformation to the word embeddings before averaging, or to the sentence embeddings after averaging.

[2] We found that using the arithmetic average for ELMo yields better results than weighted averaging.

[3] Using other dictionary pairs generally resulted in lower performance.

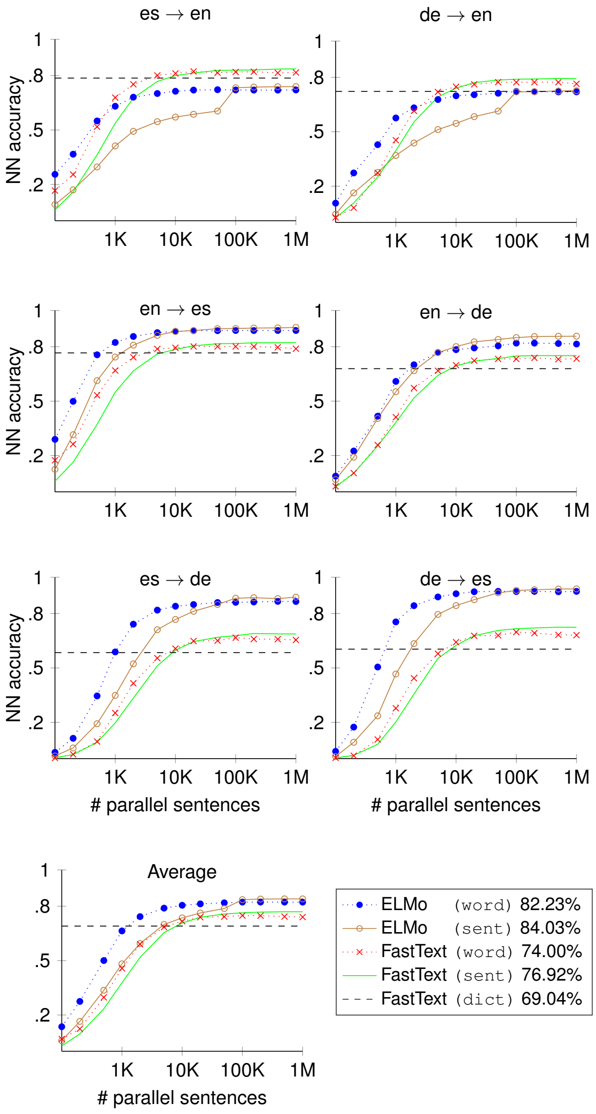

Figure 1: Nearest neighbor sentence translation accuracy as a function of (log) parallel corpus size. `(word)` refers to word-level mapping, `(sent)` to sentence-level mapping, and `(dict)` refers to the baseline (using a static dictionary for mapping). The legend shows the average accuracies of each model using 1M parallel sentences.

With 1M sentences, sentence-level mapping of FastText yielded an increase of ~3% in all directions. Sentence-level ELMo underperformed in the → *en* directions until we used 100K sentences, where we observed a sharp increase in accuracy compared to the previous step of 50K sentences. For ELMo, we note particular improvements in zero-shot translation retrieval between the source languages: *es* and *de*, where ELMo-based models performed much higher than FastText. The opposite is true for the → *en* directions, although the difference is not as notable. This is an interesting observation and may indicate that contextualized dictionaries result in a more balanced mapping, while context-independent embeddings overfit the mapping to the specific direction used for alignment.

Language pair		Mapping level

4.3.2 Word-level Evaluation

Cross-lingual word embeddings are typically evaluated in word-translation retrieval: the precision of correctly retrieving a translation from the vocabulary of another language. Since this is a context-free task, we evaluated the performance of static word embeddings, FastText, using word vs. sentence mapping (with 1M parallel sentences). The transformation matrix learned at the sentence level is used to transform the word embeddings.

We used the dictionaries from (Conneau et al., 2017). We also evaluated on the SemEval'17 cross-lingual word similarity task (Camacho-Collados et al., 2017), which is measured using the average of Pearson and Spearman correlation coefficients against human judgements. As shown in Tables 1 and 2, the mapping learned at the sentence-level yields equivalent performance to word-level mapping. While word-level mapping was slightly better in translating from source languages (German and Spanish) to English, the sentence-level mapping was better when translating between the source languages. In the word similarity task, sentence-level mappings performed slightly better in two out of the three cases. Overall, the performance of both models are comparable, which indicates that a single transformation matrix learned at the sentence-level can be used for both word and sentence-level tasks.

5 Discussion and Conclusions

We introduced alternatives to the popular word mapping approach that incorporate context in the mapping process. Given parallel corpora, context-aware mappings were learned by mapping aligned contextualized word embeddings or directly mapping the parallel sentence embeddings. Experimental results showed significant gains in sentence translation retrieval using contextualized mappings compared to context-independent word mapping. While word-level mappings worked better with smaller parallel corpora, the performance of sentence-level mapping continued to increase with additional data until it outperformed word-level mapping. In future work, we will explore the viability of the sentence mapping approach on other sentence embedding models.

Abstract

We introduce Rosita, a method to produce multilingual contextual word representations by training a single language model on text from multiple languages. Our method combines the advantages of contextual word representations with those of multilingual representation learning. We produce language models from dissimilar language pairs (English/Arabic and English/Chinese) and use them in dependency parsing, semantic role labeling, and named entity recognition, with comparisons to monolingual and non-contextual variants. Our results provide further evidence for the benefits of polyglot learning, in which representations are shared across multiple languages.

1 Introduction

State-of-the-art methods for crosslingual transfer make use of multilingual word embeddings, and much research has explored methods that align vector spaces for words in different languages (Faruqui and Dyer, 2014; Upadhyay et al., 2016; Ruder et al., 2017). On the other hand, *contextual* word representations (CWR) extracted from language models (LMs) have advanced the state of the art beyond what was achieved with word type representations on many monolingual NLP tasks (Peters et al., 2018). Thus, the question arises: can *contextual* word representations benefit from *multilinguality*?

We introduce a method to produce multilingual CWR by training a single "polyglot" language model on text in multiple languages. As our work is a multilingual extension of ELMo (Peters et al., 2018), we call it Rosita (after a bilingual character from *Sesame Street*). Our hypothesis is that, although each language is unique, different languages manifest similar characteristics (e.g., morphological, lexical, syntactic) which can be exploited by training a single model with data from multiple languages (Ammar, 2016). Previous work has shown this to be true to some degree in the context of syntactic dependency parsing (Ammar et al., 2016), semantic role labeling (Mulcaire et al., 2018), named entity recognition (Xie et al., 2018), and language modeling for phonetic sequences (Tsvetkov et al., 2016) and for speech recognition (Ragni et al., 2016). Recently, de Lhoneux et al. (2018) showed that parameter sharing between languages can improve performance in dependency parsing, but the effect is variable, depending on the language pair and the parameter sharing strategy. Other recent work also reported that concatenating data from different languages can hurt performance in dependency parsing (Che et al., 2018). These mixed results suggest that while crosslingual transfer in neural network models is a promising direction, the best blend of polyglot and language-specific elements may depend on the task and architecture. However, we find overall contextual representations from polyglot language models succeed in a range of settings, even where multilingual word type embeddings do not, and are a useful technique for crosslingual transfer.

We explore crosslingual transfer between highly dissimilar languages (English→Chinese and English→Arabic) for three core tasks: Universal Dependency (UD) parsing, semantic role labeling (SRL), and named entity recognition (NER). We provide some of the first work using polyglot LMs to produce contextual representations,[1] and the first analysis comparing them to monolingual LMs for this purpose. We also introduce an LM variant which takes multilingual word embedding input as well as character input, and explore its

---

[1] Contemporaneous work uses polyglot LMs for natural language inference and machine translation (Lample and Conneau, 2019).

Proceedings of NAACL-HLT 2019, pages 3912–3918
Minneapolis, Minnesota, June 2 - June 7, 2019.

applicability for producing contextual word representations. Our experiments focus on comparisons in three dimensions: monolingual vs. polyglot representations, contextual vs. word type embeddings, and, within the contextual representation paradigm, purely character-based language models vs. ones that include word-level input.

Previous work has shown that contextual representations offer a significant advantage over traditional word embeddings (word type representations). In this work, we show that, on these tasks, polyglot character-based language models can provide benefits on top of those offered by contextualization. Specifically, even when crosslingual transfer with word type embeddings hurts target language performance relative to monolingual models, polyglot *contextual* representations can improve target language performance relative to monolingual versions, suggesting that polyglot language models tie dissimilar languages in an effective way.

In this paper, we use the following terms: *crosslingual transfer* and *polyglot learning*. While crosslingual transfer is often used in situations where target data are absent or scarce, we use it broadly to mean any method which uses one or more source languages to help process another target language. We also draw a sharp distinction between multilingual and polyglot models. Multilingual learning can happen independently for different languages, but a polyglot solution provides a single model for multiple languages, e.g., by parameter sharing between languages in networks during training.

2 Polyglot Language Models

We first describe the language models we use to construct multilingual (and monolingual) CWR.

2.1 Data and Preprocessing

Because the Universal Dependencies treebanks we use for the parsing task predominantly use Traditional Chinese characters and the Ontonotes data for SRL and NER consist of Simplified Chinese, we train separate language models for the two variants. For English we use text from the Billion Word Benchmark (Chelba et al., 2013), for Traditional Chinese, wiki and web data provided for the CoNLL 2017 Shared Task (Ginter et al., 2017), for Simplified Chinese, newswire text from Xinhua,[2] and for Arabic, newswire text from AFP.[3] We use approximately 60 million tokens of news and web text for each language.

We tokenized the language model training data for English and Simplified Chinese using Stanford CoreNLP (Manning et al., 2014). The Traditional Chinese corpus was already pre-segmented by UDPipe (Ginter et al., 2017; Straka et al., 2016). We found that the Arabic vocabulary from AFP matched both the UD and Ontonotes data reasonably well without additional tokenization. We also processed all corpora to normalize punctuation and remove non-text.

2.2 Models and Training

We base our language models on the ELMo method (Peters et al., 2018), which encodes each word with a character CNN, then processes the word in context with a word-level LSTM.[4] Following Che et al. (2018), who used 20 million words per language to train monolingual language models for many languages, we use the same hyperparameters used to train the monolingual English language model from Peters et al. (2018), except that we reduce the internal LSTM dimension from 4096 to 2048.

For each target language dataset (Traditional Chinese, Simplified Chinese, and Arabic), we produce:

- a monolingual language model with character CNN (MONOCHAR) trained on that language's data;
- a polyglot LM (ROSITACHAR) trained with the same code, on that language's data with an additional, equal amount of English data;
- a modified polyglot LM (ROSITAWORD), described below.

The ROSITAWORD model concatenates a 300 dimensional word type embedding, initialized with multilingual word embeddings, to the character CNN encoding of the word, before passing this combined vector to the bidirectional LSTM.

---

[2] `catalog.ldc.upenn.edu/LDC95T13`

[3] `catalog.ldc.upenn.edu/LDC2001T55`

[4] A possible alternative is BERT (Devlin et al., 2018), which uses a bidirectional objective and a transformer architecture in place of the LSTM. Notably, one of the provided BERT models was trained on several languages in combination, in a simple polyglot approach (see `https://github.com/google-research/bert/blob/master/multilingual.md`). Our initial exploration of multilingual BERT models raised sufficient questions about preprocessing that we defer exploration to future work.

The idea of this word-level initialization is to bias the model toward crosslingual sharing; because words with similar meanings have similar representations, the features that the model learns are expected to be at least partially language-agnostic. The word type embeddings used for these models, as well as elsewhere in the paper, are trained on our language model training set using the fastText method (Bojanowski et al., 2017), and target language vectors are aligned with the English ones using supervised MUSE[5] (Conneau et al., 2018). See appendix for more LM training details.

3 Experiments

All of our task models (UD, SRL, and NER) are implemented in AllenNLP, version 0.7.2 (Gardner et al., 2018).[6] We generally follow the default hyperparameters and training schemes provided in the AllenNLP library regardless of language. See appendix for the complete list of our hyperparameters. For each task, we experiment with five types of word representations: in addition to the three language model types (MONOCHAR, ROSITACHAR, and ROSITAWORD) described above, we show results for the task models trained with monolingual and polyglot non-contextual word embeddings.

After pretraining, the word representations are fine-tuned to the specific task during task training. In non-contextual cases, we fine-tune by updating word embeddings directly, while in contextual cases, we only update coefficients for a linear combination of the internal representation layers for efficiency (Peters et al., 2018). In order to properly evaluate our models' generalization ability, we ensure that sentences in the test data are excluded from the data used to train the language models.

3.1 Universal Dependency Parsing

We use a state-of-the-art graph-based dependency parser with BiLSTM and biaffine attention (Dozat and Manning, 2017). Specifically, the parser takes as input word representations and 100-dimensional fine-grained POS embeddings following Dozat and Manning (2017). We use the same UD treebanks and train/dev./test splits as the CoNLL 2018 shared task on multilingual dependency parsing (Zeman et al., 2018). In particular, we use the GUM treebank for English,[7] GSD for Chinese, and PADT for Arabic. For training and validation, we use the provided gold POS tags and word segmentation.

For each configuration, we run experiments five times with random initializations and report the mean and standard deviation. For testing, we use the CoNLL 2018 evaluation script and consider two scenarios: (1) gold POS tags and word segmentations and (2) predicted POS tags and word segmentations from the system outputs of Che et al. (2018) and Qi et al. (2018).[8] The former scenario enables us to purely assess parsing performance; see column 3 in Table 1 for these results on Chinese and Arabic. The latter allows for a direct comparison to the best previously reported parsers (Chinese, Che et al., 2018; Arabic, Qi et al., 2018). See Table 2 for these results.

As seen in Table 1, the Universal Dependencies results generally show a significant improvement from the use of CWR. The best results for both languages come from the ROSITACHAR LM and polyglot task models, showing that polyglot training helps, but that the word-embedding initialization of the ROSITAWORD model does not necessarily lead to a better final model. The results also suggest that combining ROSITACHAR LM and polyglot task training is key to improve parsing performance. Table 2 shows that we outperform the state-of-the-art systems from the shared task competition. In particular, our LMs even outperform the Harbin system, which uses monolingual CWR and an ensemble of three biaffine parsers.

3.2 Semantic Role Labeling

We use a strong existing model based on BIO tagging on top of a deep interleaving BiLSTM with highway connections (He et al., 2017). The SRL model takes as input word representations and 100-dimensional predicate indicator embeddings following He et al. (2017). We use a standard PropBank-style, span-based SRL dataset for English, Chinese, and Arabic: Ontonotes (Pradhan et al., 2013). Note that Ontonotes provides annotations using a single shared annotation scheme for

---

[5] For our English/Chinese and English/Arabic data, their unsupervised method yielded substantially worse results in word translation.

[6] We make our multilingual fork available at `https://github.com/pmulcaire/rosita`

[7] While there are several UD English corpora, we choose the GUM corpus to minimize domain mismatch.

Table 1: LAS for UD parsing, F_1 for SRL, and F_1 for NER, with different input representations. For UD, each number is an average over five runs with different initialization, with standard deviation. SRL/NER results are from one run. The "task lang." column indicates whether the UD/SRL/NER model was trained on annotated text in the target language alone, or a blend of English and the target language data. RositaWord LMs use as word-level input the same multilingual word vectors as fastText models. The best prior result for Ontonotes Chinese NER is in Shen et al. (2018); the others are from Pradhan et al. (2013).

LM type	task lang.	LAS
Harbin (Che et al., 2018) CMN		76.77
Harbin (non-ensemble) CMN		75.55
RositaChar	CMN	77.40

RositaChar	ARA+ENG	**78.02**

Table 2: LAS (F_1) comparison to the winning systems for each language in the CoNLL 2018 shared task for UD. We use predicted POS and the segmentation of the winning system for that language. The RositaChar LM variant was selected based on development performance in the gold-segmentation condition.

English, Chinese, and Arabic, which can facilitate crosslingual transfer. For Chinese and English we simply use the provided surface form of the words. The Arabic text in Ontonotes has diacritics to indicate vocalization which do not appear (or only infrequently) in the original source or in our language modeling data. We remove these for better consistency with the language model vocabulary. We use gold predicates and the CoNLL 2005 evaluation script for the experiments below to ensure our results are comparable to prior work. See column 4 in Table 1 for results on the CoNLL-2012 Chinese and Arabic test sets.

The SRL results confirm the advantage of CWR. Unlike the other two tasks, multilingual word type embeddings are better than monolingual versions in SRL. Perhaps relatedly, models using RositaWord are more successful here, providing the highest performance on Chinese. One unusual result is that the model using the MonoChar LM is most successful for Arabic. This may be linked to the poor results on Arabic SRL overall, which are likely due to the much smaller size of the corpus compared to Chinese (less than 20% as many annotated predicates) and higher proportion of language-specific tags. Such language-specific tags in Arabic could limit the effectiveness of shared English-Arabic representations. Still, polyglot methods' performance is only slightly behind.

3.3 Named Entity Recognition

We use the state-of-the-art BiLSTM-CRF NER model with the BIO tagging scheme (Peters et al., 2017). The network takes as input word representations and 128-dimensional character-level embeddings from a character LSTM. We again use the Ontonotes dataset with the standard data splits. See the last column in Table 1 for results on the CoNLL-2012 Chinese and Arabic test sets. As with most other experiments, the NER results show a strong advantage from the use of contextual representations and a smaller additional advantage from those produced by polyglot LMs.

4 Discussion

Overall, our results show that polyglot language models produce very useful representations. While Universal Dependency parsing, Arabic SRL, and Chinese NER show models using contextual representations outperform those using word type representations, the advantage from polyglot training in some cases is minor. However, Chinese SRL and Arabic NER show strong improvement both from contextual word representations and from polyglot training. Thus, while the benefit of crosslingual transfer appears to be somewhat variable and task dependent, polyglot training is helpful overall for contextual word representations. Notably, the ROSITACHAR LM does not involve any direct supervision of tying two languages together, such as bilingual dictionaries or parallel corpora, yet is still most often able to learn the most effective representations. One explanation is that it automatically learns crosslingual connections from unlabeled data alone. Another possibility, though, is that the additional data provided in polyglot training produces a useful regularization effect, improving the target language representations without crosslingual sharing (except that induced by shared vocabulary, e.g., borrowings, numbers, or punctuation). Nevertheless, the success of polyglot language models is worth further study.

5 Conclusion

We presented a method for using polyglot language models to produce multilingual, contextual word representations, and demonstrated their benefits, producing state-of-the-art results in multiple tasks. These results provide a foundation for further study of polyglot language models and their use as unsupervised components of multilingual models.

Table 3: Language Model Hyperparameters.

Seen in Table 3 is a list of hyperparameters for our language models. We generally follow Peters et al. (2018) and use their publicly available code for training.[9] For character only models, we halve the LSTM and projection sizes to expedite training and to compensate for the greatly reduced training data—their hyperparameters were tuned on around 30M sentences, while we used less than 3M sentences (60-70M tokens) per language.

A.2 UD Parsing

For UD parsing, we generally follow the hyperparameters provided in AllenNLP (Gardner et al., 2018). See a list of hyperparameters in Table 4.

A.3 Semantic Role Labeling

For SRL, we again follow the hyperparameters given in AllenNLP (Table 5). The one exception is that we used 4 layers of alternating BiLSTMs instead of 8 layers to expedite the training process.

A.4 Named Entity Recognition

We again use the hyperparameter configurations provided in AllenNLP. See Table 6 for details.

Typological Features for Multilingual Delexicalised Dependency Parsing

Manon Scholivet **Franck Dary** **Alexis Nasr** **Benoit Favre** **Carlos Ramisch**

`firstname.lastname@lis-lab.fr`

Abstract

The existence of universal models to describe the syntax of languages has been debated for decades. The availability of resources such as the Universal Dependencies treebanks and the World Atlas of Language Structures make it possible to study the plausibility of universal grammar from the perspective of dependency parsing. Our work investigates the use of high-level language descriptions in the form of typological features for multilingual dependency parsing. Our experiments on multilingual parsing for 40 languages show that typological information can indeed guide parsers to share information between similar languages beyond simple language identification.

1 Introduction

Human languages may share some syntactic features, but differ on others. For example, some languages tend to place the subject before the verb (e.g., English) whereas others favour the reverse order (e.g., Arabic), and some do not exhibit a clear preference (e.g., Polish). These features can be viewed as the *parameters* of a language's syntax (Greenberg, 1963; Chomsky, 1995).

When training a multilingual parser, it could be interesting to explicitly represent these parameters, and to integrate them into the parsing model. If a successful strategy to do so was found, then, a parser could be trained simultaneously on several languages whose syntactic parameters have been explicitly represented. Such parser could then use a single model to parse texts in any language with known syntactic parameters.

In theory, if we had at our disposal a set of parameters that completely describes the syntax of languages as well as treebanks that explore the whole space of parameters and their values, then such a universal parser could be designed. To make such a program realistic, though, several issues have to be addressed. In this paper, we propose to study the feasibility of learning such multilingual parser by addressing some of these issues.

The first one is the choice of syntactic parameters that will be used (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015). In our work, we approximate these parameters by extracting syntactic information from the World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013). [1] A language is represented by a vector containing the values it selects in the WALS. This vector plays the role of the parameters mentioned above.

The second issue is the design of a unified scheme for representing syntax. Our natural choice is the Universal Dependencies (UD) initiative. [2] UD specifically proposes a set of universal dependency relations, part-of-speech tags and morphological features (Nivre et al., 2016). The UD treebanks are available for many languages, annotated according to common guidelines.

The third issue is the lexicon. UD proposes a common language for describing languages' morpho-syntax, but we do not dispose of a "universal lexicon" to which we can map the lexical units of different languages. The solution adopted in this work is to resort to delexicalised parsing (Zeman and Resnik, 2008). This technique consists in ignoring the lexicon when training a parser. Such impoverishment of the data leads to less accurate parsers, but offers a simple solution to the lexicon issue. Using an alternative solution for representing words in different languages, such as multilingual word embeddings, would have introduced in our experimental setting some biases that are difficult to assess and would have prevented

Proceedings of NAACL-HLT 2019, pages 3919–3930
Minneapolis, Minnesota, June 2 - June 7, 2019.

to measure the precise influence of the typological features on the behaviour of the parser.

The fourth issue concerns the parser, which must be language independent and produce syntactic trees based on combinations of parameter values and sentential configurations. We use a transition-based parser with a multi-layer perceptron classifier (Chen and Manning, 2014), responsible for proposing how parameter values match observable patterns in the data.

Our research hypotheses are: (a) features derived from the WALS enable cross-lingual sharing in multilingual parsing, and (b) these features do more than acting as mere language identifiers. Our main contributions are to reassess the utility of the WALS as informant of typological features of parsed languages, to evaluate their benefit in a controlled multilingual setting with full supervision, and to perform a set of analyses to better understand how they interact with the parser model. In addition to multilingual parsing, our method is suitable for zero-shot learning for under-resourced languages (Ammar et al., 2016; Guo et al., 2015).

After discussing related work (Sec. 2), we describe UD (Sec. 3), the WALS (Sec. 4) and our parser (Sec. 5). The experimental setup (Sec. 6) precedes our results (Sec. 7), analyses (Sec. 8) and conclusions (Sec. 9).

2 Related Work

Our work is at the intersection of three trends in the multilingual dependency parsing literature. The first is *transfer parsing*, when a parser is trained on a language (or a collection of languages) and tested on another one. The second is *delexicalised parsing*, which aims at abstracting away from the lexicon in order to neutralise genre, domain and topic biases which are heavily marked in the treebanks' vocabulary. The third trend is the use of a handcrafted *typological resources*, such as the WALS, in multilingual NLP methods.

Transfer parsing is often a suitable solution when dealing with low-resource languages (McDonald et al., 2011). Projected transfer relies on parallel corpora in which one of the languages does not have labelled training data to learn a parser, but the other does. One commonly employed solution is to use word alignments to project parsed sentences from one side onto the low-resource side of the parallel text, using heuristics (Hwa et al., 2005) or partial annotations (Lacroix et al., 2016). Agić et al. (2016) parse the resource-rich languages in a multi-parallel corpus, proposing a projection method to obtain POS tags and dependency trees for low-resource languages from multiple-language word alignments. The parsing model for the target language can also be obtained in an unsupervised fashion, by optimising a function that combines the likelihood of parallel data and the likelihood of the transferred model on non-annotated data in the low-resource language (Ma and Xia, 2014).

Instead of assuming the availability of parallel corpora, direct transfer approaches capitalize on language similarities. For instance, Lynn et al. (2014) build parser for Irish by first training a delexicalised parser on another language, and then applying it on Irish. They surprisingly found out that Indonesian was the language providing the best parsing results for Irish, even if they do not belong to the same language family, because long-distance dependencies are better represented in Indonesian than in the other languages tested.

Low-resource languages may have some (insufficient) amount of training material available. One can employ bilingual parsing, concatenating training corpora in two languages, to verify if there is an improvement in the results compared to a monolingual parser (Vilares et al., 2015). Direct transfer and bilingual parsing methods are close to the present article, since we also concatenate training corpora. However, in our case, we combine treebanks from many more sources (around 40 languages) and include typological features.

The combination of corpora in multiple languages for parser training is facilitated by the recent advent of multilingual standards and resources, in particular in Universal Dependencies for dependency syntax (Nivre et al., 2016). This initiative enables the annotation of POS, morphology and syntactic dependencies for all languages with the same guidelines and label sets. The availability of such corpora favours the development of cross-lingual methods (Tiedemann, 2015).

Multilingual parsing research is also encouraged by initiatives such as the CoNLL 2017 and 2018 shared tasks, on highly multilingual dependency parsing from raw text (Zeman et al., 2017, 2018).

Delexicalised parsers ignore the word forms and lemmas when analysing a sentence, usually relying on more abstract features such as word classes and POS tags. The use of delexicalised parsers is especially relevant when learning multilingual parsers, since languages generally share only a limited amount of lexical units. The approach proposed by Zeman and Resnik (2008) consists in adapting a parser for a new related language using either parallel corpora or delexicalised parsing. This method can be used to quickly construct a parser if the source and target languages are sufficiently related. McDonald et al. (2011) show that delexicalised parsers can be directly transferred between languages, yielding significantly higher accuracy than unsupervised parsers.

Moreover, typological features such as those present in the WALS provide information about the structure of languages (Dryer and Haspelmath, 2013). These could be useful to guide multilingual parsers, informing them about the model parameters that can be shared among languages with similar characteristics. Naseem et al. (2012) and Zhang and Barzilay (2015) use word-order features available for all their languages, while Ponti et al. (2018) used features they judged relevant in many categories (not only word order). The parameters proposed in the WALS are not the only way to represent properties of languages. Methods based on language embeddings (Östling and Tiedemann, 2017; Bjerva et al., 2019) also constitute interesting language representation.

Täckström et al. (2013) use a multilingual delexicalised transfer method, showing how selective parameter sharing, based on typological features and language family membership, can be incorporated in a discriminative graph-based dependency parser. They select the typological features based on those used by Naseem et al. (2012), removing two features not considered useful.

The work closest to ours experimented with concatenating treebanks to train a multilingual parser (Ammar et al., 2016). The authors use an S-LSTM transition-based parser similar to ours (although we do not include recurrent representations) trained on a set of lexicalised features that include multilingual word embeddings, Brown clusters, and fine-grained POS tags, whereas we only use coarse-grained POS and morphological features in a delexicalised setting. They include a one-hot language-ID vector, a set of six word-order features from the WALS (Naseem et al., 2012), or the whole WALS vectors. We use the two former plus a set of 22 selected features from WALS. They perform experiments on seven high-resourced languages while we report results on a larger set of 40 languages. Although Ammar et al. (2016) showed that, in a lexicalised setting, treebank concatenation could perform on par with monolingual parsers, the origins and limits of these improvements are not clear. We explore directions for assessing the benefits of typological features in a delexicalised parser.

3 Universal Dependencies

A major issue in multilingual parsing is the consistency of annotation across languages, since most corpora are annotated using different guidelines and tagsets. Universal Dependencies (UD) is an initiative whose goal is to create cross-linguistically consistent treebanks, facilitating cross-lingual analyses for language and parsing studies. Currently at version 2.3, 129 treebanks in 76 languages are available.

We use the UD v2.0 release for training and development, and the CoNLL 2017 shared task test sets for evaluation. For training and development, 64 UD treebanks in 45 languages are available. These treebanks vary in size: some are very small (e.g., 529 words for Kazakh), whereas others can be rather large (e.g., 1,842,867 words for Czech). Test corpora contain at least 10,000 words per language and are available for 49 languages.[3]

We learn delexicalised parsers from the UD treebanks using universal parts of speech (UPOS) and morphological features (FEAT) as input, and predicting labelled dependency trees which include language-specific extensions (e.g., *acl:relcl*). Morphological features are present in almost all treebanks, but exhibit high variability. Therefore, we choose to keep only the 16 most frequent features (e.g., Number, Case, VerbForm), which appear in at least 28 languages. Furthermore, morphology is represented as a list of *key=value* pairs, which we split so that each pair is considered separately, yielding a fixed set of 16 morphological features per word.

4 World Atlas of Language Structures

The World Atlas of Language Structures (WALS) is a database of structural (phonological, grammatical and lexical) properties of languages gathered by 55 authors from descriptive materials such

---

[3] 4 languages do not have training sets.

as reference grammars. We have used this resource to associate to every language of UD corpora a set of features describing its properties that are relevant for syntactic parsing.

The WALS describes 2,676 languages with a set of 192 features, organized into 11 feature genus (e.g. Phonology, Word Order). It can therefore be represented as a matrix W of 2,676 rows and 192 columns, in which cell $W(l, f)$ gives the value of feature f for language l, and each row $W(l)$ is the feature vector of a language l. This matrix has been pruned and completed to match our experimental setup. First, we have kept only the rows corresponding to the 49 languages of our test corpora. Conversely, four UD languages do not appear in the WALS and have been left aside: Old Church Slavonic (cu), Gothic (got), Ancient Greek (grc), and Latin (la). As a result, we obtain a reduced version of W containing 45 rows.

We experimented with two language representations obtained from the WALS. The first one, henceforth W_N, is based on the work of Naseem et al. (2012). They selected the six Word Order features available for all their 17 target languages, identified by the codes 81A, 85A, 86A, 87A, 88A, 89A[4]. These features cover phenomena such as verb-object and adjective-noun order, and have been widely discussed in the literature (Täckström et al., 2013; Zhang and Barzilay, 2015; Ammar et al., 2016). The resulting matrix has 45 rows (languages) and 6 columns (features). However, the WALS seen as a matrix is sparse, as some features are unspecified for some languages. Therefore, we chose to keep only languages for which at most half of this vector is unspecified, resulting in the removal of 5 more languages: Galician (gl), Upper Sorbian (hsb), Kazakh (kk), Slovak (sk), and Uyghur (ug). All our experiments are carried out on this set of 40 languages.

The second language representation proposed in this work, henceforth W_{80}, is a relaxed version of W_N. Since the WALS is sparse, we include in W_{80} all features specified for at least 80% of our 40 languages. Furthermore, in addition to features from the Word Order family, we also include features from the Simple Clauses family. This results in a matrix of 40 rows and 22 columns corresponding to 3 features from the Simple Clauses family (101A, 112A, 116A), and 19 from the Word Order family (81A, 82A, 83A, 85A, 86A, 87A, 88A, 89A, 90A, 92A, 94A, 95A, 96A, 97A, 144A, 143A, 143E, 143F, 143G).[5]

	Romance	Germanic	Slavic	Random
W_N	0.33	1.33	0.67	2.41
W_{80}	4.13	4.47	4.19	10.15

Table 1: MID values of typological language genus compared to Random. Random MID is the average of the MID for 50,000 sets of 6 languages randomly selected.

The final matrices W_N and W_{80} obtained after feature selection are not complete: they contain respectively 4 and 35 unspecified values, which were filled automatically. Each matrix W (shorthand for W_N and W_{80}) offers a straightforward way to compare languages l_1 and l_2 using the Hamming distance[6] between their vectors $W(l_1)$ and $W(l_2)$, noted $d(l_1, l_2)$. To fill in the missing values, we have selected, for every language l_1 containing unspecified feature values ('?'), the corresponding value from its closest fully specified language l_2, that is, $l_2 = \underset{l_i \,\mid\, ? \notin W(l_i)}{\arg\min}\ d(l_1, l_i)$.

The W_N and W_{80} matrices only provide partial descriptions of languages, heavily biased towards parsing and ignoring other aspects (e.g., phonology). Nevertheless, it is tempting to compare how they relate languages that belong to the same typological genus. In order to do so, we have concentrated on three genus present in our set of 40 languages: Romance (6 languages), Germanic (6 languages) and Slavic (7 languages), and computed how close the vectors of these languages are. We define the *mean internal distance* (MID) of a language set $L = \{l_1, \ldots, l_n\}$, as the average of the distances of every pair of languages in L:

$$MID(L) = \frac{1}{n^2 - n} \sum_{\substack{(l_i,l_j) \in L\times L \\ i\neq j}} d(l_i, l_j)$$

We have computed the MID of each language genus, and compared it with the MID of randomly chosen sets of 6 languages (number of languages in the Romance and Germanic genus). The results in Table 1 clearly indicate that WALS vectors capture language genus similarities.

Others methods could have been used to assess whether the language descriptions that we have

---

[4] The description of the features of the WALS relevant for this paper can be found in appendix A.

[5] We have also considered the Complex Sentences family, but no feature exceeded the 80% threshold.

[6] The number of dimensions for which their values differ.

extracted from the WALS can measure language proximity. It could be interesting, for example, to reproduce the results of (Rabinovich et al., 2017) on reconstructing phylogenetic trees of language from the WALS features.

5 Parser

The parser used in our experiments is an arc-eager transition-based parser (Nivre, 2008), trained with a dynamic oracle (Goldberg and Nivre, 2012). The prediction of transitions is performed with a multilayer perceptron (MLP), as in Chen and Manning (2014). The MLP consists of an input layer, one hidden layer, and an output layer. Two sets of delexicalised features have been defined for the prediction: BASIC and EXTENDED. BASIC is a standard set composed of 9 POS features, 7 syntactic features, 32 morphological features, and a distance feature (the distance between the head and the dependent).[7] EXTENDED adds to BASIC new features that correspond to the WALS vectors W_N (6 features) and W_{80} (22 features), and/or the language ID of the sentence's language (1 feature). Each feature, including ID, is associated with a zero-initialized learnable embedding of size 3. The input layer of the MLP corresponds to the concatenation of the embeddings of the different features, with dimensions varying from 396 to 465, depending on the configuration (with or without language vectors W_N and W_{80}, or a language identifier ID). The output layer has 263 neurons, corresponding to the number of transitions that the parser can predict. The hidden layer has 1,000 units, the dropout rate used during training is equal to 0.4, the number of epochs is equal to 10, the activation function is a ReLU, the loss function is negative softmax log likelihood, and the learning algorithm is AMSgrad, using default parameters from Dynet (Neubig et al., 2017).[8]

At every step of the parsing process, the parser predicts an action to perform, which may yield the creation of a new dependency between two words of the sentence. The prediction of the actions is based on the values of the features fed to the MLP. In BASIC mode, these features describe different aspects of the head and the dependent, as well as their neighbourhood. For example, if the head is a verb and the dependent is a noun located before the verb, a subject dependency has high probability in languages that prefer subject-verb ordering (SV). In EXTENDED mode, the information of whether the language is SV is made explicit. The MLP has therefore the possibility to combine a *sentential configuration* (e.g., a noun before a verb) with a *language configuration* (e.g., the language is SV) when predicting an action. All languages that share a common feature in W will therefore be able to perform the same prediction for sentential configurations that are specific to this common feature (e.g., the noun preceding the verb and the language being SV).[9]

6 Experimental Settings

Corpora Our experiments were performed on the CoNLL 2017 shared task data (Zeman et al., 2017), on gold tokenisation and ignoring contractions (i.e., ranges). We evaluate our models individually on each of the 40 languages for which we have a $W(l)$ vector (section 4), using the original CoNLL 2017 shared task test sets. The test corpora for each language are simply the concatenation of all test treebanks for that language.

Training and development are performed on multilingual corpora (henceforth TRAIN-ML and DEV-ML) derived from the training and development treebanks of 37 UD languages.[10] The UD training and development corpora have different sizes for different languages, ranging from 529 words for Kazakh (kk) to 1,842,867 for Czech (cs). Thus, simply concatenating all corpora to constitute TRAIN-ML and DEV-ML would overrepresent certain languages and possibly bias the parser towards them. This is why we have decided to balance TRAIN-ML and DEV-ML across languages.

First, all available training and development corpora of the 37 languages have been concatenated. From this large corpus, we build two new intermediate corpora, PRE-TRAIN-ML and PRE-DEV-ML, with each sentence having 90% chances to belong to PRE-TRAIN-ML, and 10% chances

---

[7] Corpora, configuration files and WALS vectors available at: `http://pageperso.lis-lab.fr/~carlos.ramisch/?page=downloads/wals-ud-parse`

[8] Hyperparameters were tuned in preliminary experiments, in conditions similar to $\Sigma\ W_N$ (see Section 6).

[9] Our parser cannot predict non projective trees, systematically generating a wrong parse at test time. The average non projectivity rate of the test corpora is equal to 1%, with a standard deviation of 1% among the 40 languages. We ran some tests with pseudo projective tree transformation (Nivre and Nilsson, 2005), but it had a negligible impact on the results, so we have decided to keep the original projective algorithm.

[10] Three languages among our 40 target languages have no corresponding training nor development data (bxr, kmr, sme).

to belong to PRE-DEV-ML. Second, we build TRAIN-ML (respectively DEV-ML) by randomly selecting sentences from PRE-TRAIN-ML (resp. PRE-DEV-ML) until the number of tokens exceeds 20,000 (resp. 2,000 for DEV-ML) per language. At the end, we shuffle the selected sentences to obtain the final training and development corpora TRAIN-ML and DEV-ML. Using this procedure, the same sentence can appear several times in a corpus. Nonetheless, this method guarantees a balanced representation of every language in TRAIN-ML and DEV-ML.

Metrics The quality of the predicted trees is assessed with a standard measure for dependency parsing: labelled attachment score (LAS).[11], [12] We report LAS per language, as well as MACRO-LAS which is the macro-average of LAS on all languages that have a training set. This measure is therefore independent of the size of the test corpus of each language, and is not biased towards over-represented languages in the test sets.

Training Configurations Our experiments on several ⟨training corpus, language vector⟩ pairs are designated by the following codes:

***L*:** Monolingual corpus. The training corpus of a language l consists of the sentences of l in TRAIN-ML. Thirty-seven BASIC delexicalised parsers have been trained, one per language. This configuration corresponds to the standard one in parsing experiments: training and testing on the same language.

Σ: Multilingual corpus. A BASIC parser is trained on the whole TRAIN-ML corpus, with no indication of the inputs language. The parsing model is delexicalised, so the corpus contains only POS tags (gold), morphological features (gold) and syntactic relations (to be learned).[13]

Σ ID: Multilingual corpus + language ID. An EXTENDED parser is trained on the TRAIN-ML corpus using as extra feature the identifier of the language attached to each word.

Σ W_N, Σ W_{80}: Multilingual corpus + WALS. Two EXTENDED parsers are trained on the TRAIN-ML corpus, with W_N (resp. W_{80}) vectors derived from the WALS attached to each word.

7 Results

The detail of the LAS obtained for every language, as well as the macro-averaged LAS (MACRO) are displayed in Table 2. We comment below the results for L, and compare the results of meaningful pairs of experiments, summarised in Table 3.

Table 2: LAS for each language and MACRO LAS, for the five configurations. Languages followed by a S belong to the Slavic genus, G belong to the German genus and R belong to the Romance genus.

***L*:** The results obtained in the L experiment show an important variation of performances for different languages. LAS ranges from 46.78 for

---

[11] For brevity, we omit UAS figures in our experiments, as UAS and LAS are tightly correlated ($r = 0.98$)

[12] Using the CoNLL shared task 2017 evaluation script.

[13] The decision to use gold POS tags and morphological features may seem unrealistic. This article is the first step of a process in which we intend to predict the POS tags and the morphological features in the same fashion.

X	Y	$\overline{X-Y}$	σ	min	max
L	Σ	5.68	3.32	-0.51 es	14.37 zh
$\Sigma\ W_{80}$	Σ	4.00	2.58	0.59 hi	13.10 ru
$\Sigma\ W_{80}$	$\Sigma\ W_N$	1.24	1.45	-1.64 tr	5.80 ru
Σ ID	Σ	3.27	3.00	-0.06 nl	13.48 zh
L	Σ ID	2.41	1.99	-0.91 es	7.65 ko
$\Sigma\ W_{80}$	Σ ID	0.73	1.54	-4.07 zh	3.12 el

Table 3: Differences between X and Y configurations: average ($\overline{X-Y}$), standard deviation (σ), minimum and maximum with corresponding languages.

Turkish to 81.44 for Italian. A detailed investigation for the reasons of such a variability is beyond the scope of this paper. Let us just mention a few hypotheses. Some are language specific, such as the balance between morphological and syntactic marking of linguistic constructions (i.e., morphologically rich languages are probably favoured in our setting, since the morphological analysis is given as input to the parser). Others are genre specific: the corpora for different languages pertain to different genres. Although delexicalisation neutralises some genre biases (some genres can feature a moderate lexical variability which can ease parsing) genres can also influence syntax, through sentence length (longer sentences are generally harder to parse), or the ratio of error-prone constructions, such as ambiguous prepositional phrases and coordination. Finally, annotation quality is heterogeneous across languages, potentially explaining the variability in LAS.

***L* vs Σ:** An expected drop in performances is observed when switching from *L* to Σ. The MACRO LAS loses 5.68 points. The main hypothesis to explain such a drop is the noise introduced when mixing different languages. This noise takes the form of contradictory information seen by the parser during training. For example, the sentential configuration associated to a subject dependency in SV and VS languages are very different, yet the parser is unaware of this distinction and will see contradictory examples. The variation of the LAS drop is different across languages. In the case of Spanish, switching from *L* to Σ even increases LAS (+0.51 points). We do not have a conclusive explanation for this result. The intuitive explanation is that Σ is a (noisy) language which on average is closer to Spanish than it is to Chinese (which performance drops by 14.37 points). This fact itself is the consequence that, on average, languages that compose Σ are closer to Spanish than they are to Chinese.

Σ vs $\Sigma\ W_{80}$: This is our first major result: when adding W_{80} to the parser, the MACRO LAS increases by 4 points when compared to Σ. LAS increases for all languages. There are two interpretations of this result. The optimistic one is that W_{80} helps decreasing the noise introduced by mixing languages in Σ by “explaining” some apparently contradictory information in the data through the use of linguistic features encoded in the WALS. The pessimistic interpretation is that the WALS vectors are merely an arbitrary encoding of the languages. In this case, the parser’s MLP would be associating sentential configurations to specific languages, thus learning different models for different languages. Figuring out what the model is actually learning is not an easy task. We propose in section 8 some clues to answer this question. Moreover, there is not a clear tendency to increase or decrease when using the WALS vector in the case of the 3 languages without training data. More experiments are required to study the performances when the language is not in the training corpus.

$\Sigma\ W_N$ vs $\Sigma\ W_{80}$: When added to Σ, vectors W_N and W_{80} do not have the same impact on the performances. Adding W_{80} to Σ yields an increase of 4 points while adding W_N increases the performance by 2.77 points only. The parser is therefore able to take advantage from a richer description of languages when learning the model. This result indicates that the disappointing parsing results reported by Ammar et al. (2016), who adopted the W_N vector, are probably due to the fact that the features extracted from the WALS were not rich enough to explain differences between languages that are important for a parser.

Σ vs Σ ID: Adding the ID vector to Σ yields an improvement of 3.28 MACRO points. This increase was expected since, in this setting, sentential configurations are associated to a language ID, which helps decreasing the noise in the data.

***L* vs Σ ID:** One could expect that Σ ID would reach the result obtained by *L* since in both configurations the same amount of data is available and languages are unambiguously identified. This is not the case: the performance of Σ ID is 2.41 points behind *L*. The difference in performances is due to the MLP architecture (in particular the size of the hidden layer), which is the same for Σ ID and for each of the *L* models. Each language is described with more parameters in an L model than it is in the Σ ID model.

Σ ID vs Σ W_{80}: This is our second major result: adding W_{80} to Σ yields better results than adding ID to Σ. This result indicates that it is more interesting, in our setting, to describe a language as a vector of typological features, allowing to identify features that are common to several languages, than describing a language by an arbitrary code. As mentioned above, such a conclusion is valid for models of a fixed size only, which is the case here. It could be the case that, when increasing the number of parameters of the models, Σ ID gets better results than Σ W_{80}.

We do not report here a series of experiences combining ID and W_{80}. We observed a slight improvement (MACRO=67.86) when adding ID in the input of the parser. This effect indicates that the information contained in ID and W_{80} vectors are complementary and the parser has the opportunity to rely on both of them. Figuring out exactly how the parser uses this information is a complex issue that we address in the following section.

8 How does the parser use W?

As already conjectured, one hypothesis for explaining the behaviour of the parser in the presence of W is that it uses the additional features to identify a language, not to better generalise on the syntactic phenomena that the features address. Table 4 shows the accuracy of a logistic regression classifier trained to predict the language ID based on either the input features of the parser's MLP, or on the activations after the hidden layer, with Σ, Σ W_N and Σ W_{80}. The table shows that indeed, WALS features, especially W_{80}, greatly improve the capability of the language classifier, suggesting that the parser can use language identity in its predictions. The fact that this information is still available just before the decision layer means that it can be used for predicting parsing actions.

Another interesting analysis consists in comparing the distribution of activations for two languages. In the following, the activations are measured at the hidden layer before the ReLU nonlinearity, and are assumed to follow normal distributions at the neuron level. We compute the Jensen-Shannon Divergence (JSD) between the activations of a given neuron for a pair of languages. Table 5 shows the mean, maximum and minimum neuron-level JSD between cherry-picked language pairs. We selected three language pairs with increasing distance. Dutch and German (nl-de) belong to the same typological genus and have identical W_{80} vectors. Portuguese and French (pt-fr) also belong to the same genus but their vectors differ in six features (e.g. 101A pronominal subject, 143E postverbal negation). On the other extreme, Russian Buriat and Irish (brx-ga) have very different W_{80} vectors, with only two shared values out of 22.

Configuration	Features	Accuracy
Σ	input	0.432
Σ W_N	input	0.678
Σ W_{80}	input	0.954
Σ	hidden	0.436
Σ W_N	hidden	0.682
Σ W_{80}	hidden	0.956

Table 4: Language identification accuracy for a logistic regression classifier trained on the activations after the hidden layer, or at the input. The classifier is trained on the development set, results are reported on the test set.

L1	L2	Model	Mean	Max	Min
nl	de	Σ	0.860	1.027	0.798
		Σ W_{80}	0.854	0.940	0.793
pt	fr	Σ	0.878	1.335	0.794
		Σ W_{80}	0.912	3.550	0.700
bxr	ga	Σ	0.890	1.600	0.782
		Σ W_{80}	1.160	4.888	0.757

Table 5: Neuron-level JSD statistics between activations at the hidden layer of the parser models for selected pairs of languages.

For nl-de, the average difference between the activation distributions in Σ W_{80} (0.854) is lower than in Σ (0.86), suggesting that W_{80} helps leveraging the similarity between those languages, which is also confirmed by an increase in LAS (Table 2). For pt-fr, however, the addition of W_{80} results in an increase in the average distance between the activation distributions (0.912) when compared to Σ (0.878). Analogously, this difference also increases by a larger margin (from 0.89 to 1.16) for the most distant pair bxr-ga. Overall, these observations indicate that W_{80} reinforces parameter sharing between similar languages and increases contrast between dissimilar ones. As an example, Figure 1 shows that the distributions for the neuron with highest JSD are very similar for nl-de while they are different for bxr-ga.

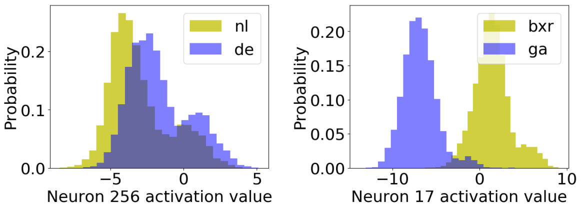

Figure 1: Activation distributions for the neuron with highest JSD on Σ for (nl, de) and (bxr, ga) pairs.

9 Conclusions and Future Work

This paper has studied how high-level typological language descriptions coming from the WALS can guide a multilingual parser to learn cross-language generalisations. Two interpretations of what the parser is doing in the light of such information have been opposed. In the first (optimistic) one, the parser uses the high-level descriptions to cluster coherent observable patterns across languages. In the second (pessimistic) one, the parser uses the high-level descriptions given as input to figure out the identity of the language and uses this ID to trigger parts of the model that are language specific. Our results and parsing model analyses hint that, although it is difficult to draw definitive conclusions, the model indeed uses information in the WALS vectors as language identifiers, but some extra gain is observed, favouring the cross-lingual sharing hypothesis.

As future work, we plan to study the influence of typological features on each dependency type. Whereas a delexicalised parser offers a simple experimental setup, it impacts parsing performance. Thus, we would like to use multilingual word embeddings to make lexical information accessible to the parser, making it more realistic. The results in section 8 suggest that the parser struggles between two behaviours. One way to intervene would be to penalise the parser when it correctly identifies the language, using adversarial learning (Ganin et al., 2016). Our experiments on the three languages with no training corpus are not conclusive on the usefulness of the WALS vector in zero-shot setting, and we plan to make more tests in this setting.

Recommendations for Datasets for Source Code Summarization

Alex LeClair, Collin McMillan
Department of Computer Science and Engineering
University of Notre Dame
{aleclair, cmc}@nd.edu

Abstract

Source Code Summarization is the task of writing short, natural language descriptions of source code. The main use for these descriptions is in software documentation e.g. the one-sentence Java method descriptions in JavaDocs. Code summarization is rapidly becoming a popular research problem, but progress is restrained due to a lack of suitable datasets. In addition, a lack of community standards for creating datasets leads to confusing and unreproducible research results – we observe swings in performance of more than 33% due only to changes in dataset design. In this paper, we make recommendations for these standards from experimental results. We release a dataset based on prior work of over 2.1m pairs of Java methods and one sentence method descriptions from over 28k Java projects. We describe the dataset and point out key differences from natural language data, to guide and support future researchers.

1 Introduction

Source Code Summarization is the task of writing short, natural language descriptions of source code (Eddy et al., 2013). The most common use for these descriptions is in software documentation, such as the summaries of Java methods in JavaDocs (Kramer, 1999). Automatic generation of code summaries is a rapidly-expanding research area at the crossroads of Computational Linguistics and Software Engineering, as a growing tally of new workshops and NSF-sponsored meetings have recognized (Cohen and Devanbu, 2018; Quirk, 2015). The reason, in a nutshell, is that the vast majority of code summarization techniques are adaptations of techniques originally designed to solve NLP problems.

A major barrier to ongoing research is a lack of standardized datasets. In many NLP tasks such as Machine Translation there are large, curated datasets (e.g. Europarl (Koehn, 2018)) used by several research groups. The benefit of these standardized datasets is twofold: First, scientists are able to evaluate new techniques using the same test conditions as older techniques. And second, the datasets tend to conform to community customs of best practice, which avoids errors during evaluation. These benefits are generally not yet available to code summarization researchers; while large, public code repositories do exist, most research projects must parse and process these repositories on their own, leading to significant differences on one project to another. The result is that research progress is slowed as reproducibilty of earlier results is difficult.

Inevitably, differences in dataset creation also occur that can mislead researchers and over or understate the performance of some techniques. For example, a recent source code summarization paper reports achieving 25 BLEU when generating English descriptions of Java methods with an existing technique (Gu et al., 2018), which is 5 points higher than the original paper reports (Iyer et al., 2016). The paper also reports 35+ BLEU for a vanilla seq2seq NMT model, which is 16 points higher than what we are able to replicate. While it is not our intent to single out any one paper, we do wish to call attention to a problem in the research area generally: a lack of standard datasets leads to results that are difficult to interpret and replicate.

In this paper, we propose a set of guidelines for building datasets for source code summarization techniques. We support our guidelines with related literature or experimentation where strong literary consensus is not available. We also compute several metrics related to word usage to guide future researchers who use the dataset. We have made a dataset of over 2.1m Java methods and summaries from over 28k Java projects available via an online appendix (URL in Section 6).

Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Related Work

Related work to this paper consists of approaches for source code summarization. As with many research areas, data-driven AI-based approaches have superseded heuristic/template-based techniques, though overall the field is quite new. Work by Haiduc *et al.* (Haiduc et al., 2010a,b) in 2010 coined the term "source code summarization", and several heuristic/template-based techniques followed including work by Sridhara *et al.* (Sridhara et al., 2010, 2011), McBurney *et al.* (McBurney and McMillan, 2016), and Rodeghero *et al.* (Rodeghero et al., 2015).

More recent techniques are data-driven, though the overall size of the field is small. Literature includes work by Hu *et al.* (Hu et al., 2018a,b) and Iyer *et al.* (Iyer et al., 2016). Projects targeting problems similar to code summarization have been published widely, including on commit message generation (Jiang et al., 2017; Loyola et al., 2017), method name generation (Allamanis et al., 2016), pseudocode generation (Oda et al., 2015), and code search (Gu et al., 2018). Nazar *et al.* (Nazar et al., 2016) provide a survey.

Of note is that no standard datasets for code summarization have yet been published. Each of the above papers takes an ad hoc approach, in which the authors download large repositories of code and apply their own preprocessing. There are few standard practices, leading to major differences in the reported results in different papers, as discussed in the previous section. For example, the works by LeClair *et al.* (LeClair and McMillan, 2019) and Hu *et al.* (Hu et al., 2018a) both modify the CODENN model from Iyer *et al.* (Iyer et al., 2016) to work on Java methods and comments. LeClair *et al.* and Hu *et al.* report very disparate results: A BLEU-4 score of 6.3 for CODENN on one dataset, and 25.3 on another, even though both datasets were generated from Java source code repositories.

These disparate results happen for a variety of reasons, such as a difference in data set sizes and tokenization schemes. LeClair *et al.* use a data set of 2.1 million Java method-comment pairs while Hu *et al.* use a total of 69,708. Hu *et al.* also replace out of vocabulary (OOV) tokens in the comments with <UNK> in the training, validation, and testing sets, while LeClair *et al.* remove OOV tokens from the training set only.

3 Dataset Preparations

The dataset we use in this paper is based on the dataset provided by LeClair *et al.* (LeClair and McMillan, 2019) in a pre-release. We used this dataset because it is both the largest and most recent in source code summarization. That dataset has its origins in the Sourcerer project by Lopes *et al.* (Lopes et al., 2010), which includes over 51 million Java methods. LeClair *et al.* provided the dataset after minimal initial processing that filtered for Java methods with JavaDoc comments in English, and removed methods over 100 words long and comments $>$13 and $<$3 words. The result is a dataset of 2.1m Java methods and associated comments. LeClair *et al.* do additional processing, but do not quantify the effects of their decisions – this is a problem because other researchers would not know which of the decisions to follow. We explore the following research questions to help provide guidelines and justifications for our design decisions in creating the dataset.

3.1 Research Questions

Our research objective and contribution in this paper is to quantify the effect of key dataset processing configurations, with the aim to make recommendations on which configurations should be used. We ask the following Research Questions:

RQ$_1$ What is the effect of splitting by method versus splitting by project?

RQ$_2$ What is the effect of removing automatically generated Java methods?

The scope of the dataset in this paper is source code summarization of Java methods – the dataset contains pairs of Java methods and JavaDoc descriptions of those methods. However, we believe these RQs will provide guidance for similar datasets e.g. C/C++ functions and descriptions, or other units of granularity e.g. code snippets instead of methods/functions.

The rationale behind RQ$_1$ is that many papers split the dataset into training, validation, and test sets at the unit of granularity under study. For example, dividing all Java methods in the dataset into 80% in training, 10% in validation, and 10% in testing. However, this results in a situation where it is possible for code from one project to be in both the testing set and the training set. It is possible that similar vocabulary and code patterns

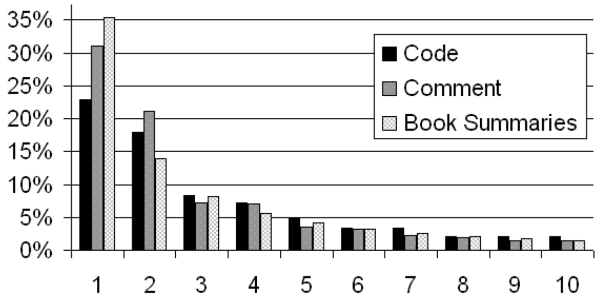

Figure 1: Word count histogram for code, comment, and the book summaries. About 22% of words occur one time across all Java methods, versus 35% in the book summaries.

are used in methods from the same project, and even worse, it is possible that overloaded methods appear in both the training and test sets. However, this possibility is theoretical and a negative effect has never been shown. In contrast, we split by project: randomly divide the Java projects into training/validation/test groups, then place all methods from e.g. test projects into the test set.

The rationale behind RQ_2 is that automatically generated code is common in many Java projects (Shimonaka et al., 2016), and that it is possible that very similar code is generated for projects in the training set and the testing/validation sets. Shimonaka *et al.* (Shimonaka et al., 2016) point out that the typical approach for identifying auto-generated code is a simple case-insensitive text search for the phrase "generated by" in the comments of the Java files. LeClair *et al.* (LeClair and McMillan, 2019) report that this search turns out to be quite aggressive, catching nearly all auto-generated code in the repository. However, as with RQ_1, the effect of this filter is theoretical and has not been measured in practice.

3.2 Methodology

Our methodology for answering RQ_1 is to compare the results of a standard NMT algorithm with the dataset split by project, to the results of the same algorithm on the same dataset, except with the dataset split by function. But because random splits could be "lucky", we created four random datasets split by project, and four split by function, seen in Table 2. We then use an off-the-shelf, standard NMT technique called `attendgru` provided pre-release by LeClair *et al.* (LeClair and McMillan, 2019) and used as a baseline approach in their recent paper. The technique is just an attentional encoder/decoder based on single-layer GRUs, and represents a strong NMT baseline used by many papers. We train `attendgru` with each of the four training sets, find the best-performing model using the validation set associated with that training set (out of 10 maximum epochs), and then obtain test performance for that model. We report the average of the results over the four random splits. Note that we used the same configuration for `attendgru` as LeClair *et al.* report, except that we reduced the output vocabulary to 10k to reduce model size.

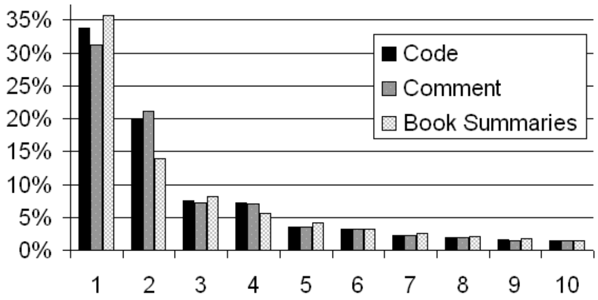

Figure 2: Histogram of word occurrences per document. Approximately 34% of words occur in only one Java method, 20% occur in two methods, etc.

Our process for RQ_2 is similar. We created four random split-by-project sets in which automatically generated code was *not* removed. Then we compared them to the four random split-by-project sets we created for RQ_1 (in which auto-generated code was removed).

3.3 Dataset Characteristics

We make three observations about the dataset that, in our view, are likely to affect how researchers design source code summarization algorithms. First, as depicted in Figure 1, words appear to be used more often in code as compared to natural language – there are fewer words used only one or two times, and in general more used 3+ times. At the same time (Figure 2), the pattern for word occurrences per document appears similar, implying that even though words in code are repeated, they are repeated often in the same method and not across methods. Even though this may suggest that the occurrence of unique words in source code is isolated enough to have little affect on BLEU score, we show in Section 4 that this word overlap causes BLEU score inflation when you split by function. This is important because the typical MT use case assumes that a "dictionary" can be created (e.g., via attention) to map words in a source to words in a target language. An algorithm applied to code summarization needs to tolerate multiple occurrences of the same words. To compare the source code, comments, and natural language datasets we tokenized our data by removing all special characters, lower casing, and for source code – splitting camel case into separate tokens.

SplittingStrategy	Set1	Set2	Set3	Set4
Split by project	17.81	16.73	17.11	17.99
Split by function	20.97	23.74	23.67	23.68
Auto-generated code included	19.11	19.09	18.04	15.66

Table 1: Average BLEU Scores from 15 epochs for each of the four sets.

A related observation is that Java methods tend to be much longer than comments (Figure 3 areas (c) and (d)). Typically, code summarization tools take inspiration from NMT algorithms designed for cases of similar encoder/decoder sequence length. Many algorithms such as recurrent networks are sensitive to sequence length, and may not be optimal off-the-shelf.

A third observation is that the words in methods and comments tend to overlap, but in fact a vast majority of words are different (70% of words in code summary comments do not occur in the code method, see Figure 3 area (b)). This situation makes the code summarization problem quite difficult because the words in the comments represent high level concepts, while the words in the source code represent low level implementation details – a situation known as the "concept assignment problem" (Biggerstaff et al., 1993). A code summarization algorithm cannot only learn a word dictionary as it might in a typical NMT setting, or select summarizing words from the method for a summary as a natural language summarization tool might. A code summarization algorithm must learn to identify concepts from code details, and assign high level terms to those concepts.

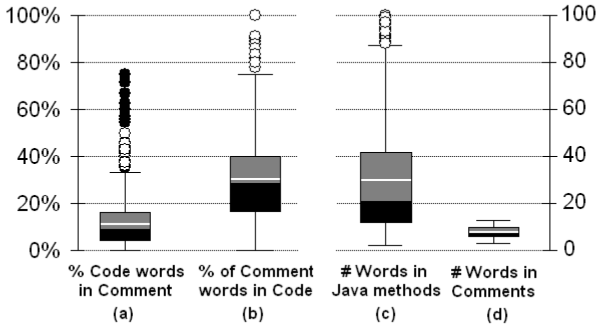

Figure 3: Overlap of words between methods and comments (areas a and b). Over 30% of words in comments, on average also occur in the method it describes. About 11% of words in code, on average, also occur in the comment describing it. Also, word length of methods and comments (areas c and d). Methods average around 30 words, versus 10 for comments.

4 Experimental Results & Conclusion

In this section, we answer our Research Questions and provide supporting evidence and rational.

4.1 RQ$_1$: Splitting Strategy

We observe a large "false" boost in BLEU score when split by function instead of split by project (see Figure 4). We consider this boost false because it involves placing functions from projects in the test set into the training set – an unrealistic scenario. An average of four runs when split by project was 17.41 BLEU, a result relatively consistent across the splits (maximum was 18.28 BLEU, minimum 16.10). In contrast, when split by function, the average BLEU score was 23.02, and increase of nearly one third as seen in Table 1. Our conclusion is that splitting by function is to be avoided during dataset creation for source code summarization. Beyond this narrow answer to the RQ, in general, any leakage of information from test set projects into the training or validation sets ought to be strongly avoided, even if the unit of granularity is smaller than a whole project. We reiterate from Section 1 that this is not a theoretical problem: many papers published using data-driven techniques for code summarization and other research problems split their data at the level of granularity under study.

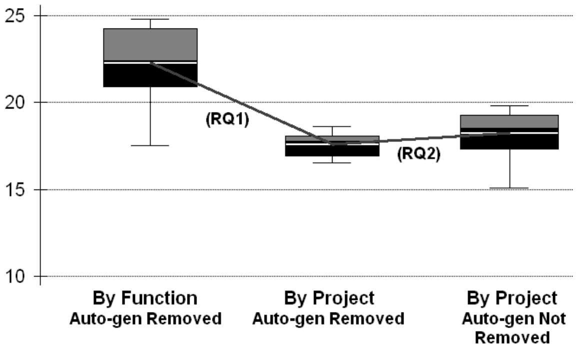

Figure 4: Boxplots of BLEU scores from attendgru for four runs under configurations for RQ$_1$ and RQ$_2$.

	BP Set1	BP Set2	BP Set3	BP Set4	BF All Sets
Training Set	1,935,860	1,950,026	1,942,291	1,933,677	1,943,723
Validation Set	105,693	100,920	104,837	105,997	107,984
Testing Set	107,568	98,175	101,993	109,447	107,984

Table 2: Number of method-comment pairs in the train, validation, test sets used in each random split set when split by project (BP) and by function (BF).

4.2 RQ$_2$: Removing Autogen. Code

We also found a boost in BLEU score when not removing automatically generated code, though the difference was less than observed for RQ$_1$. The baseline performance increased to 18 BLEU when not removing auto-generated code, and it varied much more depending on the split (some projects have much more auto-generated code than others). Our recommendation is that, in general, reasonable precautions should be implemented to remove auto-generated code from the dataset because we do find evidence that auto-generated code can affect the results of experiments.

5 Discussion

This paper provides benefits to researchers in the field of automatic source code summarization in two areas. First, we provide insight into the effects of splitting a Java method and comment dataset by project or by function, and how these different splitting methods effect the task of source code summarization. Second, we provide a dataset of 2.1m pairs of Java methods and one sentence method descriptions in a cleaned and tokenized format (discussed in 6) as well as a training, validation, testing split.

Note however that there may be cases where researchers wish to adapt our recommendations for a specific context. For example, when generating comments in an IDE. The problem of code summarization in an IDE is slightly different than what we have presented, and would benefit from including code-comment pairs from the same project. IDEs have the advantage of access to a programmer's source code and edit history in real time – they do not rely on a repository collected post-hoc. Moreno *et al.* (Moreno et al., 2013) take advantage of this information to generate Java class summaries in an eclipse plugin – their tool uses both the class and project level information from completed projects to generate these summaries, while not using any information from outside sources.

However, even in this case, care must be taken to avoid unrealistic scenarios, such as ensuring that the training set consists only of code older than the code in the test set. For example, consider a programmer at revision 75 of his or her project who requests automatically generated comments from the IDE, then goes on to write a total of 100 revisions for the project. An experiment simulating this situation should only use revisions 1-74 as training data – revisions 76+ are "in the future" from the perspective of the real world situation.

6 Downloadable Dataset

In our online appendix we have made three downloadable sets available. The first is our SQL database, generated using the tool from McMillan *et al.* (McMillan et al., 2011), that contains the file name, method comment, and start/end lines for each method, we call this dataset our "Raw Dataset". We also provide a link to the Sourcerer dataset (Linstead et al., 2009) which is used as a base for the dataset in LeClair *et al.* (LeClair and McMillan, 2019). In addition to the Raw Dataset, we also provide a "Filtered Dataset" that consists of a set of 2.1m method comment pairs. In the Filtered Dataset we removed auto-generated source code files, as well all method's that do not have an associated comment. No preprocessing was applied to the source code and comment strings in the Filtered Dataset. The third downloadable set we supply is the "Tokenized Dataset". In the Tokenized Dataset, we processed the source code and comments from the Filtered Dataset identically to the tokenization scheme described in Section 5 of (LeClair and McMillan, 2019). This set also provides a training, validation, and test set as well as a script to easily reshuffle these sets.

Abstract

Recent work in the field of automatic summarization and headline generation focuses on maximizing ROUGE scores for various news datasets. We present an alternative, extrinsic, evaluation metric for this task, ***A****nswering* ***P****erformance for* ***E****valuation of* ***S****ummaries*. APES utilizes recent progress in the field of reading-comprehension to quantify the ability of a summary to answer a set of manually created questions regarding central entities in the source article. We first analyze the strength of this metric by comparing it to known manual evaluation metrics. We then present an end-to-end neural abstractive model that maximizes APES, while increasing ROUGE scores to competitive results.

1 Introduction

The task of automatic text summarization aims to produce a concise version of a source document while preserving its central information. Current summarization models are divided into two approaches, *extractive* and *abstractive*. In extractive summarization, summaries are created by selecting a collection of key sentences from the source document (*e.g.*, Nallapati et al. (2017); Narayan et al. (2018)). Abstractive summarization, on the other hand, aims to rephrase and compress the input text in order to create the summary. Progress in sequence-to-sequence models (Sutskever et al., 2014) has led to recent success in abstractive summarization models. Current models (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017; Celikyilmaz et al., 2018) made various adjustments to sequence-to-sequence models to gain improvements in ROUGE (Lin, 2004) scores.

ROUGE has achieved its status as the most common method for summaries evaluation by showing high correlation to manual evaluation methods, *e.g.*, the Pyramid method (Nenkova et al., 2007). Tasks like TAC AESOP (Owczarzak and Dang, 2011) used ROUGE as a strong baseline and confirmed the correlation of ROUGE with manual evaluation.

See et al. (2017)'s Summary: bolton will offer new contracts to emile heskey, 37, eidur gudjohnsen, 36, and adam bogdan, 27. heskey and gudjohnsen joined on short-term deals in december. eidur gudjohnsen has scored five times in the championship .
APES score: 0.33

Baseline Model Summary (Encoder / Decoder / Attention / Copy / Coverage): bolton will offer new contracts to emile heskey, 37, eidur gudjohnsen, 36, and goalkeeper adam bogdan, 27. heskey and gudjohnsen joined on short-term deals in december, and have helped neil lennon 's side steer clear of relegation. eidur gudjohnsen has scored five times in the championship, as well as once in the cup this season .
APES score: 0.33

Our Model (APES optimization): bolton will offer new contracts to emile heskey, 37, eidur gudjohnsen, 36, and goalkeeper adam bogdan, 27. heskey joined on short-term deals in december, and have helped neil lennon 's side steer clear of relegation. eidur gudjohnsen has scored five times in the championship, as well as once in the cup this season. lennon has also fined midfielders barry bannan and neil danns two weeks wages this week. both players have apologised to lennon .
APES score: 1.00

Questions from the CNN/Daily Mail Dataset:
Q: goalkeeper ____ also rewarded with new contract; **A**: adam bogdan
Q: ____ and neil danns both fined by club after drinking incident; **A**: barry bannan
Q: barry bannan and ____ both fined by club after drinking incident; **A**: neil danns

Figure 1: Example 3083 from the test set.

While it has been shown that ROUGE is correlated to Pyramid, Louis and Nenkova (2013) show that this summary level correlation decreases significantly when only a single reference is given. In contrast to the smaller manually curated DUC datasets used in the past, more recent large-scale summarization and headline generation datasets (*CNN/Daily Mail* (Hermann et al., 2015), Gigaword (Graff et al., 2003), New York Times (Sandhaus, 2008)) provide only a single reference summary for each source document. In this work,

Proceedings of NAACL-HLT 2019, pages 3938–3948
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

we introduce a new automatic evaluation metric more suitable for such single reference news article datasets.

We define APES, ***A****nswering* ***P****erformance for* ***E****valuation of* ***S****ummaries*, a new metric for automatically evaluating summarization systems by querying summaries with a set of questions central to the input document (see Fig. 1).

Reducing the task of summaries evaluation to an extrinsic task such as question answering is intuitively appealing. This reduction, however, is effective only under specific settings: (1) Availability of questions focusing on central information and (2) availability of a reliable question answering (QA) model.

Concerning issue 1, questions focusing on salient entities can be available as part of the dataset: the headline generation dataset most used in recent years, the *CNN/Daily Mail* dataset (Hermann et al., 2015), was constructed by creating questions about entities that appear in the reference summary. Since the target summary contains salient information from the source document, we consider all entities appearing in the target summary as *salient entities*. In other cases, salient questions can be generated in an automated manner, as we discuss below.

Concerning issue 2, we focus on a relatively easy type of questions: given source documents and associated questions, a QA system can be trained over fill-in-the-blank type questions as was shown in Hermann et al. (2015) and Chen et al. (2016). In their work, Chen et al. (2016) achieve 'ceiling performance' for the QA task on the *CNN/Daily Mail* dataset. We empirically assess in our work whether this performance level (accuracy of 72.4 and 75.8 over *CNN* and *Daily Mail* respectively) makes our evaluation scheme feasible and well correlated with manual summary evaluation.

Given the availability of salient questions and automatic QA systems, we propose APES as an evaluation metric for news article datasets, the most popular summarization genre in recent years.

To measure the APES metric of a candidate summary, we run a trained QA system with the summary as input alongside a set of questions associated with the source document. The APES metric for a summarization model is the percentage of questions that were answered correctly over the whole dataset, as depicted in Fig. 2. We leave the task of extending this method to other genres for future work.

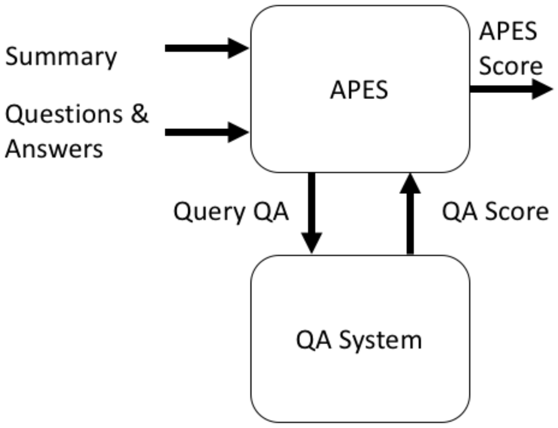

Figure 2: Evaluation flow of APES.

Our contributions in this work are: (1) We first present APES, a new extrinsic summarization evaluation metric; (2) We show APES strength through an analysis of its correlation with Pyramid and Responsiveness manual metrics; (3) we present a new abstractive model which maximizes APES by increasing attention scores of salient entities, while increasing ROUGE to competitive level. We make two software packages available online: (a) An evaluation library which receives the same input as ROUGE and produces both APES and ROUGE scores.[1] (b) Our PyTorch (Paszke et al., 2017) based summarizer that optimizes APES scores together with trained models.[2]

2 Related Work

2.1 Evaluation Methods

Automatic evaluation metrics of summarization methods can be categorized into either *intrinsic* or *extrinsic* metrics. Intrinsic metrics measure a summary's quality by measuring its similarity to a manually produced target gold summary or by inspecting properties of the summary. Examples of such metrics include ROUGE (Lin, 2004), Basic Elements (Hovy et al., 2006) and Pyramid (Nenkova et al., 2007). Alternatively, extrinsic metrics test the ability of a summary to support performing related tasks and compare the performance of humans or systems when completing a task that requires understanding the source document (Steinberger and Ježek, 2012). Such extrinsic tasks may include text categorization, infor-

---

[1] `www.github.com/mataney/APES`

[2] `www.github.com/mataney/APES-optimizer`

mation retrieval, question answering (Jing et al., 1998) or assessing the relevance of a document to a query (Hobson et al., 2007).

ROUGE, or "Recall-Oriented Understudy for Gisting Evaluation" (Lin, 2004), refers to a set of automatic intrinsic metrics for evaluating automatic summaries. ROUGE-N scores a candidate summary by counting the number of N-gram overlaps between the automatic summary and the reference summaries. Other notable metrics from this family are ROUGE-L, where scores are given by the Longest Common Subsequence (LCS) between the suggested and reference documents, and ROUGE-SU4, which uses skip-bigram, a more flexible method for computing the overlap of bigrams.

The Pyramid method (Nenkova et al., 2007) is a manual evaluation metric that analyzes multiple human-made summaries into "Summary Content Units" (SCUs) and assigns importance weights to each SCU. Different summaries are scored by assessing the extent to which they convey SCUs according to their respective weights. Pyramid is most effective when multiple human-made summaries alongside manual intervention to detect SCUs in source and target documents. The Basic Elements method (Hovy et al., 2006), an automated procedure for finding short fragments of content, has been suggested to automate a method related to Pyramid. Like Pyramid, this method requires multiple human-made gold summaries, making this method expensive in time and cost. Responsiveness (Dang, 2005), another manual metric is a measure of overall quality combining both content selection, like Pyramid, and linguistic quality. Both Pyramid and Responsiveness are the standard manual approaches for content evaluation of summaries.

Automated Pyramid evaluation has been attempted in the past (Owczarzak, 2009; Yang et al., 2016; Hirao et al., 2018). This task is complex because it requires (1) identifying SCUs in a text, which requires syntactic parsing and the extraction of key subtrees from the identified units, and (2) the clustering of these extracted textual elements into semantically similar SCUs. These two operations are noisy, and the compounded performance summary evaluation is relying on noisy intermediary representation accordingly suffers.

Other relevant quantities for summaries quality assessment include: readability (or fluency), grammaticality, coherence and structure, focus, referential clarity, and non-redundancy. Although some automatic methods were suggested as summarization evaluation metrics (Vadlapudi and Katragadda, 2010; Tay et al., 2017), these metrics are commonly assessed manually, and, therefore, rarely reported as part of experiments.

Our proposed evaluation method, APES, attempts to capture the capability of a summary to enable readers to answer questions – similar to the manual task initially discussed in Jing et al. (1998) and recently reported in Narayan et al. (2018). Our contribution consists of automating this method and assessing the feasibility of the resulting approximation.

2.2 Neural Methods for Abstractive and Extractive Summarization

The first paper to use an end-to-end neural network for the summarization task was Rush et al. (2015): this work is based on a sequence-to-sequence model (Sutskever et al., 2014) augmented with an attention mechanism (Bahdanau et al., 2014). Nallapati et al. (2016) was the first to tackle the headline generation problem using the *CNN/Daily Mail* dataset (Hermann et al., 2015) adopted for the summarization task.

See et al. (2017) followed the work of Nallapati et al. (2016) and added an additional loss term to reduce repetitions at decoding time. Paulus et al. (2017) introduces intra-attention in order to attend over both the input and previously generated outputs. The authors also present a hybrid learning objective designed to maximize ROUGE scores using Reinforcement Learning.

All the papers mentioned above have been evaluated using ROUGE, and all, except for Rush et al. (2015), used *CNN/Daily Mail* as their main headline generation dataset. Of all the mentioned models we compare our suggested model only to (See et al., 2017), as it is the only paper to publish output summaries.

3 APES

Evaluating a summarization system with APES applies the following method: APES receives a set of news articles summaries, question-and-answer pairs referring to central information from the text and an automatic QA system. Then, APES uses this QA system to determine the total number of questions answered correctly according to the re-

Original Reference Summary:

Arsenal beat Burnley 1-0 in the EPL. a goal from Aaron Ramsey secured all three points. win cuts Chelsea 's EPL lead to four points .

Produces questions:

Q: ____ beat @entity7 1-0 in the @entity4; **A**: Arsenal
Q: @entity0 beat ____ 1-0 in the @entity4; **A**: Burnley
Q: @entity0 beat @entity7 1-0 in the ____; **A**: EPL
Q: a goal from ____ secured all three points; **A**: Aaron Ramsey
Q: win cuts ____'s @entity4 lead to four points; **A**: Chelsea
Q: win cuts @entity19 's ____ lead to four points; **A**: EPL

Figure 3: Example 202 from the *CNN/Daily Mail* test set.

ceived summaries. The evaluation process is depicted in Fig. 2. We use Chen et al. (2016)'s model trained on the *CNN* dataset as our QA system for all our experiments. For a given summarizer and a given dataset, APES reports the average number of questions correctly answered from the summaries produced by the system.

This method is especially relevant for the main headline generation dataset used in recent years, the *CNN/Daily Mail* dataset, as it was initially created for the question answering task by Hermann et al. (2015). It contains 312,085 articles with relevant questions scraped from the two news agencies' websites. The questions were created by removing different entities from the manually produced highlights to create 1,384,887 fill-in-the-blank questions. The dataset was later repurposed by Cheng and Lapata (2016) and Nallapati et al. (2016) to the summarization task by reconstructing the original highlights from the questions. Fig. 3 shows an example for creating questions out of a given summary.

3.1 Using APES as an Evaluation Metric for any News Datasets

When questions are not intrinsically available, one requires to (1) automatically generate relevant questions; (2) use an appropriate automatic QA system.

Similarly to the method used in Hermann et al. (2015), we produce fill-in-the-blank questions in the following way: given a reference summary, we find all possible entities, (*i.e.*, Name, Nationality, Organization, Geopolitical Entity or Facility) using an NER system (Honnibal and Johnson, 2015) and we create fill-in-the-blank type questions where the answers are these entities. We provide code for this procedure and apply it on the *AESOP* datasets in our experiments[3].

For the automatic QA system, we reused in our experiment the same QA system trained on *CNN/Daily Mail* for different News datasets (including AESOP). To enable reproducibility, the trained models used are available online.

4 APES on the TAC2011 AESOP Task

To evaluate if an automatic metric can accurately measure a summarization system performance, we measure its correlation to manual metrics. The TAC 2011 *Automatically Evaluating Summaries of Peers* (*AESOP*) task (Owczarzak and Dang, 2011) has provided a dataset that includes, alongside the source documents and reference summaries, three manual metrics: Pyramid (Nenkova et al., 2007), Overall Responsiveness (Dang, 2005) and Overall Readability. Two sets of documents are provided, we use only the documents from the first set (Generic summarization), as the second set is relevant to the update summarization task.

To evaluate APES on the AESOP dataset, we create the required set of questions as presented in Fig. 3. We used the same QA system (Chen et al., 2016) trained on the *CNN* dataset. This system is a competent QA system for this dataset, as both AESOP and *CNN* consist of news articles. Training a QA model on the AESOP dataset would be optimal, but it is not possible due to the small size of this dataset. Nonetheless, even this incomplete QA system reports valuable results that justify APES value.

While the two datasets are similar, they differ dramatically in the type of topics the articles cover. *CNN/Daily Mail* articles deal with people, or more generally, Named Entities, averaging 6 named entities per summary. In contrast, TAC summaries average 0.87 entities per summary. The TAC dataset is divided into various topics. The first four topics, *Accidents and Natural Disasters*, *Attacks*, *Health and Safety* and *Endangered Resources* average 0.65 named entities per summary, making them incomparable to the typical case in the *CNN/Daily Mail* dataset. The last topic, *Investigations and Trials*, averages 3.35 named entities per summary, making it more similar. We report correlation only on this segment of TAC, which contains 204 documents.

See et al. (2017)	38.2	4.90	2.57
Baseline model	39.8	4.99	2.61
Gold Summaries	85.5	6.00	4.90

Table 3: Average number of entities and salient entities.

We follow the work of Louis and Nenkova (2013) and compare input level APES scores with manual Pyramid and Responsiveness scores provided in the AESOP task. Results are in Table 1. In *Input level*, correlation is computed for each summary against its manual score. In contrast, *system level* reports the average score for a summarization system over the entire dataset.

While ROUGE baselines were beaten only by a very small number of suggested metrics in the original AESOP task, we find that APES shows better correlation than the popular R-1, R-2 and R-L, and the strong R-SU. Although showing statistical significance for our hypothesis is difficult because of the small dataset size, we claim APES gives an additional value comparing to ROUGE: ROUGE metrics are highly correlated with each other (around 0.9) as shown in Table 2, indicating that multiple ROUGE metrics provide little additional information. In contrast, APES is not correlated with ROUGE metrics to the same extent (around 0.6). The above suggests that APES offers additional information regarding the text in a manner that ROUGE does not. For this reason, we believe APES complements ROUGE.

Louis and Nenkova (2013) further shows that ROUGE correlation to manual scores tends to drop when reducing the number of reference summaries. While APES is not immune to this, as the number of questions becomes smaller when the number of reference summaries is reduced, it still performs well when reducing the number of references to a single document. In the AESOP dataset, when comparing with respect to each of the 8 assessors separately on Pyramid and Responsiveness, the correlation of APES is highest in 7 out of 16 trials, while that of R1 is highest in 6 trials and RL in 2 trials. In general, the correlation between any of the metrics and single references is extremely noisy, indicating that reliance on evaluations of a single reference, which is standard on large-scale summarization datasets, is far from satisfactory.

We have established that APES achieves equal or improved correlation with manual metrics when compared to ROUGE, and captures a different type of information than ROUGE, by that, APES can complement ROUGE as an automatic evaluation metric. We now turn to develop a model that directly attempts to optimize APES.

5 Model

News articles include a high number of named entities. When analyzing systems performance on APES (Table 3), a system may fail either when it misses to generate a salient entity in the summary, or when it includes the salient entity, but in a context not relevant to corresponding questions. When this happens, the QA system would not be able to identify the entity as an answer to a question referring to the context.

We compared the average number and type of entities in summaries generated by existing automatic summarizers to that in reference summaries. We note that the observed models, while producing state-of-the-art ROUGE scores and a high number of named entities (5 vs. 6 on average), fail to focus on salient entities when generating a summary (about 2.6 salient entities are mentioned on average vs. 4.9 in the reference summaries). Notice that solely increasing the number of entities is damaging: mentioning too many entities causes a decrease in the QA accuracy, as the number of possible answers increases, which would distract the QA system. This has motivated us in suggesting the following model.

5.1 Baseline Model

To experiment with direct optimization of APES, we reconstruct as a starting point a model that encapsulates the key techniques used in recent abstractive summarization models. Our model is based on the OpenNMT project (Klein et al., 2017). All PyTorch (Paszke et al., 2017) code, including entities attention and beam search refinement is available online[4]. We also include generated summaries and trained models in this repository.

Recent work in the field of abstractive summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2017) share a common architecture as the foundation for their neural models: an encoder-decoder model (Sutskever et al., 2014) with an attention mechanism (Bahdanau et al., 2014). Nallapati et al. (2016) and See et al. (2017) augment this model with a copy mechanism (Vinyals et al., 2015). This architecture minimizes the following loss function:

$$\begin{aligned} \text{loss}_t &= -\log P(w_t^*) \\ \text{loss} &= \frac{1}{T_y}\sum_{t=0}^{T_y} \text{loss}_t \end{aligned} \tag{1}$$

$loss_t$, is the negative log likelihood of generating the gold target word w_t^* at timestep t where $P(\cdot)$ is the probability distribution over the vocabulary. We refer the reader to See et al. (2017) for a more detailed description of this architecture.

Unlike See et al. (2017), we do not train a specific coverage mechanism to avoid repetitions. Instead, we incorporate Wu et al. (2016)'s refinements of beam search in order to manipulate both the summaries' coverage and their length. In the standard beam search, we search for a sequence Y that maximizes a score function $s(Y, X) = \log(P(Y|X))$. Wu et al. (2016) introduce two additional regularization factors, *coverage penalty* and *length penalty*. These two penalties, with an additional refinement suggested in Gehrmann et al. (2018), yield the following score function:

$$\begin{aligned} s(Y,X) &= \log(P(Y|X))/lp(Y) - cp(X;Y) \\ lp(Y) &= \frac{(5+|Y|)^\alpha}{(5+1)^\alpha} \\ cp(X;Y) &= \beta(-T_X + \sum_{i=1}^{T_X}\max(\sum_{j=1}^{T_Y} a_{i,j}, 1.0)) \end{aligned} \tag{2}$$

where α, β are hyper-parameters that control the length and coverage penalties respectively and $a_{i,j}$ is the attention probability of the j-th target word on the i-th source word.

$cp(X;Y)$, the coverage penalty, is designed to discourage repeated attention to the same source word and favor summaries that cover more of the source document with respect to the attention distribution.

$lp(Y)$, the length normalization, is designed to compare between beam hypotheses of different length accurately. In general, beam search favors shorter outputs as log-probability is added at each step, yielding lower scores for longer sequences. lp compensates for this tendency.

In the following section, we describe how we extend this baseline model in order to maximize the APES metric. The new model learns to incorporate more of the salient entities from the source document in order to optimize its APES metric.

5.2 Entities Attention Layer

As we observed, failure to capture salient entities in summaries is one cause for low APES score. To drive our model towards the identification and mention of salient entities from the source document, we introduce an additional attention layer that learns the important entities of a source document. We hypothesize that these entities are more likely to appear in the target summary, and thus are better candidate answers to one of the salient questions for this document.

We learn for each word in the source document its probability of belonging to a salient entity mention. We adopt the classical soft attention mechanism of Bahdanau et al. (2014): after encoding the source document, we run an additional single alignment model with an empty query and a sigmoid layer instead of the standard softmax layer.

$$\begin{aligned} a_j^e &= \sigma(e_j^e) \\ e_j^e &= v^T \tanh(Uh_j + b) \end{aligned} \tag{3}$$

Our model	**46.1**	**40.2**	**17.7**	**37.0**
Our model with gold entities positions	46.3	40.4	17.8	37.3

Table 4: APES: Percent of questions answered correctly using by document. *Obtained from the model uploaded to `github.com/abisee/pointer-generator`.

where U, b, v are learnable weight matrices, h_j is the encoder hidden state for the j-th word and $\sigma(\cdot)$ is a logistic sigmoid function. a_j^e reflects the probability of the j-th token of being a salient entity.

The second modification comparing to Bahdanau et al. (2014) is that we replace the softmax function with a sigmoid: while in the standard alignment model, we intend to obtain a normalized probability distribution over all the tokens of the source document, here we would like to get a probability of each token being a salient entity independently of other tokens. In order to drive this attention layer towards salient entities, we define an additional term in the loss function.

$$loss_e = BCE(a^e, s^*) \tag{4}$$

where s^* is a binary vector of source length size, where $s_j^* = 1$ if x_j is a salient entity, and 0 otherwise, and BCE is the binary cross entropy function. This term is added to the standard log-likelihood loss, changing equation (1) to the following composite loss function:

$$\text{loss} = \delta\, loss_e + (1-\delta)\frac{1}{T_y}\sum_{t=0}^{T_y} \text{loss}_t \tag{5}$$

where δ is a hyper-parameter. We join these two terms in the loss function in order to learn the entities attention layer while keeping the summarization ability learned by Eq. (1).

5.3 Entities Attention and Beam Search

After the attention layer has learned the probability of each source token to belong to a salient entity, we pass the predicted alignment to the beam search component at test-time. Using this alignment data, we wish to encourage beam search to favor hypotheses attending salient entities.

Accordingly, we introduce a new term ep to the beam search score function of equation (2):

$$\begin{aligned} s(Y,X) &= \log(P(Y|X))/lp(Y) - cp(X;Y) \\ &\quad - ep(X;Y) \\ ep(X;Y) &= \gamma \sum_{i=1}^{T_X} \max(a_i^e - \sum_{j=1}^{T_Y} a_{i,j}, 0.0) \end{aligned} \tag{6}$$

$ep(X;Y)$ penalizes summaries that do not attend parts of the source document we believe are central.

Fig. 4 compares summaries produced by this model and the baseline model by showing their respective attention distribution and the impact on the decision of which words to include in the summary based on the attention level derived from salient entities.

6 Results

We report our results in Table 4. For each system, we present its APES score alongside its F1 scores for ROUGE-1, ROUGE-2 and ROUGE-L, computed using pyrouge [5].

We first report APES results on full source documents and gold summaries, in order to assess the capabilities of the QA system used for APES. A simple answer extractor could answer 100% of the questions given the gold-summaries. But the QA system is trained over the source documents and learns to generalize and not "just" extract the answer. Answering questions from the full documents is indeed more difficult than from the gold-summaries because the QA system must locate the answer among multiple distractors. While gold-summaries present a very high APES score, the

jack wilshere may rub shoulders with the likes of alexis sanchez and mesut ozil on a daily basis but he was left starstruck on thursday evening when he met brazil legend pele . even better for wilshere , the arsenal midfielder was given the opportunity to interview the three-time world cup winner during the launch party of 10ten talent . both wilshere and pele , along with glenn hoddle , are clients and the england international made sure his fans on twitter knew about their meeting by posting several tweets . brazil legend pele -lrb- left -rrb- and arsenal midfielder jack wilshere pose for a photo during launch of 10ten talent . wilshere was given the ‘ honour to interview the legendary pele and asked twitter questions from fans : earlier on thursday , wilshere tweeted : ‘ looking forward to meeting @pele tonight . i ll be asking the best questions you sent . #jackmeetspele . the 23-year-old then followed this up with several tweets about the event , many of which included photos of pele . meanwhile , pele has acknowledged that last year s world cup was a ‘ disaster for brazil but is not surprised how quickly the likes of oscar and ramires have bounced back in the barclays premier league this season : brazil were humiliated by germany in a 7-1 semi-final defeat and the hosts were then thrashed 3-0 by holland in the third-place play-off . pele scored 77 goals in 92 games for brazil and won the world cup three times but the former santos striker still finds last year s capitulation difficult to understand .

Target Summary:

jack wilshere was joined by former **england** manager **glenn hoddle**. the **arsenal** midfielder interviewed **pele** at launch of **10ten talent**. **pele** scored 77 goals in 92 games for **brazil** and won three world cups. the **brazil** legend says the 2014 world cup performance was not expected. the hosts were humiliated 7-1 by **germany** in the semi-finals last summer. **pele** is, however, not surprised by reaction of **oscar** and **ramires** this year.

Baseline Model Prediction:

jack wilshere was given the opportunity to interview the three-time world cup winner. both wilshere and pele are clients and the england international. pele has acknowledged that last year’s world cup was a ‘disaster’

Our Model Prediction:

jack wilshere was given the ‘honour to interview the legendary pele’ and asked twitter questions from fans. pele has acknowledged that last year’s world cup was a ‘disaster’ for brazil but is not surprised how quickly the likes of oscar and ramires have bounced back in the premier league this season. the brazil legend scored 77 goals in 92 games for brazil and won the world cup three times.

Figure 4: Example 4134 from the *CNN/Daily Mail* test set. Colors and underlines in the source reflect differences between baseline and our model attention weights: Red and a single underline reflects words attended by baseline model and not our model, Green and double underline reflects the opposite. Entities in bold in the target summary are answers to the example questions.

score reported for the source documents (61.1%) is a realistic upper bound for APES.

We then present shuffled gold-summaries, where we randomly shuffled the location of each unigram in the gold summary. This score shows that even when all salient entities are in the shuffled text, APES is sensitive to the loss of coherence, readability and meaning. This confirms that APES does not only match the presence of entities. In contrast, ROUGE-1 fails to punish such incoherent sequences. Finally, we report ROUGE and APES for the strong Lead 3 sentences of the source document - a baseline known to beat most existing abstractive methods.

We then present APES and ROUGE scores for abstractive models, See et al. (2017)’s model, our baseline model and our APES-optimized model. Our model achieves significantly higher APES scores (46.1 vs. 39.8) and improves all ROUGE metrics (by about 1 F-point over the baselines). The scores on the validation set are 46.6, 41.2, 18.4, 38.1 for APES, R1, R2, RL respectively.

While our objective is maximizing APES score, our model also increases its corresponding ROUGE scores. Unlike Paulus et al. (2017) where the authors suggested a Reinforcement Learning based model to optimize ROUGE specifically, we optimize for APES and gain better ROUGE score.

We finally report the results obtained by our model when gold salient entities positions are given as oracle inputs instead of the predicted a^e scores. The corresponding score (46.3 vs. 46.1) is only slightly above the score obtained by our model. This indicates that the component of our model predicting entity saliency is good enough to drive summarization.

We carried out an informal error analysis to examine why some summaries perform worse than others with our architecture. We compared summaries that produce perfect APES score (1,630 out of 11,490 total) to the summaries with zero APES score (1,691). We measure the density of salient named entities in the source document: #(salient entity mentions)/#(distinct salient entities). This density in the case of perfect APES summaries is much higher than that for low APES summaries (4.9 vs. 3.6). This observation suggests that we fail to produce higher APES scores when the salient entities aren't marked through sheer repetition.

7 Conclusion

We introduced APES, a new automatic summarization evaluation metric for news articles datasets based on the ability of a summary to answer questions regarding salient information from the text. This approach is useful in domains with source documents of about 1k words that focus on named entities - such as news articles, where named entities are effectively aligned with Pyramid SCUs. In other non-news domains, and longer documents, other methods for generating questions should be designed. We compare APES to manual evaluation metrics on the TAC 2011 AESOP task and confirm its value as a complement to ROUGE.

We introduce a new abstractive model that optimizes APES scores on the *CNN/Daily Mail* dataset by attending salient entities from the input document, which also provides competitive ROUGE scores.

A Experiment Settings

For our experiments, we used a bidirectional LSTM encoder with 256-dimensional hidden states for each direction, an LSTM decoder with 512-dimensional hidden states and 128-dimensional embeddings for a 50k shared-vocabulary words. We do not use pretrained word embeddings.

We use the Adagrad (Duchi et al., 2011) optimizer with a starting learning rate of 0.15 and gradient clipping with a maximum gradient norm of 2. At train-time source and target documents are truncated to 400 and 100 tokens respectively. After training our baseline model for 20 epochs, we fine-tune the network with Eq. (5) loss for an additional 5 epochs starting again with 0.15 as initial learning rate. Results reported in this paper correspond to $\lambda = 0.01$.

At test-time, we do not truncate the source documents enabling the network to attend overall input text. We use Eq. (6) as the beam search score function, penalizing using $cp(X;Y)$ every single decoding step and $lp(Y)$ and $ep(X;Y)$ only when all hypotheses are done. We choose α, β, γ values of $0.9, 0.5, 0.5$ respectively for our model. We also used Paulus et al. (2017) suggestion of repetition avoidance by blocking trigrams appearing more than once at inference time.

Running APES evaluation on a generated test set (of size 11,490 summaries) takes about 40 minutes using a single process.

Understanding the Behaviour of Neural Abstractive Summarizers using Contrastive Examples

Abstract

Neural abstractive summarizers generate summary texts using a language model conditioned on the input source text, and have recently achieved high ROUGE scores on benchmark summarization datasets. We investigate how they achieve this performance with respect to human-written gold-standard abstracts, and whether the systems are able to understand deeper syntactic and semantic structures. We generate a set of contrastive summaries which are perturbed, deficient versions of human-written summaries, and test whether existing neural summarizers score them more highly than the human-written summaries. We analyze their performance on different datasets and find that these systems fail to understand the source text, in a majority of the cases.

1 Introduction

Open-domain abstractive summarization is a long-standing goal of the field of automatic summarization. Compared to extractive techniques, abstraction offers the potential to generate much more useful summaries by simplifying and rephrasing the source text (Knight and Marcu, 2002), and furthermore by aggregating information and performing operations which are not possible with extractive techniques (Genest and Lapalme, 2012; Carenini and Cheung, 2008).

Recently, a number of abstractive summarization systems based on neural sequence-to-sequence architectures have been proposed (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017; Paulus et al., 2018; Chen and Bansal, 2018). These systems learn a compressed representation of the source text using an encoder, then generate the output summary using a conditional decoder. Such neural abstractive systems have achieved very good ROUGE scores on different datasets.

Table 1: Examples of generated contrastive summaries. Bold indicate switched words

Our interest in this paper is to investigate how these abstractive systems achieve such results, and whether they represent progress towards language understanding and generation. ROUGE arguably provides a limited view of the performance of such systems, as they only relate the system summary to a fixed number of gold-standard summaries. We propose a novel method to directly test the abstractive summarizers in terms of how they score potential candidate summaries, viewing them as conditional language models. This allows us to test whether the summarizers favour output summaries with specific desired qualities, such as generating a summary that is semantically consistent and entailed by the source text.

We test how well the neural abstractive summarizers distinguish human-written abstracts from contrastive distractors, which are clearly incorrect summaries that are generated using a rule-based procedure. Table 1 shows contrastive examples which are clearly incorrect[1]. In majority of source texts, we are able to find a contrastive example that scores more highly than the gold-standard summary.

---

[1] For other NLP tasks, others have proposed a similar notion called *adversarial* examples (Jia and Liang, 2017). Since the term 'adversarial' has traditionally implied learning to specifically attack the weakness of a model, which we do not do, we refrain from using the word 'adversarial'.

Proceedings of NAACL-HLT 2019, pages 3949–3954
Minneapolis, Minnesota, June 2 - June 7, 2019.

Our work demonstrates the difficulty of controlling expressive neural abstractive systems to produce correct and fluent output. It also underscores the need to revisit fundamental issues in summarization evaluation for neural abstractive models, so that a comprehensive evaluation scheme that captures all relevant aspects of summary quality can be developed. Our code for generating contrastive summaries is available online.[2]

2 Related Work

Most work in neural abstractive summarization has focused on optimizing ROUGE, whether implicitly by maximum likelihood training or explicitly by reinforcement learning. While this could certainly capture aspects of the content selection problem, we believe that the focus should now shift towards semantic correctness and readability.

Cao et al. (2018) took a step in this direction through their fact-aware neural abstractive summarization system. They use fact descriptions of the source as additional features for the summarizer, and showed improved faithfulness according to human judgments. Multi-task learning is another approach used by Pasunuru et al. (2017) to reduce semantic errors in the generated summaries. They jointly learn summarization and entailment generation tasks, using different encoders but a shared decoder.

A number of automatic evaluation metrics have shown high correlation with human judges (Liu and Liu, 2008; Graham, 2015), but these results are either restricted to extractive systems or were performed with respect to human-generated summaries. Correlation values are significantly reduced when performed on abstractive summarization systems and datasets (Toutanova et al., 2016).

3 Generating Contrastive Summaries

In this section, we describe our method for evaluating summarization systems based on whether they can separate human-written gold summaries from automatically generated contrastive summaries. We define a contrastive summary to be similar to a gold summary, except it contains a perturbation. The perturbation results in either a semantic discrepancy, where facts in source and summary do not corroborate, or a readability issue, where issues with grammar or fluency renders the summary clearly incorrect. Below, we first describe our basic method of introducing these discrepancies, then describe a number of restrictions we apply to ensure that the generated contrastive summaries are of high quality.

Rule	**Switching Criteria**
Noun	NN, NNP or NNS must match. For NNP child DET if present is also switched.
Preposition	For IN tags: parents and their dependencies must match.
Verb	VBP, VBG, VBZ, VBN, VBD or VB must match
Adjective	JJ, JJR or JJS must match

Table 2: Rules for selecting words to switch when generating the contrastive summaries. The tags are as per the Penn Tree-bank (Santorini, 1990).

Perturbation by switching words. Given pairs of source texts and gold summaries, we generate multiple contrastive summaries for each source text by perturbing its associated gold summary. There are many types of possible perturbations, but we focus on two strategies: 1) switching words within a gold summary, and 2) replacing a word in gold summary by a word from the source text. We chose these types of perturbations as they are likely to result in "difficult" contrastive summaries that contain words which are likely to appear in a reasonable summary of the source text, but which are nevertheless incorrect.

In order to select the words to be swapped, we apply four rules, separated by syntactic category, as shown in Table 2, using the dependency parse of the texts (Manning et al., 2014). We switch words either within a gold summary, or from the source text and use a single rule at a time for generating a contrastive summary. For example, if the POS tag *NNS* is matched between a word *'sides'* in the source text and the word *'combatants'* in the gold summary, then the Noun rule would apply, and the words would be switched to obtain the contrastive summary.

Further, for the Noun and Verb categories, the switched words may not match in number or verb conjugation. We use SimpleNLG (Gatt and Reiter, 2009) to convert the word to the appropriate inflectional form of the destination's POS tag.

---

[2] `https://github.com/krtin/ContrastiveSummaries`

Further restrictions. We place a number of restrictions on the words switched, to ensure that the generated summary is contrastive compared to the gold summary. We do not allow switching of the same words. We also do not allow words to be switched if they are separated by any of the following: *'or'*, *'and'* or *','*, as these are likely to be commutative operators.

Furthermore, we only allow switching of words from the source text if the context of the words to be switched sufficiently differ from each other. We compute unigram overlap around a context window of size 2 on each side, and allow a switch when the overlap proportion is less than 0.65. These settings were determined by manual inspection of the generated summaries, and allowed us to reduce the number of examples where generated summary is not contrastive, without significantly reducing the number of generated summaries.

We will describe the results of a human verification study in Section 5, in which we ask human raters to check the quality of our contrastive summaries.

4 Evaluation

We apply our set of contrastive summaries to evaluate a number of neural abstractive summarizers. For each summarizer under evaluation, we assume access to a conditional language model which defines a probability distribution over words conditioned on the source. Formally, such a language model is given by Equation 1:

$$P(y_i|\theta, \mathcal{S}, y_1...y_{i-1}), \qquad (1)$$

here $\mathcal{S}$ is the source, θ are model parameters, $y_i \in V_{sm}$ represents the i^{th} word in the summary, V_{sm} is the vocabulary space of the summary and P is the conditional probability. $\mathcal{S} \subseteq (s_1, ..., s_n)$ where $s_i \in V_{so}$, V_{so} is the vocabulary space of the source and n is the maximum source length. Further, we use Equation 2 as our scoring function,

$$p(y) = \sum_{i=1}^{m} \log P(y_i|\theta, \mathcal{S}, y_1...y_{i-1}), \qquad (2)$$

here m is maximum summary length and y represents a gold or contrastive summary. For a given triple of source, gold (g) and contrastive (c) summary, if $p(g) > p(c)$, then we label the triple *'dodged'*, since the summarizer successfully dodged the generated contrastive summary. If a system is able to dodge all contrastive summaries generated from a source and gold summary tuple, then we label the tuple as *'escaped'*.

5 Experiments

Datasets. We experimented on two datasets, for two abstractive summarization tasks. The first is a short summarization task, where the summary is one sentence long, for which we use the **Gigaword** corpus (Graff et al., 2011; Napoles et al., 2012). We use the scripts provided by Rush et al. (2015) to process the Gigaword corpus, which contains the first sentence of the article and the headline as source and gold summary pairs. The test set contains about 250K source-summary pairs from which we randomly selected 10K pairs and generated 509K contrastive summaries.

The second is a long summarization task, in which the summary consists of multiple sentences. We use the **CNN/Dailymail** corpus, where the highlights of the articles are used as the gold summary (Hermann et al., 2015). We used the scripts from Nallapati et al. (2016) to get the data and use the non-anonymized version like See et al. (2017). We use 11.49K test pairs and were able to generate 563K contrastive summaries.

Models. We analyze and evaluate three state-of-the-art neural abstractive summarization systems: ABS+ (Rush et al., 2015), GTP (See et al., 2017) and FAS (Chen and Bansal, 2018). The **ABS+** system uses an attention-based neural language model as an encoder and a feed-forward neural network for decoding, and is trained on the Gigaword corpus. The **GTP** system is a seq2seq model with attention on the encoder and a pointer-generator mechanism to choose words from the source in the decoder and, is trained on the CNN/Dailymail corpus. **FAS** uses reinforcement learning algorithm to extract the most important sentences from the source text, and then summarizes each sentence using a similar architecture as GTP on the CNN/Dailymail corpus.

These systems have performed well on small and large text summarization tasks, and have open-source implementation available from the authors. We would have liked to test other relevant systems (Pasunuru et al., 2017; Cao et al., 2018), but were unable to obtain their implementations.

Experimental Details. The CNN/Dailymail corpus has a large source length, thus the set of

	Rule	**Dodged (%)**		
		CNN		**Gigaword**
		GTP	**FAS**	**ABS+**
Gold	Noun	98.8	96.5	49.5
	Prep	97.8	96.9	55.4
	Verb	99.0	98.5	48.7
	Adj	97.8	95.6	55.7
Source	Noun	94.3	88.5	47.9
	Prep	92.0	88.2	50.1
	Verb	94.9	91.9	50.2
	Adj	92.6	87.2	49.7

Table 3: Rule-wise Performance, here Source and Gold are based upon rule perturbations in Section 3

Model	**Dataset**	**Dodged**	**Escaped**
GTP	CNN	96.3%	29.8%
FAS	CNN	92.9%	12.2%
ABS+	Gigaword	48.6%	10.8%

Table 4: Performance on *dodged*, *escaped* metrics.

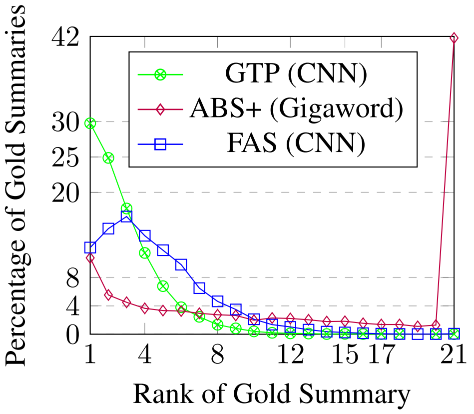

Figure 1: Distribution of Gold Summary Rank

contrastive summaries is very large. To restrict the number of contrastive summaries we randomly select approximately 50 generated summaries, while maintaining the rule-wise distribution. The rule-wise distribution was estimated based upon contrastive summaries, generated from a subset of 100 gold standard summaries from CNN/Dailymail corpus.

In order to correctly evaluate the FAS system, for each extracted sentence we generate all sentences in the gold summary, and pick the set of summaries with the maximum probability.

Human verification. To ensure that we are generating incorrect contrastive summaries, 200 randomly sampled summaries from the Gigaword corpus were evaluated by a human annotator, to verify if a semantic discrepancy or a readability issue was present. We ensured that we sample equally across all the 8 rules, and that we restrict our set of contrastive summaries which the ABS+ system was not able to *'dodge'*. We found that 49.5% had a readability issue while 43.5% had a discrepancy issue, and 93% of the examples had at least one of these issues. This indicates that the vast majority of our contrastive examples are "true negatives"; i.e., a perfect summarization system should score them lower than the gold standard summary.

6 Results

We summarize our results in Table 4, and report rule-wise results in Table 3. We also include examples where the ABS+ system is unsuccessful in dodging the generated contrastive summaries, in Table 5. Since these metrics directly evaluate the posterior distribution of a summarizer, it allows us to explicitly recognize problematic examples for a model. We also look at what percentage of gold summaries lie across different ranks of gold summaries in Figure 1. This gives us an insight into distribution of gold summaries, across different ranks. The rank of a gold summary is 1 plus the number of contrastive summaries that scored higher than it.

Dodged and Escaped. On the CNN/Dailymail dataset, we find both the models were able to dodge most of the contrastive summaries, but a large number of summaries had at least a few contrastive summaries which scored higher than the gold summary, as reflected by the *escaped* metric.

The FAS model performs worse than GTP model, this might be because the abstraction model only observes one sentence, and thus the probability of observing a word outside the source sentence is higher for the contrastive summaries.

Rule-wise Analysis. The GTP and FAS models perform better on rules which switch words within the gold-standard summary. Thus, the decoder LSTM has captured the data distribution very well for words within the summary but is not generalizing for words outside it. This suggest that using words outside the source vocabulary might help in generating harder contrastive examples. The ABS+ model is better in capturing data distributions of prepositions and adjectives. This points towards biases towards particular distributions and can be helpful in further improving these models.

Rank of Gold Summary. As shown in Figure 1, almost all the gold summaries have rank lower than 8 for the GTP model, while a large percentage of gold summaries have rank greater than 20, for the ABS+ model. The maximum rank in both the cases is of the order 500K, which is the size of contrastive summaries (Section 5). We suspect that this might be due to behaviourally extractive nature of GTP model, which allows it to easily distinguish any perturbations in the contrastive summaries.

7 Conclusion

We proposed to analyze existing neural abstractive summarizers by testing how they score contrastive summaries, compared to gold-standard ones. For the majority of the gold-standard summaries, we were able to find contrastive examples which score more highly according to current state-of-the-art systems. These examples can be useful not only in evaluating the performance of these systems, but also for improving these systems in the future.

Abstract

We present a new neural model for text summarization that first extracts sentences from a document and then compresses them. The proposed model offers a balance that sidesteps the difficulties in abstractive methods while generating more concise summaries than extractive methods. In addition, our model dynamically determines the length of the output summary based on the gold summaries it observes during training, and does not require length constraints typical to extractive summarization. The model achieves state-of-the-art results on the CNN/DailyMail and Newsroom datasets, improving over current extractive and abstractive methods. Human evaluations demonstrate that our model generates concise and informative summaries. We also make available a new dataset of oracle compressive summaries derived automatically from the CNN/DailyMail reference summaries.[1]

1 Introduction

Text summarization is an important NLP problem with a wide range of applications in data-driven industries (e.g., news, health, and defense). Single document summarization—the task of generating a short summary of a document preserving its informative content (Spärck Jones, 2007)—has been a highly studied research topic in recent years (Nallapati et al., 2016b; See et al., 2017; Fan et al., 2018; Pasunuru and Bansal, 2018).

Modern approaches to single document summarization using neural network architectures have primarily focused on two strategies: *extractive* and *abstractive*. The former select a subset of the sentences to assemble a summary (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018a,c). The latter generates sentences that do not appear in the original document (See et al., 2017; Narayan et al., 2018b; Paulus et al., 2018). Both methods suffer from significant drawbacks: extractive systems are wasteful since they cannot trim the original sentences to fit into the summary, and they lack a mechanism to ensure overall coherence. In contrast, abstractive systems require natural language generation and semantic representation, problems that are inherently harder to solve than just extracting sentences from the original document.

(ExConSumm Extractive) • (CNN) A top al Qaeda in the Arabian Peninsula leader–who a few years ago was in a U.S. detention facility–was among five killed in an airstrike in Yemen, the terror group said, showing the organization is vulnerable even as Yemen appears close to civil war.
• Ibrahim al-Rubaish died Monday night in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike."

(ExConSumm Compressive) • ~~(CNN)~~ A top al Qaeda in the Arabian Peninsula leader–who a few years ago was in a U.S. detention facility–was among five killed in an airstrike in Yemen ~~, the terror group said, showing the organization is vulnerable even as Yemen appears close to civil war~~.
• Ibrahim al-Rubaish died ~~Monday night~~ in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike."

Figure 1: Summaries produced by our model. For illustration, the compressive summary shows the removed spans strike-through.

In this paper, we present a novel architecture that attempts to mitigate the problems above via a middle ground, **compressive summarization** (Martins and Smith, 2009). Our model selects a set of sentences from the input document, and

---

Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

compresses them by removing unnecessary words, while keeping the summaries informative, concise and grammatical. We achieve this by dynamically modeling the generated summary using a Long Short Term Memory (LSTM; Hochreiter and Schmidhuber, 1997) to produce **summary state representations**. This state provides crucial information to iteratively increment summaries based on previously extracted information. It also facilitates the generation of variable length summaries as opposed to fixed lengths, in previous extractive systems (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018c; Zhang et al., 2018). Our model can be trained in both extractive (labeling sentences for extraction) or compressive (labeling words for extraction) settings. Figure 1 shows a summary example generated by our model.

Our contributions in this paper are three-fold:

- we present the first end-to-end neural architecture for EXtractive and COmpressive Neural SUMMarization (dubbed EXCONSUMM, see §3),
- we validate this architecture on the CNN/DailyMail and the Newsroom datasets (Hermann et al., 2015; Grusky et al., 2018), showing that our model generates variable-length summaries which correlate well with gold summaries in length and are concise and informative (see §5), and
- we provide a new CNN/DailyMail dataset annotated with automatic compressions for each sentence, and a set of compressed oracle summaries (see §4).

Experimental results show that when evaluated automatically, both the extractive and compressive variants of our model provide state-of-the-art results. Human evaluation further shows that our model is better than previous state-of-the-art systems at generating informative and concise summaries.

2 Related Work

Recent work on neural summarization has mainly focused on sequence-to-sequence (seq2seq) architectures (Sutskever et al., 2014), a formulation particularly suited and initially employed for abstractive summarization (Rush et al., 2015). However, state-of-the-art results have been achieved by RNN-based methods which are extractive. They select sentences based on an LSTM classifier that predicts a binary label for each sentence (Cheng and Lapata, 2016), based on ranking using reinforcement learning (Narayan et al., 2018c), or even by training an extractive latent model (Zhang et al., 2018). Other methods rely on an abstractive approach with strongly conditioned generation on the source document (See et al., 2017). In fact, the best results for abstractive summarization have been achieved with models that are more extractive in nature than abstractive, since most of the words in the summary are copied from the document (Gehrmann et al., 2018).

Due to the lack of training corpora, there is almost no work on neural architectures for compressive summarization. Most compressive summarization work has been applied to smaller datasets (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013). Other non-neural summarization systems apply this idea to select and compress the summary. Dorr et al. (2003) introduced a method to first extract the first sentence of a news article and then use linguistically-motivated heuristics to iteratively trim parts of it. Durrett et al. (2016) also learns a system that selects textual units to include in the summary and compresses them by deleting word spans guided by anaphoric constraints to improve coherence. Recently, Zhang et al. (2018) trained an abstractive sentence compression model using attention-based sequence-to-sequence architecture (Rush et al., 2015) to map a sentence in the document selected by the extractive model to a sentence in the summary. However, as the sentences in the document and in the summary are not aligned for compression, their compression model is significantly inferior to the extractive model.

In this paper, we propose a novel seq2seq architecture for compressive summarization and demonstrate that it avoids the over-extraction of existing extractive approaches (Cheng and Lapata, 2016; Dlikman and Last, 2016; Nallapati et al., 2016a).

Our model builds on recent approaches to neural extractive summarization as a sequence labeling problem, where sentences in the document are labeled to specify whether or not they should be included in the summary (Cheng and Lapata, 2016; Narayan et al., 2018a). These models often condition their labeling decisions on the document representation only. Nallapati et al. (2017) tries to model the summary as the average representation

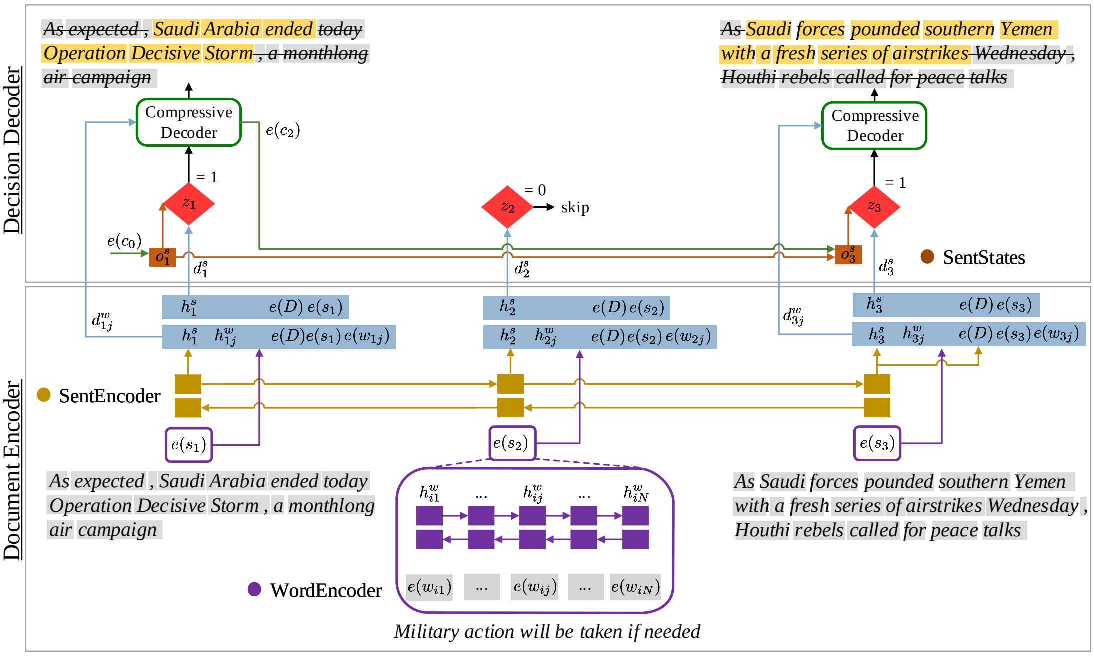

Figure 2: Illustration of our summarization system. The model extracts the most relevant sentences from the document by taking into account the WordEncoder representation of the current sentence $e(s_i)$, the SentEncoder representation of the previous sentence $\boldsymbol{h}_i^s$, the current summary state representation $\boldsymbol{o}_i^s$, and the representation of the document $e(D)$. If a sentence is selected ($z_i = 1$), its representation is fed to SentStates, and we move to the next sentence. Here, sentences s_1 and s_3 were selected. If the model is also compressing, the compressive layer selects words for the final summary (Compressive Decoder). See Figure 3 for details on the decoders.

of the positively labeled sentences. However, as we show later, this strategy is not the most adequate to ensure summary coherence, as it does not take the order of the selected sentences into account. Our approach addresses this problem by maintaining an LSTM cell to dynamically model the generated summary. To the best of our knowledge, our work is the first to use a model that keeps a state of already generated summary to effectively model variable-length summaries in an extractive setting, and the first to learn a compressive summarizer with an end-to end approach.

3 Summarization with Summary State Representation

Our model extracts sentences from a given document and further compresses these sentences by deleting words. More formally, we denote a document $D = (s_1, \ldots, s_M)$ as a sequence of M sentences, and a sentence $s_i = (w_{i1}, \ldots, w_{iN})$ as a sequence of N words. We denote by $\boldsymbol{e}(w_{ij})$, $\boldsymbol{e}(s_i)$ and $\boldsymbol{e}(D)$ the embedding of words, sentences and document in a continuous space. We model document summarization as a sequence labeling problem where the labeler transitions between internal states. Each state is dynamically computed based on the context, and it combines an extractive summarizer followed by a compressive one. First, we encode a document in a multi-level approach, to extract the embeddings of words and sentences ("Document Encoder"). Second, we decode these embeddings using a hierarchical "Decision Decoder." The extractive summarizer labels each sentence s_i with a label $z_i \in \{0, 1\}$ where 1 indicates that the sentence should be included in the final summary and 0 otherwise. An extractive summary is then assembled by selecting all sentences with the label 1. Analogously, the compressive summarizer labels each word w_{ij} with a label $y_{ij} \in \{0, 1\}$, denoting whether the word j in sentence i is included in the summary or not. The final summary is then assembled as the sequence of words w_{ij} for each $z_i = 1$ and $y_{ij} = 1$. See Figures 2 and 3 for an overview of our model. We next describe each of its components in more detail.

3.1 Document Encoder

The document encoder is a two layer biLSTM, one layer encoding each sentence, and the second layer encoding the document. The first layer takes as input the word embeddings $\boldsymbol{e}(w_{ij})$ for each word j in sentence s_i, and outputs the hidden representa-

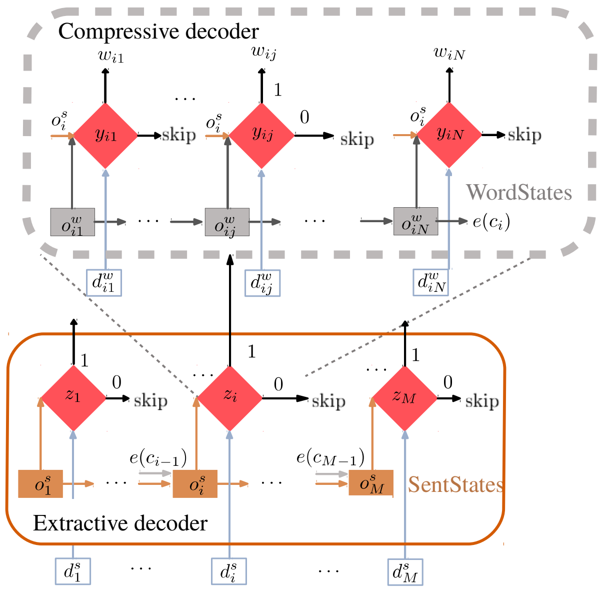

Figure 3: Decision decoder architecture. Decoder contains an extractive level for sentences (orange box) and a compressive level for words (dashed gray box), using an LSTM to model the summary state. Red diamond shapes represent decision variables $z_i = 1$ if $p(z_i \mid \boldsymbol{p}_i) > 0.5$ for selecting the sentence s_i, and $z_i = 0$ if $p(z_i \mid \boldsymbol{p}_i) \leq 0.5$ for skipping this sentence. The same for y_{ij} and $p(y_{ij} \mid \boldsymbol{q}_{ij}) > 0.5$ for deciding over words w_{ij} to keep in the summary.

tion of each word $\boldsymbol{h}_{ij}^w$. The hidden representation consist of the concatenation of a forward $\overrightarrow{\boldsymbol{h}}_{ij}^w$ and a backward $\overleftarrow{\boldsymbol{h}}_{ij}^w$ LSTM (WordEncoder in Figure 2). This layer eventually outputs a representation for each sentence $\boldsymbol{e}(s_i) = [\overrightarrow{\boldsymbol{h}}_{iN}^w, \overleftarrow{\boldsymbol{h}}_{i1}^w]$ that corresponds to the concatenation of the last forward and first backward LSTMs. The second layer encodes information about the document and is also a biLSTM that runs at the sentence-level. This biLSTM takes as input the sentence representation from the previous layer $\boldsymbol{e}(s_i)$ and outputs the hidden representation for each sentence s_i in the document as $\boldsymbol{h}_i^s$ (SentEncoder in Figure 2). We consider the output of the last forward LSTM over M sentences and first backward LSTM to be the final representation of the document $\boldsymbol{e}(D) = [\overrightarrow{\boldsymbol{h}}_M^s, \overleftarrow{\boldsymbol{h}}_1^s]$.

The encoder returns two output vectors, $\boldsymbol{d}_i^s = [\boldsymbol{e}(D), \boldsymbol{e}(s_i), \boldsymbol{h}_i^s]$ associated with each sentence s_i, and $\boldsymbol{d}_{ij}^w = [\boldsymbol{e}(D), \boldsymbol{e}(s_i), \boldsymbol{e}(w_{ij}), \boldsymbol{h}_i^s, \boldsymbol{h}_{ij}^w]$ for each word j at the specific state of the encoder i.

3.2 Decision Decoder

Given that our model operates both at the sentence-level and at the word-level, the decision decoder maintains two state LSTMs denoted by SentStates and WordStates as in Figure 3. For the sentence-level decoder sentences are selected and the state of the summary gets updated by SentStates. For the word-level, all compressed word representations in a sentence are pushed to the word-level layer. In the compressive decoder, words that get selected are pushed onto the WordStates, and once the decoder has reached the end of the sentence, it pushes the output representation of the last state onto the sentence-level layer for the next sentence.

Extractive Decoder The extractive decoder selects the sentences that should go to the summary. For each sentence s_i at time step i, the decoder takes a decision based on the encoder representation $\boldsymbol{d}_i^s$ and the state of the summary $\boldsymbol{o}_i^s$, computed as follows:

$$\boldsymbol{o}_i^s = \text{SentStates}(\{\boldsymbol{e}(c_k)\}_{k<i,z_k=1}).$$

where the $\boldsymbol{o}_i^s$ is modeled by an LSTM taking as input the already selected and compressed sentences comprising the summary so far $\{\boldsymbol{e}(c_k)\}_{k<i,z_k=1}$. This way, at each point in time, we have a representation of the summary given by the SentStates LSTM that encodes the state of summary generated so far, based on the past sentences already processed by the compressive decoder $\boldsymbol{e}(c_{i-1})$ (in WordStates).[2] The summary representation at step i ($\boldsymbol{o}_i^s$) is then used to determine whether to keep or not the current sentence in the summary ($z_i = 1$ or 0 respectively). The summarizer state subsumes information about the document, sentence and summary as:

$$\boldsymbol{p}_i = \tanh(W_E[\boldsymbol{d}_i^s; \boldsymbol{o}_i^s] + \boldsymbol{b}^s),$$

where W_E is a model parameter, $\boldsymbol{o}_i^s$ is the dynamic LSTM state, and $\boldsymbol{b}^s$ is a bias term.

This modeling decision is crucial in order to generate variable length summaries. It captures information about the sentences or words already present in the summary, helping in better understanding the "true" length of the summary given the document.

Finally, the summarizer state $\boldsymbol{p}_i$ is used to compute the probability of the action at time i as:

$$p(z_i \mid \boldsymbol{p}_i) = \frac{\exp\left(W_{z_i}\boldsymbol{p}_i + \boldsymbol{x}_{z_i}\right)}{\sum_{z' \in \{0,1\}} \exp\left(W_{z'}\boldsymbol{p}_i + \boldsymbol{x}_{z'}\right)},$$

---

[2] When using only the extractive model the summary state $\boldsymbol{o}_i^s$ is generated from an LSTM whose inputs correspond to the sentence encoded embeddings $\{\boldsymbol{e}(s_k)\}_{k<i,z_k=1}$ instead of the previously generated compressed representations $\{\boldsymbol{e}(c_k)\}_{k<i,z_k=1}$.

where W_z is a model parameter and $\boldsymbol{x}_z$ is a bias term for the summarizer action z.

We minimize the negative log-likelihood of the observed labels at training time (Dimitroff et al., 2013), where λ_0^s and λ_1^s represent the distribution of each class for the given sentences:[3]

$$L(\theta^s) = -\sum_{c\in\{0,1\}} \frac{\lambda_c^s}{\sum_{i=1}^{M} \mathbb{1}_{z_i=c}} \sum_{i,z_i=0} \log p(z_i|\boldsymbol{p}_i),$$

where $\mathbb{1}_{z_i=c}$ is the indicator function of class c and θ^s represents all the training parameters of the sentence encode/decoder. At test time, the model emits probability $p(z_i \mid \boldsymbol{p}_i)$, which is used as the soft prediction sequentially extracting the sentence i. We admit sentences when $p(z_i = 1 \mid \boldsymbol{p}_i) > 0.5$.

Compressive Decoder Our compressive decoder shares its architecture with the extractive decoder. The compressive layer is triggered every time a sentence is selected in the summary and is responsible for selecting the words within each selected sentence. In practice, WordStates LSTM (see Figure 3) is applied hierarchically after the sentence-level decoder, using as input the collected word embeddings so far:

$$\boldsymbol{o}_{ij}^w = \text{WordStates}(\{\boldsymbol{e}(w_{ik})\}_{k\leq j, y_{ik}=1}).$$

After making the selection decision for all words pertaining to a sentence, the final state of the WordStates, $\boldsymbol{e}(c_i) = \boldsymbol{o}_{iN}^w$ is fed back to SentStates of the extractive level decoder for the consecutive sentence, as depicted in Figure 3.

The word-level summarizer state representation depends on the encoding of words, document and sentence $\boldsymbol{d}_{ij}^w$, on the dynamic LSTM encoding for the summary based on the selected words (WordStates) $\boldsymbol{o}_{ij}^w$ and sentences (SentStates) $\boldsymbol{o}_i^s$:

$$\boldsymbol{q}_{ij} = \tanh(W_C[\boldsymbol{d}_{ij}^w; \boldsymbol{o}_i^s; \boldsymbol{o}_{ij}^w] + \boldsymbol{b}^w),$$

where W_C is a model parameter and $\boldsymbol{b}^w$ is a bias term. Each action at time step j is computed by

$$p(y_{ij} \mid \boldsymbol{q}_{ij}) = \frac{\exp\left(W_{y_{ij}}\boldsymbol{q}_{ij} + \boldsymbol{x}_{y_{ij}}\right)}{\sum_{y'\in\{0,1\}} \exp\left(W_{y'}\boldsymbol{q}_{ij} + \boldsymbol{x}_{y'}\right)},$$

with parameter $W_{y_{ij}}$ and bias $\boldsymbol{x}_{y_{ij}}$. The final loss for the compressive layer is

$$L(\theta^w) = \sum_{i=1}^{M} z_i \phi(i \mid \theta^w),$$

where θ^w represents the set of all the training parameters of the word-level encoder/decoder, $\phi(i)$ is the compressive layer loss over N words:

$$\phi(i \mid \theta^w) = -\sum_{c\in\{0,1\}} \frac{\lambda_c^w}{\sum_{i=1}^{M} \mathbb{1}_{y_{ij}=c}} \sum_{i,z_i=0} \log p(y_{ij}|\boldsymbol{q}_{ij}).$$

The total final loss is then given by the sum of the extractive and compressive counterparts, $L(\theta) = L(\theta^s) + L(\theta^w)$.

4 Experimental Setup

We mainly used the CNN/DailyMail corpus (Hermann et al., 2015) to evaluate our models. We used the standard splits of Hermann et al. (2015) for training, validation, and testing (90,266/1,220/1,093 documents for CNN and 196,961/12,148/10,397 for DailyMail). To evaluate the flexibility of our model, we also evaluated our models on the Newsroom dataset (Grusky et al., 2018), which includes articles form a diverse collection of sources (38 publishers) with different summary style subsets: extractive (Ext.), mixed (Mixed) and abstractive (Abs.). We used the standard splits of Grusky et al. (2018) for training, validation, and testing (331,778/36,332/36,122 documents for Ext., 328,634/35,879/36,006 for Mixed and 332,554/36,380/36,522 for Abs.). We did not anonymize entities or lower case tokens.

4.1 Estimating Oracles

Datasets for training extractive summarization systems do not naturally contain sentence/word-level labels. Instead, they are typically accompanied by abstractive summaries from which extraction labels are extrapolated. We create extractive and compressive summaries prior to training using two types of *oracles*.

We used an *extractive oracle* to identify the set of sentences which collectively gives the highest ROUGE (Lin and Hovy, 2003) with respect to the gold summary (Narayan et al., 2018c).

To build a *compressive oracle*, we trained a supervised sentence labeling classifier, adapted from

---

[3] If $M - \sum_{i=1}^{M} z_i$=0 or $\sum_{i=1}^{M} z_i$=0, we simply consider the whole term to be zero. Here M represents the number of sentences in the document.

Oracle	R1	R2	RL
Extractive Oracle	54.67	30.37	50.81
Compressive Oracle	**57.12**	**32.59**	**53.27**

Table 1: Oracle scores obtained for the CNN and DailyMail testsets. We report ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL) F1 scores.

the Transition-Based Chunking Model (Lample et al., 2016), to annotate spans in every sentence that can be dropped in the final summary. We used the publicly released set of 10,000 sentence-compression pairs from the Google sentence compression dataset (Filippova and Altun, 2013; Filippova et al., 2015) for training. After tagging all sentences in the CNN and DailyMail corpora using this compression model, we generated oracle compressive summaries based on the best average of ROUGE-1 (R1) and ROUGE-2 (R2) F_1 scores from the combination of all possible sentences and all removals of the marked compression chunks.

To verify the adequacy of our proposed oracles, we show in Table 1 a comparison of their scores. Our compressive oracle achieves much better scores than the extractive oracle, because of its capability to make summaries concise. Moreover, the linguistic quality of these oracles was preserved due to the tagging of the entire span by the sentence compressor trained on the sentence compression dataset.[4] We believe that our dataset with oracle compression labels will be of significant interest to the sentence compression and summarization community.

4.2 Training Parameters

The parameters for the loss at the sentence-level were λ_0^s=2 and λ_1^s=1 and at the word-level, λ_0^w=1 and λ_1^w=0.5. We used LSTMs with d = 512 for all hidden layers. We performed mini-batch negative log-likelihood training with a batch size of 2 documents for 5 training epochs.We observed the convergence of the model between the 2nd and the 3rd epochs. It took around 12 hrs on a single GTX 1080 GPU to train. We evaluated our model on the validation set after every 5,000 batches. We trained with Adam (Kingma and Ba, 2015) with an initial learning rate of 0.001. Our system was implemented using DyNet (Neubig et al., 2017).

4.3 Model Evaluation

We evaluated summarization quality using F_1 ROUGE (Lin and Hovy, 2003). We report results in terms of unigram and bigram overlap (R1) and (R2) as a means of assessing informativeness, and the longest common subsequence (RL) as a means of assessing fluency.[5] In addition to ROUGE, which can be misleading when used as the only means to assess summaries (Schluter, 2017), we also conducted a question-answering based human evaluation to assess the informativeness of our summaries in their ability to preserve key information from the document (Narayan et al., 2018c).[6] First, questions are written using the gold summary, we then examined how many questions participants were able to answer by reading system summaries alone, without access to the article.[7] Figure 5 shows a set of candidate summaries along with questions used for this evaluation.

4.4 Model and Baselines

We evaluated our model EXCONSUMM in two settings: Extractive (selects sentences to assemble the summary) and Compressive (selects sentences and compresses them by removing unnecessary spans of words). We compared our models against a baseline (LEAD) that selects the first m leading sentences from each document,[8] three neural extractive models, and various abstractive models. For the extractive models, we used SUMMARUNNER (Nallapati et al., 2017), since it shares some similarity to our model, REFRESH (Narayan et al., 2018c) trained with reinforcement learning and LATENT (Zhang et al., 2018) a neural architecture that makes use of latent variable to avoid creating oracle summaries. We further compare against LATENT+COMPRESS (Zhang et al., 2018), an extension of the LATENT model that learns to map extracted sentences to final summaries using an attention-based seq2seq model (Rush et al., 2015). All models, unlike ours, extract a fixed number of sentences to assemble their summaries. For abstractive models, we compare against the state-of-the art models of POINTER+COVERAGE (See et al., 2017), ML+RL (Paulus et al., 2018), and Tan et al. (2017) among others.

---

[4] We show examples of both oracles in Appendix §A.1.

[5] We used `pyrouge` to compute the ROUGE scores. The parameters we used were "-a -c 95 -m -n 4 -w 1.2."

[6] We used the CNN/DailyMail QA test set of Narayan et al. (2018c) for evaluation. It includes 20 documents with a total of 71 manually written question-answer pairs.

[7] See Appendix §A.2 for more details.

[8] We follow Narayan et al. (2018c) and set m = 3 for CNN and 4 for DailyMail. We follow Grusky et al. (2018) and set m = 2 for Newsroom.

Table 3: Results for combined CNN/DailyMail test set.

5 Results

5.1 Automatic Evaluation

Table 2 and 3 show results for the evaluations on the CNN/DailyMail and Newsroom test sets.

Comparison with Extractive Systems. EXCONSUMM Compressive performs best on the CNN dataset and EXCONSUMM Extractive on the DailyMail dataset, probably due to the fact that the CNN dataset is less biased towards extractive methods than the DailyMail dataset (Narayan et al., 2018b). We report similar results on the Newsroom dataset. EXCONSUMM Compressive tends to perform better for mixed (Mixed) and abstractive (Abs.) subsets, while EXCONSUMM Extractive performs better for the extractive (Ext.) subset. Our experiments demonstrate that our compressive model tends to perform better on the dataset which promotes abstractive summaries.

We find that EXCONSUMM Extractive consistently performs better on all metrics when compared to any of the other extractive models, except for the single case where it is narrowly behind LATENT on R2 (18.6 vs 18.8) for the CNN/DailyMail combined test set. It even outperforms REFRESH, which is trained with reinforcement learning. We hypothesize that its superior performance stems from the ability to generate variable length summaries. REFRESH or LATENT, on the other hand, always produces a fixed length summary.

Comparison with Compressive System. EXCONSUMM Compressive reports superior performance compared to LATENT+COMPRESS (+4.2 for R1, +2.6 for R2 and +3.1 for RL). Our results demonstrate that our compressive system is more suitable for document summarization. It first selects sentences and then compresses them by removing irrelevant spans of words. It makes use of an advance oracle sentence compressor trained on a dedicated sentence compression dataset (Sec. 4.1). In contrast, LATENT+COMPRESS naively trains a sequence-to-sequence compressor to map a sentence in the document to a sentence in the summary.

Comparison with Abstractive Systems. Both EXCONSUMM Extractive and Compressive outperform most of the abstractive systems including Pointer+Coverage (See et al., 2017). When comparing with more recent methods (Pasunuru and Bansal, 2018; Gehrmann et al., 2018), our model has comparable performance.

Summary Versatility. We evaluate the ability of our model to generate variable length summaries. Table 4 show the Pearson correlation coefficient between the lengths of the human generated summaries against each unbounded model. Our compressive approach obtains the best results, with a Pearson correlation coefficient of 0.72 ($p < 0.001$).

Figure 4 also shows the distribution of words

	Bounded					Unbounded

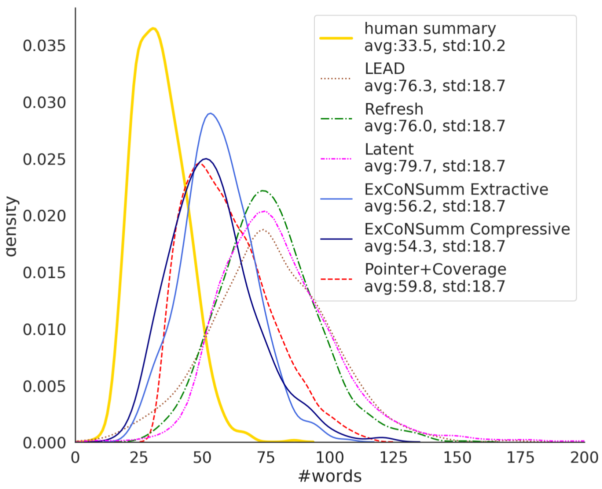

Figure 4: Word distribution in comparison with the human summaries for CNN dataset. Density curves show the length distributions of human authored and system produced summaries.

per summary for the models where predictions were available. Interestingly, both ExConSumm Extractive and Compressive follow the human distribution much better than other extractive systems (Lead, Refresh and Latent), since they are able to generate variable-length summaries depending on the input text. Our compressive model generates a word distribution much closer to the abstractive Pointer+Coverage model but achieves better compression ratio; the summaries generated by Pointer+Coverage contain 59.8 words, while those generated by ExConSumm Compressive have 54.3 words on average.

5.2 QA Evaluation

Table 4 shows results from our question answering based human evaluation. We elicited human judgements in two settings: the "Unbounded", where participants were shown the full system produced summaries; and the "Bounded", where participants were shown summaries that were limited to the same size as the gold summaries.

For the "Unbounded" setting, the output summaries produced by Refresh were able to answer most of the questions correctly, our Compressive and Extractive systems were placed at the 2nd and 3rd places respectively.[9]

We observed that our systems were able to produce more concise summaries than those produced by Refresh (avg. length in words: 76.0 for Refresh, 56.2 for ExConSumm Extractive and 54.3 for ExConSumm Compressive; see Figure 4). Refresh is prone to generating verbose summaries, consequently it has an advantage of accumulating more information. In the "Bounded" setting, we aim to reduce this unfair advantage. Scores are overall lower since the summary sizes are truncated to gold size. The ExConSumm Compressive summaries rank first and can answer 39.44% of questions correctly. ExConSumm Extractive retains its 3rd place answering 36.34% of questions correctly.[10] These results demonstrate that our models generate concise and informative summaries that correlate well with the human summary lengths.[11]

5.3 Summary State Representation

Next, we performed an ablation study to investigate the importance of the summary state representation $\boldsymbol{o}_i^s$ w.r.t. the quality of the overall sum-

---

[9] We carried out pairwise comparisons between all models to assess whether system differences are statistically significant. We found that there is no statistically significant difference between Refresh and ExConSumm Compressive. We use a one-way ANOVA with posthoc Tukey HSD tests with $p < 0.01$. The differences among Latent and both variants of ExConSumm, and between LEAD and Pointer+Coverage are also statistically insignificant. All other differences are statistically significant.

[10] The differences among both variants of ExConSumm and Latent, and among LEAD, Refresh and Pointer+Coverage are statistically insignificant. All other differences are statistically significant. We use a one-way ANOVA with posthoc Tukey HSD tests with $p < 0.01$.

[11] App. §A.2 shows more examples of our summaries.

LEAD
- (CNN) A top al Qaeda in the Arabian Peninsula leader–who a few years ago was in a U.S. detention facility–was among five killed in an airstrike in Yemen, the terror group said, showing the organization is vulnerable even as Yemen appears close to civil war.
- Ibrahim al-Rubaish died Monday night in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike."
- The Al-Malahem Media obituary characterized al-Rubaish as a religious scholar and combat commander.

- Ibrahim al-Rubaish died Monday night in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike." The Al-Malahem Media obituary characterized al-Rubaish as a religious scholar and combat commander.
- A Yemeni Defense Ministry official and two Yemeni national security officials not authorized to speak on record confirmed that al-Rubaish had been killed, but could not specify how he died.

ExConSumm Extractive
- (CNN) A top al Qaeda in the Arabian Peninsula leader–who a few years ago was in a U.S. detention facility–was among five killed in an airstrike in Yemen, the terror group said, showing the organization is vulnerable even as Yemen appears close to civil war.
- Ibrahim al-Rubaish died Monday night in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike."

ExConSumm Compressive
- A top al Qaeda in the Arabian Peninsula leader–who a few years ago was in a U.S. detention facility–was among five killed in an airstrike in Yemen. • Ibrahim al-Rubaish died in what AQAP's media wing, Al-Malahem Media, called a "crusader airstrike."

Pointer+Coverage
- Ibrahim al-Rubaish was among a number of detainees who sued the administration of then-president George W. Bush to challenge the legality of their confinement in Gitmo. • al-Rubaish was once held by the U.S. government at its detention facility in Guantanamo bay, Cuba.

GOLD
- AQAP says a "crusader airstrike" killed Ibrahim al-Rubaish
- Al-Rubaish was once detained by the United States in Guantanamo

---

Question-Answer Pairs
- Who said that an airstrike killed Ibrahim al-Rubaish? (AQAP) • What was the airstrike called? (crusader airstrike) • Where was Ibrahim al-Rubaish once detained? (Guantanamo)

Figure 5: Example output summaries on the CNN/DailyMail dataset, gold standard summary, and corresponding questions. The questions are manually written using the GOLD summary. The same ExConSumm summaries are shown in Figure 1, but the strike-through spans are now removed.

mary. We tested against a State averaging variant, where we replace $\boldsymbol{o}_i^s$ by a weighted average, analogous to Nallapati et al. (2017), $\boldsymbol{o}_i^{avg\ s} = \sum_{i=1}^{j-1} \boldsymbol{e}(s_i)p(z_i \mid \boldsymbol{p}_i^{avg})$, where $\boldsymbol{p}_i^{avg}$ has the same form as $\boldsymbol{p}_i$ but depends recursively on the previous summary state $\boldsymbol{o}_{i-1}^{avg\ s}$. Table 5 shows that using an LSTM state $\boldsymbol{o}_i^s$ to model the current sentences in the summary is very important. The other ablation study shows how learning to extract and compress in a disjoint approach (ExConSumm Ext+Comp oracle) performs against a joint learning approach (ExConSumm Compressive). We compared summaries generated from our best extractive model and compressed them with a compressive oracle. Our joint learning model achieves the best performance in all metrics compared with the other ablations, suggesting that joint learning and using a summary state representation is beneficial for summarization.

State	ROUGE R1	ROUGE R2	ROUGE RL
ExConSumm Extractive	**32.5**	**12.6**	**28.5**
State averaging	30.0	12.3	26.9
ExConSumm Compressive	**32.5**	**12.7**	**29.2**
ExConSumm Ext+Comp oracle	25.5	9.3	23.7

Table 5: Summary state ablation for the CNN dataset.

6 Conclusions

We developed ExConSumm, a novel summarization model to generate variable length extractive and compressive summaries. Experimental results show that the ability of our model to learn a dynamic representation of the summary produces summaries that are informative, concise, and correlate well with human generated summary lengths. Our model outperforms state-of-the-art extractive and most of abstractive systems on the CNN and DailyMail datasets, when evaluated automatically, and through human evaluation for the bounded scenario. We further obtain state-of-the-art results on Newsroom, a more abstractive summary dataset.

Abstract

In this work, we define the task of teaser generation and provide an evaluation benchmark and baseline systems for the process of generating teasers. A teaser is a short reading suggestion for an article that is illustrative and includes curiosity-arousing elements to entice potential readers to read particular news items. Teasers are one of the main vehicles for transmitting news to social media users. We compile a novel dataset of teasers by systematically accumulating tweets and selecting those that conform to the teaser definition. We have compared a number of neural abstractive architectures on the task of teaser generation and the overall best performing system is See et al. (2017)'s seq2seq with pointer network.

1 Introduction

A considerable number of people get their news in some digital format.[1] The trend has made many publishers and editors shift their focus to the web and experiment with new techniques to lure an Internet-savvy generation of readers to read their news stories. Therefore, there has been a noticeable increase in the sharing of short illustrative pieces of texts about the news on social media.

We define a ShortcutText as a short text (about 15 words or less) describing and pointing to a news article and whose purpose is to invite the recipient to read the article. A headline is a ShortcutText that optimizes the relevance of the story to its reader by including interesting and high news value content from the article (Dor, 2003). Clickbait is a pejorative term for web content whose main goal is to make a user click an adjoining link by exploiting the information gap. According to the definition, a principal part of the headline is an extract of the article, thereby creating an impression of the upcoming story. However, click-bait, a ShortcutText, contains mostly elements that create anticipation, thereby making a reader click on the link; however, the reader comes to regret their decision when the story does not match the click-bait's impression (Blom and Hansen, 2015). Thus, click-bait provides a false impression (non-bona fide) and contains insufficient information (highly abstractive).

	bona-fide	teasing	abstractive
headline	yes	no	low
clickbait	no	yes	high
teaser	yes	yes	high

Table 1: The table shows three categories of ShortcutTexts and their properties

We introduce the new concept of *teaser* and define it as a ShortcutText devised by fusing curiosity-arousing elements with interesting facts from the article in a manner that concurrently creates a valid impression of an upcoming story and a sense of incompleteness, which motivates the audience to read the article. A teaser is one of the main vehicles for transmitting news on social media. Table 2 shows some teasers from a popular newswire *The Wall Street Journal*.

We also introduce properties such as teasing, abstractive, and bona-fide, which not only differentiate teasers from other ShortcutTexts but also help in compiling a dataset for the study. Teasing indicates whether curiosity-arousing elements are included in the ShortcutText. Abstractive indicates whether a fair proportion of the ShortcutText is distilled out of the news article. Bona-fide answers whether the news story matches the impression created by the ShortcutText. Table 1 lists the common forms of the ShortcutTexts along with the presence or absence of the properties mentioned

Proceedings of NAACL-HLT 2019, pages 3967–3977
Minneapolis, Minnesota, June 2 - June 7, 2019.

Article	Global trade is in trouble, and investors dont seem to care. One of the ironies of the election of a fierce nationalist in the U.S. . . .
Headline	Steel Yourself for Trumps Anti-Trade Moves
Teaser	Investors don't seem worried about a trade war. Could tariffs by Trump start one?
Article	The U.S. Supreme Court on Monday partially revived President Donald Trumps executive order suspending travel from six countries . . .
Headline	High Court Says Travel Ban Not For Those With 'Bona Fide' Relationships
Teaser	In a 'bona fide' relationship? You can visit the U.S.
Article	Gan Liping pumped her bike across a busy street, racing to beat a crossing light before it turned red. She didnt make it. . . .
Headline	China's All-Seeing Surveillance State Is Reading Its Citizens' Faces
Teaser	China is monitoring its citizens very closely. Just ask jaywalkers.

Table 2: The table contains tuples of news articles and their ShortcutTexts: headline and teaser. These tuples are from a popular newswire, *The Wall Street Journal*.

above.

In this study, we focus on teasers shared on Twitter[2], a social media platform whose role as a news conduit is rapidly increasing. An indicative tweet is a Twitter post containing a link to an external web page that is primarily composed of text. The presence of the URL in an indicative tweet signals that it functions to help users decide whether to read the article, and the short length confirms it as a ShortcutText like a headline or teaser. Lloret and Palomar (2013) made an early attempt at generating indicative tweets using off-the-shelf extractive summarization models, and graded the generated texts as informative but uninteresting. Additionally, Sidhaye and Cheung (2015)'s analysis showed extractive summarization as an inappropriate method for generating such tweets as the overlaps between the tweets and the corresponding articles often are low. Our study shows that teasers, bona fide indicative tweets, do exhibit significant, though not complete, overlaps, and, therefore, are not appropriate for extractive but certainly for abstractive summarization.

Our contributions:

1) To the best of our knowledge, this is the first attempt to compare different types of ShortcutTexts associated with a news article. Furthermore, we introduce a novel concept of a teaser, an amalgamation of article content and curiosity-arousing elements, used for broadcasting news on social media by a news publisher.

2) We compiled a novel dataset to address the task of teaser generation. The dataset is a collection of news articles, ShortcutTexts (both teasers and headlines), and story-highlights. Unlike ShortcutText, a story-highlight is brief and includes self-contained sentences (about 25-40 words) that allow the recipient to gather information on news stories quickly. As all corpora based on news articles include only one of these short texts, our dataset provides the NLP community with a unique opportunity for a joint study of the generation of many short texts.

3) We propose techniques like unigram overlap and domain relevance score to establish abstractivity and teasingness in the teasers. We also apply these techniques to headlines and compare the results with teasers. The comparison shows teasers are more abstractive than headlines.

4) High abstractivity makes teaser generation a tougher task; however, we show seq2seq methods trained on such a corpus are quite effective. A comparison of different seq2seq methods for teaser generation shows a seq2seq combining two levels of vocabularies, source and corpus, is better than one using only the corpus level. Therefore, we set a strong baseline on the teaser generation task with a seq2seq model of See et al. (2017).

The remaining paper is structured as follows. In Section 2, we provide a detailed description of the data collection and analyses. In Section 3, we describe and discuss the experiments. In Section 4, we describe a user study of model-generated teasers. In Section 5, we discuss the related works. Section 6 concludes the study.

2 Teaser Dataset

Several linguistic patterns invoke curiosity, e.g., provocative questions and extremes for comparison. A retrieval of teasers from a social media platform using such patterns requires the formulation of a large number of complex rules as these patterns often involve many marker words and correspondingly many grammar rules. A computationally easy approach is to compile circulations from bona-fide agents involved in luring business on such media, and then filtering out those that don't comply with defined characteristics of a teaser; see Table 1. We followed the latter approach and chose Twitter to conduct our study.

2.1 Collection

We identified the official Twitter accounts of English-language news publications that had

---

[2] https://twitter.com/

tweeted a substantial number of times before the collection began; this removes a potential source of noise, namely indicative tweets by third-party accounts referencing the articles via their URL. See supplementary A.1 for the list of Twitter accounts. We downloaded each new tweet from the accounts via Twitter's live streaming API. We limited the collection to indicative tweets and extracted the article text and associated metadata from the webpage using a general-purpose HTML parser for news websites.[3] Overall, we collected approximately 1.4 million data items.

2.2 Analysis

We propose methods that evaluate teasingness and abstractivity in the teasers and verify them through analyses. We then combine those methods and devise a teaser recognition algorithm. Analyses are performed on lowercase, and stopwords-pruned texts.

2.2.1 Extractivity

For a given pair of strings, one is an extract of another if it is a substring of it. Teasers are abstractive, which we confirm by making sure that the ShortcutText is not an extract of article sentences. Additionally, a teaser of an article is designed differently than the headline; therefore, they must be independent of one other, i.e., non-extractive.

2.2.2 Abstractivity

Abstractivity, a principle characteristic of the teaser, implies that the teaser should exhibit content overlap with its source, but not a full overlap.

We rely on Sidhaye and Cheung (2015)'s method of computing the percentage match between two stemmed texts for grading abstractivity. We obtain unigrams of the first, X_1, and second text, X_2, using function $uni(X)$ and compute the percentage match using Eq. 1:

$$perc\_match(X_1, X_2) = \frac{|uni(X_1) \cap uni(X_2)|}{|uni(X_1)|} \tag{1}$$

Given a ShortcutText and article, initially, a sequence of texts is obtained by sliding a window of size p on the article sentences. Then, $perc\_match$ scores between the ShortcutText and sequence of texts are computed. A text with the highest score is selected as the prominent section for the ShortcutText in the article.

Article	Diabetes medication, such as insulin, lowers blood sugar levels and . . . . But experts have revealed a natural treatment for diabetes could be lurking in the garden. . . . Fig leaves have properties that can help diabetes . . . . An additional remedy . . .
headline	Diabetes treatment: Natural remedy made from fig leaves revealed
Teaser	**Would** you **Adam** and **Eve** it? Natural treatment for DIABETES could be **growing** in your garden

Table 3: ShortcutTexts and their non-overlaps (bold).

A full-overlap, i.e., $perc\_match$ of 1 is likely to be a case where the ShortcutText disseminates information of its prominent section. However, a non-overlap is very likely to be click-bait or noise. Thus, we filter out instances where the match score between a ShortcutText, potential teaser, and its prominent section is above 80% or below 20%. The intuition for the filtering is that the teasing words are likely to be absent from the prominent section, and an absence of a minimum of 2-3 words (often 20%) is the easiest way to ascertain this fact. Table 3 shows an example. Analogously, a presence of a minimum of 2-3 words from the source asserts that it is not click-bait or noise.

We use the sliding window size, p, of 5,[4] and filter the data instances where the $perc\_match$ between the tweet and prominent section is lower than 0.2 or greater than 0.8.

2.2.3 Teasingness

Apart from abstractivity, teasers include words and phrases that tease and are are embedded by authors who often draw on their vast knowledge of style and vocabulary to devise teasers. A commonly recognizable pattern among them is the inclusion of unusual and interesting words in a given context, e.g., words like *Adam* and *Eve* in the example of Table 3.

The Pareto principle or the law of the vital few, states that the 2,000 of the most frequently used words in a domain cover about 80% of the usual conversation texts (Nation, 2001; Newman, 2005). At first glance, filtering those abstractive ShortcutTexts that constitute only frequent words should intuitively prune uninteresting ones and save ones that are similar to the example in Table 3. However, a closer look at the pruned ShortcutTexts shows several interesting teasers with substrings comprised of out-of-place frequent-words, e.g., *Las Vegas gunman Stephen bought nearly %%*

---

[3] https://github.com/codelucas/newspaper/

[4] Most of the prominent information is supposedly within a few leading sentences in the news articles due to the inverted pyramid news writing style.

guns legally. But none of the purchases set off any red flags, with an interesting sentence fragment containing the phrase *red flags*. This suggests that the methodology that uses plain frequency of words is not sufficient for determining interesting information.

$$\begin{aligned} tf_{domain}(w,d) &= \frac{|\text{term } w \text{ in domain } d|}{|\text{terms in domain } d|} \\ idf_{domain}(w) &= log\, \frac{|\text{domains}|}{|\text{domains containing } w|} \\ dr(w,d) &= tf_{domain}(w,d) \times idf_{domain}(w) \end{aligned} \tag{2}$$

Thus, we look at unusualness at a level lower than the corpus. We rely on domain relevance (dr) (Schulder and Hovy, 2014), an adapted TF-IDF (term frequency inverse document frequency) metric that measures the impact of a word in a domain and, therefore, identifies unusual words in a specific domain, and is computed using Eq. 2.

A word is assigned a very low dr score if the word is either non-frequent in the domain and too frequent among other domains (unusualness) or non-frequent in all domains (rare); see Table 4. As a very low dr score corresponds to unusualness, a presence of very low dr values among the non-overlapping words of the ShortcutText suggest a high likelihood of it being a teaser, and therefore, we compile them as teasers. However, the filtering requires a threshold dr value that defines anything lower than it as a very low dr. Also, computing dr requires domain information of the text.

	$freq$_Out	¬ $freq$_Out
$freq$_IN	low	high
¬ $freq$_IN	very low	very low

Table 4: The table shows dr score range. IN and Out refer to in-domain and out-of-domain respectively.

Would	**Adam**	**Eve**	Natural	treatment
0.104	**0.0027**	**0.0025**	0.025	0.016
DIABETES	could	**growing**	garden	
0.005	0.105	0.022	0.01	

Table 5: Teaser words and their dr values. Non-overlaps are in bold blue.

Obtaining Domains

We make use of articles and their keywords to determine domains. Keywords are meta-information available for a subset of corpus instances. We rely on Doc2vec (Le and Mikolov, 2014) for obtaining the representations for the articles and cluster these representations by K-Means clustering (Hartigan and Wong, 1979).

We rely on elbow criterion and uniformity among keywords in the clusters to determine the number of clusters. The uniformity is validated by manual inspection of 100 most-frequent keywords. Clustering the corpus into eight domains resulted in the final abrupt decrease of the Sum of Squared Error (SSE) as well as uniformly distributed keyword sets. See Table 6 for domain-wise keywords and other statistics.

Selecting a Threshold

We use the domain information and compute dr values of potential teaser texts in the corpus. Table 5 shows nonstop words and dr scores for Table 3 example. Evidently, unusual words have very low dr scores (bold values).

To determine an appropriate threshold, we design an unsupervised methodology based on the Pareto principle. The cue remains the same, i.e., a right threshold will filter only the teasers, and the non-overlapping words in them are less likely to be frequent words.

Thus, we define a range of possible threshold values, and for each value, we compile a corpus of teasers where a non-overlapping word has dr below it. Meanwhile, we also compile sets of most-frequent words that cover 80% of the total word occurrences in all 8 domains (sizes ≈ 2000). Then, we determine the ratio of the teasers that have their non-overlapping words completely overlapping the frequent word sets. Finally, we select a value which has the least overlap as the threshold; see Figure 1. We chose 0.005 as it is the boundary below which there is no overlap. We apply this value to abstractive ShortcutTexts and obtain a teaser corpus.

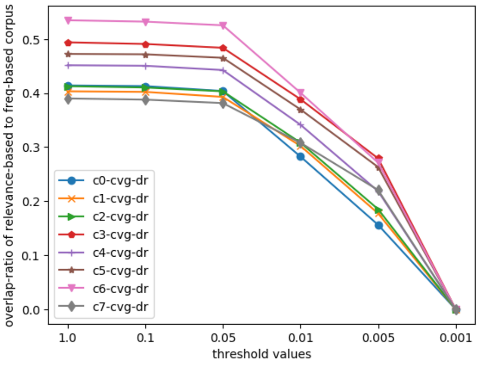

Figure 1: Overlap-ratio of frequency-based and threshold-based filtered teasers for domains (c#).

	Cluster 0	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5	Cluster 6	Cluster 7
Keywords	politics, UK, world, Brexit, Europe, UK Politics, Theresa May	Trump, United States, election, immigration, White House	culture, travel, home and garden, food and beverage	entertainment, celebrities, movies, concerts, Netflix	Europe, Russia, North Korea, Diplomacy, Conflicts	shooting, police, murder, killed, dead, fire, suspect, crash	Corporate, business, Company, automotive, Equities	Sport, Football, Premier League, NFL, Dallas Cowboys, Rugby
Avg. size (words)	763	842	526	838	886	651	791	741

Table 6: The table shows clusters of domains and corresponding frequent-keywords and average article size (words) in them.

2.3 Teaser Recognition Algorithm

We combine the above three methodologies and devise a teaser recognition algorithm; see Algorithm. 1.

We use notations like uppercase bold for a matrix, lowercase italic for a variable and uppercase italic for an array. A data instance in the corpus has an article A, headline H, tweet T, and domain d. An article, A, has a sequence of sentences, $S = \langle S_1, \ldots, S_{|A|} \rangle$, and each sentence, S_i, has a sequence of words, $\langle w_1, \ldots, w_{|S_i|} \rangle$. WINDOW takes a sequence of sentences, S, and returns a sequence of texts, Z, of size $\frac{|S|-p}{q} + 1$, where p and q are window size and sliding step respectively. The domain-wise dr values for words in the vocabulary, U, is stacked into a matrix, $\mathbf{D}$. IS_TEASER takes $\mathbf{D}$ and items of a data instance, and determines whether its tweet, T, is a teaser.

Algorithm 1 Teaser Recognition

```
1:  procedure IS_TEASER($A, H, T, d, \mathbf{D}$)
2:      if ($T$ in $H$) Or ($H$ in $T$) then
3:          return False                              ▷ sub-string match
4:      for $S$ in $A$ do
5:          if ($T$ in $S$) Or ($S$ in $T$) then
6:              return False                          ▷ sub-string match
7:      $Z \leftarrow$ WINDOW($A, p = 5, q = 1$)
8:      $V \leftarrow$ Array()
9:      for $i$ = 1 to $|Z|$ do
10:         $V$.ADD($perc\_match(Z[i], T)$)           ▷ see Eq. 1
11:     if $max(V) > 0.8$ Or $max(V) < 0.2$ then:
12:         return False                              ▷ abstractivity
13:     $\hat{Y} \leftarrow Z[max(V)]$                ▷ prominent section
14:     $T' \leftarrow \hat{Y} \backslash T$          ▷ non-overlap
15:     $L \leftarrow \mathbf{D}[d;T']$               ▷ indexing
16:     if any ($L < 0.005$) then
17:         return True                               ▷ teasingness
18:     return False
```

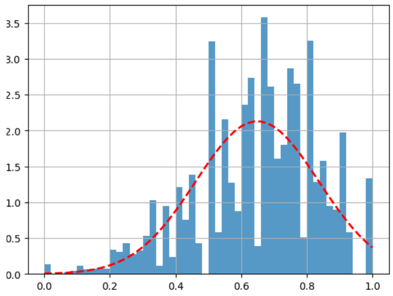
Overall, in Algorithm. 1, steps 2 to 6 checks Extractivity, steps 7 to 12 checks Abstractivity, and steps 13 to 17 checks Teasingness. Table 7 shows the percentage distribution of the total data points that are pruned by each of those analyses. Finally, we compile the remaining 23% data points, i.e., 330k as a teaser corpus.

Analysis		% pruned
Extractivity	wrt headline	37%
	wrt article	5%
Abstractivity		22%
Teasingness		13%

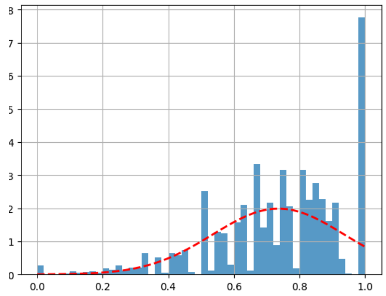
Table 7: The table shows different analyses performed in Algorithm. 1 and the corresponding approximate percentage of data points pruned using them. "wrt" = with respect to.

2.4 Comparing ShortcutTexts

The two ShortcutTexts, headline and teaser, have distinct conveyance mediums and therefore are designed differently, e.g., mean lengths of 10 and 14 respectively. However, abstractivity is also presumed for the headline. Therefore, we conduct additional overlap-based studies to understand the



(a) teasers ($t1$) and articles ($t2$).



(b) headlines ($t1$) and articles ($t2$)

Figure 2: Histogram of unigram overlaps obtained using Eq. 1. The histograms are normalized, i.e., the area under the curve ($\sum$bin-height×bin-width) sum up to one.

differences in the abstractive property between them. We compute and plot the distribution of the overlaps between teasers (T_1) and articles (T_2), and one between headlines (T_1) and articles (T_2); see Figure 2a and Figure 2b for respective plot. Clearly, compared to the teaser, headline distribution is left-skewed (mean 74% and std 20%), and thereby implies that headlines have a lesser abstractive value than teasers.

Further, a review of a few instances of headline-article instances with lesser than 60% overlap reveals cases of noisy headlines or HTML-parse failures; therefore, in a typical scenario a headline with a size of 10 words takes nearly all of its content (≈80%) from the source while a teaser of size 14 has sufficient non-extractive contents (≈32%). See Table 3 for an example.

3 Experiments

3.1 Models

We experiment with two state-of-the-art neural abstractive summarization techniques, attentive seq2seq (Bahdanau et al., 2014) and pointer seq2seq (See et al., 2017), for teaser generation. Attentive seq2seq learns to generate a target with words from a fixed vocabulary, while pointer seq2seq uses a flexible vocabulary, which is augmented with words from the source delivered through the pointer network. We refer to the individual papers for further details.

Evaluation Metrics: Studies on text-summarization evaluate their system using Rouge; therefore, we report Rouge-1 (unigram), Rouge-2 (bigram), and Rouge-L (longest-common substring) as the quantitative evaluation of models on our corpus.

Parameters: We initialized all weights, including word embeddings, with a random uniform distribution with mean 0 and standard deviation 0.1. The embedding vectors are of dimension 100. All hidden states of encoder and decoder in the seq2seq models are set to dimension 200. We pad short sequences with a special symbol $\langle PAD \rangle$. We use Adam with initial learning rate .0007 and batch size 32 for training. Texts are lowercased and numbers are replaced by the special symbol %. The token length for the source is limited to 100 and target sequence to 25. The teaser baseline experiments and headline generation use vocabulary size of 20000.

	Rouge-1	Rouge-2	Rouge-L
ABS	29.55	11.32	26.42
ABS+	29.76	11.88	26.96
RAS-Elman	33.78	**15.97**	31.15
Nallapati et al.	32.67	15.59	30.64
seq2seq	31.21	12.96	28.87
seq2seq_point	**34.81**	15.59	**32.05**

Table 8: Rouge scores on the standard task of Headline Generation (Gigaword). seq2seq and seq2seq_point are reimplementations of Bahdanau et al. (2014) and See et al. (2017) respectively.

3.2 Baseline Setting

As we reimplemented (Bahdanau et al., 2014) and (See et al., 2017) models, we initially evaluate them on a standard task of headline generation.[5] We use popular headline generation corpus, Gigaword (Napoles et al., 2012), with 3.8M training examples. We fetched the test set from Rush et al. (2015) and report the results on it. The results are compared with the state-of-the-art headline generation methods like Nallapati et al. (Nallapati et al., 2016), ABS (Rush et al., 2015), ABS+ (Rush et al., 2015), and RAS-Elman (Chopra et al., 2016). Since our aim for this experiment is to demonstrate the strength of the models, we limit the model parameters to the extent that we produce comparable results in less computation time. Table 8 compares performances of seq2seq and seq2seq_pointer models with other state-of-the-art methods. The results indicate that the implementations have performance competitive with other state-of-the-art methods.

	Validation		
	Rouge-1	Rouge-2	Rouge-L
seq2seq	15.77	03.52	13.53
seq2seq_point	**21.57**	**07.03**	**18.64**
	Test		
seq2seq	15.26	03.38	13.15
seq2seq_point	**21.05**	**07.11**	**18.49**

Table 9: Rouge F1 scores for seq2seq model and seq2seq_point models on the teaser task.

These models are then trained and evaluated on the teaser corpus obtained using Algorithm. 1 that initially has 330k instances. We then sample 255k instances that have all associated short texts in them. The sampled corpus is split into

---

[5] codes for collection, analyses and experiments: https://github.com/sanjeevkrn/teaser_collect.git and https://github.com/sanjeevkrn/teaser_generate.git

non-overlapping 250k, 2k and 2k sets for training, validation, and testing, respectively. The split is constructed such that training, validation and test sets have equal representation of all eight domains. Any instances that describe events that were also described in training are removed from validation and test sets; thus, instances encountered in validation / test are quite distinct from instances encountered in training. Models were selected based on their performance on the validation set. Table 9 shows the performance comparison. Clearly, seq2seq_point performs better than seq2seq due to the boost in the recall gained by copying source words through the pointer network.

	Rouge-1	Rouge-2	Rouge-L
	Teaser		
seq2seq	15.26	03.38	13.15
seq2seq_point	**21.05**	**07.11**	**18.49**
	Headline		
seq2seq	18.52	05.34	16.74
seq2seq_point	**23.83**	**08.73**	**21.68**
	Highlights		
seq2seq	31.18	17.57	27.30
seq2seq_point	**35.92**	**22.44**	**31.53**

Table 10: Rouge F1 scores for seq2seq model and seq2seq_point models on the teaser, headline and highlights generation task.

Additionally, models are also trained and evaluated on the other short texts that are available in the novel corpus: headlines (also a ShortcutText) and story-highlights. All the model parameters remain the same except the generation size, which depends on the short text average size, e.g., 35 for highlights. Table 10 compares the performance on the test data. Clearly, seq2seq_point performs better than seq2seq for all the types of short texts. Additionally, the change in the rouge scores with the change of dataset, i.e., Teaser<Headline<Highlights, also corresponds to the level of distillation of source information in them.

Table 11 shows an example of a data instance in the corpus and seq2seq_point model generations. Among generations, only headline and teaser have non-overlapping words; however, the headline non-overlap, *says*, is a frequent word with a high dr (0.11) while the teaser non-overlap, *catch*, is a domain-wise non-frequent one, and therefore, has a very low dr (0.006).

Further, the teaser is the most detached from the core news information among the three generations, while still being relevant. The generated highlight is extractive, and this is a reason for relatively high Rouge scores for highlights (see Table 10). Rouge is an overlap-based measure and, therefore, is inclined towards extractive datasets.

Article	Millions of disease carrying mosquitoes are to be freed in a well-meaning bid . . .. The lab-grown versions are infected with a disease which prevents natural mosquito . . . . But some activists fear the disease could transfer to humans ultimately making all human males sterile . . . . Table 11: seq2seq_pointer generated examples. Non-overlapping words are in bold blue. More examples in supplementary A.2.

3.3 Impact of very low dr

We performed additional experiments to study the impact that can be generated using the domain relevance (dr). All the settings are kept intact as in Section 3.2 except the training corpus; this is changed by increasing the proportion of very low dr (<0.005) terms in the teasers. New models are trained using equal size training instances sampled out of the revised corpora.

A bucketing of very low dr percentages into [0%, 25%), [25%, 35%), [35%, 45%), [45%, 55%) and [55%, 100%) divides the corpus into approximately equal sizes. Also, the mean and standard deviation of teaser-article overlap ratio is nearly equal in all the buckets, i.e., 0.559±0.148, 0.559±0.146, 0.564±0.146, 0.566±0.142, 0.566±0.146, respectively. Thus, the range of buckets corresponds to a range in the percentage of uncommon words. We evaluate the precision and recall of the models. Recall ($|overlap|/|ground\text{-}truth|$) estimates the model capacity in recovering the ground-truth content, while precision ($|overlap|/|generation|$) estimates the relevancy in the generation.

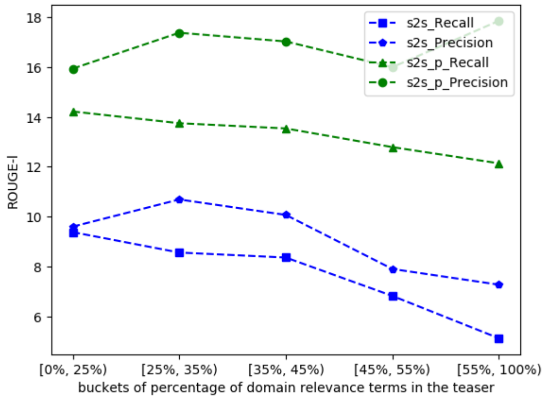

Figure 3: Variation in ROUGE-l on increasing the proportion of domain-relevant terms in the teasers. Models trained on 40k sampled instances.

As shown in Figure 3, the test recall for both models decreases with the increase in uncommon words in their training. An increase in the proportion of uncommon words makes the models also generate uncommon words, which are not likely to match the ground-truth, thereby reducing the recall. However, in extreme cases, i.e., [45%, 100%), not only training teasers get slightly shorter but also a relatively large proportion of out-of-vocabulary (UNK) is introduced in them, and thereby in the generations. The UNK appears for novel informative words, which are rare words with a very low *dr* as well (see Table 4). Unlike seq2seq, seq2seq_pointer recovers those from the source using pointer network and thus doesn't suffer an abrupt drop in the scores.

Further, the precision scores in extreme cases have a slightly different trend than recall scores, and this is due to shorter generations, which supports precision, but is irrelevant for recall.

4 Human Evaluation

The quantitative evaluations show that state-of-the-art models perform moderately on the novel task. This is mostly due to deficiencies of Rouge, which fails to reward heterogeneous contents. We took a closer look at some of the generated examples, see Table 12, and observed frequent cases where the generation suffered from the typical seq2seq issues, e.g., repetition of words; however, there are also cases where generation is more distinctive than ground-truth and is well formed too. Thus, we carried out a small user study to understand the quality of the generated teasers; however, we only selected non-repeating and non-UNK generations to anonymize the source. The participants in the user study are undergraduate or graduate students with some computer science background and familiarity with social media platforms. Additionally, all the participants have used or have been using twitter.

- pres . trump lashed out on twitter at the hosts of “ msnbcs morning ”
- migration agency says more than %% people drowned and presumed dead in myanmar to bangladesh
- computer glitch led to google to be dramatically undervalued this morning
- alt-right activist jason kessler says he was swarmed by a group of charlottesville
- of identical triplets who beat the incredible odds of %%% million to survive
- singer and guitar player who declined to appear on britain ’s got talent

Table 12: The table shows seq2seq_point generated teasers used in the survey-based study. More examples in supplementary A.2.

	On Twitter		Stimulating	
	Mean	Std	Mean	Std
ground-truth	0.660	0.064	0.621	0.079
seq2seq_point teaser	0.588	0.078	0.559	0.089
baseline	0.476	0.127	0.501	0.111

Table 13: The table shows the mean values and standard deviations of the likelihood of being social-media text and stimulating for users to read. Baseline = lead sentences

We assembled a set of texts by randomly sampling 40 seq2seq_point teasers, 40 ground-truth teasers, and 40 lead sentences (baseline), and also established equal representation of the domains. We then assigned 72 sentences (3 per domain per category) to ten participants and asked them to rate texts for two questions: 1) How likely is it that the text is shared on Twitter for a news story by a news organization? and 2) How likely is it that the text makes a reader want to read the story? The first question helps us recognize the participant's understanding of the teasers, as an informed reader will rate a ground-truth significantly higher than the baseline, and 8 of them recognized it correctly, and their ratings are selected for the evaluation. The second question provides a cue as to the model capacity in generating teasing texts by learning interesting aspects present in the teaser corpus.

The annotators rated samples on a scale of 1 to

5; however, we normalized the ratings to avoid the influence of annotators having different rating personalities. The results, summarized in Table 13, show that the human written teasers are most likely to be recognized as social media texts due to their style, which is distinct from the lead sentence; the model trained on such teasers closely follows it. Similarly, human written teasers are good at stimulating readers to read a story compared to the lead sentence and the generated teasers.

5 Related Work

There are two kinds of summarization: abstractive and extractive. In abstractive summarization, the model utilizes a corpus-level vocabulary and generates novel sentences as the summary, while extractive models extract or rearrange the source words as the summary. Abstractive models based on neural sequence-to-sequence (seq2seq) (Rush et al., 2015) proved to generate summaries with higher Rouge scores than the feature-based abstractive models. The integration of attention into seq2seq (Bahdanau et al., 2014) led to further advancement of abstractive summarization (Nallapati et al., 2016; Chopra et al., 2016; See et al., 2017).

There are studies utilizing cross-media correlation like coupling newswire with microblogs; however, most of them involve improving tasks on newswire by utilizing complementary information from microblogs, e.g., improving news article summarization using tweets (Gao et al., 2012; Wei and Gao, 2014), generating event summaries through comments (Wang et al., 2015), etc. There is very limited work on using newswire and generating microblogs, e.g., article tweet generation (Lloret and Palomar, 2013) and indicative tweet generation (Sidhaye and Cheung, 2015). Lloret and Palomar (2013) observed that off-the-shelf extractive models produce summaries that have high quantitative scores, but that are not interesting enough. Similarly, Sidhaye and Cheung (2015)'s analysis of indicative tweets shows the narrow overlap between such tweets and their source limits the application of an extractive method for generating them. Our controlled compilation of such tweets shows a mean percentage match of 68.3% (std: 16%) with its source. These analyses strongly suggest that indicative tweets are not regular information-disseminating short texts. Also, the mixed nature of such texts suggests an abstractive, rather than extractive study.

Most abstractive summarization systems use a popular dataset, CNN/DailyMail(Napoles et al., 2012), that includes news articles and story highlights to train and test their performance. However, story highlights are brief and self-contained sentences (about 25-40 words) that allow the recipient to quickly gather information on news stories; it is largely extractive (Woodsend and Lapata, 2010). Our novel corpus includes not only extractive short texts (i.e., story-highlights) and nearly extractive (i.e., headlines), but also very abstractive teasers, and therefore is a challenging and more appropriate dataset to measure abstractive systems.

6 Conclusion

We defined a novel concept of a teaser, a Shortcut-Text amalgamating interesting facts from the news article and teasing elements. We compiled a novel dataset that includes all of the short texts that are associated with news articles. We identified properties like abstractive, teasing, and bona-fide that assist in comparing a teaser with the other forms of short texts. We illustrated techniques to control these properties in teasers and verified their impact through experiments. An overlap-based comparative study of headlines and teasers shows teasers as abstractive while headlines as nearly extractive. Thus, we performed neural abstractive summarization studies on teasers and set a strong benchmark on the novel task of teaser generation.

Cross-referencing using Fine-grained Topic Modeling

Abstract

Cross-referencing, which links passages of text to other related passages, can be a valuable study aid for facilitating comprehension of a text. However, cross-referencing requires first, a comprehensive thematic knowledge of the entire corpus, and second, a focused search through the corpus specifically to find such useful connections. Due to this, cross-reference resources are prohibitively expensive and exist only for the most well-studied texts (e.g. religious texts). We develop a topic-based system for automatically producing candidate cross-references which can be easily verified by human annotators. Our system utilizes fine-grained topic modeling with thousands of highly nuanced and specific topics to identify verse pairs which are topically related. We demonstrate that our system can be cost effective compared to having annotators acquire the expertise necessary to produce cross-reference resources unaided.

1 Introduction

Cross-references are references within or between bodies of text that can help elaborate upon or clarify that text. They can be a useful tool for deep understanding and can also be used to analyze the relational structure of a text. In contrast to a word concordance which simply shows passages which share a common keyword, cross-references often include links which do not necessarily share the same keywords, but are still related topically. The existence of a thorough and complete cross-reference resource can facilitate better scholarship of a text and help readers to quickly find clarifying information or see repeated themes throughout a text.

Compared to language tasks such as part-of-speech tagging, producing cross-reference annotations is much more labor intensive. To produce cross-references, annotators must become intimately familiar with a text in order to note that a particular passage is related to another passage they happen to recall. This level of familiarity and expertise with a particular text typically requires the annotator to spend a great deal of time studying and reading. Possibly for this reason, expansive cross-references have only been produced for the most well-studied texts, such as the Bible. Other texts, such as academic textbooks, may include indices or other similar references, but these tend to be sparse, focusing on a small number of keywords rather than linking each individual passage with other relevant passages.

The process of creating such a resource can be expensive and time consuming. For example, the Bible[1] published by The Church of Jesus Christ of Latter-day Saints includes numerous cross-references and topic-based categories. These cross-references took hundreds of volunteers thousands of hours over seven years to produce (Anderson, 1979). This process involved collecting more than 19,900 manually curated entries from volunteers, and then editing and refining those references with a small committee of experts down to a final cross-reference database containing 12,475 entries.

Cross-referencing grows quadratically with the size of the data because for each of n passages, there are $n-1$ possibly related passages, yielding $\mathcal{O}(n^2)$ potential pairs. This differs from tasks such as part-of-speech tagging where annotators can tag individual sentences in isolation ($\mathcal{O}(n)$). We can, however, evaluate pairs in isolation. Therefore, our approach is to produce a system which utilizes fine-grained topic modeling in order to dramatically lower the cost of producing a cross-reference resource for new texts. We do not expect that such

a system will produce only–or even primarily–valid cross-references, but we hope that the system could be accurate enough to allow annotators to simply review the proposed cross-references and reduce the search cost.

2 Methodology

In this section, we describe our experimental setup and how we approach the problem of automatic cross-reference generation.

2.1 Cross-reference Datasets

While exact statistics are impossible to obtain, the number of printed copies of the Bible is estimated to be more than 5 billion (Guiness). It is one of the most well-studied texts in existence, and one of the few texts in the world with extensive cross-reference data. We utilize the English Standard Version of the Holy Bible (Crossway, 2001) in order to validate our method. We use this specific translation of the Bible because it is used on `openbible.info`. While our work focuses on this specific religious text out of necessity, it can also be applied to other texts, including literary classics and collections of historical documents.

To aid any readers who are unfamiliar with this religious text, we note that the term 'verse' refers to a short division of a chapter. The entirety of the text is divided up into books. Typically, individual verses are referenced by the name of the book, the chapter number, and the verse number, e.g., Isaiah 25:8. For convenience, each referenced verse in electronic versions of this paper is a hyperlink to `openbible.info`, showing the verse along with associated cross-references. For the sake of narrowing our focus, our efforts in cross-referencing the Bible will focus on finding topically related verses, though other work could potentially link larger passages, such as entire chapters or passages spanning multiple verses.

As a ground truth for cross-references, we utilize two sources. The first is the "Treasury of Scripture Knowledge, Enhanced" (Morton, 2010) (an extended version of the original "Treasury of Scripture Knowledge" (Torry, 2002)), which includes 670,796 cross-references between the 31,085 verses of the Bible. To our knowledge, this is the most exhaustive resource of human curated cross-references for the Bible to date. We will denote this cross-reference dataset as *TSKE*.

The second source of ground truth cross-references is a dataset from `openbible.info`. This dataset was seeded with various public domain cross-reference data, including the Treasury of Scripture Knowledge. As shown in Figure 1, users search for a verse they are interested in and can then vote on whether they found a particular cross-reference to be helpful or not. With each helpful or not helpful vote counting as $+1$ and -1 respectively, the dataset includes the net result of the votes for each included cross-reference.

Thus we can filter the dataset of cross-references based on how helpful each verse was rated to be. Counting only those cross-references which have a non-negative vote total, this dataset contains 344,441 cross-references. In figures, we denote this subset of the `openbible.net` cross-reference dataset as *OpenBible+0*. We also use the subset of cross-references which received a net total of at least 5 helpful votes. This subset, denoted as *OpenBible+5*, has 50,098 cross-references.

We do note however that the voting data has some skewness in the number of votes for each cross-reference. The overwhelming majority of cross-references received fewer than five total votes for or against the reference. A small number of verses, including both popular verses as well as verses which happen to come from the very beginning of the Bible, have received hundreds of votes.

2.2 Baselines for Automated Cross-reference Generation

These cross-reference datasets were produced at a tremendous cost in time and human effort. To the best of our knowledge, efforts at automating this process are limited and have not received much attention in computer science literature. That said, a reasonable baseline for automated efforts is a simple word-based concordance, which lists words along with references to where the words occur in the text[2].

Using the TSKE as the ground truth for cross-references, this simple baseline will recover roughly 65% of the cross-references. For example, as shown in Figure 1 and assuming that stemming is performed, the verse Isaiah 25:8 would be properly linked to 1 Corinthians 15:54 due to the two verses sharing the terms 'death' and 'swallow'. On the other hand, verses such as Hosea 13:14 or 1 Corinthians 15:55 which reference the

---

[2] For an example of such a concordance for the King James Version of the Bible, see Strong's Concordance (Strong, 1890).

‘sting of death’ should not be linked to verses such as Revelation 9:10, which references the sting of a scorpion. For this reason, roughly 99% of cross-references found using word-based concordance are spurious according to the TSKE, making this baseline less useful as a cross-referencing resource.[3] We refer to this baseline as *word match*.

As a slightly stronger baseline, we also consider a topical concordance in which verses assigned to the same topic by some topic model are considered to be linked. We refer to this baseline as *topic match*. For example, suppose that a topic model includes a topic which gives high probability to terms such as ‘death’, ‘swallow’, ‘victory’ and ‘sting’. Assuming that such a model would assign the previously mentioned verse to this topic, then verses such as Isaiah 25:8, Hosea 13:14, and 1 Corinthians 14:54 would be linked, but Revelation 9:10 which uses the term ‘sting’ in a different context (i.e., the sting of a scorpion) would not be linked.

We can further increase the precision of this baseline by only linking references which share a topic and a word, although this does come at the cost of recall. We refer to this final baseline method as *topic-word match*.

2.3 Topic-based Cross-referencing

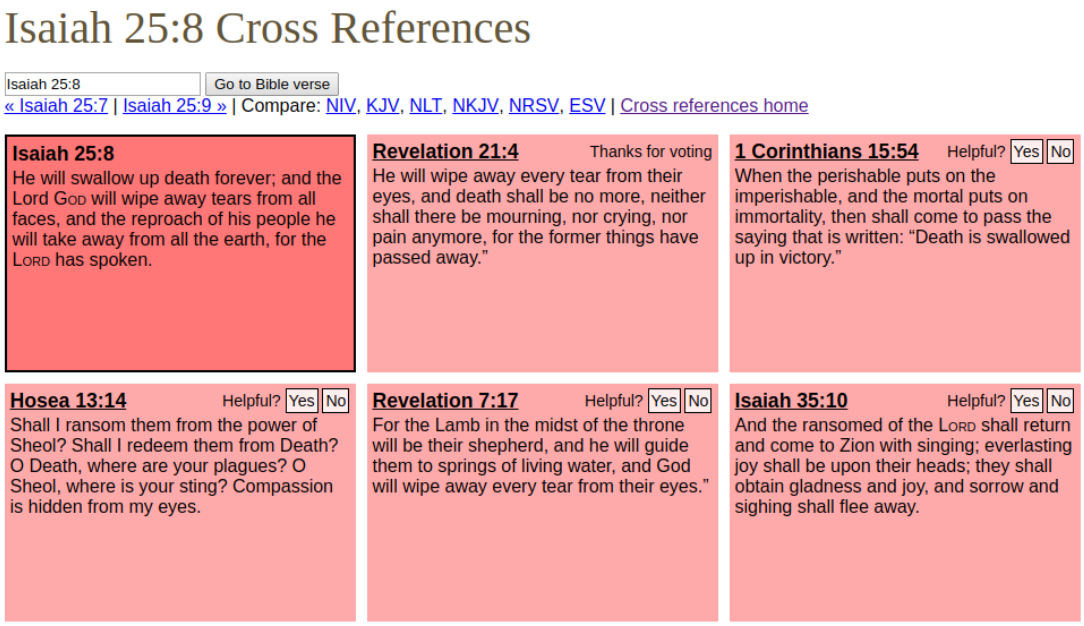
We now describe our approach to topic-based cross-referencing. The baselines built upon word or topic concordances simply propose any cross-reference for which a word or topic matches another verse, meaning that we cannot set a threshold on the quality of the proposed cross-references. Instead, we propose comparing document-topic distributions as K-dimensional vectors, where K is the number of topics, using standard vector distance metrics to compare verses. This idea has been used before (Towne et al., 2016), although not for the task of producing cross-references. By using a vector distance metric to compare the topical similarity of verse pairs, we can set a threshold on the number of proposed cross-references and propose only the most topically related verse pairs as cross-references. We experiment with four distance metrics: cosine distance, Euclidean distance, cityblock (or Manhattan) distance, and Chebyshev distance. However, given that previous work comparing document-topic vectors from LDA seem to default to cosine similarity (Towne et al., 2016; Chuang et al., 2012), we anticipate that cosine distance will be the best metric for selecting cross-references.

2.4 Model Selection

We claim that a fine-grained topic model, i.e., a topic model with a large number of highly nuanced topics, will be able to provide more value

---

[3] For this reason, published biblical word concordances typically only give a manually curated subset of significant vocabulary terms.



Isaiah 25:8 Cross References

Isaiah 25:8
He will swallow up death forever; and the Lord God will wipe away tears from all faces, and the reproach of his people he will take away from all the earth, for the Lord has spoken.

Revelation 21:4
He will wipe away every tear from their eyes, and death shall be no more, neither shall there be mourning, nor crying, nor pain anymore, for the former things have passed away.”

1 Corinthians 15:54
When the perishable puts on the imperishable, and the mortal puts on immortality, then shall come to pass the saying that is written: “Death is swallowed up in victory.”

Hosea 13:14
Shall I ransom them from the power of Sheol? Shall I redeem them from Death? O Death, where are your plagues? O Sheol, where is your sting? Compassion is hidden from my eyes.

Revelation 7:17
For the Lamb in the midst of the throne will be their shepherd, and he will guide them to springs of living water, and God will wipe away every tear from their eyes.”

Isaiah 35:10
And the ransomed of the Lord shall return and come to Zion with singing; everlasting joy shall be upon their heads; they shall obtain gladness and joy, and sorrow and sighing shall flee away.

Figure 1: Voting interface for cross-reference data from `openbible.info`.

for tasks like cross-referencing than traditional coarse-grained topic models. In order to validate this claim, we will compare our fine-grained models with topics from a traditional Latent Dirichlet Allocation model with 100 topics. We refer to this baseline model as *coarse*.

Traditional probabilistic topic models such as Latent Dirichlet Allocation are not able to utilize large numbers of topics (Wallach et al., 2009). However, we successfully train anchor-based topic models with thousands of topics. Consequently, for our fine-grained models, we will employ the Anchor Word algorithm (Arora et al., 2013). Anchor-based topic models view topic modeling as non-negative matrix factorization. This class of topic models attempts to decompose a document-word matrix into two matrices, including a topic-word matrix which gives the conditional probabilities of a particular word given a topic. Ordinarily, this factorization is NP-Hard (Arora et al., 2012). However, given a set of anchor words, or words which uniquely identify a topic, the computation requires only $\mathcal{O}(KV^2 + K^2VI)$ where K is the number of topics, V is the size of the vocabulary, and I (typically around 100) is the average number of iterations (Arora et al., 2013).

We train our anchor-based model using 3,000 topics. We choose this number based on the number of documents we expect each topic to explain: there are roughly 30,000 verses and, according to OpenBible+0, a median of 10 cross-references per verse, so we want each topic to be responsible for roughly 10 documents.

By default, the anchors for the 3,000 topics are produced using a modified form of the Gram-Schmidt process (Arora et al., 2013). This process views each word as a vector in high-dimensional space and attempts to pick anchor words which maximally span that space. For more details, see Arora et al. (2013). In our results and figures, we refer to this model with the default anchor selection method as *Gram-Schmidt*.

This does present us with some difficulty with anchor words as this process tends to select the most extreme and esoteric anchors possible (Lee and Mimno, 2014), which can lead to less useful topics as we increase their number. Lund et al. (2017) introduced a method of using multiple words to form a single anchor. This method, called tandem anchoring, was originally formulated as a way to extend the anchor algorithm to allow for interactive topic modeling.

Instead of utilizing human interaction to seed the topic anchors, we will seed the tandem anchors using the terms from randomly selected verses. For example, suppose we randomly select Isaiah 25:8 as a verse from which to form an anchor. As shown in Figure 1, this verse includes terms such as 'swallow', 'death', and 'tears'. Each of these terms is represented as a point in high-dimensional space. To produce a single anchor from these terms, we average the words using the element-wise harmonic mean[4]. While this new point may not correspond to any particular word, it does capture the joint occurrence pattern of the words which form the anchor. We repeat this process 3,000 times to produce an anchor-based topic model with tandem anchors. While this exact methodology of seeding topic anchors using randomly selected verses is novel, we note the similarity to the method used to seed topics in Rephil, a web scale topic model used by Google (Murphy, 2012). In figures, we refer to this model with tandem anchors as *tandem*.

For each of these models, we must take the topic-word distributions from the topic model and produce document specific topic assignments. We utilize mean field variational inference in order to assign the individual verses to topics, similar to Nguyen et al. (2015).

3 Results

In this section we present the results of our experiments with topic-based cross-referencing. As discussed in Section 2, we experiment with three different cross-reference datasets: TSKE, OpenBible+0, and OpenBible+5. We utilize three different topic models: coarse, Gram-Schmidt, and tandem. We seek to demonstrate that our topic-based cross-referencing system can effectively utilize fine-grained topic modeling to produce candidate cross-references which can be annotated by humans in a cost effective manner.

3.1 Metric Comparisons

We first explore the various metrics for selecting cross-references discussed in Section 2.3. With each proposed distance metric, we are able to set a threshold and determine which Bible verse pairs to keep as candidate cross-references and which

---

[4] See Lund et al. (2017) for details on why the harmonic mean is useful for forming tandem anchors

to discard. Figure 2 and Figure 3 summarize our results with respect to metrics.

Figure 2 gives a receiver operator characteristic (or ROC) curve, which compares the true positive rate (or recall) against the false positive rate (or fall-out). We show the curve for the various metrics using the TSKE as our ground truth. We show these curves on each of the three different models discussed in Section 2.4.

Overall, cosine distance is the best method for selecting cross-references, as it gives the largest area under the ROC curve. The major exception to this is with the traditional coarse-grained topic model for which Euclidean distance performs the best. Considering that cosine distance has frequently been used in conjunction with topics from LDA (Towne et al., 2016; Chuang et al., 2012), this result is somewhat surprising.

Also of interest is the fact that the word-match baseline does reasonably well with respect to the true positive rate, at least if a false positive rate of roughly 0.196 is acceptable. Note that this corresponds to 188,974,806 false positives in the TSKE dataset, so while the raw number of true positives may be impressive, this baseline is not likely to be useful in practice.

While the ROC plot is undoubtedly more popular than the precision-recall plot, in cases where the data is imbalanced, the precision-recall plot can be much more informative. This is mainly because of the use of false-positives in the ROC curve, which can present an overly optimistic picture of the classifier performance (Saito and Rehmsmeier, 2015). Consequently, in Figure 3, we also compare each of the proposed metrics using a precision-recall curve (or PRC).

The PRC plot reinforces the claim that cosine distance is the best distance metric to threshold cross-references since for any reasonable level of precision, cosine distance yields the best results. Once again, with the exception of Euclidean distance performing better with the coarse-grained topic model. However, we note that the precision using coarse-grained topics is much lower than using fine-grained topics with cosine distance. Even with Gram-Schmidt based fine-grained topics, where Euclidean distance eventually wins out against cosine distance, the high amount of false

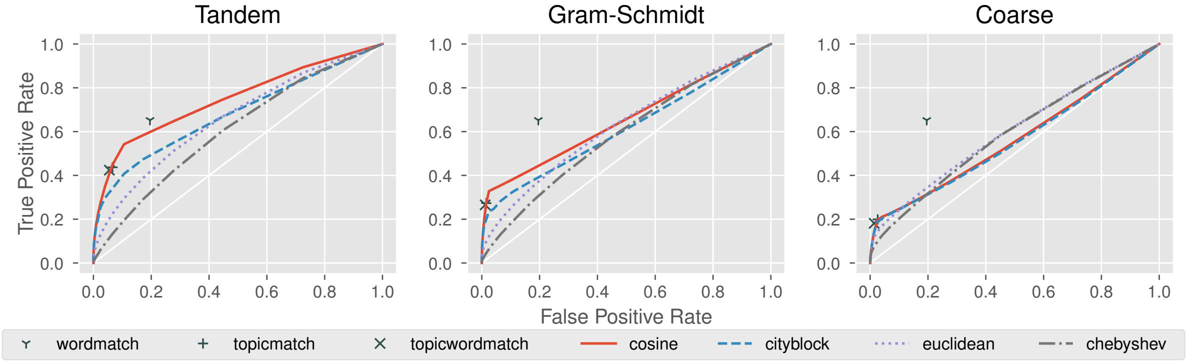


Figure 2: Cross-reference ROC curves for different metrics for cross-reference selection with topics from three different topic models and TSKE as the cross-reference ground truth.

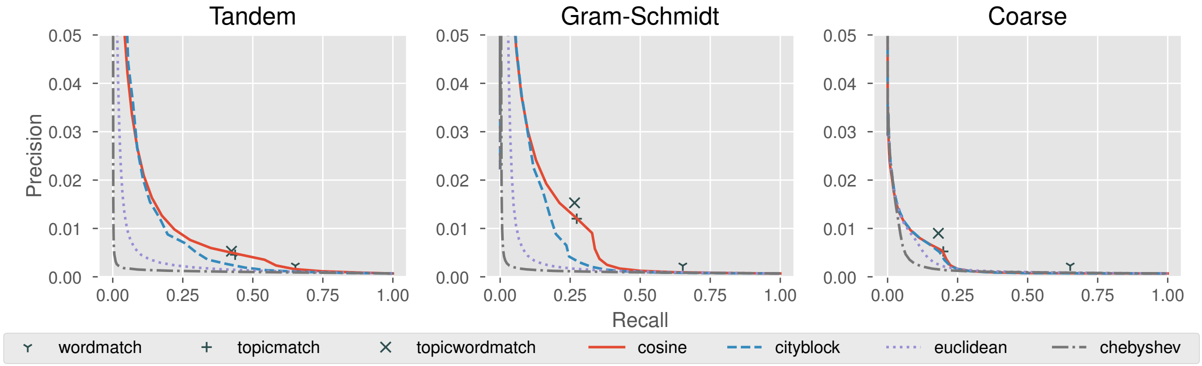

Figure 3: Cross-reference PRC plots with different metrics for cross-reference selection with topics from three different topic models and TSKE as the cross-reference ground truth.

positives means that cosine distance is the most useful metric for this task. The PRC plot also illustrates why the matching baselines are not practically useful—they do have decent true positive rates, but the precision with these baselines is extremely low.

3.2 Topic Model Comparison

We now explore the various topic models discussed in Section 2.4. Figure 4 and Figure 5 summarize these results. Based on Section 3.1, each reported result in this section uses cosine distance to determine verse pairs which should be considered as candidate cross-references. We compare the results of the three topic models on the three datasets discussed in Section 2.1.

The overall trend on each of the three datasets is simply that we lower the true positive rate and precision as we use more selective datasets. Considering that OpenBible+5 is a subset of OpenBible+0, and that OpenBible+0 is nearly a subset of TSKE[5], this result is not surprising. In the final cost analysis (see Section 3.3), the selectivity of the actual annotators must be taken into account when attempting to predict the true positive rate or the precision of a system.

As shown in Figure 4, regardless of the anchor selection strategy, both fine-grained topic models outperform the traditional coarse-grained model. Our model using tandem anchors built from randomly selected verses performs the best for nearly all levels of false positive rate. However, the Gram-Schmidt based anchors produce better true positive rates for very low false positive rates.

This trend is better illustrated with the PRC plots in Figure 5. While for higher values of recall the tandem anchor selection strategy does win out, it is only after precision significantly drops that tandem anchors produce superior predictions to Gram-Schmidt anchors.

---

[5] OpenBible+0 has 533 references seeded from other public domain sources, which are not included in TSKE.

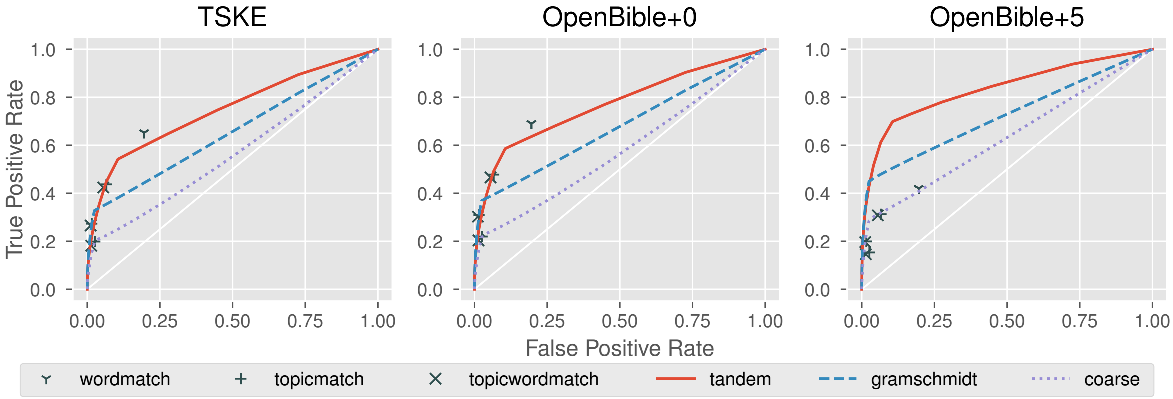

Figure 4: Cross-reference ROC curves with different models for cross-reference selection with three different datasets.

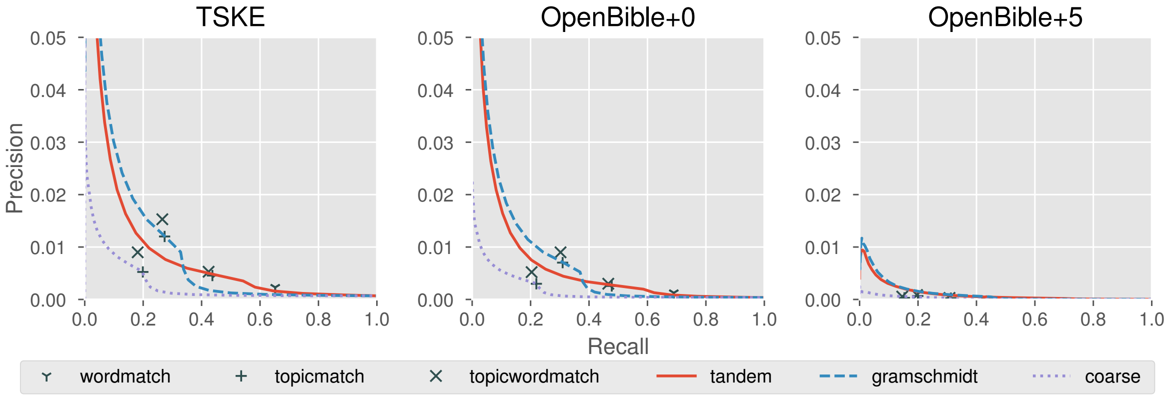

Figure 5: Cross-reference PRC plots with different models for cross-reference selection with three different datasets.

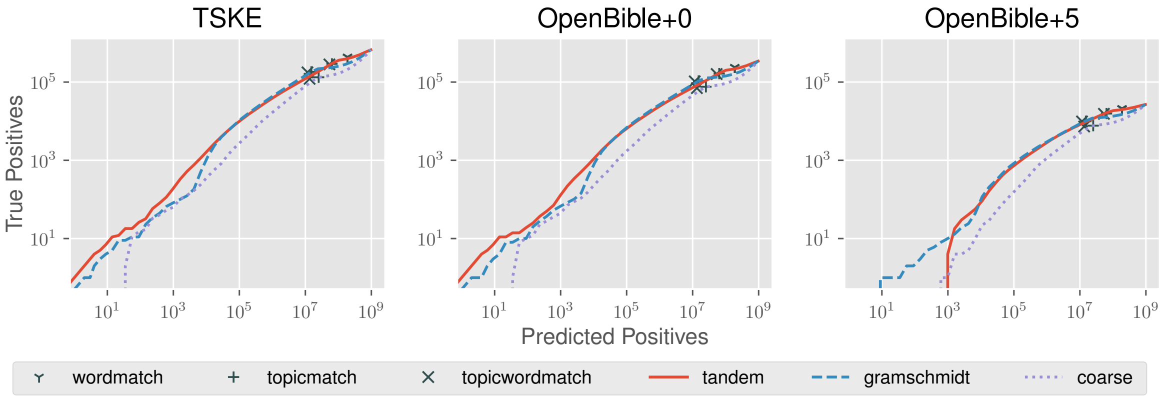

Figure 6: Cross-reference cost curves with different models for cross-reference selection with three different datasets. Note the log-log scale. The x-axis denotes the number of cross-references produced by our method, while the y-axis indicates how many of those cross-references are valid according to the human-provided ground truth.

3.3 Cost Analysis

While the precision-recall curves in Figure 5 may suggest that Gram-Schmidt based topic models produce superior topics for cross-referencing, we suggest that this analysis may be missing a key point in real world analysis. As an alternative to both PRC and ROC curves, we suggest that this task might be best served with an analysis of cost per true positive.

We envision that our system would be used to produce a set of candidate cross-references which would then be curated using human annotators. These annotators would be tasked with evaluating each potential reference and determining whether or not each cross-reference is valid. Critically, the annotator would only be required to evaluate individual cross-references, not the entire text.

As a working example of the cost of such an annotation process, suppose we use a popular crowdsourcing service (e.g., Amazon Mechanical Turk) to produce human annotations. We might reasonably expect to pay something around $0.01 USD per annotation. We would likely require some form of quality control in the form of redundant annotations, so we might end up paying $0.05 USD per annotated cross-reference candidate. Of course, the exact cost per annotated cross-reference will vary depending on the service and difficulty of the specific text being cross-referenced. However, we will use these estimates for the purpose of illustration.

Suppose as part of this working example, we are interested in producing a resource with 12,000 valid cross-reference annotations (roughly matching the size of the previously mentioned LDS edition of the Bible (Anderson, 1979)). Consulting Figure 6 we can then determine how many candidate cross-references we would need to produce for human annotation in order to create the final curated cross-reference resource. For example, using the TSKE as our ground truth, we would need approximately 150,000 predicted positives in order to find 12,000 true positives. At $0.05 USD per annotation, this would cost about $7,500 USD. Supposing that our annotators were more selective, we could use the OpenBible+0 as the ground truth, which would roughly double the cost. With OpenBible+5, which is considerably more selective, this cost rises to approximately $1,000,000 USD. In contrast, with traditional coarse-grained topic modeling, this cost is anywhere from $40,000 USD using the TSKE as the ground truth, to $17,500,000 USD using OpenBible+5 as the ground truth.

While these costs may seem prohibitive, consider that the alternative is to have experts understand the entire text to the degree that they can read one passage and recall other relevant passages they have previously read. In the case of religious texts, this is often possible since adherents study those texts as part of their daily routine. For example, in the case of the LDS edition, it took a committee of experts seven years of work to produce their cross-reference resource, even with the aid of hundreds of volunteers. However, without those experts and volunteers, the cost would have been even greater. In the naive case where every possible reference is manually checked, the cost skyrockets to around $48,000,000 USD.

Passage 1	**Passage 2**
“I have an excessive regard for Miss Jane Bennet, she is really a very sweet girl, and I wish with all my heart she were well settled. But with such a father and mother, and such low connections, I am afraid there is no chance of it.”	“I wish you may not get into a scrape, Harriet, whenever he does marry;–I mean, as to being acquainted with his wife–for though his sisters, from a superior education, are not to be altogether objected to, it does not follow that he might marry any body at all fit for you to notice. The misfortune of your birth ought to make you particularly careful as to your associates. There can be no doubt of your being a gentleman’s daughter, and you must support your claim to that station by every thing within your own power, or there will be plenty of people who would take pleasure in degrading you.”

Table 1: Passage 1 is taken from the eighth chapter of *Pride and Prejudice*, and Passage 2 is taken from the fourth chapter of *Emma*. These two passages are a valid cross-reference because they both discuss social standing and family connections in the context of marriage. Their connection was found even with their lack of shared words.

4 Discussion

Without extensive cross-referencing resources for more secular datasets, it is difficult to empirically prove the usefulness of our system generally without an extremely costly user study. That said, we make a small attempt by manually examining cross-references generated from the complete works of Jane Austen and Plato. Based on our cost analysis in Section 3.3, and since we will be examining only a small number of cross-references, we utilize tandem anchors to generate topics. With each dataset, we examine the first 300 cross-references produced by our system.

We also examine what our model got wrong in proposing Bible cross-references.

4.1 Jane Austen

Of the first 300 cross-references, we find that 39 of them are valid, linking passages from all six works by Jane Austen. As with our experiments with the Bible, this level of precision is sufficient that we believe that we could dramatically lower the cost of producing a full cross-referencing resource for this text.

We note that 109 of these are cross-references linking a paragraph in the eighth chapter of *Pride and Prejudice* to other passages in our corpus. Of the references involving this one paragraph, 22 were valid. An example of such a cross-reference is shown in Table 1. While marriage in general is a common theme in the works of Jane Austen, this particular paragraph more specifically discusses the role of social status and family connection as it relates to choosing a marriage partner. We note that the connection between the passages in Table 1 is thematic; they share no significant words in common, demonstrating the capability of the system to detect nuanced topics and themes.

4.2 Plato

Of the first 300 cross-references generated from the works of Plato, we found 119 that were valid. Many of the cross references were between distinct works, and included discussions about the nature of justice, arguments about the composition of things, the nature and role that certain things play, and discussions of appropriate legislation.

It is important to note that the model found significantly more cross references in the works of Plato than those by Jane Austen. This is likely due to the nature of the writing. We find in the works of Plato that ideas themselves are discussed directly, similar to the bible, and thus we would expect it to be easier for a model to find words and phrases that link to a specific topic. An example of this is that words like “virtue,” “courage,” “mean,” and “cowardice” would likely identify a topic about virtue that comes up in the works of Plato. However, in Jane Austen we find ideas discussed implicitly through interactions of the characters and commentary by the author. The meaning, while present, is found by “reading between the lines.” An example of this is that we might find marriage discussed in the works of Jane Austen, but more often through characters discussing their feelings after getting married. Here, words that we might see could be words such as “happy,” “elated,” “love,” “efficient,” etc. However, these words could also correlate equally well with other topics, and thus it would be harder for our model to discern. As further evidence of this we point out that the cross reference we used above from Jane Austen is an explicit discussion of marriage. It is likely that an implicit discussion of marriage would be harder for our model to find. We also point out that in such cases it is a non-trivial task for humans to come to a specific consensus about what a given passage could mean or relate to.

That said, given the relevant and influential nature that the works of Plato still hold even today, we can see that these cross references are highly useful in that they facilitate study and understanding of his works that a study of each individual work separately might miss.

4.3 Error Analysis

We examine the errors of running tandem anchors using cosine distance on the Bible. There are two types of errors to examine: candidate cross-references proposed early in the process that are not valid cross-references and valid cross-references that are not proposed until the end of the process (as determined by the Treasury of Scripture Knowledge).

Early invalid candidate cross-references all exhibit the same characteristic; the documents are exactly or substantively the same (e.g. *Deuteronomy 2:17 the Lord said to me,* and *Deuteronomy 2:2 Then the Lord said to me*). Indeed, a human given only those two documents would also mark them as related, and many valid cross-references exhibit this same characteristic (e.g. Psalms 107:6 and Psalms 107:28 are exactly the same and are a valid cross-reference).

Cross-references are partially so difficult because what constitutes a valid cross-reference is at least partially determined by what the community surrounding the text views as significant, and so two documents that are identical may or may not be a valid cross-reference depending on the view of that community. This particular issue would make any end-to-end automated solution to cross-referencing particularly difficult.

We also examined the last one hundred valid cross-references proposed. We consider these errors because in a system where a predetermined number of candidate cross-references are considered, these candidate cross-references would most likely never be considered. For 28 of the last one hundred valid cross-references, it is unclear why they are considered valid cross references (e.g., *Ezekiel 16:10 I clothed you also with embroidered cloth and shod you with fine leather. I wrapped you in fine linen and covered you with silk.* and *Deuteronomy 8:11 "Take care lest you forget the Lord your God by not keeping his commandments and his rules and his statutes, which I command you today,*).

Many of the other 72 valid cross-references are also difficult in some way. Many of the connections involve some use of metaphor (25) or are linked by a single key word, such as a name, but are otherwise topically dissimilar (34). The other 13 cross-references are all documents describing the construction of the tabernacle, and we have enough extra context to recognize this, however it isn't surprising that the model doesn't find this connection.

It is useful to note that of the final 600,000 candidate cross-references, only one hundred of them were valid cross-references.

5 Conclusion

We have produced a system using fine-grained topic modeling which is able to propose candidate cross-references which can be verified by non-expert human annotators for the purpose of creating a cross-reference resource at a fraction of the cost of current manual techniques. Our method, which utilizes tandem anchors to produce large numbers of highly nuanced topics coupled with an effective assignment strategy, is able to produce document-topic vectors which are comparable using cosine distance.

Our results also demonstrate that this system would not be as cost effective with traditional coarse-grained topic modeling. While we can find sets of topically related documents using coarse-grained topics, for the task of finding the most closely related documents we require a system which is more specific. We suggest that this success serves as motivation for exploration of fine-grained topic modeling for other topic-based use cases which require nuance and precision.

Abstract

In our everyday chit-chat, there is a conversation initiator, who proactively casts an initial utterance to start chatting. However, most existing conversation systems cannot play this role. Previous studies on conversation systems assume that the user always initiates conversation, and have placed emphasis on how to respond to the given user's utterance. As a result, existing conversation systems become passive. Namely they continue waiting until being spoken to by the users. In this paper, we consider the system as a conversation initiator and propose a novel task of generating the initial utterance in open-domain non-task-oriented conversation. Here, in order not to make users bored, it is necessary to generate diverse utterances to initiate conversation without relying on boilerplate utterances like greetings. To this end, we propose to generate initial utterance by summarizing and chatting about news articles, which provide fresh and various contents everyday. To address the lack of the training data for this task, we constructed a novel large-scale dataset through crowd-sourcing. We also analyzed the dataset in detail to examine how humans initiate conversations (the dataset will be released to facilitate future research activities). We present several approaches to conversation initiation including information retrieval based and generation based models. Experimental results showed that the proposed models trained on our dataset performed reasonably well and outperformed baselines that utilize automatically collected training data in both automatic and manual evaluation.

1 Introduction

Conversation[1] systems are becoming increasingly important as a means to facilitate human-computer communication. However, most of the studies on conversation systems have been based on the assumption that a human always initiates conversation. As a result, the systems are designed to be passive (Yan, 2018), meaning that they keep waiting until they are spoken to by the human and will never speak to the human proactively. For example, popular encoder-decoder models (Sutskever et al., 2014; Vinyals and Le, 2015) are designed to respond to input utterances provided by humans, and it is difficult for them to proactively initiate the conversation. Although some systems are able to initiate conversations, they basically adopt template-based generation methods and thus lack diversity.

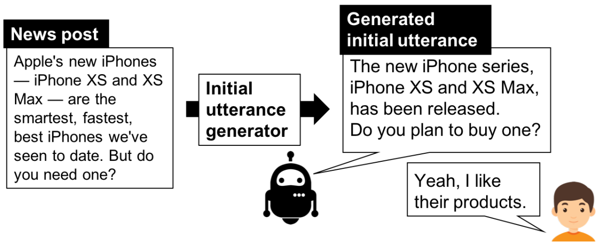

Figure 1: Conversation initiation task. The system in this example is given a news post about "iPhone" and generates an initial utterance for chatting about it.

This paper investigates generating the very first utterance in a conversation. We feel strongly that conversation systems should not always be passive; sometimes, they have to proactively initiate the conversation to enable more natural conversation. In addition, it is crucial to be able to initiate conversation in various ways in actual applications, since systems that initiate a conversation by always saying "*Let's talk about something*" or "*Hello*" are inherently boring.

We propose a task setting in which the system initiates a conversation by talking about a news topic. In this task, the system is provided with

[1] "Conversation" in this paper refers to open-domain non-task-oriented conversations and chit-chat.

Proceedings of NAACL-HLT 2019, pages 3988–3998
Minneapolis, Minnesota, June 2 - June 7, 2019.

a news post to talk about and uses it to generate the initial utterance of the conversation (Fig. 1). This task is referred to as *conversation initiation* in this paper. We have two primary reasons for using news posts. First, sharing and exchanging opinions about the latest news with friends is common in our daily conversations (Purcell et al., 2010) (*e.g,* asking something like *"What do you think about today's news on Trump?"*). Second, and more importantly, this task setting allows us to proactively generate diverse utterances to initiate conversations by simply using the latest news posts, which include a wide variety of content published daily.

We created a large-scale dataset for training and evaluating conversation initiation models through a crowd-sourcing service. The crowd-sourcing workers were presented with news posts collected from Twitter and asked to create utterances to initiate a conversation about the post. The resulting dataset will be released to facilitate future studies at the time of publication.

We developed several neural models, including retrieval-based and generation-based ones, to empirically compare their performances. We also compared the proposed models against baselines that utilize automatically constructed training dataset to investigate the effectiveness of our dataset. Both automatic and manual evaluation were used to assess not only the quality but also the diversity of the generated initial utterances. The results indicate that the proposed models successfully generated initial utterances for the given news posts, and significantly outperformed the baseline models.

Our contributions are the following:

- We investigate the task of conversation initiation, which has been largely overlooked in previous studies.
- We construct and release a large-scale dataset for conversation initiation.
- We develop several neural models and empirically compare their effectiveness on our dataset.

2 Related work

2.1 Non-task-oriented Conversation System

There are many existing studies on non-task-oriented conversation systems. Research started with rule-based methods (Weizenbaum, 1966; Wallace, 2009) and gradually shifted to statistical approaches (Ritter et al., 2011; Vinyals and Le, 2015), and many follow-up studies have since been undertaken to improve the quality of the generated responses (Hasegawa et al., 2013; Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016b; Serban et al., 2017).

However, the task of conversation initiation has been largely absent in these studies.

2.2 Data Grounded Conversation

There have also been efforts to develop systems that can chat with users about specific documents such as Wikipedia articles (Zhou et al., 2018) or reviews (Moghe et al., 2018). However, these studies did not investigate how to initiate such conversations, and as a result, their models assume that the initial utterance is always given by users. Also, their datasets are designed to be used to train models of multi-turn conversations about the given documents, rather than models of conversation initiation. For example, Moghe et al. (2018) utilized fixed templates to initiate conversations, and there are only a few (around 4k) utterances that can be used to train the model of conversation initiation in Zhou's dataset (2018).

In contrast, we focus on the conversation initiation task, which those studies have largely overlooked, and develop a large-scale dataset that includes 109,460 utterances for this task (see Section 3). Therefore, our work can be considered complementary to the previous studies.

In an approach that uses images rather than documents, (Mostafazadeh et al., 2016) proposed a method of generating questions about an image to initiate conversation. Although, like us, they explored initiating conversation, they focused only on generating questions. In contrast, we investigate generating other types of initial utterances than questions. Also, they investigated a task setting in which users can see the images along with the conversation, while we do not present the news posts to users. This difference makes our generation task a bit more complicated (see Section 3).

2.3 Proactive Conversation System

Some studies have attempted to make conversation systems more proactive rather than passively waiting for utterances from a user. (Li et al., 2016c) proposed a system that detects a stalemate in the conversation and then proactively casts a specific response for breaking the stalemate. They use the history of the user's utterances to select response candidates. (Yan et al., 2017; Yan and Zhao, 2018) proposed a method of proactively suggesting the user's next utterance. Although these methods have been successfully used in proactive conversation systems, the conversation initiation has not been investigated.

2.4 Diverse Response Generation

A well-known problem of encoder-decoder-based conversational models is that they tend to generate generic responses such as "*I don't know*" (Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016). Such responses understandably bore users, so there has been much research focus on generating more diverse responses (Li et al., 2016a; Xu et al., 2018; Baheti et al., 2018).

We explore the problem of generating diverse initial utterances from a different perspective than other studies. In our problem setting, it is not obvious how to go beyond simple template-based systems, which cannot generate diverse utterances. We address this problem by generating initial utterances based on news posts, which feature various content and are updated every day.

This study is complementary to previous attempts at diversification. Our method exploits existing neural conversation models, which tend to generate generic responses, as a component. The previous diversification methods can be used to improve the initial utterances in our method.

2.5 Other Related Work

Question Answering (QA) tasks have long been studied in the research community (Rajpurkar et al., 2016, 2018). In recent years, conversational variants of this task such as visual QA (Antol et al., 2015; Das et al., 2017) and conversational QA (Reddy et al., 2018) have been proposed. All of these tasks differ from our conversation initiation task since they focus on how to respond to questions.

(Yoshino and Kawahara, 2014) proposed an information navigation system that presents users with the contents of news articles through conversation. Although this setting is similar to ours, their system always opens conversation by just presenting the news headline. Our study investigates initiating conversation in a more chatty way, and should contribute to making the systems more conversational and attractive.

(Qin et al., 2018) proposed the task of generating comments about given news articles. Although this task is similar to ours, it is not designed to converse with users. Our task focuses on conversation and tries to generate initial utterances using news articles (posts).

3 Conversation Initiation Dataset

In this section, we explain how we constructed the dataset for the task of conversation initiation. We then analyze the constructed dataset to provide insights into its effectiveness.

3.1 Data Construction

We first collected 104,960 Japanese news posts from the Twitter account @YahooNewsTopics,[2] which delivers the latest news in the world every day. The data were collected between December 31, 2013 and October 31, 2017. Some example posts collected from this account are listed in the third column of Table 1.[3]

We investigate the task setting in which the system opens a conversation about a given news post. Here, we presume the post is not presented to the user during the conversation. Although letting users see the news posts would be possible, such a setting is not investigated here because our focus is a situation where users converse with the system only by voice. Such situations are growing more popular in recent years with the rise of voice-controlled conversation systems such as intelligent assistants (*e.g.,* Siri, Alexa, and Cortana) (Jiang et al., 2015; Sano et al., 2016; Akasaki and Kaji, 2017) and smart speakers (*e.g.,* Amazon Echo and Google Home).

Therefore, in our task setting, since the user does not always know about the news, it is preferred to first introduce the news summary so as to share the background knowledge before starting the conversation (see Fig. 1). In this sense, our task can be understood as a combination of summarization and chit-chat. Interestingly, the summarization subtask goes beyond the ordinary one in that we not only compress the content but also generate the text in a chit-chat-like style.

[3] Original news posts were written in Japanese. We have translated them for clarity.

dialogue acts	# examples	news posts (translated)	initial utterances (translated)
IMPRESSION	7,929	Yu Abiru announces her marriage on a broadcast. Her affiliation office and partner also commented.	It seems that Yu Abiru announced her marriage on a broadcast. *Congrats!*
		Major beer companies will increase beer production by about 10% this summer compared to the same period last year. Managerial resources have been shifted from other products due to a hot summer and tax cuts.	I heard that major beer companies are planning to increase beer production by about 10% this summer compared to last summer. *It makes me want to drink a cold beer on a hot day.*
URGING	273	The Korean Defense Department revealed that the North Korean army launched several ”short-range projectiles” toward the Sea of Japan on the morning of the 3rd.	North Korean forces launched missiles toward the Sea of Japan. *Let's evacuate quickly!*
		Severe damage to the mind and body due to abuse cannot be healed easily. We followed the cases of women who suffered abuse as children.	Wounds by abuse are stored deeply in the body and mind. *Let's do something to help if child abuse is happening around you.*
QUESTION	1,028	Players of the national men's handball team smoked in a non-smoking area while staying at Ajinomoto national training center. They received an indefinite ban from JOC.	The national men's handball team players smoked in a non-smoking area and were expelled, I heard. *Have you ever seen a handball game?*
		An infant was caught between a bed guard and a mattress and subsequently died. In the US, 13 children were killed in the past 11 years due to such accidents. Japan Pediatric Society has called attention to this.	There seems to have been an accident caused by an infant's bed guard. *Do you think that bed guards are necessary?*

Table 1: Distribution over sampled dialogue acts and example initial utterances. *Italics* are chit-chat parts.

	# word	# sent.	vocab. size
News post	33.85	1.96	54,830
Initial utterance	31.50	2.03	49,211
*Summary part	22.27	1.00	45,850
*Chit-chat part	9.23	1.03	19,520

Table 2: Statistics of the dataset. First and second columns show the average numbers per utterance.

To construct the dataset, we had cloud workers create the initial utterance of a conversation on the basis of a given news post. We instructed workers to not only chat about the news post but also to provide its brief summary. The workers were asked to use colloquial expressions because users feel strange when spoken to in literary expressions. We obtained a total of 104,960 pairs of news post and initial utterance[4]. Note that we created only the initial utterances (same as (Mostafazadeh et al., 2016)) because our focus is how to initiate conversation[5].

3.2 Data Analysis

Here we discuss our investigation of the 104,960 initial utterances. Some examples of the utterances are listed in Table 1. Most initial utterances first summarize the contents of the news post and then begin to chat about it, as we instructed. For subsequent analysis and model designing, we divided each initial utterance into sentences and then designated the one with the smallest edit distance from the input news post as “summary part” and the rest as “chit-chat parts”. The rationale behind the use of this heuristic is that the summary part shares more words with the original news post than the chit-chat part and consists of just one sentence in most cases. The statistics of the dataset are shown in Table 2.

For the summary part, as seen in Tables 1 and 2, original news posts are compressed by 32.29% on average and are converted into a colloquial style. This indicates that the recruited cloud workers properly extracted the important contents from the input news posts and used them for making the summary part.

Compared with the summary part, the number of words and vocabulary size for the chit-chat part are relatively small (Table 2). This is a natural phenomenon since the summary part uses more con-

---

[4] Some news posts (typically emergency news such as earthquake) were posted more than once, and as the consequence the dataset includes 102,844 unique news posts. In the experiment, we took care so that the training and test datasets do not include the same news posts.

[5] Of course it is necessary to continue successive conversation in an actual application, but we here leave this setting as a future work.

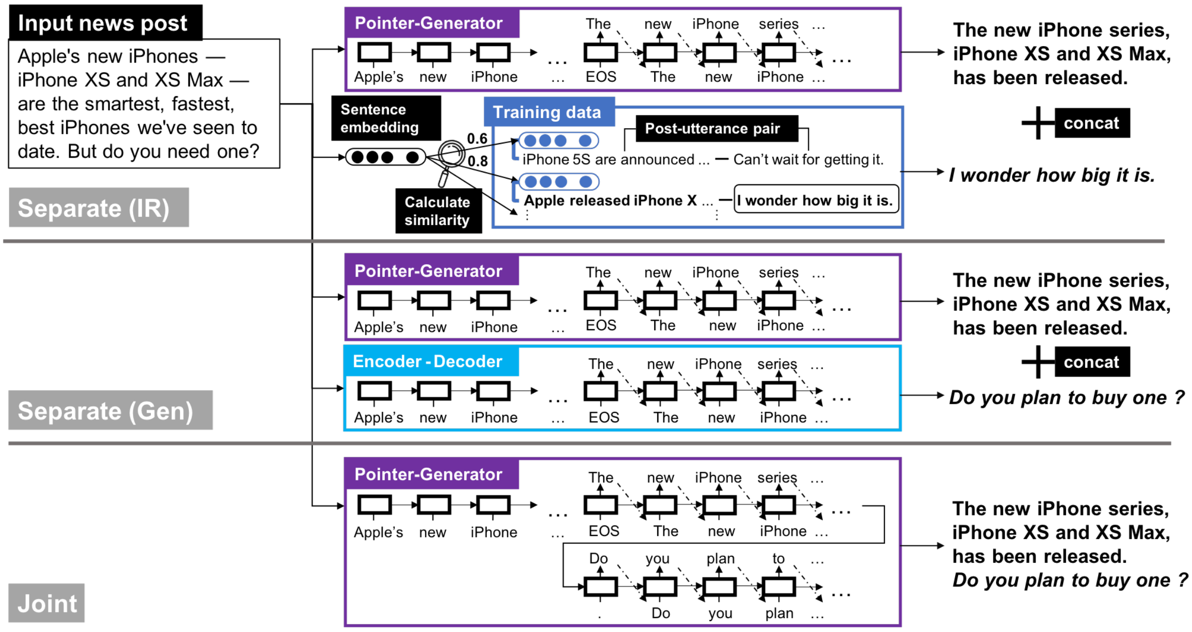

Figure 2: Overview of initial utterance generation by our proposed approaches. *Italics* are chit-chat parts.

tent words for summarization than the chit-chat part. To clarify how workers created these chit-chats, we randomly sampled 10,000 utterances and manually classified them according to their dialogue acts, as shown in Table 1. We found that the majority (92% = (7929 + 273 + 1082) / 10000) are classified into three dialogue acts (IMPRESSION, URGING, and QUESTION). The remaining 8% miscellaneous utterances that do not belong to any of the three dialog acts.

Most of the labeled initial utterances are the impressions and opinions of cloud workers about news posts (see the IMPRESSION act). Some of them are boilerplates (*e.g., "Congrats"*) while others show tremendous diversity (*e.g., "It makes me want to drink a cold beer on a hot day"*). It is interesting that some workers make an urging (*e.g., "Let's evacuate quickly"*) or ask a question (*e.g., "Have you ever seen a handball game?"*). These acts that attempt to solicit the user's response are important elements for conversation initiation.

4 Generation Method

As described in Section 2, most of the initial utterances in the dataset can be divided into a summary part and a chit-chat part. Because it is possible to generate these two parts by two separate models or by a single joint model, we investigate both approaches and compare their performance in an experiment. The overview of our proposed approaches is given in Fig. 2.

4.1 Separate Approach

The separate approach utilizes two different models to generate the summary part and the chit-chat part, respectively.

The summary part is generated by the pointer-generator model, which allows both copying words by pointing to the input sentence and generating words from a fixed vocabulary (See et al., 2017). This model is suitable for generating the summary part because it can appropriately select the contents of the input sentence while compressing them to a proper length.

To generate the chit-chat part, both generation-based and information retrieval (IR)-based methods are investigated. We use a common encoder-decoder model (Vinyals and Le, 2015) as the generation-based method (see **Separate (Gen)** in Fig. 2). Since this model tends to generate generic sentences that lack diversity (Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016), we also adopt the MMI-antiLM method proposed by (Li et al., 2016a) to promote diversity. This method uses the following score function, instead of the commonly used log-likelihood, when decoding:

$$\log P(T|S) - \lambda \log U(T), \qquad (1)$$

where T is an initial utterance and S is a news post. $P(T|S)$ is the conditional likelihood of T

given S, and U is a language model. In decoding, output candidates are generated using beam search and are then reranked by Eq. 1. This model penalizes generic sentences by $U(T)$.

As the IR-based method, we utilize the embedding of an input news post to retrieve the closest news posts in the training data using cosine distance, and then extract the corresponding chit-chat part (Ritter et al., 2011) (see **Separate (IR)** in Fig. 2). We adopt Smooth Inverse Frequency (SIF)-based embedding (Arora et al., 2017) for inducing news post embeddings. This method first calculates a weighted average of word embeddings in a news post s as:

$$v_s = \frac{1}{|s|} \sum_{w \in s} \frac{a}{a + P(w)} v_w, \qquad (2)$$

where a is a hyperparameter and $P(w)$ is the unigram probability calculated from the training data. Then, it reduces the influence of the first principal component by using the first singular vector u of the word vector matrix:

$$v_s = v_s - uu^{\mathrm{T}} v_s, \qquad (3)$$

This method has demonstrated a competitive performance across various tasks (Arora et al., 2017).

4.2 Joint Approach

We concatenate the summary part and the chit-chat part of the training data and train only one pointer-generator model, as mentioned in Section 4.1 (see **Joint** in Fig. 2).

Unlike the separate approach, this method can be considered multi-task learning of the summary and the chit-chat part generation. Thus, we expect it can generate the initial utterance precisely by considering the coherence between the summary and the chit-chat part. We examine the effectiveness of this approach through experiments in the following section.

5 Experiments

We empirically evaluate the performance of the proposed methods on the constructed dataset.

5.1 Models

In addition to the proposed methods, we implemented baselines that do not use labor-intensive labeled data, since carefully preparing the dataset is one of our contributions. These baselines generate summary and chit-chat parts separately in the following way and concatenate them as output.

RNN type	Bi-LSTM
Layers	2
Hidden layer dim.	512
Embedding dim.	256
Dropout rate	0.2
Parameter init.	(-0.08, 0.08) (uniform)
Vocabulary size	50,000
Batch size	64
Epochs	30
Max. grad. norm.	1
Optimization	Adam
Learning rate	0.001
Beam size	5
λ (MMI)	0.3
γ (MMI)	0.15

Table 3: Hyperparameter settings for training encoder-decoder models.

We gathered tweets (news posts) of major news accounts from Twitter and their corresponding replies (regarded as chit-chats). Those tweet-reply pairs can be used as pseudo training data to generate the chit-chat part. Since we cannot automatically acquire training data for generating the summary part, we output the first sentence of the input news post as the summary part.

Overall, the following proposed and baseline methods were implemented for comparison:

Baseline Generate the summary part and the chit-chat part by separate models using the pseudo-training data collected from Twitter. There are three variants of this method for generating the chit-chat part. **Baseline (IR)** and **Baseline (Gen)** use the IR-based method and the generation-based method, respectively. **Baseline (Gen+MMI)** uses MMI-antiLM (Li et al., 2016a) for decoding.

Separate Generate the summary part and the chit-chat part separately using the approach described in Section 4.1 and the dataset described in Section 3.1. There are also three variants of this method, same as the baselines (**Separate (IR)**, **Separate (Gen),** and **Separate (Gen+MMI),** respectively).

Joint Generate the summary part and the chit-chat part jointly using the approach described

Model	R-1	R-2	R-L	D-1	D-2	D-S
Baseline	**70.2**	**59.1**	**67.5**	**17.7**	**60.1**	**99.8**
Separate	66.5	50.6	63.8	15.7	52.4	**99.8**
Joint	68.8	54.1	66.3	15.2	51.8	**99.8**

Table 4: Results of summary part generation.

Model	BLEU	D-1	D-2	D-S
Baseline (IR)	0.2	**21.8**	**65.0**	**90.3**
Baseline (Gen)	0.2	1.2	3.4	2.8
Baseline (Gen+MMI)	0.2	1.1	3.1	3.7
Separate (IR)	3.5	12.6	34.9	65.2
Separate (Gen)	6.3	1.5	2.9	3.2
Separate (Gen+MMI)	**9.6**	2.2	5.6	13.4
Joint	6.4	6.7	15.8	28.5

Table 5: Results of chit-chat part generation.

in Section 4.2 and the dataset described in Section 3.1.

5.2 Experimental Settings

We divided the 104,960 items of data (news post and initial utterance pairs) into 90,000, 10,000, and 4,960 for training data, development data, and test data, respectively. Input news posts that appear in the training data were removed from the test data. Consequently, 4,776 data were used as the final test data.

To train the baseline model, we collected 277,813 tweets and their corresponding replies from six major Japanese news accounts[6] on Twitter. We then divided those pairs into 260,000 and 17,813 for training data and development data for the baselines.

We performed tokenization using a Japanese morphological analyzer, MeCab,[7] with IPAdic dictionary,[8] and then removed usernames, URLs, and hashtags. We used OpenNMT-py (Klein et al., 2017)[9] for building the models described in Section 4. Their hyperparameter settings are given in Table 3. We used GloVe (Pennington et al., 2014)[10] to learn 300-dimensional word embeddings. We trained word embedding using a Japanese Wikipedia dump released on February 22nd, 2018. These embeddings were used for acquiring news post embeddings, as described in Section 4.1.

5.3 Automatic Evaluation

As discussed in Section 3.2, since the initial utterance can be divided into separate parts that have different properties, we evaluated each part separately to examine the generated initial utterances.

We automatically divided the generated sentences and reference sentences into summary parts and chit-chat parts, as explained in Section 3.2. We used ROUGE-1, ROUGE-2, and ROUGE-L (Lin, 2004) for evaluating the summary part (denoted as **R-1**, **R-2**, and **R-L**, respectively) and BLEU (Papineni et al., 2002) for evaluating the chit-chat part. We use different metrics for each part because ROUGE is often used for summarization tasks while BLEU is used for conversational tasks. Since these automatic metrics are insufficient for evaluation (Novikova et al., 2017), we also perform a manual evaluation in Section 5.4.

To evaluate diversity, we calculate the proportion of distinct unigrams, bigrams, and sentences (**D-1**, **D-2**, and **D-S**, respectively) in the generated initial utterances (Li et al., 2016a).

Table 4 lists the results of the summary part. The baseline method that outputs the first sentence of an input news post achieved higher ROUGE scores than the proposed methods. This does not necessarily mean that the proposed methods are poor because even the SOTA summarization system exceeds such a baseline by only a small margin (See et al., 2017). Also, our task has a requirement to convert sentences into colloquial expressions, and the ROUGE metric cannot capture such a subtle difference. We perform a deeper investigation into the quality of the generated initial utterance in the next section. Regarding the diversity, almost all of the generated initial utterances are distinct, as shown in Table 4.

Table 5 shows the result of the chit-chat part. The proposed methods outperformed the baselines in terms of BLEU score. Although the baselines use two times as much training data as the proposed methods, their scores were quite low. This demonstrates the quality of our dataset. The score of **Separate (IR)** was relatively low among the proposed methods, presumably because the chit-chat parts retrieved from the training data do not always match the content of the input news post.

Table 6: Results of evaluating **Naturalness** and **Coherency** of the generated utterances by the manual evaluation (higer is better).

Model	Dullness
Human	2.18
Boilerplate	3.06
Separate (IR)	2.47
Separate (Gen+MMI)	2.39
Joint	**2.36**

Table 7: Results of evaluating **Dullness** of the generated utterances by the manual evaluation (lower is better). Boilerplate uses manually created boilerplate utterances.

We also see that all the BLEU scores of the models are quite lower than ROUGE scores in Table 4. In general, both summarization and chat generation tasks often use automatic evaluation metrics to evaluate generated sentences, their scores tend to be much lower in the chat generation task. This is because the answer sentences (utterances) of the chat generation task have more diverse candidates than other generation tasks such as machine translation and summarization (Li et al., 2016a,b; Baheti et al., 2018). We also examine the diversity of the chit-chat part in Table 5. Although the diversity of the IR-based methods was high, their BLEU scores deteriorated considerably. Among the generation-based methods, although **Separate (Gen+MMI)** achieved the highest BLEU score, it lacked diversity. In contrast, **Joint** achieved a reasonable BLEU score while maintaining diversity to some extent.

5.4 Manual Evaluation

Although diversity of utterances can be quantified automatically, ROUGE and BLEU scores do not always follow human intuition (Novikova et al., 2017; Lowe et al., 2017). Therefore, we evaluate the generated initial utterances manually. We picked the three proposed models with good performance in the automatic evaluation along with one baseline for this manual evaluation. 300 posts were sampled as the input news posts, and the outputs of the four methods were manually evaluated from two perspectives: 1) **Naturalness**: *Does the utterance naturally initiate conversation?* and 2) **Coherency**: *Is the content of the utterance coherent with the given news post?* We recruited crowd workers to score each utterance on a 4-point scale (Agree, Slightly Agree, Slightly Disagree, Disagree).

Table 6 show the results of the manual evaluation for **Naturalness** and **Coherency** of the generated initial utterances. The proposed methods excluding **Separate (IR)** outperformed **Baseline (Gen+MMI)** in both perspectives and achieved reasonable scores compared to human upperbound. The scores of **Separate (IR)** are quite low because the retrieval result does not follow the input news post in many cases. This reveals that although those sentences have high diversity, their quality is poor as initial utterances. Although **Baseline (Gen+MMI)** achieved high ROUGE scores in Table 4, its style is not colloquial. Thus, workers felt odd and lowered their scores. In conclusion, it is better to use the generation-based methods for conversation initiation.

We also evaluated **Dullness**: *Is the given utterance dull or boring?* We used 15 manually created boilerplate utterances (*e.g.,* Hello., How are you?, Let's talk with me.) rather than **Baseline (Gen+MMI)** to confirm the effectiveness of utilizing news contents as the initial utterances. Table 7 show the results of the manual evaluation for **Dullness** of the generated initial utterances. We see that compared to our proposed methods, the score of the boilerplate baseline is quite high. This indicates that using boilerplate utterances for conversation initiation often bores users and possibly leads to early abandonment of the conversation.

To determine the statistical significance of our results, we performed Wilcoxon signed-rank tests with Bonferroni correction (Wilcoxon, 1945). In Table 6, for all combinations except **Baseline (Gen+MMI)** vs. **Separate (IR)** and **Separate (Gen+MMI)** vs. **Joint**, there were significant differences (p-value < 0.005 (corrected)) in both perspectives. Similarly, in Table 7, there were statistically significant differences for all combinations except **Separate (IR)** vs. **Separate (Gen+MMI)** and **Separate (Gen+MMI)** vs. **Joint**.

5.5 Examples

Finally, we investigated the initial utterances generated by **Separate (Gen+MMI)** and **Joint**. Ex-

news posts	initial utterances
A parade for the Rio Olympics and Paralympic medalists will be held in October. Approximately 500,000 people gathered at the time of the London Olympics.	**Separate (Gen+MMI):** I heard that a parade for the Rio Olympics and Paralympic medalists will be held in October. *That's amazing.*
	Joint: I heard that a parade for the Rio Olympics and Paralympic medalists will be held in October. *I would like to see what parade it is.*
A Chinese captain who was poaching a coral in the offshore of Kagoshima was arrested. The number of poaching boats has sharply declined in Ogasawara.	**Separate (Gen+MMI):** I heard that the coral was arrested in Kagoshima prefecture offshore because of poaching. *Get it together.*
	Joint: I heard that a Chinese captain who poached a coral in the offshore of Kagoshima was arrested. *Do not do poaching!*
On a suicide bombing that happened at a concert in England, the homeless action around the scene attracted praise. The UK raised the terrorist threat level to the "highest."	**Separate (Gen+MMI):** I heard that the homeless action around the scene of a suicide bombing that happened in England was praised. *That's scary.*
	Joint: I heard that the homeless action on a suicide bombing in England was praised. *Do you take measures against terrorism?*
The Meteorological Agency announced that Typhoon 11 will approach Tohoku in the early morning of 21st. Typhoon 9 is expected to approach Tokai on 21st and Typhoon 10 will approach Tokai or Kanto.	**Separate (Gen+MMI):** It seems that Typhoon 11 will approach Tohoku on 21st. *Let's watch out!*
	Joint: I heard that The Meteorological Agency announced that Typhoon 11 will approach Tohoku in the early morning of 21st. *We should pay attention to the future movement.*

Table 8: Examples of generated initial utterances. *Italics* are chit-chat parts.

amples of these utterances are provided in Table 8.

We found that **Separate (Gen+MMI)** tended to generate generic utterances (*e.g., "That's amazing", "Get it together"*) as the chit-chat part that fit any context, even though it uses a diversity-promoting function when decoding. In contrast, **Joint** could generate more diverse chit-chat parts by utilizing contents words such as *"parade"* and *"poaching"*. One possible reason for this phenomena is that the generated summary part acts like an additional condition of $P(T|S)$ at the time of decoding the chit-chat part. This does not happen with **Separate (Gen+MMI)**, which simply concatenates the outputs of separate models.

Interestingly, we found that there are some utterances giving a *question* (third example of **Joint** in Table 8) or making an *urging* (fourth example of **Separate (Gen+MMI)** in Table 8). Controlling utterances of the model by such dialogue acts (Wen et al., 2015; Zhao et al., 2017) can make the conversation initiation more diverse and attractive. We leave them as the future work at this time.

We should note that although it is a problem common to all the generation-models, there is a possibility of transmitting false news contents (as in the second example of **Separate (Gen+MMI)** in Table 8) or ethically inappropriate contents to the users. Therefore, when adopting our method into an actual conversation application, we have to pay close attention to this problem.

6 Conclusion

In this paper, we proposed the new task of conversation initiation. To generate diverse initial utterances that can improve user engagement, we utilized news articles that provide fresh and varied information every day and constructed a large-scale dataset using crowd workers. To perform the conversation initiation, we designed separate and joint approaches including both IR-based and generation-based methods. Empirical experiments showed that the proposed methods outperformed the baselines in both automatic and manual evaluation, and can generate diverse initial utterances that template-based methods cannot make. These results demonstrate the quality of our constructed dataset, that will be released for future studies[11].

As a natural next step, we plan to develop a more sophisticated conversation model, which can not only generate initial utterances but also continue the conversation for the given news contents (Yoshino and Kawahara, 2014). In that case, depending on the user's interest, the model needs to determine whether to do a usual chat or talk about the news contents. We also plan to improve the proposed method so that it can generate even better initial utterances. Since our task has two elements, summarization and chit-chat, the focus of our future work will be a more sophisticated multi-task model that considers these relations.

Positional Encoding to Control Output Sequence Length

Sho Takase   **Naoaki Okazaki**
Tokyo Institute of Technology

Abstract

Neural encoder-decoder models have been successful in natural language generation tasks. However, real applications of abstractive summarization must consider additional constraint that a generated summary should not exceed a desired length. In this paper, we propose a simple but effective extension of a sinusoidal positional encoding (Vaswani et al., 2017) to enable neural encoder-decoder model to preserves the length constraint. Unlike in previous studies where that learn embeddings representing each length, the proposed method can generate a text of any length even if the target length is not present in training data. The experimental results show that the proposed method can not only control the generation length but also improve the ROUGE scores.

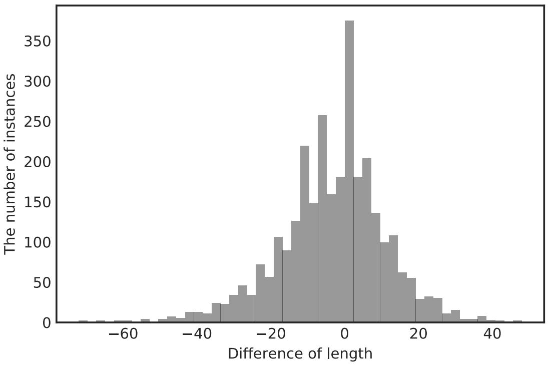

Figure 1: Difference in number of characters between correct headlines and outputs of a widely used LSTM encoder-decoder (Luong et al., 2015) which is trained on sentence-headline pairs created by Rush et al. (2015) from the annotated English Gigaword corpus. The difference was investigated for 3,000 sentence-headline pairs randomly sampled from the test splits.

1 Introduction

Neural encoder-decoder models have been successfully applied to various natural language generation tasks including machine translation (Sutskever et al., 2014), summarization (Rush et al., 2015), and caption generation (Vinyals et al., 2015). Still, it is necessary to control the output length for abstractive summarization, which generates a summary for a given text while satisfying a space constraint. In fact, Figure 1 shows a large variance in output sequences produced by a widely used encoder-decoder model (Luong et al., 2015), which has no mechanism for controlling the length of the output sequences.

Fan et al. (2018) trained embeddings that correspond to each output length to control the output sequence length. Since the embeddings for different lengths are independent, it is hard to generate a sequence of the length that is infrequent in training data. Thus, a method that can model any lengths continuously is required.

Kikuchi et al. (2016) proposed two learning based methods for an LSTM encoder-decoder: LenEmb and LenInit. LenEmb inputs an embedding representing the remaining length in each decoding step. Since this approach also prepares embeddings for each length independently, it suffers from the same problem as that in Fan et al. (2018).

On the other hand, LenInit can handle arbitrary lengths because it combines the scalar value of a desired length with a trainable embedding. LenInit initializes the LSTM cell of the decoder with the embedding depending on the scalar value of the desired length. Liu et al. (2018) incorporated such scalar values into the initial state of the decoder in a CNN encoder-decoder. These approaches deal with any length but it is reasonable to incorporate the distance to the desired terminal position into each decoding step such as in LenEmb.

In this study, we focused on Transformer (Vaswani et al., 2017), which recently achieved the state-of-the-art score on the machine

Proceedings of NAACL-HLT 2019, pages 3999–4004
Minneapolis, Minnesota, June 2 - June 7, 2019.

translation task. We extend the sinusoidal positional encoding, which represents a position of each token in Transformer (Vaswani et al., 2017), to represent a distance from a terminal position on the decoder side. In this way, the proposed method considers the remaining length explicitly at each decoding step. Moreover, the proposed method can handle any desired length regardless of its appearance in a training corpus because it uses the same continuous space for any length.

We conduct experiments on the headline generation task. The experimental results show that our proposed method is able to not only control the output length but also improve the ROUGE scores from the baselines. Our code and constructed test data are publicly available at: https://github.com/takase/control-length.

2 Positional Encoding

Transformer (Vaswani et al., 2017) uses a sinusoidal positional encoding to represent the position of an input. Transformer feeds the sum of the positional encoding and token embedding to the input layer of its encoder and decoder. Let pos be the position and d be the embedding size. Then, the i-th dimension of the sinusoidal positional encoding $PE_{(pos,i)}$ is as follows:

$$PE_{(pos,2i)} = \sin\left(\frac{pos}{10000^{\frac{2i}{d}}}\right), \quad (1)$$

$$PE_{(pos,2i+1)} = \cos\left(\frac{pos}{10000^{\frac{2i}{d}}}\right). \quad (2)$$

In short, each dimension of the positional encoding corresponds to a sinusoid whose period is $10000^{2i/d} \times 2\pi$. Since this function returns an identical value at the same position pos, the above positional encoding can be interpreted as representing the absolute position of each input token.

In this paper, we extend Equations (1) and (2) to depend on the given output length and the distance from the terminal position. We propose two extensions: length-difference positional encoding ($LDPE$) and length-ratio positional encoding ($LRPE$). Then we replace Equations (1) and (2) with (3) and (4) (or (5) and (6)) on the decoder side to control the output sequence length. We define $LDPE$ and $LRPE$ as follows:

$$LDPE_{(pos,len,2i)} = \sin\left(\frac{len - pos}{10000^{\frac{2i}{d}}}\right), \quad (3)$$

$$LDPE_{(pos,len,2i+1)} = \cos\left(\frac{len - pos}{10000^{\frac{2i}{d}}}\right), \quad (4)$$

$$LRPE_{(pos,len,2i)} = \sin\left(\frac{pos}{len^{\frac{2i}{d}}}\right), \quad (5)$$

$$LRPE_{(pos,len,2i+1)} = \cos\left(\frac{pos}{len^{\frac{2i}{d}}}\right), \quad (6)$$

where len presents the given length constraint. $LDPE$ returns an identical value at the position where the remaining length to the terminal position is the same. $LRPE$ returns a similar value at the positions where the ratio of the remaining length to the terminal position is similar. Let us consider the d-th dimension as the simplest example. Since we obtain $\sin(pos/len)$ (or $\cos(pos/len)$) at this dimension, the equations yield the same value when the remaining length ratio is the same, e.g., $pos = 5$, $len = 10$ and $pos = 10$, $len = 20$.

We add $LDPE$ (or $LRPE$) to the input layer of Transformer in the same manner as in Vaswani et al. (2017). In the training step, we assign the length of the correct output to len. In the test phase, we control the output length by assigning the desired length to len.

3 Experiments

3.1 Datasets

We conduct experiments on the headline generation task on Japanese and English datasets. The purpose of the experiments is to evaluate the ability of the proposed method to generate a summary of good quality within a specified length. We used JAMUL corpus as the Japanese test set (Hitomi et al., 2019). This test set contains three kinds of headlines for 1,181[1] news articles written by professional editors under the different upper bounds of headline lengths. The upper bounds are 10, 13, and 26 characters ($len = 10, 13, 26$). This test set is suitable for simulating the real process of news production because it is constructed by a Japanese media company.

In contrast, we have no English test sets that contain headlines of multiple lengths. Thus, we randomly extracted 3,000 sentence-headline

---

[1] We obtained this test set by applying the pre-processing script at https://github.com/asahi-research/Gingo to the original JAMUL corpus.

pairs that satisfy a length constraint from the test set constructed from annotated English Gigaword (Napoles et al., 2012) by pre-processing scripts of Rush et al. (2015)[2]. We set three configurations for the number of characters as the length constraint: 0 to 30 characters ($len = 30$), 30 to 50 characters ($len = 50$), and 50 to 75 characters ($len = 75$). Moreover, we also evaluate the proposed method on the DUC-2004 task 1 (Over et al., 2007) for comparison with published scores in previous studies.

Unfortunately, we have no large supervision data with multiple headlines of different lengths associated with each news article in both languages. Thus, we trained the proposed method on pairs with a one-to-one correspondences between the source articles and headlines. In the training step, we regarded the length of the target headline as the desired length len. For Japanese, we used the JNC corpus, which contains a pair of the lead three sentences of a news article and its headline (Hitomi et al., 2019). The training set contains about 1.6M pairs[3]. For English, we used sentence-headline pairs extracted from the annotated English Gigaword with the same pre-processing script used in the construction of the test set. The training set contains about 3.8M pairs.

In this paper, we used a character-level decoder to control the number of characters. On the encoder side, we used subword units to construct the vocabulary (Sennrich et al., 2016; Kudo, 2018). We set the hyper-parameter to fit the vocabulary size to about 8k for Japanese and 16k for English.

3.2 Baselines

We implemented two methods proposed by previous studies to control the output length and handle arbitrary lengths. We employed them and Transformer as baselines.

LenInit Kikuchi et al. (2016) proposed LenInit, which controls the output length by initializing the LSTM cell m of the decoder as follows:

$$m = len \times b, \tag{7}$$

where b is a trainable vector. We incorporated this method with a widely used LSTM encoder-decoder model (Luong et al., 2015)[4]. For a fair comparison, we set the same hyper-parameters as in Takase et al. (2018) because they indicated that the LSTM encoder-decoder model trained with the hyper-parameters achieved a similar performance to the state-of-the-art on the headline generation.

Length Control (LC) Liu et al. (2018) proposed a length control method that multiplies the desired length by input token embeddings. We trained the model with their hyper-parameters.

Transformer Our proposed method is based on Transformer (Vaswani et al., 2017)[5]. We trained Transformer with the equal hyper-parameters as in the base model in Vaswani et al. (2017).

3.3 Results

Table 1 shows the recall-oriented ROUGE-1 (R-1), 2 (R-2), and L (R-L) scores of each method on the Japanese test set[6]. This table indicates that Transformer with the proposed method (Transformer+$LDPE$ and Transformer+$LRPE$) outperformed the baselines for all given constraints ($len = 10, 13, 26$). Transformer+$LRPE$ performed slightly better than Transformer+$LDPE$. Moreover, we improved the performance by incorporating the standard sinusoidal positional encoding (+PE) on $len = 10$ and 26. The results imply that the absolute position also helps to generate better headlines while controlling the output length.

Table 2 shows the recall-oriented ROUGE scores on the English Gigaword test set. This table indicates that $LDPE$ and $LRPE$ significantly improved the performance on $len = 75$. Moreover, the absolute position (PE) also improved the performance in this test set. In particular, PE was very effective in the setting of very short headlines ($len = 30$). However, the proposed method slightly lowered ROUGE-2 scores from the bare Transformer on $len = 30, 50$. We infer that the bare Transformer can generate headlines whose lengths are close to 30 and 50 because the majority of the training set consists of headlines whose lengths are less than or equal to 50. However, most of the generated headlines breached the length constraints, as explained in Section 3.4.

To investigate whether the proposed method can generate good headlines for unseen lengths, we excluded headlines whose lengths are equal to the

desired length (len) from the training data. The lower parts of Table 1 and 2 show ROUGE scores of the proposed method trained on the modified training data. These parts show that the proposed method achieved comparable scores to ones trained on whole training dataset. These results indicate that the proposed method can generate high-quality headlines even if the length does not appear in the training data.

Table 3 shows the recall-oriented ROUGE scores on the DUC-2004 test set. Following the evaluation protocol (Over et al., 2007), we truncated characters over 75 bytes. The table indicates that $LDPE$ and $LRPE$ significantly improved the performance compared to the bare Transformer, and achieved better performance than the baselines except for R-2 of LenInit. This table also shows the scores reported in the previous studies. The proposed method outperformed the previous methods that control the output length and achieved the competitive score to the state-of-the-art scores.

Since the proposed method consists of a character-based decoder, it sometimes generated

Table 4: Variances of generated headlines.

words unrelated to a source sentence. Thus, we applied a simple re-ranking to each n-best headlines generated by the proposed method ($n = 20$ in this experiment) based on the contained words. Our re-ranking strategy selects a headline that contains source-side words the most. Table 3 shows that Transformer+$LRPE$+PE with this re-ranking (+Re-ranking) achieved better scores than the state-of-the-art (Suzuki and Nagata, 2017).

3.4 Analysis of Output Length

Following Liu et al. (2018), we used the variance of the generated summary lengths against the desired lengths as an indicator of the preciseness of the output lengths. We calculated variance (var) for n generated summaries as follows[7]:

$$var = \frac{1}{n}\sum_{i=1}^{n} |l_i - len|^2, \qquad (8)$$

where len is the desired length and l_i is the length of the generated summary.

Table 4 shows the values of Equation (8) computed for each method and the desired lengths. This table indicates that $LDPE$ could control the length of headlines precisely. In particular, $LDPE$ could generate headlines with the identical length to the desired one in comparison with LenInit and LC. $LRPE$ also generated headlines with a precise length but its variance is larger than those of previous studies in very short lengths, i.e., $len = 10$ and 13 in Japanese. However, we consider $LRPE$ is enough for real applications because the averaged difference between its output and the desired length is small, e.g., 0.1 for $len = 10$.

The lower part of Table 4 shows the variances of the proposed method trained on the modified training data that does not contain headlines whose lengths are equal to the desired length, similar to the lower parts of Table 1 and 2. The variances for this part are comparable to the ones obtained when we trained the proposed method with whole training dataset. This fact indicates that the proposed method can generate an output that satisfies the constraint of the desired length even if the training data does not contain instances of such a length.

4 Conclusion

In this paper, we proposed length-dependent positional encodings, $LDPE$ and $LRPE$, that can control the output sequence length in Transformer. The experimental results demonstrate that the proposed method can generate a headline with the desired length even if the desired length is not present in the training data. Moreover, the proposed method significantly improved the quality of headlines on the Japanese headline generation task while preserving the given length constraint. For English, the proposed method also generated headlines with the desired length precisely and achieved the top ROUGE scores on the DUC-2004 test set.

The Lower The Simpler: Simplifying Hierarchical Recurrent Models

Chao Wang and Hui Jiang

Abstract

To improve the training efficiency of hierarchical recurrent models without compromising their performance, we propose a strategy named as "the lower the simpler", which is to simplify the baseline models by making the lower layers simpler than the upper layers. We carry out this strategy to simplify two typical hierarchical recurrent models, namely Hierarchical Recurrent Encoder-Decoder (HRED) and R-NET, whose basic building block is GRU. Specifically, we propose Scalar Gated Unit (SGU), which is a simplified variant of GRU, and use it to replace the GRUs at the middle layers of HRED and R-NET. Besides, we also use Fixed-size Ordinally-Forgetting Encoding (FOFE), which is an efficient encoding method without any trainable parameter, to replace the GRUs at the bottom layers of HRED and R-NET. The experimental results show that the simplified HRED and the simplified R-NET contain significantly less trainable parameters, consume significantly less training time, and achieve slightly better performance than their baseline models.

1 Introduction

With the advance of various deep learning frameworks, neural network based models proposed for natural language understanding tasks are becoming increasingly complicated. To the best of our knowledge, a considerable part of these complicated models are both hierarchical and recurrent. For example, Hierarchical Recurrent Encoder-Decoder (HRED) (Sordoni et al., 2015; Serban et al., 2016), which is a conversational model, is constructed by stacking three layers of GRUs (Cho et al., 2014). Besides, several well-known Machine Reading Comprehension (MRC) models, such as R-NET (Wang et al., 2017) and Fusion-Net (Huang et al., 2017), are mainly composed of multiple layers of bidirectional GRUs (BiGRUs) or bidirectional LSTMs (BiLSTMs) (Hochreiter and Schmidhuber, 1997). The above hierarchical recurrent models have achieved excellent performance, but training them usually consumes a lot of time and memory, that is because their computational graphs contain a large amount of operators and trainable parameters, which makes their training computationally expensive.

According to Williams and Zipser (1995), in the training of recurrent neural networks, it is the backward propagation rather than the forward propagation that consumes the majority of the computational resources. Besides, considering the chain rule in the backward propagation, the complexity of computing gradients for a hierarchical recurrent model increases exponentially from the top layer of the model down to the bottom layer. Therefore, to improve the training efficiency of hierarchical recurrent models, our strategy is to **simplify the baseline models by making the lower layers simpler than the upper layers**, which we name as "**the lower the simpler**". Here "simpler" means containing less operators and trainable parameters. This strategy is guaranteed to work, since it can accelerate the computation of gradients, which is the substance of the backward propagation. However, there is still a big concern: once the baseline models are simplified, will their performance be compromised?

To address this concern, we carry out our proposed strategy to simplify two typical hierarchical recurrent models, namely HRED and R-NET, whose basic building block is GRU. Specifically, we propose Scalar Gated Unit (SGU), which is a simplified variant of GRU, and use it to replace the GRUs at the middle layers of HRED and R-NET. Besides, we also use Fixed-size Ordinally-Forgetting Encoding (FOFE) (Zhang et al., 2015), which is an efficient encoding method without any trainable parameter, to replace the GRUs at the bottom

Proceedings of NAACL-HLT 2019, pages 4005–4009
Minneapolis, Minnesota, June 2 - June 7, 2019.

layers of HRED and R-NET. In the experiments, we separately compare the simplified HRED and the simplified R-NET with their baseline models in terms of both the training efficiency and the performance. The experimental results show that the simplified models contain significantly less trainable parameters, consume significantly less training time, and achieve slightly better performance than their baseline models.

2 Baseline Models

2.1 Hierarchical Recurrent Encoder-Decoder

Hierarchical Recurrent Encoder-Decoder (HRED) is a conversational model for building end-to-end dialogue systems. Since a dialogue is a sequence of sentences, where each sentence is a sequence of words, HRED models this hierarchy with a hierarchical recurrent structure. Specifically, HRED consists of three layers of GRUs, which from bottom to top separately serve as the sentence-level encoder, the dialogue-level encoder, and the decoder. The sentence-level encoder GRU iteratively takes the embeddings of the words in a sentence to update its hidden state, thus its final hidden state is a representation of the sentence. The dialogue-level encoder GRU iteratively takes the representations of the sentences in a dialogue to update its hidden state, thus its hidden state at each time-step is a representation of the current dialogue. The decoder GRU takes the current dialogue representation to initialize its hidden state so as to generate a response sentence word by word.

2.2 R-NET

R-NET is an end-to-end MRC model that predicts an answer span for each given passage-question pair. Specifically, R-NET consists of five layers, which from bottom to top are separately the embedding layer, the encoding layer, the matching layer, the self-matching layer, and the output layer. The embedding layer maps the words to the word-level embeddings and the character-level embeddings. The character-level embeddings are generated by processing the character embeddings of the words with a BiGRU and concatenating the forward GRU final hidden states and the backward GRU final hidden states. The encoding layer processes the concatenation of the word-level embeddings and the character-level embeddings with another BiGRU and concatenates the forward GRU outputs and the backward GRU outputs so as to generate the context representations. The matching layer uses a gated attention-based BiGRU to fuse the context representations of the question into those of the passage so as to generate the question-aware passage representations. The self-matching layer uses another gated attention-based BiGRU to fuse the question-aware passage representations into themselves so as to generate the final passage representations. On this basis, the output layer uses a pointer network (Vinyals et al., 2015) to generate an answer span.

3 Model Simplification

3.1 Scalar Gated Unit

Just like LSTM, GRU is a recurrent structure that leverages gating mechanisms to capture long-term dependencies in sequential data:

$$\begin{aligned}
&\text{Update Gate: } z_t = \sigma(W_z[h_{t-1}, x_t]) \\
&\text{Reset Gate: } r_t = \sigma(W_r[h_{t-1}, x_t]) \\
&\text{New Memory: } \hat{h}_t = tanh(W_h[r_t \odot h_{t-1}, x_t]) \\
&\text{Hidden State: } h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \hat{h}_t
\end{aligned}$$

Researchers have proposed several simplified variants of GRU. For example, Zhou et al. (2016) proposed Minimal Gated Unit (MGU), which combines the update gate and the reset gate into a single forget gate. Compared with GRU, MGU contains less trainable parameters, consumes less training time, and achieves similar performance. However, in this paper, to better carry out our proposed "the lower the simpler" strategy, we propose Scalar Gated Unit (SGU), which is an even more simplified variant of GRU:

$$\begin{aligned}
&\text{Scalar Update Gate: } z_t = \sigma(w_z[h_{t-1}, x_t]) \\
&\text{Scalar Reset Gate: } r_t = \sigma(w_r[h_{t-1}, x_t]) \\
&\text{New Memory: } \hat{h}_t = tanh(W_h[r_t * h_{t-1}, x_t]) \\
&\text{Hidden State: } h_t = (1 - z_t) * h_{t-1} + z_t * \hat{h}_t
\end{aligned}$$

By comparing the formulation of SGU with that of GRU, it is easy to see that both the update gate z_t and the reset gate r_t change from the vectors in GRU to the scalars in SGU. Accordingly, the weights for generating the gates change from the matrices W_z and W_r in GRU to the vectors w_z and w_r in SGU. Besides, the gating operator also changes from the element-wise multiplication $\odot$ in GRU to the scalar multiplication $*$ in SGU. Therefore SGU is guaranteed to be the simplest among all the variants of GRU.

3.2 Fixed-size Ordinally-Forgetting Encoding

Fixed-size Ordinally-Forgetting Encoding (FOFE) is an encoding method that uses the following recurrent structure to map a varied-length word sequence to a fixed-size representation:

$$h_t = \begin{cases} 0, & \text{if } t = 0 \\ \alpha * h_{t-1} + x_t, & \text{otherwise} \end{cases}$$

where h_t is the hidden state at time step t, x_t is the embedding of the t-th word, and α $(0 < \alpha < 1)$ is the forgetting factor that decays the previous hidden state. Given a word sequence of length N, the final hidden state h_N is a fixed-size representation of the word sequence. Although formulated as a recurrent structure, FOFE can actually be implemented with an efficient matrix multiplication. Besides, the forgetting factor α is designed as a hyper-parameter so that FOFE contains no trainable parameter. Therefore FOFE is guaranteed to be the simplest among all the recurrent structures. As for the performance, according to Zhang et al. (2015), FOFE based language models outperform their LSTM based competitors.

3.3 Simplified Models

According to the above descriptions, SGU is simpler than GRU, and FOFE is simpler than SGU. Therefore, now we can carry out our proposed "the lower the simpler" strategy by using SGUs and FOFEs to replace certain GRUs in HRED and R-NET. For HRED, we keep the decoder GRU at the top layer unchanged, use a SGU to replace the dialogue-level encoder GRU at the middel layer, and use a FOFE to replace the sentence-level encoder GRU at the bottom layer. For R-NET, we keep the output layer, the self-matching layer, and the matching layer unchanged, use a bidirectional SGU (BiSGU) to replace the BiGRU that generates context representations at the encoding layer, and use a bidirectional FOFE (BiFOFE, i.e., running FOFE both forward and backward) to replace the BiGRU that generates character-level embeddings at the embedding layer. After conducting the above replacements, we finally obtain a simplified HRED and a simplified R-NET.

4 Experiments

4.1 Experimental Datasets

Dialogue Datasets. We compare the simplified HRED with the baseline HRED on two dialogue datasets, namely MovieTriples (Serban et al., 2016) and Ubuntu (Lowe et al., 2017). MovieTriples contains over $240,000$ dialogues collected from various movie scripts, with each dialogue consisting of three sentences. Ubuntu contains over $490,000$ dialogues collected from the Ubuntu chat-logs, with each dialogue consisting of seven sentences on average. Both MovieTriples and Ubuntu have been randomly partitioned into three parts: a training set (80%), a development set (10%), and a test set (10%).

MRC Dataset. We compare the simplified R-NET with the baseline R-NET on an MRC dataset, namely SQuAD (Rajpurkar et al., 2016). SQuAD contains over $100,000$ passage-question pairs with human-generated answer spans, where the passages are collected from Wikipedia, and the answer to each question is guaranteed to be a fragment in the corresponding passage. Besides, SQuAD has also been randomly partitioned into three parts: a training set (80%), a development set (10%), and a test set (10%). Both the training set and the development set are publicly available, but the test set is confidential.

4.2 Implementation Details

HRED. We implement both the simplified HRED and the baseline HRED with TensorFlow (Abadi et al., 2016). For the word embeddings, we set their size to 200, 400, and 600 on MovieTriples and 600 on Ubuntu, initialize them randomly, and update them during the training. For the forgetting factor α of FOFE, we set it to 0.9 on both MovieTriples and Ubuntu. For the hidden state size of the sentence-level encoder GRU, we set it to 200, 400, and 600 on MovieTriples and 600 on Ubuntu. For the hidden state size of the dialogue-level encoder GRU and SGU, we set it to 1200 on both MovieTriples and Ubuntu. For the hidden state size of the decoder GRU, we set it to 200, 400, and 600 on MovieTriples and 600 on Ubuntu. For model optimization, we apply the Adam (Kingma and Ba, 2014) optimizer with a learning rate of 0.0001 and a mini-batch size of 32. For performance evaluation, we use both perplexity and error rate as evaluation metrics.

R-NET. We implement both the simplified R-NET and the baseline R-NET with TensorFlow. For the word-level embeddings, we initialize them with the 300-dimensional pre-trained GloVe (Pennington et al., 2014) vectors, and fix them during the

Model	Word Embedding	Hidden States (bottom-up)	Trainable Parameters	Training Time (secs * epochs)	Performance (ppl, err rate)

Model	Word Embedding	Hidden States (bottom-up)	Trainable Parameters	Training Time (secs * epochs)	Performance (ppl, err rate)
Baseline HRED	600	600-1200-600	40,231,401	51,770 * 33	46.29, 68.76%
Simplified HRED	600	600-1200-600	30,150,203	21,690 * 33	45.55, 68.55%

Table 2: Comparing the simplified HRED with the baseline HRED on Ubuntu.

Model	Trainable Parameters	Training Time (secs * epochs)	Dev Performance (EM / F1)
Baseline R-NET	2,307,991	2454 * 41	71.1 / 79.5
Simplified R-NET	2,007,435	2085 * 38	71.2 / 79.7

Table 3: Comparing the simplified HRED with the baseline HRED on SQuAD.

training. For the character embeddings, we initialize them with the same pre-trained GloVe vectors, and update them during the training. For the forgetting factor α of FOFE, we set it to 0.7. For the hidden state size of both the BiGRUs and the BiSGU, we set it to 128. For model optimization, we apply the Adam optimizer with a learning rate of 0.0005 and a mini-batch size of 32. For performance evaluation, we use both Exact Match (EM) and F1 score as evaluation metrics, which are calculated on the development set.

4.3 Experimental Results

For model comparison in the training efficiency, we use the same hardware (i.e., Intel Core i7-6700 CPU and NVIDIA GeForce GTX 1070 GPU) to train both the baseline models and the simplified models. The experimental results show that our proposed "the lower the simpler" strategy improves the training efficiency of both HRED and R-NET without compromising their performance. On the one hand, as shown in Table 1 and Table 2, the simplified HRED contains 25%–35% less trainable parameters, consumes over 50% less training time, and achieves slightly better performance than the baseline HRED. Besides, Table 1 also shows that appropriately scaling up the model brings better performance but consumes more resource, which implies that the simplified HRED will perform better than the baseline HRED when time or memory is limited. On the other hand, as shown in Table 3, the simplified R-NET contains 13% less trainable parameters, consumes 21% less training time, and achieves slightly better performance than the baseline R-NET.

5 Conclusion

In this paper, we propose a strategy named as "the lower the simpler", which is aimed at improving the training efficiency of hierarchical recurrent models without compromising their performance. This strategy has been verified on two typical hierarchical recurrent models, namely HRED and R-NET, where we replace their middle layers and bottom layers with two simpler recurrent structures. The significance of this paper lies in that it reveals a methodology for avoiding unnecessary complexity in training hierarchical recurrent models, which we believe is applicable to many other hierarchical recurrent models.

dgoldwas@purdue.edu

Abstract

When evaluating an answer choice for Reading Comprehension task, other answer choices available for the question and the answers of related questions about the same paragraph often provide valuable information. In this paper, we propose a method to leverage the natural language relations between the answer choices, such as entailment and contradiction, to improve the performance of machine comprehension. We use a stand-alone question answering (QA) system to perform QA task and a Natural Language Inference (NLI) system to identify the relations between the choice pairs. Then we perform inference using an Integer Linear Programming (ILP)-based relational framework to re-evaluate the decisions made by the standalone QA system in light of the relations identified by the NLI system. We also propose a multitask learning model that learns both the tasks jointly.

1 Introduction

Given an input text and a set of related questions with multiple answer choices, the reading comprehension (RC) task evaluates the correctness of each answer choice. Current approaches to the RC task quantify the relationship between each question and answer choice independently and pick the highest scoring option. In this paper, we follow the observation that when humans approach such RC tasks, they tend to take a holistic view ensuring that their answers are consistent across the given questions and answer choices. In this work we attempt to model these pragmatic inferences, by leveraging the *entailment* and *contradiction* relations between the answer choices to improve machine comprehension. To help clarify these concepts, consider the following examples:

How can the military benefit from the existence of the CIA?
c_1: They can use them
c_2: These agencies are keenly attentive to the military's strategic and tactical requirements (✗)
c_3: The CIA knows what intelligence the military requires and has the resources to obtain that intelligence (✓)

The above example contains multiple correct answer choices, some are easier to capture than others. For example, identifying that c_3 is true might be easier than c_2 based on its alignment with the input text. However, capturing that c_3 entails c_2 allows us to predict c_2 correctly as well. Classification of the answer in red (marked ✗) could be corrected using the blue (marked ✓) answer choice.

Q1: *When were the eggs added to the pan to make the omelette?*
c_1^1: When they turned on the stove
c_2^1: When the pan was the right temperature (✓)
Q2: *Why did they use stove to cook omelette?*
c_1^2: They didn't use the stove but a microwave
c_2^2: Because they needed to heat up the pan (✗)

Similarly, answering Q1 correctly helps in answering Q2. Our goal is to leverage such inferences for machine comprehension.

Our approach contains three steps. First, we use a stand-alone QA system to classify the answer choices as true/false. Then, we classify the relation between each pair of choices for a given question as *entailment*, *contradiction* or *neutral*. Finally, we re-evaluate the labels assigned to choices using an Integer Linear Programming based inference procedure. We discuss different training protocols and representation choices for the combined decision problem. An overview is in figure 1.

We empirically evaluate on two recent datasets, MultiRC (Khashabi et al., 2018) and SemEval-

Proceedings of NAACL-HLT 2019, pages 4010–4015
Minneapolis, Minnesota, June 2 - June 7, 2019.

2018 task-11 (Ostermann et al., 2018) and show that it improves machine comprehension in both.

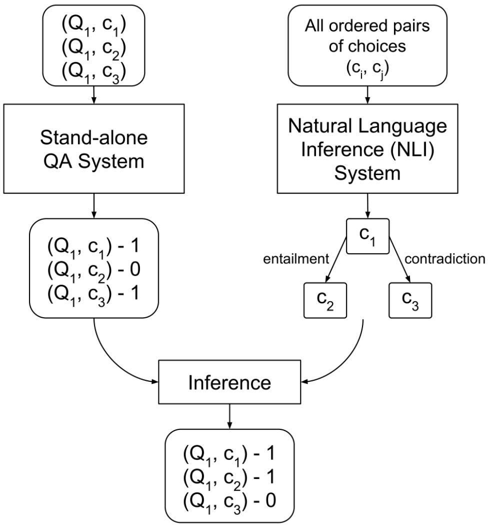

Figure 1: Proposed Approach

2 Related Work

Recently, several QA datasets have been proposed to test machine comprehension (Richardson, 2013; Weston et al., 2015; Rajpurkar et al., 2016; Trischler et al., 2016a; Nguyen et al., 2016). Yatskar (2018) showed that a high performance on these datasets could be achieved without necessarily achieving the capability of making commonsense inferences. Trischler et al. (2016b), Kumar et al. (2016), Liu and Perez (2017), Min et al. (2018) and Xiong et al. (2016) proposed successful models on those datasets. To address this issue, new QA datasets which require commonsense reasoning have been proposed (Khashabi et al., 2018; Ostermann et al., 2018; Mihaylov et al., 2018). Using common sense inferences in Machine Comprehension is a far from solved problem. There have been several attempts in literature to use inferences to answer questions. Most of the previous works either attempt to infer the answer from the given text (Sachan and Xing, 2016; Sun et al., 2018) or an external commonsense knowledge base (Das et al., 2017; Mihaylov and Frank, 2018; Bauer et al., 2018; Weissenborn et al., 2017).

While neural models can capture some dependencies between choices through shared representations, to the best of our knowledge, inferences capturing the dependencies between answer choices or different questions have been not explicitly modeled.

3 Model

Formally, the task of machine comprehension can be defined as: given text $\mathcal{P}$ and a set of n related questions $\mathcal{Q} = \{q_1, q_2, \ldots, q_n\}$ each having m choices $\mathcal{C} = \{c_1^i, c_2^i, \ldots, c_m^i\} \forall q_i \in \mathcal{Q}$, the task is to assign true/false value for each choice c_j^i.

3.1 Model Architecture

Our model consists of three separate systems, one for each step, namely, the stand-alone question answering (QA) system, the Natural Language Inference (NLI) system and the inference framework connecting the two. First, we assign a true/false label to each question-choice pair using the stand-alone QA system along with an associated confidence score s_1. Consequently, we identify the natural language relation (entailment, contradiction or neutral) between each ordered pair of choices for a given question, along with an associated confidence score s_2. Then, we use a relational framework to perform inference using the information obtained from the stand-alone QA and the NLI systems. Each of the components is described in detail in the following sub-sections.

We further propose a joint model whose parameters are trained jointly on both the tasks. The joint model uses the answer choice representation generated by the stand-alone QA system as input to the NLI detection system. The architecture of our joint model is shown in figure 2.

3.1.1 Stand-alone QA system

We use the TriAN-single model proposed by Wang et al. (2018) for SemEval-2018 task-11 as our stand-alone QA system. We use the implementation[1] provided by Wang et al. (2018) for our experiments. The system is a tri-attention model that takes passage-question-choice triplet as input and produces the probability of the choice being true as its output.

3.2 NLI System

Our NLI system is inspired from decomposable-attention model proposed by Parikh et al. (2016). We modified the architecture proposed in Parikh et al. (2016) to accommodate the question-choice pairs as opposed to sentence pairs in the original model. We added an additional sequence-attention layer for the question-choice pairs to allow for the

---

[1] `https://github.com/intfloat/commonsense-rc`

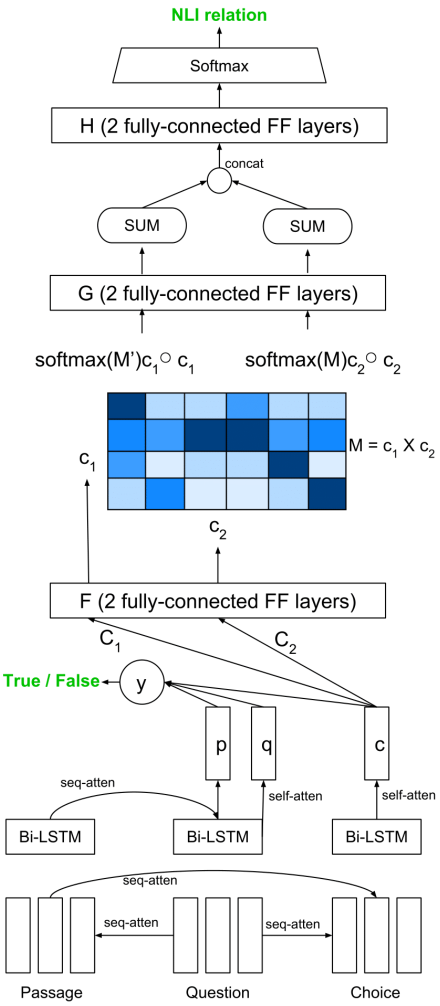

Figure 2: Architecture of the Joint Model

representation of both the answer choice and the question. Sequence-attention is defined in Wang et al. (2018) as:

$$Att_{seq}(\mathbf{u}, \{\mathbf{v}_i\}_{i=1}^{n}) = \sum_{i=1}^{n} \alpha_i \mathbf{v}_i \tag{1}$$

$$\alpha_i = softmax_i(f(\mathbf{W}_1\mathbf{u})^T f(\mathbf{W}_1\mathbf{v}_i))$$

where $\mathbf{u}$ and $\mathbf{v}_i$ are word embeddings, $\mathbf{W}_1$ is the associated weight parameter and f is non-linearity. Self-attention is Att_{seq} of a vector onto itself.

The embedding of each word in the answer choice is attended to by the sequence of question word embeddings. We use pre-trained GloVe (Pennington et al., 2014) embeddings to represent the words. The question-attended choices are then passed through the decomposable-attention layer proposed in Parikh et al. (2016).

3.2.1 Inference using DRAIL

We use Deep Relational Learning (DRaiL) framework proposed by Zhang et al. (2016) to perform the final inference. The framework allows for declaration of predicate logic rules to perform relational inference. The rules are scored by the confidence scores obtained from the stand-alone QA and the NLI systems. DRaiL uses an Integer Linear Programming (ILP) based inference procedure to output binary prediction for each of the choices. We use the following constraints for our inference:

1. c_i is true & c_i entails $c_j \implies c_j$ is true.
2. c_i is true & c_i contradicts $c_j \implies c_j$ is false.

On the MultiRC dataset, we use the dependencies between the answer choices for a given question. On SemEval dataset, we use the dependencies between different questions about the same paragraph.

3.3 Joint Model

The design of our joint model is motivated by the two objectives: 1) to obtain a better representation for the question-choice pair for NLI detection and 2) to leverage the benefit of multitask learning. Hence, in the joint model, choice representation from stand-alone QA system is input to the decomposable-attention layer of the NLI system.

The joint model takes two triplets (p, q_i, c_i) and (p, q_j, c_j) as input. It outputs a `true/false` for each choice and an NLI relation (entailment, contradiction or neutral) between the choices. The representations for passage, question and choice are obtained using Bi-LSTMs. The hidden states of the Bi-LSTM are concatenated to generate the representation. This part of the model is similar to TriAN model proposed in Wang et al. (2018). The choice representations of c_i and c_j are passed as input to the decomposable attention layer proposed in Parikh et al. (2016). The architecture of the joint model is shown in figure 2.

3.4 Training

We train the stand-alone QA system using the MultiRC and SemEval datasets for respective experiments. We experiment with 2 different training settings for the NLI system. In the first setting, we use SNLI dataset (Bowman et al., 2015) to train the NLI system. The sequence-attention layer is left untrained during this phase. Hence, we only use the answer choice and do not consider the question for NLI detection.

Self-Training: Subsequently, to help the system adapt to our settings, we devise a self-training protocol over the RC datasets to train the NLI system. Self-training examples for the NLI system were obtained using the following procedure: if the SNLI-trained NLI model predicted entailment and the gold labels of the ordered choice pair were `true-true`, then the choice pair is labeled as *entailment*. Similarly, if the SNLI-trained NLI model predicted contradiction and the gold labels of the ordered choice pair were `true-false`, then the choice pair is labeled as *contradiction*. This is noisy labelling as the labels do not directly indicate the presence of NLI relations between the choices. The NLI model was additionally trained using this data.

Model	**Entailment**	**Contradiction**	**Overall**
NLI_{SNLI}	40.80	74.25	55.11
$NLI_{MultiRC}$	57.30	69.22	66.31

Table 1: Accuracy of entailment and contradiction detection on the development set of self-training data for NLI model trained on SNLI data (NLI_{SNLI}) vs training set of self-training data ($NLI_{MultiRC}$)

To train the joint model we use ordered choice pairs, labeled as *entailment* if the gold labels are `true-true` and labeled as *contradiction* if the gold labels are `true-false`. This data was also used to test the effectiveness of the self-training procedure. The results on the development set of MultiRC dataset are in table 1.

The NLI model trained on SNLI dataset achieves 55.11% accuracy. Training the NLI model on the data from MultiRC data increases the overall accuracy to 66.31%. Further discussion about self-training is provided in section 5.

4 Experiments

We perform experiments in four phases. In the first phase, we evaluate the stand-alone QA system. In the second phase, we train the NLI system on SNLI data and evaluate the approach shown in figure 1. In the third phase, we train the NLI system using the self-training data. In the fourth phase, we evaluate the proposed joint model. We evaluate all models on MultiRC dataset. The results are shown in table 2. We evaluate the joint model on SemEval dataset, shown in table 3.

4.1 Datasets

We use two datasets for our experiments, MultiRC dataset[2] and the SemEval 2018 task 11 dataset[3]. MultiRC dataset consisted of a training and development set with a hidden test set. We split the given training set into training and development sets and use the given development set as test set.

Each question in the MultiRC dataset has approximately 5 choices on average. Multiple of them may be `true` for a given question. The training split of MultiRC consisted of 433 paragraphs and $4,853$ questions with $25,818$ answer choices. The development split has 23 paragraphs and 275 questions with $1,410$ answer choices. Test set has 83 paragraphs and 953 questions with $4,848$ answer choices.

SemEval dataset has 2 choices for each question, exactly one of them is `true`. The training set consists of $1,470$ paragraphs with $9,731$ questions. The development set has 219 paragraphs with $1,411$ questions. And the test set has 430 paragraphs with $2,797$ questions.

4.2 Evaluation Metrics

For MultiRC dataset, we use two metrics for evaluating our approach, namely $EM0$ and $EM1$. $EM0$ refers to the percentage of questions for which all the choices have been correctly classified. $EM1$ is the the percentage of questions for which at most one choice is wrongly classified. For the SemEval dataset, we use *accuracy* metric.

4.3 Results

Results of our experiments are summarized in tables 2 & 3. $EM0$ on MC task improves from 18.15% to 19.41% when we use the NLI model trained over SNLI data and it further improves to 21.62% when we use MultiRC self-training data. Joint model achieves 20.36% on $EM0$ but achieves the highest $EM1$ of 57.08%. Human $EM0$ is 56.56%.

Method	**EM0**	**EM1**
Stand-alone QA	18.15	52.99
QA + NLI_{SNLI}	19.41	56.13
QA + $NLI_{MultiRC}$	21.62	55.72
Joint Model	20.36	57.08
Human	56.56	83.84

Table 2: Summary of the results on MultiRC dataset. $EM0$ is the percentage of questions for which all the choices are correct. $EM1$ is the the percentage of questions for which at most one choice is wrong.

Results of SemEval experiments are summarized in table 3. TriAN-single results are as re-

---

[2] `http://cogcomp.org/multirc/`

[3] `https://competitions.codalab.org/competitions/17184`

ported in (Wang et al., 2018). The results we obtained using their implementation are stand-alone QA results. With the same setting, joint model got 85.4% on dev set and 82.1% on test set. The difference in performance of the models in tables 2 and 3 is statistically significant according to McNemar's chi-squared test.

Model	Dev	Test
TriAN-single (Wang et al., 2018)	83.84%	81.94%
Stand-alone QA	83.20%	80.80%
Joint Model	85.40%	82.10%

Table 3: Accuracy of various models on SemEval'18 task-11 dataset

5 Discussion

We have shown that capturing the relationship between various answer choices or subsequent questions helps in answering questions better. Our experimental results, shown in tables 2 & 3, are only a first step towards leveraging this relationship to help construct better machine reading systems. We suggest two possible extensions to our model, that would help realize the potential of these relations.

1. Improving the performance of entailment and contradiction detection.
2. Using the information given in the text to identify the relations between choices better.

As shown in table 1, identification of entailment/contradiction is far from perfect. Entailment detection is particularly worse because often the system returns *entailment* when there is a high lexical overlap. Moreover, the presence of a strong negation word (*not*) causes the NLI system to predict *contradiction* even for *entailment* and *neutral* cases. This issue impedes the performance of our model on SemEval'18 dataset as roughly 40% of the questions have *yes/no* answers. Naik et al. (2018) show that this is a common issue with state-of-the-art NLI detection models.

Self-training (table 1) results suggest that there are other types of relationships present among answer choice pairs that do not come under the strict definitions of *entailment* or *contradiction*. Upon investigating, we found that although some answer hypotheses do not directly have an inference relation between them, they might be related in context of the given text. For example, consider the sentence, '*I snack when I shop*' and the answer choices: c_1: '*She went shopping this extended weekend*' and c_2: '*She ate a lot of junk food recently*'. Although the sentences don't have an explicit relationship when considered in isolation, the text suggests that c_1 might entail c_2. Capturing these kinds of relationships could potentially improve MC further.

6 Conclusion

In this paper we take a first step towards modeling an accumulative knowledge state for machine comprehension, ensuring consistency between the model's answers. We show that by adapting NLI to the MC task using self-training, performance over multiple tasks improves.

In the future, we intend to generalize our model to other relationships beyond strict entailment and contradiction relations.

Abstract

Deep learning has emerged as a compelling solution to many NLP tasks with remarkable performances. However, due to their opacity, such models are hard to interpret and trust. Recent work on explaining deep models has introduced approaches to provide insights toward the model's behaviour and predictions, which are helpful for assessing the reliability of the model's predictions. However, such methods do not improve the model's reliability. In this paper, we aim to teach the model to make the right prediction for the right reason by providing explanation training and ensuring the alignment of the model's explanation with the ground truth explanation. Our experimental results on multiple tasks and datasets demonstrate the effectiveness of the proposed method, which produces more reliable predictions while delivering better results compared to traditionally trained models.

1 Introduction

It is unfortunate that our data is often plagued by meaningless or even harmful statistical biases. When we train a model on such data, it is possible that the classifier focuses on irrelevant biases to achieve high performance on the biased data. Recent studies demonstrate that deep learning models noticeably suffer from this issue (Agrawal et al., 2016; Wadhwa et al., 2018; Gururangan et al., 2018). Due to the black-box nature of deep models and the high dimensionality of their inherent representations, it is difficult to interpret and trust their behaviour and predictions. Recent work on explanation and interpretation has introduced a few approaches (Simonyan et al., 2013; Ribeiro et al., 2016; Lei et al., 2016; Li et al., 2016, 2017; Ghaeini et al., 2018b; Ribeiro et al., 2018) for explanation. Such methods provide insights toward the model's behaviour, which is helpful for detecting biases in our models. However, they do not correct them. Here, we investigate how to incorporate explanations into the learning process to ensure that our model not only makes correct predictions but also makes them for the right reason.

Specifically, we propose to train a deep model using both ground truth labels and additional annotations suggesting the desired explanation. The learning is achieved via a novel method called *saliency learning*, which regulates the model's behaviour using saliency to ensure that the most critical factors impacting the model's prediction are aligned with the desired explanation.

Our work is closely related to Ross et al. (2017), which also uses the gradient/saliency information to regularize model's behaviour. However, we differ in the following points: 1) Ross et al. (2017) is limited to regularizing model with gradient of the model's input. In contrast, we extend this concept to the intermediate layers of deep models, which is demonstrated to be beneficial based on the experimental results; 2) Ross et al. (2017) considers annotation at the dimension level, which is not appropriate for NLP tasks since the individual dimensions of the word embeddings are not interpretable; 3) most importantly, Ross et al. (2017) learns from annotations of *irrelevant* parts of the data, whereas we focus on positive annotations identifying parts of the data that contributes positive evidence toward a specific class. In textual data, it is often unrealistic to annotate a word (even a stop word) to be completely irrelevant. On the other hand, it can be reasonably easy to identify group of words that are positively linked to a class.

We make the following contributions: 1) we propose a new method for teaching the model where to pay attention; 2) we evaluate our method on multiple tasks and datasets and demonstrate that our method achieves more reliable predictions while delivering better results than traditionally trained models; 3) we verify the sensitivity of our

Proceedings of NAACL-HLT 2019, pages 4016–4025

saliency-trained model to perturbations introduced on part of the data that contributes to the explanation.

2 Saliency-based Explanation Learning

Our goal is to teach the model where to pay attention in order to avoid focusing on meaningless statistical biases in the data. In this work, we focus on positive explanations. In other words, we expect the explanation to highlight information that contributes positively towards the label. For example, if a piece of text contains the mention of a particular event, then the explanation will highlight parts of the text indicating the event, not non-existence of some other events. This choice is because positive evidence is more natural for human to specify.

Formally, each training example is a tuple (X, y, Z), where $X = [X_1, X_2, \dots, X_n]$ is the input text (length n), y is the ground-truth label, and $Z \in \{0, 1\}^n$ is the ground-truth explanation as a binary mask indicating whether each word contributes positive evidence toward the label y.

Recent studies have shown that the model's predictions can be explained by examining the saliency of the inputs (Simonyan et al., 2013; Hechtlinger, 2016; Ross et al., 2017; Li et al., 2016) as well as other internal elements of the model (Ghaeini et al., 2018b). Given an example, for which the model makes a prediction, the saliency of a particular element is computed as the derivative of the model's prediction with respect to that element. Saliency provides clues as to where the model is drawing strong evidence to support its prediction. As such, if we constrain the saliency to be aligned with the desired explanation during learning, our model will be coerced to pay attention to the right evidence.

In computing saliency, we are dealing with high-dimensional data. For example, each word is represented by an embedding of d dimensions. To aggregate the contribution of all dimensions, we consider sum of the gradients of all dimensions as the overall vector/embedding contribution. For the i-th word, if $Z[i] = 1$, then its vector should have a positive gradient/contribution, otherwise the model would be penalized. To accomplish this, we incorporate a saliency regularization term to the model cost function using hinge loss. Equation 1 describes our cost function evaluated on a single example (X, y, Z).

$$\begin{aligned}\mathcal{C}(\theta, X, y, Z) &= \mathcal{L}(\theta, X, y) \\ &+ \lambda \sum_{i=1}^{n} \max\left(0, -Z_i \sum_{j=1}^{d} \frac{\partial f_\theta(X, y)}{\partial X_{i,j}}\right)\end{aligned} \tag{1}$$

where $\mathcal{L}$ is a traditional model cost function (e.g. cross-entropy), λ is a hyper parameter, f specifies the model with parameter θ, and $\frac{\partial f}{\partial X_{i,j}}$ represents the saliency of the j-th dimension of word X_i. The new term in the $\mathcal{C}$ penalizes negative gradient for the marked words in Z (contributory words).

Since $\mathcal{C}$ is differentiable respect to θ, it can be optimized using existing gradient-based optimization methods. It is important to note that while Equation 1 only regularizes the saliency of the input layer, the same principle can be applied to the intermediate layers of the model (Ghaeini et al., 2018b) by considering the intermediate layer as the input for the later layers.

Note that if $Z = 0$ then $\mathcal{C} = \mathcal{L}$. So, in case of lacking proper annotations for a specific sample or sequence, we can simply use 0 as its annotation. This property enables our method to be easily used in semi-supervised or active learning settings.

3 Tasks and Datasets

To teach the model where to pay attention, we need ground-truth explanation annotation Z, which is difficult to come by. As a proof of concept, we modify two well known real tasks (Event Extraction and Cloze-Style Question Answering) to simulate approximate annotations for explanation. Details of the main tasks and datasets could be found in section B of the Appendix. We describe the modified tasks as follows:

1) **Event Extraction:** Given a sentence, the goal is to determine whether the sentence contains an event. Note that event extraction benchmarks contain the annotation of event triggers, which we use to build the annotation Z. In particular, the Z value of every word is annotated to be zero unless it belongs to an event trigger. For this task, we consider two well known event extraction datasets, namely ACE 2005 and Rich ERE 2015.

2) **Cloze-Style Question Answering:** Given a sentence and a query with a blank, the goal is to determine whether the sentence contains the correct replacement for the blank. Here, annotation of each word is zero unless it belongs to the gold

replacement. For this task, we use two well known cloze-style question answering datasets: Children Book Test Named Entity (CBT-NE) and Common Noun (CBT-CN) (Hill et al., 2015).

Here, we only consider the simple binary tasks as a first attempt to examine the effectiveness of our method. However, our method is not restricted to binary tasks. In multi-class problems, each class can be treated as the positive class of the binary classification. In such a setting, each class would have its own explanation and annotation Z.

Note that for both tasks if an example is negative, its explanation annotation will be all zero. In other words, for negative examples we have $\mathcal{C} = \mathcal{L}$.

4 Model

We use simple CNN based models to avoid complexity. Figure 1 illustrates the models used in this paper. Both models have a similar structure. The main difference is that QA has two inputs (sentence and query). We first describe the event extraction model followed by the QA model.

Figure 1 (a) shows the event extraction model. Given a sentence $W = [w_1, \ldots, w_n]$ where $w_i \in \mathbb{R}^d$, we first pass the embeddings to two CNNs with feature size of d and window size of 3 and 5. Next we apply max-pooling to both CNN outputs. It will give us the representation $I \in \mathbb{R}^{n \times d}$, which we refer to as the *intermediate representation*. Then, we apply sequence-wise and dimension-wise max-poolings to I to capture $D_{seq} \in \mathbb{R}^d$ and $D_{dim} \in \mathbb{R}^n$ respectively. D_{dim} will be referred as *decision representation*. Finally we pass the concatenation of D_{seq} and D_{dim} to a feed-forward layer for prediction.

Figure 1 (b) depicts the QA model. The main difference is having *query* as an extra input. To process the query, we use a similar structure to the main model. After CNNs and max-pooling we end up with $Q \in \mathbb{R}^{m \times d}$ where m is the length of query. To obtain a sequence independent vector, we apply another max-pooling to Q resulting in a query representation $q \in \mathbb{R}^d$. We follow a similar approach to in event extraction for the given sentence. The only difference is that we apply a dot product between the *intermediate representations* and query representation ($I_i = I_i \odot q$).

As mentioned previously, we can apply saliency regularization to different levels of the model. In this paper, we apply saliency regularization on the following three levels: 1) Word embeddings (W). 2) Intermediate representation (I). 3) Decision representation (D_{dim}). Note that the aforementioned levels share the same annotation for training. For training details please refer to Section C of the Appendix.

5 Experiments and Analysis

5.1 Performance

Table 1 shows the performance of the trained models on ACE, ERE, CBT-NE, and CBT-CN datasets using the aforementioned models with and without saliency learning. The results indicate that using saliency learning yields better accuracy and F1 measure on all four datasets. It is interesting to note that saliency learning consistently helps the models to achieve noticeably higher precision without hurting the F1 measure and accuracy. This observation suggests that saliency learning is effective in providing proper guidance for more accurate predictions – Note that here we only have guidance for positive prediction. To verify the statistical significance of the observed performance improvement over traditionally trained

models without saliency learning, we conducted the one-sided McNemar's test. The obtained p-values are 0.03, 0.03, 0.0001, and 0.04 for ACE, ERE, CBT-NE, and CBT-CN respectively, indicating that the performance gain by saliency learning is statistically significant.

5.2 Saliency Accuracy

In this section, we examine how well does the saliency of the trained model aligns with the annotation. To this end, we define a metric called *saliency accuracy* (s_{acc}), which measures what percentage of all positive positions of annotation Z indeed obtain a positive gradient. Formally, $s_{acc} = 100\frac{\sum_i \delta(Z_i G_i > 0)}{\sum_i Z_i}$ where G_i is the gradient of element i and δ is the indicator function.

Table 2 shows the saliency accuracy at different layers of the trained model with and without saliency learning. According to Table 2, our method achieves a much higher saliency accuracy for all datasets indicating that the learning was indeed effective in aligning the model saliency with the annotation. In other words, important words will have positive contributions in the saliency-trained model, and as such, it learns to focus on the right part(s) of the data. This claim can also be verified by visualizing the saliency, which is provided in the next section.

5.3 Saliency Visualization

Here, we visualize the saliency of three positive samples from the ACE dataset for both the traditionally trained (Baseline Model) and the saliency-trained model (saliency-trained Model). Table 3 shows the top 6 salient words (words with highest saliency/gradient) of three positive samples along with their contributory words (annotation Z), the baseline model prediction (P_B), and the saliency-trained model prediction (P_S). Darker red color indicates more salient words. According to Table 3, both models correctly predict 1 and the saliency-trained model successfully pays attention to the expected meaningful words while the baseline model pays attention to mostly irrelevant ones. More analyses are provided in section D of the Appendix.

5.4 Verification

Up to this point, we show that using saliency learning yields noticeably better precision, F1 measure, accuracy, and saliency accuracy. Here, we aim to verify our claim that saliency learning coerces the model to pay more attention to the critical parts. The annotation Z describes the influential words toward the positive labels. Our hypothesis is that *removing such words would cause more impact on the saliency-trained models* since by training, they should be more sensitive to these words. We measure the impact as the percentage change of the model's true positive rate. This measure is chosen because negative examples do not have any annotated contributory words, and hence we are particularly interested in how removing contributory words of positive examples would impact the model's true positive rate (TPR).

Table 4 shows the outcome of the aforementioned experiment, where the last column lists the TPR reduction rates. From the table, we see a consistently higher rate of TPR reduction for saliency-trained models compared to traditionally trained models, suggesting that the saliency-trained models are more sensitive to the perturbation of the contributory word(s) and confirming our hypothesis.

It is worth noting that we observe less substantial change to the true positive rate for the event task. This is likely due to the fact that we are using trigger words as simulated explanations. While trigger words are clearly related to events, there are often other words in the sentence relating to events but not annotated as trigger words.

6 Conclusion

In this paper, we proposed *saliency learning*, a novel approach for teaching a model where to pay attention. We demonstrated the effectiveness

of our method on multiple tasks and datasets using simulated explanations. The results show that saliency learning enables us to obtain better precision, F1 measure and accuracy on these tasks and datasets. Further, it produces models whose saliency is more properly aligned with the desired explanation. In other words, *saliency learning* gives us more reliable predictions while delivering better performance than traditionally trained models. Finally, our verification experiments illustrate that the saliency-trained models show higher sensitivity to the removal of contributory words in a positive example. For future work, we will extend our study to examine saliency learning on NLP tasks in an active learning setting where real explanations are requested and provided by a human.

A Background: Saliency

The concept of saliency was first introduced in vision for visualizing the spatial support on an image for particular object class (Simonyan et al., 2013). Considering a deep model prediction as a differentiable model f parameterized by θ with input $X \in \mathbb{R}^{n \times d}$. Such a model could be described using the Taylor series as follow:

$$f(x) = f(a)+f^{'}(a)(x-a)+\frac{f^{''}(a)}{2!}(x-a)^2+\dots \tag{2}$$

By approximating that a deep model is a linear function, we could use the first order Taylor expansion.

$$f(x) \approx f^{'}(a)x + b \tag{3}$$

According to Equation 3, the first derivative of the model's prediction respect to its input ($f^{'}(a)$ or $\frac{\partial f}{\partial x}|_{x=a}$) describes the model's behaviour near the input. To make it more clear, bigger derivative/gradient indicates more impact and contribution toward the model's prediction. Consequently, the large-magnitude derivative values determine elements of input that would greatly affect $f(x)$ if changed.

B Task and Dataset

Here, we first describe the main and real Event Extraction and Close-Style Question Answering tasks (before our modification). Next, we provide data statistics of the modified version of ACE, ERE, CBT-NE, and CBT-CN datasets in Table 5.

- **Event Extraction:** Given a set of ontologized event types (e.g. Movement, Transaction, Conflict, etc.), the goal of event extraction is to identify the mentions of different events along with their types from natural texts (Chen et al., 2015; Ghaeini et al., 2016; Orr et al., 2018).

- **Cloze-Style Question Answering:** Documents in CBT consist of 20 contiguous sentences from the body of a popular children book and queries are formed by replacing a token from the 21^{st} sentence with a blank. Given a document, a query, and a set of candidates, the goal is to find the correct replacement for blank in the query among the given candidates. To avoid having too many negative examples in our modified datasets, we only consider sentences that contain at least one candidate. To be more clear, each sample from the CBT dataset is split to at most 20 samples – each sentence of the main sample as long as it contains one of the candidates (Trischler et al., 2016; Kadlec et al., 2016; Cui et al., 2017; Dhingra et al., 2017; Ghaeini et al., 2018a).

[b] Negative Sample Count

Table 5: Dataset statistics of the modified tasks and datasets.

C Training

All hyper-parameters are tuned based on the development set. We use pre-trained $300-D$ Glove $840B$ vectors (Pennington et al., 2014) to initialize our word embedding vectors. All hidden states and feature sizes are 300 dimensions ($d = 300$). The weights are learned by minimizing the cost function on the training data via Adam optimizer. The initial learning rate is 0.0001 and $\lambda = 0.5, 0.7, 0.4$, and 0.35 for ACE, ERE, CBT-NE, and CBT-CN respectively. To avoid overfitting, we use dropout with a rate of 0.5 for regularization, which is applied to all feedforward connections. During training, the word embeddings are updated to learn effective representations for each task and dataset. We use a fairly small batch size of 32 to provide more exploration power to the model. Finally, Equation 4 indicates the the cost function that is used for the training where W, I, and D_{dim} are the *word embeddings*, *Intermediate representation*, and *Decision representa-*

D Saliency Visualization

In this section, we empirically analyze the traditionally trained (Baseline Model) and the saliency-trained model (saliency-trained Model) behaviour by observing the saliency of 23 positive samples from ACE and ERE datasets. Tables 6 and 7 show the top 6 salient words (words with highest saliency/gradient) of positive samples from ACE or ERE dataset along with their contributory word(s) (Z), the baseline model prediction (P_B), and the saliency-trained model prediction (P_S). Darker red color indicates more salient words. Our observations could be divided into six categories as follow:

- Samples 1-7: Both models correctly predict 1 for these samples. The saliency-trained model successfully pays attention to the expected meaningful words while the baseline model pays attention to mostly irrelevant ones.

- Samples 8-11: Both models correctly predict 1 and pays attention to the contributory words. Yet, we observe lower saliency for important words and higher saliency for irrelevant ones.

- Samples 12-14: Here, the baseline model fails to pay attention to the contributory words and predicts 0 while the saliency-trained model one successfully pays attention to them and predicts 1.

- Samples 15-18: Although the models have high saliency for the contributory words, still they could not correctly disambiguate these samples. This observation suggests that having high saliency for important words does not guarantee positive prediction. High saliency for these words indicate their positive contribution toward the positive prediction but still, the model might consider higher probability for negative prediction.

- Samples 19-21: Here, only the baseline model could correctly predict 1. However, the baseline model does not pay attention to the contributory words. In other words, the explanation does not support the prediction (unreliable).

- Samples 22-23: Not always the saliency-trained model could pay proper attention to the contributory words. In these examples, the baseline model has high saliency for contributory words. It is worth noting that when the saliency-trained model does not have high saliency for contributory words, it does not predict 1. Such observation could suggest that the saliency-trained model predictions are more reliable. The aforementioned claim is also verified by consistently obtaining noticeably higher precision for all datasets and tasks (Section 5.1 and Table 1 in the paper).

Understanding Dataset Design Choices for Multi-hop Reasoning

Jifan Chen and **Greg Durrett**
The University of Texas at Austin
`{jfchen,gdurrett}@cs.utexas.edu`

Abstract

Learning multi-hop reasoning has been a key challenge for reading comprehension models, leading to the design of datasets that explicitly focus on it. Ideally, a model should not be able to perform well on a multi-hop question answering task without doing multi-hop reasoning. In this paper, we investigate two recently proposed datasets, WikiHop (Welbl et al., 2018) and HotpotQA (Yang et al., 2018). First, we explore sentence-factored models for these tasks; by design, these models cannot do multi-hop reasoning, but they are still able to solve a large number of examples in both datasets. Furthermore, we find spurious correlations in the unmasked version of WikiHop, which make it easy to achieve high performance considering only the questions and answers. Finally, we investigate one key difference between these datasets, namely span-based vs. multiple-choice formulations of the QA task. Multiple-choice versions of both datasets can be easily gamed, and two models we examine only marginally exceed a baseline in this setting. Overall, while these datasets are useful testbeds, high-performing models may not be learning as much multi-hop reasoning as previously thought.

1 Introduction

Question answering from text (Richardson et al., 2013; Hill et al., 2015; Hermann et al., 2015; Rajpurkar et al., 2016) is a key challenge problem for NLP that tests whether models can extract information based on a query. However, even sophisticated models that perform well on QA benchmarks (Seo et al., 2017; Shen et al., 2017; Yu et al., 2018) may only be doing shallow pattern matching of the question against the supporting passage (Weissenborn et al., 2017). More recent work (Kumar et al., 2016; Joshi et al., 2017; Welbl et al., 2018) has emphasized gathering information from different parts of a passage to answer the question, leading to a number of models designed to do *multi-hop reasoning*. Two recent large-scale datasets have been specifically designed to test multi-hop reasoning: WikiHop (Welbl et al., 2018) and HotpotQA (Yang et al., 2018).

In this paper, we seek to answer two main questions. First, although the two datasets are explicitly constructed for multi-hop reasoning, do models really need to do multi-hop reasoning to do well on them? Recent work has shown that large-scale QA datasets often do not exhibit their advertised properties (Chen et al., 2016; Kaushik and Lipton, 2018). We devise a test setting to see whether multi-hop reasoning is necessary: can a model which treats each sentence independently select the sentence containing the answer? This provides a rough estimate of the fraction of questions solvable by a non-multi-hop system. Our results show that more than half of the questions in WikiHop and HotpotQA do not require multi-hop reasoning to solve. Surprisingly, we find that a simple baseline which ignores the passage and only uses the question and answer can achieve strong results on WikiHop and a modified version of HotpotQA, further confirming this view.

Second, we study the nature of the supervision on the two datasets. One critical difference is that HotpotQA is span-based (the answer is a span of the passage) while WikiHop is multiple-choice. How does this difference affect learning and evaluation of multi-hop reasoning systems? We show that a multiple-choice version of HotpotQA is vulnerable to the same baseline that performs well on WikiHop, showing that this distinction may be important from an evaluation standpoint. Furthermore, we show that a state-of-the-art model, BiDAF++, trained on span-based HotpotQA and adapted to the multiple-choice setting outperforms the same model trained natively on

Proceedings of NAACL-HLT 2019, pages 4026–4032
Minneapolis, Minnesota, June 2 - June 7, 2019.

the multiple-choice setting. However, even in the span-based setting, the high performance of the sentence-factored models raises questions about whether multi-hop reasoning is being learned.

Our conclusions are as follows: (1) Many examples in both WikiHop and HotpotQA do not require multi-hop reasoning to solve, as the sentence-factored model can find the answers. (2) On WikiHop and a multiple-choice version of HotpotQA, a no context baseline does very well. (3) Span-based supervision provides a harder testbed than multiple choice by having more answers to choose from, but given the strong performance of the sentence-factored models, it is unclear whether any of the proposed models are doing a good job at multi-hop reasoning in any setting.

2 Datasets

WikiHop Welbl et al. (2018) introduced this English dataset specially designed for text understanding across multiple documents. The dataset consists of 40k+ questions, answers, and passages, where each passage consists of several documents collected from Wikipedia. Questions are posed as a query of a relation r followed by a head entity h, with the task being to find the tail entity t from a set of entity candidates E. Annotators followed links between documents and were required to use multiple documents to get the answer.

HotpotQA Yang et al. (2018) proposed a new dataset with 113k English Wikipedia-based question-answer pairs. The questions are diverse, falling into several categories, but all require finding and reasoning over multiple supporting documents to answer. Models should choose answers by selecting variable-length spans from these documents. Sentences relevant to finding the answer are annotated in the dataset as "supporting facts" so models can use these at training time as well.

3 Probing Multi-hop Datasets

In this section, we seek to answer whether multi-hop reasoning is really needed to solve these two multi-hop datasets.

3.1 Sentence-Factored Model Test

If a question requires a multi-hop model, then we should not be able to figure out the answer by only looking at the question and each sentence separately. Based on this idea, we propose a sentence-factored modeling setting, where a model must predict which sentence contains the answer but must score each sentence independently, i.e., without using information from other sentences in this process. Identifying the presence of the answer is generally easier than predicting the answer directly, particularly if a sentence is complicated, and is still sufficient to provide a bound on how strongly multi-hop reasoning is required. Figure 1 shows a typical example from these datasets, where identifying the answer (*Delhi*) requires bridging to an entity not mentioned in the question.

Method	Random	Factored	Factored BiDAF
WikiHop	6.5	60.9	66.1
HotpotQA	5.4	45.4	57.2
SQuAD	22.1	70.0	88.0

Table 1: The accuracy of our proposed sentence-factored models on identifying answer location in the development sets of WikiHop, HotpotQA and SQuAD. *Random*: we randomly pick a sentence in the passage to see whether it contains the answer. *Factored* and *Factored BiDAF* refer to the models of Section 3.1. As expected, these models perform better on SQuAD than the other two datasets, but the model can nevertheless find many answers in WikiHop especially.

Simple Factored Model We encode each passage sentence s_i and the question q into a contextual representation h_{s_i} and h_q using a bi-directional GRU (Chung et al., 2014). Then, $S_i = h_{s_i}^\top W h_q$; that is, compute a bilinear product of these representations with trainable weights W to get the score of the ith sentence. Finally, let $p_i = \text{softmax}_i(S_i)$; softmax over the sentences to get a probability distribution. We maximize the marginal log probability of picking a sentence containing the correct answer: $\log(\sum_{i:s_i \in \mathbf{s}^*} p_i)$, where $\mathbf{s}^*$ is the set of sentences containing the answer. During evaluation, we pick the sentence s with the highest score and treat it as correct if it contains the answer.

Factored BiDAF We encode the question and each sentence *separately* using bi-GRUs. Then, we generate the question-aware token representation for each token of sentence by using a co-attention layer (Seo et al., 2017). Finally, we max-pool over each sentence to get the sentence representation and feed those to a FFNN to compute the sentence score. Training and inference are the same as for the simple model.

We run this test on both datasets as well as

Question: **The Oberoi family** is part of a hotel company that has a head office in what city?

……

The Oberoi family is an Indian family that is famous for its involvement in hotels, namely through **The Oberoi Group**.

……

The Oberoi Group is a hotel company with its head office in **Delhi**.

Figure 1: An example from the HotpotQA dev set. Here, a model should have to form a reasoning chain *Oberoi family* → *Oberoi Group* → *Delhi* to arrive at the answer. However, the sentence containing *Delhi* has a substantial lexical overlap with the question, so strong QA systems can answer it directly.

SQuAD (Rajpurkar et al., 2016), where multi-hop reasoning is only needed in a few questions. Results in Table 1 indicate that although intentionally created for multi-hop reasoning, for more than half of questions in WikiHop and HotpotQA, we can figure out where the answer is without doing multi-hop reasoning. This result is initially surprising, but one reason it may be possible is suggested by the example from HotpotQA shown in Figure 1. We can see that the model could easily figure out the answer sentence without looking at the bridging entities using lexical cues alone. This observation is also in accordance with the work of Jansen (2018), which demonstrates that high performance for a simple baseline can be achieved in cases when passages have increasing lexical overlap with the question.

We note that this method potentially overestimates performance of a non-multi-hop model on HotpotQA, since there are some examples where many plausible answers are in the same sentence and require other context to resolve. However, these still form a minority in the dataset (see Table 3 of Yang et al. (2018)).

3.2 No Context Baseline

The results of the previous section show that a model can identify correspondences between questions and answer sentences. One other pair of correlations we can study is suggested in the work of Kaushik and Lipton (2018), namely examining question-answer correlations independent of the passage. We construct a “no context” baseline to verify whether it is possible to pick the correct answer without consulting the passage. In a similar fashion to the factored model, we encode the query q and each answer candidate c_i using a bi-GRU and once again compute a bilinear product between them to get the scores over candidates, making no reference to the document.

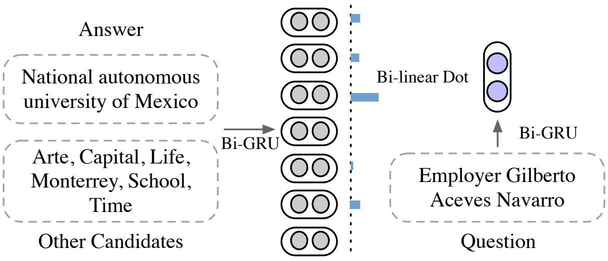

Figure 2: An example of question and candidates from WikiHop. Here we can see that among the candidates, only *National autonomous university of Mexico* is an organization which could be Navarro’s employer; the model may pick up on this entity typing.

NoContext	Coref-GRU	MHQA-GRN	Entity-GCN
59.70	56.00	62.80	64.80

Table 2: The results of our no-context baseline compared with Coref-GRU (Dhingra et al., 2018), MHQA-GRN (Song et al., 2018), and Entity-GCN (De Cao et al., 2018) on the WikiHop dev set.

Results of this model on the multiple-choice WikiHop dataset are shown in Table 2. Surprisingly, the no-context baseline achieves high performance, comparable to some recently-published systems, showing that WikiHop is actually possible to solve reasonably well without using the document at all. One possible reason for this is that this model can filter possible answers based on expected answer type (Sugawara et al., 2018), as shown in the example of Figure 2, or perhaps capture other correlations between training and test. This model substantially outperforms the unlearned baseline reported in the WikiHop paper (Welbl et al., 2018) (38.8%) as well as the BiDAF (Seo et al., 2017) results reported there (42.9%).

4 Span-based vs. Multiple-choice

The no context model indicates that having multiple-choice questions may provide an avenue for a dataset to be gamed. In order to investigate the difference in multiple-choice vs. span supervision while controlling for other aspects of dataset difficulty, we first recast each dataset in the other’s framework, then investigate the performance of two models each of these settings.

To modify Hotpot to be multiple-choice, we

Dataset	HotpotQA-MC	WikiHop-MC
Metric	Accuracy	Accuracy
NoContext	68.01	59.70
MC-BiDAF++	70.01	61.32
MC-MemNet	68.75	61.80
Span2MC-BiDAF++	76.01	59.85

Table 3: The performance of different models on the dev sets of WikiHop and HotpotQA. MC denotes using both the multiple-choice dataset and model. Span2MC means we train the model with span-based supervision and evaluate the model on a multiple choice setting. Our models only mildly outperform the no-context baseline in all settings.

randomly select 9 entities in all of the documents as distractors, and add the answer to make a 10-choice candidates set. To modify WikiHop to be span-based, we concatenate all documents and treat the first appearance of the answer mention as the gold span for training. Any answer occurrence is treated as correct for evaluation.

4.1 Systems to Compare

MemNet Memory networks (Weston et al., 2015) define a generic model class which can gather information from different parts of the passage. Kumar et al. (2016) and Miller et al. (2016) have demonstrated its effectiveness in certain multi-hop settings. These models process a document over several timesteps. On the ith step, the model takes a question representation q_i, attends to the context representation $\mathbf{p}$, gets an attention distribution α_i, computes a new memory cell value $m_i = \sum \alpha_i p_i$, then forms an updated $q_{i+1} = f(m_i, q_i)$. The final memory cell m_T is used to compute a score $s_i = g(m_T, c_j)$ with the jth candidate representation c_j. We modify this architecture slightly using a standard hierarchical attention module (Li et al., 2015).

We can also modify this architecture to predict an answer span – we use the memory cell m_T of the last step, and do a bi-linear product with the context representation $\mathbf{p}$ to compute a distribution over start points $P_{start} = \text{softmax}(\mathbf{p}W_{start}m_T)$ and end points distribution $P_{end} = \text{softmax}(\mathbf{p}W_{end}m_T)$ of the answer span, where W_{start} and W_{end} are two parameter matrix to be learned. We call this Span-MemNet.

BiDAF++ Recently proposed by Clark and Gardner (2018), this is a high-performing model on SQuAD. It combines the bi-directional attention flow (Seo et al., 2017) and self-attention mechanisms. We use the implementation described in Yang et al. (2018).

Dataset	HotpotQA-Span		WikiHop-Span	
Metric	EM	F1	EM	F1
BiDAF++ (Yang+ 18)	42.79	56.19	–	–
Span-BiDAF++	42.45	56.46	24.23	46.13
Span-MemNet	18.75	26.11	13.54	19.23

Table 4: The performance of different models on the dev sets of WikiHop and HotpotQA. Span denotes using both span-based dataset and model. BiDAF++ denotes the performance reported in HotpotQA (Yang et al., 2018).

We can modify this model for the multiple-choice setting as well. Specifically, we use the start P_{start} and end P_{end} distribution to do a weighted sum over the context $\mathbf{p}$ to get a summarized representation $D_{start} = \sum P_{start_i} p_i$, $D_{end} = \sum P_{end_i} p_i$ of the context. Then we concatenate them to do a bilinear dot product with each candidate representation to get the answer score as we described for MemNet. We call this model MC-BiDAF++.

4.2 Results

Table 3 and Table 4 show our results in the two settings. As a baseline on multiple-choice HotpotQA, we also test the no-context baseline, which achieves an accuracy of 68.01%, around 10% absolute higher than on WikiHop. Our candidates were randomly chosen, so this setting may not be quite as challenging as a well-constructed multiple-choice dataset. From Table 3 and Table 4 we draw the following conclusions.

When trained and tested on multiple-choice datasets, our models do not learn multi-hop reasoning. Comparing MC-BiDAF++ and MC-MemNet on the multiple-choice setting of both datasets as shown in Table 3, the models appear to have similar capabilities to learn multi-hop reasoning. However, looking at the no-context baseline for comparison, we find that it is only around 2% lower than the two relatively more complex models. This indicates that much of the performance is achieved by "cheating" through the correlation between the candidates and question/context. Surprisingly, this is true even for HotpotQA, which seems stronger based on the analysis in Table 1.

Span-based data is less "hackable", but models still may not be doing multi-hop reasoning. We then compare the results of Span-BiDAF++

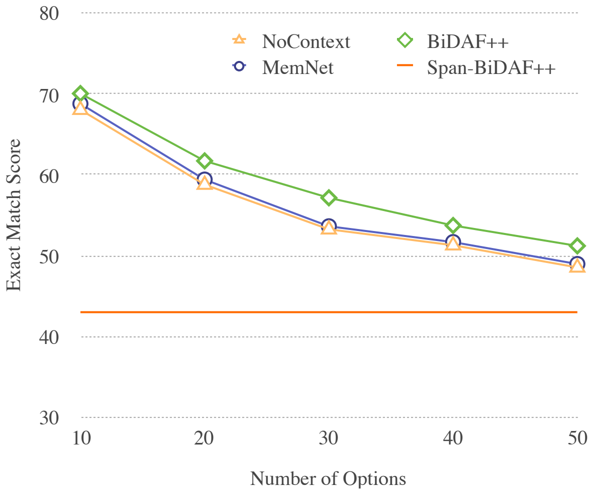

Figure 3: Performance of different options on HotpotQA-MC. Adding more options does not strengthen the model's ability of learning multi-hop reasoning.

and Span-MemNet on the span-based settings of both datasets, which are substantially different from the multiple-choice setting as shown in Table 4. BiDAF++ substantially outperforms the MemNet on both datasets, indicating that BiDAF++ is a stronger model for multi-hop reasoning, despite being less explicitly designed for this task. However, this model still underperforms the Factored BiDAF model, indicating that it could just be doing strong single-sentence reasoning.

Adding more options does not qualitatively change the multiple choice setting. The span-based model requires dealing with a much larger output space than the multiple-choice setting. To test the effects of this, we conduct another experiment by making more spurious options on HotpotQA-MC using the method described in Section 4. The results are shown in Figure 3. As we increase the number of options, we can see that the performance of all models drops. However, even with more options, the no-context baseline can still achieve comparable performance to the other two more complex models, which indicates that these models still aren't learning multi-hop reasoning in such a strengthened setting.

Span-based training data is more powerful. To further understand the two different supervision signals, we conduct another experiment where we train using span-based supervision and evaluate on the multiple-choice setting. Specifically, during evaluation, we select all document spans that map onto some answer candidate, then max over the scores of all spans to pick the predicted answer candidate. The multiple choice options therefore filter the span model's predictions.

From the results in Table 3, we can see that Span2MC-BiDAF++ achieves higher performance compared to MC-BiDAF++ on HotpotQA and nearly comparable performance on WikiHop even with random span selection during training. This shows that with the span-based supervision, the model can learn at least the same thing as the multiple-choice and avoid "cheating" through learning question-candidate correspondences.

5 Discussion and Conclusion

There exist several other multi-hop reasoning datasets including WorldTree (Jansen et al., 2018), OpenBookQA (Mihaylov et al., 2018), and MultiRC (Khashabi et al., 2018). These datasets are more complex to analyze since the answers may not appear directly in the passage and may simply be entailed by passage content. We leave a detailed investigation of these for future work.

For researchers working on the problem of multi-hop reasoning, we think the following points should be considered: (1) Prefer models using span-based supervision to avoid "cheating" by using the extra candidate information. (2) If using multiple-choice supervision, check the no-context baseline to see whether there are strong correlations between question and candidates. (3) When constructing a multi-hop oriented dataset, it would be best to do an adversarial test using a sentence-factored model to see whether multi-hop reasoning is really needed. Both HotpotQA and WikiHop contain good examples for evaluating multi-hop reasoning, but this evaluation is clouded by the presence of easily-solvable examples, which can confuse the learning process as well.

Abstract

Grammatical error correction (GEC) is one of the areas in natural language processing in which purely neural models have not yet superseded more traditional symbolic models. Hybrid systems combining phrase-based statistical machine translation (SMT) and neural sequence models are currently among the most effective approaches to GEC. However, both SMT and neural sequence-to-sequence models require large amounts of annotated data. Language model based GEC (LM-GEC) is a promising alternative which does not rely on annotated training data. We show how to improve LM-GEC by applying modelling techniques based on finite state transducers. We report further gains by rescoring with neural language models. We show that our methods developed for LM-GEC can also be used with SMT systems if annotated training data is available. Our best system outperforms the best published result on the CoNLL-2014 test set, and achieves far better relative improvements over the SMT baselines than previous hybrid systems.

1 Introduction

Grammatical error correction (GEC) is the task of automatically correcting all types of errors in text; e.g. [*In a such situaction* → *In such a situation*]. Using neural models for GEC is becoming increasingly popular (Xie et al., 2016; Yuan and Briscoe, 2016; Ji et al., 2017; Sakaguchi et al., 2017; Schmaltz et al., 2017; Chollampatt and Ng, 2018; Ge et al., 2018a,b), possibly combined with phrase-based SMT (Chollampatt et al., 2016; Chollampatt and Ng, 2017; Grundkiewicz and Junczys-Dowmunt, 2018). A potential challenge for purely neural GEC models is their vast output space since they assign non-zero probability mass to any sequence. GEC is – compared to machine translation – a highly constrained problem as corrections tend to be very local, and lexical choices are usually limited. Finite state transducers (FSTs) are an efficient way to represent large structured search spaces. In this paper, we propose to construct a hypothesis space using standard FST operations like composition, and then constrain the output of a neural GEC system to that space. We study two different scenarios: In the first scenario, we do not have access to annotated training data, and only use a small development set for tuning. In this scenario, we construct the hypothesis space using word-level context-independent confusion sets (Bryant and Briscoe, 2018) based on spell checkers and morphology databases, and rescore it with count-based and neural language models (NLMs). In the second scenario, we assume to have enough training data available to train SMT and neural machine translation (NMT) systems. In this case, we make additional use of the SMT lattice and rescore with an NLM-NMT ensemble. Our contributions are:

- We present an FST-based adaptation of the work of Bryant and Briscoe (2018) which allows exact inference, and does not require annotated training data. We report large gains from rescoring with a neural language model.
- Our technique beats the best published result with comparable amounts of training data on the CoNLL-2014 (Ng et al., 2014) test set when applied to SMT lattices. Our combination strategy yields larger gains over the SMT baselines than simpler rescoring or pipelining used in prior work on hybrid systems (Grundkiewicz and Junczys-Dowmunt, 2018).

2 Constructing the Hypothesis Space

Constructing the set of hypotheses The core idea of our approach is to first construct a

(weighted) hypothesis space H which is large enough to be likely to contain good corrections, but constrained enough to embrace the highly structured nature of GEC. Then, we use H to constrain a neural beam decoder. We make extensive use of the FST operations available in OpenFST (Allauzen et al., 2007) like composition (denoted with the $\circ$-operator) and projection (denoted with $\Pi_{\text{input}}(\cdot)$ and $\Pi_{\text{output}}(\cdot)$) to build H. The process starts with an input lattice I. In our experiments without annotated training data, I is an FST which simply maps the input sentence to itself as shown in Fig. 1(a). If we do have access to enough annotated data, we train an SMT system on it and derive I from the SMT n-best list.[1] For each hypothesis $\mathbf{y}$ we compute the Levenshtein distance $\text{lev}(\mathbf{x}, \mathbf{y})$ to the source sentence $\mathbf{x}$. We construct a string $\mathbf{z}$ by prepending $\text{lev}(\mathbf{x}, \mathbf{y})$ many `<mcorr>` tokens to $\mathbf{y}$, and construct I such that:

$$\mathbf{z} = (\texttt{<mcorr>})^{\text{lev}(\mathbf{x},\mathbf{y})} \cdot \mathbf{y} \qquad (1)$$

$$[[I]](\mathbf{z}) = -\lambda_{\text{SMT}} \text{SMT}(\mathbf{y}|\mathbf{x}). \qquad (2)$$

---

[1] In the rare cases in which the n-best list did not contain the source sentence $\mathbf{x}$ we added it in a postprocessing step.

We adapt the notation of Mohri (2003) and denote the cost I assigns to mapping a string $\mathbf{z}$ to itself as $[[I]](\mathbf{z})$, and set $[[I]](\mathbf{z}) = \infty$ if I does not accept $\mathbf{z}$. $\text{SMT}(\mathbf{y}|\mathbf{x})$ is the SMT score. In other words, I represents the weighted SMT n-best list after adding $\text{lev}(\mathbf{x}, \mathbf{y})$ many `<mcorr>` tokens to each hypothesis as illustrated in Fig. 1(c). We scale SMT scores by a factor λ_{SMT} for tuning.

Bryant and Briscoe (2018) addressed substitution errors such as non-words, morphology-, article-, and preposition-errors by creating confusion sets $C(x_i)$ that contain possible (context-independent) 1:1 corrections for each input word x_i. Specifically, they relied on CyHunspell for spell checking (Rodriguez and Seal, 2014), the AGID morphology database for morphology errors (Atkinson, 2011), and manually defined confusion sets for determiner and preposition errors, hence avoiding the need for annotated training data. We use the same confusion sets as Bryant and Briscoe (2018) to augment our hypothesis space via the edit flower transducer E shown in Fig. 2. E can map any sequence to itself via its σ-self-loop. Additionally, it allows the mapping $x_i \rightarrow$ `<corr>` $\cdot\, y$ for each $y \in C(x_i)$. For example, for the misspelled word $x_i =$ 'situaction' and the confusion set $C(\text{'situaction'}) = \{\text{'situation'}, \text{'acquisition'}\}$, E allows mapping 'situaction' to '`<corr>` situation' and '`<corr>` acquisition', and to itself via the σ-self-loop. The additional `<corr>` token will help us to keep track of the edits. We obtain our *base lattice* B which defines the set of possible hypotheses by composition and projection:

$$B := \Pi_{\text{output}}(I \circ E). \tag{3}$$

Fig. 1(d) shows B for our running example.

Scoring the hypothesis space We apply multiple scoring strategies to the hypotheses in B. First, we penalize `<mcorr>` and `<corr>` tokens with two further parameters, λ_{mcorr} and λ_{corr}, by composing B with the penalization transducer P shown in Fig. 3.[2] The λ_{mcorr} and λ_{corr} parameters control the trade-off between the number and quality of the proposed corrections since high values bias towards fewer corrections.

To incorporate word-level language model scores we train a 5-gram count-based LM with KenLM (Heafield, 2011) on the One Billion Word Benchmark dataset (Chelba et al., 2014), and convert it to an FST L using the OpenGrm NGram Library (Roark et al., 2012). For tuning purposes we scale weights in L with λ_{KenLM}:

$$[[L]](\mathbf{y}) = -\lambda_{\text{KenLM}} \log P_{\text{KenLM}}(\mathbf{y}). \tag{4}$$

Our combined word-level scores can be expressed with the following transducer:

$$H_{\text{word}} = B \circ P \circ L. \tag{5}$$

Since we operate in the tropical semiring, path scores in H_{word} are linear combinations of correction penalties, LM scores, and, if applicable, SMT scores, weighted with the λ-parameters. Note that exact inference in H_{word} is possible using FST shortest path search. This is an improvement over the work of Bryant and Briscoe (2018) who selected correction options greedily. Our ultimate goal, however, is to rescore H_{word} with neural models such as an NLM and – if annotated training data is available – an NMT model. Since our neural models use subword units (Sennrich et al., 2016, BPEs), we compose H_{word} with a transducer T which maps word sequences to BPE sequences. Our final transducer H_{BPE} which we use to constrain the neural beam decoder can be written as:

$$\begin{aligned} H_{\text{BPE}} &= \Pi_{\text{output}}(H_{\text{word}} \circ T) \\ &= \Pi_{\text{output}}(I \circ E \circ P \circ L \circ T). \end{aligned} \tag{6}$$

To help downstream beam decoding we apply ϵ-removal, determinization, minimization, and weight pushing (Mohri, 1997; Mohri and Riley, 2001) to H_{BPE}. We search for the best hypothesis $\mathbf{y}^*_{\text{BPE}}$ with beam search using a combined score of word-level symbolic models (represented by H_{BPE}) and subword unit based neural models:

$$\begin{aligned} \mathbf{y}^*_{\text{BPE}} = \arg\max_{\mathbf{y}_{\text{BPE}}} \Big(&-[[H_{\text{BPE}}]](\mathbf{y}_{\text{BPE}}) \\ &+ \lambda_{\text{NLM}} \log P_{\text{NLM}}(\mathbf{y}_{\text{BPE}}) \\ &+ \lambda_{\text{NMT}} \log P_{\text{NMT}}(\mathbf{y}_{\text{BPE}}|\mathbf{x}_{\text{BPE}}) \Big) \end{aligned} \tag{7}$$

The final decoding pass can be seen as an ensemble of a neural LM and an NMT model which is constrained and scored at each time step by the set of possible tokens in H_{BPE}.

---

[2] Rather than using `<mcorr>` and `<corr>` tokens and the transducer P we could directly incorporate the costs in the transducers I and E, respectively. We chose to use explicit correction tokens for clarity.

Table 2: Results with using annotated training data. Systems are tuned with respect to the metric highlighted in gray. Input lattices I are derived from the Moses 1000-best list as in Fig. 1(c). Row 3 is the SMT baseline.

We have introduced three λ-parameters λ_{corr}, λ_{KenLM}, and λ_{NLM}, and three additional parameters λ_{SMT}, λ_{mcorr}, and λ_{NMT} if we make use of annotated training data. We also use a word insertion penalty λ_{wc} for our SMT-based experiments. We tune all these parameters on the development sets using Powell search (Powell, 1964).[3]

3 Experiments

Experimental setup In our experiments with annotated training data we use the SMT system of Junczys-Dowmunt and Grundkiewicz (2016)[4] to create 1000-best lists from which we derive the input lattices I. All our LMs are trained on the One Billion Word Benchmark dataset (Chelba et al., 2014). Our neural LM is a Transformer decoder architecture in the `transformer_base` configuration trained with Tensor2Tensor (Vaswani et al., 2018). Our NMT model is a Transformer model (`transformer_base`) trained on the concatenation of the NUCLE corpus (Dahlmeier et al., 2013) and the Lang-8 Corpus of Learner English v1.0 (Mizumoto et al., 2012). We only keep sentences with at least one correction (659K sentences in total). Both NMT and NLM models use byte pair encoding (Sennrich et al., 2016, BPE) with 32K merge operations. We delay SGD updates by 2 on four physical GPUs as suggested by Saunders et al. (2018). We decode with beam size 12 using the SGNMT decoder (Stahlberg et al., 2017). We evaluate on CoNLL-2014 (Ng et al., 2014) and JFLEG-Test (Napoles et al., 2017), using CoNLL-2013 (Ng et al., 2013) and JFLEG-Dev as development sets. Our evaluation metrics are GLEU (Napoles et al., 2015) and M2 (Dahlmeier and Ng, 2012). We generated M2 files using ERRANT (Bryant et al., 2017) for JFLEG and Tab. 1 to be comparable to Bryant and Briscoe (2018), but used the official M2 files in Tab. 2 to be comparable to Grundkiewicz and Junczys-Dowmunt (2018).

Results Our LM-based GEC results without using annotated training data are summarized in Tab. 1. Even when we use the same resources (same LM and same confusion sets) as Bryant and Briscoe (2018), we see gains on JFLEG (rows 1 vs. 2), probably because we avoid search errors in our FST-based scheme. Adding an NLM yields significant gains across the board. Tab. 2 shows that adding confusion sets to SMT lattices is effective even without neural models (rows 3 vs. 4). Rescoring with neural models also benefits from the confusion sets (rows 5 vs. 6). With our ensemble systems (rows 7 and 8) we are able to outperform prior work[5] (row 1) on CoNLL-2014 and

---

[3] Similarly to Bryant and Briscoe (2018), even in our experiments without annotated *training* data, we do need a very small amount of annotated sentences for tuning.

[4] `https://github.com/grammatical/baselines-emnlp2016`

[5] We compare our systems to the work of Grundkiewicz and Junczys-Dowmunt (2018) as they used similar training data. We note, however, that Ge et al. (2018b) reported even better results with much more (non-public) training data. Comparing (Ge et al., 2018a) and (Ge et al., 2018b) suggests that most of their gains come from the larger training set.

	G&J-D (2018)		This work

SMT	50.27	55.79	48.18	50.86
Hybrid	56.25	61.50	58.40	58.63
Rel. gain	**11.90%**	**10.23%**	**21.21%**	**15.28%**

Table 3: Improvements over SMT baselines.

come within 3 GLEU on JFLEG. Since the baseline SMT systems of Grundkiewicz and Junczys-Dowmunt (2018) were better than the ones we used, we achieve even higher relative gains over the respective SMT baselines (Tab. 3).

Error type analysis We also carried out a more detailed error type analysis of the best CoNLL-2014 M2 system with/without training data using ERRANT (Tab. 4). Specifically, this table shows that while the trained system was consistently better than the untrained system, the degree of the improvement differs significantly depending on the error type. In particular, since the untrained system was only designed to handle Replacement word errors, much of the improvement in the trained system comes from the ability to correct Missing and Unnecessary word errors. The trained system nevertheless still improves upon the untrained system in terms of replacement errors by 10 $F_{0.5}$ (45.53 vs. 55.63).

In terms of more specific error types, the trained system was also able to capture a wider variety of error types, including content word errors (adjectives, adverbs, nouns and verbs) and other categories such as pronouns and punctuation. Since the untrained system only targets spelling, orthographic and morphological errors however, it is interesting to note that the difference in scores between these categories tends to be smaller than others; e.g. noun number (53.43 vs 64.96), orthography (62.77 vs 74.07), spelling (67.91 vs 75.21) and subject-verb agreement (66.67 vs 68.39). This suggests that an untrained system is already able to capture the majority of these error types.

Oracle experiments Our FST-based composition cascade is designed to enrich the search space to allow the neural models to find better hypotheses. Tab. 5 reports the oracle sentence error rate for different configurations, i.e. the fraction of reference sentences in the test set which are not in the FSTs. Expanding the SMT lattice significantly reduces the oracle error rate from 55.63% to 48.17%.

	ERRANT $F_{0.5}$

Hypothesis space	**Error rate**
Expanded input sentence (Tab. 1)	61.28%
SMT lattice (Tab. 2, rows 3, 5)	55.64%
Expanded SMT lattice (Tab. 2, rows 4, 6-8)	48.17%

Table 5: Oracle error rates for different hypothesis spaces using the first annotator in CoNLL-2014.

4 Conclusion

We demonstrated that our FST-based approach to GEC outperforms prior work on LM-based GEC significantly, especially when combined with a neural LM. We also applied our approach to SMT lattices and reported much better relative gains over the SMT baselines than previous work on hybrid systems. Our results suggest that FSTs provide a powerful and effective framework for constraining neural GEC systems.

Abstract

Self-attention networks (SANs) have drawn increasing interest due to their high parallelization in computation and flexibility in modeling dependencies. SANs can be further enhanced with multi-head attention by allowing the model to attend to information from different representation subspaces. In this work, we propose novel *convolutional self-attention networks*, which offer SANs the abilities to 1) strengthen dependencies among neighboring elements, and 2) model the interaction between features extracted by multiple attention heads. Experimental results of machine translation on different language pairs and model settings show that our approach outperforms both the strong Transformer baseline and other existing models on enhancing the locality of SANs. Comparing with prior studies, the proposed model is parameter free in terms of introducing no more parameters.

1 Introduction

Self-attention networks (SANs) (Parikh et al., 2016; Lin et al., 2017) have shown promising empirical results in various natural language processing (NLP) tasks, such as machine translation (Vaswani et al., 2017), natural language inference (Shen et al., 2018a), and acoustic modeling (Sperber et al., 2018). One appealing strength of SANs lies in their ability to capture dependencies regardless of distance by explicitly attending to all the elements. In addition, the performance of SANs can be improved by multi-head attention (Vaswani et al., 2017), which projects the input sequence into multiple subspaces and applies attention to the representation in each subspace.

Despite their success, SANs have two major limitations. First, the model fully take into account all the elements, which disperses the attention distribution and thus overlooks the relation of neighboring elements and phrasal patterns (Yang et al., 2018; Wu et al., 2018; Guo et al., 2019). Second, multi-head attention extracts distinct linguistic properties from each subspace in a parallel fashion (Raganato and Tiedemann, 2018), which fails to exploit useful interactions across different heads. Recent work shows that better features can be learned if different sets of representations are present at feature learning time (Ngiam et al., 2011; Lin et al., 2014).

To this end, we propose novel *convolutional self-attention networks* (CSANs), which model locality for self-attention model and interactions between features learned by different attention heads in an unified framework. Specifically, in order to pay more attention to a local part of the input sequence, we restrict the attention scope to a window of neighboring elements. The localness is therefore enhanced via a parameter-free 1-dimensional convolution. Moreover, we extend the convolution to a 2-dimensional area with the axis of attention head. Thus, the proposed model allows each head to interact local features with its adjacent subspaces at attention time. We expect that the interaction across different subspaces can further improve the performance of SANs.

We evaluate the effectiveness of the proposed model on three widely-used translation tasks: WMT14 English-to-German, WMT17 Chinese-to-English, and WAT17 Japanese-to-English. Experimental results demonstrate that our approach consistently improves performance over the strong TRANSFORMER model (Vaswani et al., 2017) across language pairs. Comparing with previous work on modeling locality for SANs (e.g. Shaw et al., 2018; Yang et al., 2018; Sperber et al., 2018), our model boosts performance on both translation quality and training efficiency.

(a) Vanilla SANs (b) 1D-Convolutional SANs (c) 2D-Convolutional SANs

Figure 1: Illustration of (a) vanilla SANs; (b) 1-dimensional convolution with the window size being 3; and (c) 2-dimensional convolution with the area being 3 × 3. Different colors and patterns represent different subspaces modeled by multi-head attention, and transparent colors denote masked tokens that are invisible to SANs.

2 Multi-Head Self-Attention Networks

SANs produce representations by applying attention to each pair of tokens from the input sequence, regardless of their distance. Vaswani et al. (2017) found it is beneficial to capture different contextual features with multiple individual attention functions. Given an input sequence $\mathbf{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_I\} \in \mathbb{R}^{I \times d}$, the model first transforms it into queries $\mathbf{Q}$, keys $\mathbf{K}$, and values $\mathbf{V}$:

$$\mathbf{Q}, \mathbf{K}, \mathbf{V} = \mathbf{X}\mathbf{W}_Q, \mathbf{X}\mathbf{W}_K, \mathbf{X}\mathbf{W}_V \in \mathbb{R}^{I \times d} \quad (1)$$

where $\{\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_V\} \in \mathbb{R}^{d \times d}$ are trainable parameters and d indicates the hidden size. The three types of representations are split into H different subspaces, e.g., $[\mathbf{Q}^1, \dots, \mathbf{Q}^H] = \mathbf{Q}$ with $\mathbf{Q}^h \in \mathbb{R}^{I \times \frac{d}{H}}$. In each subspace h, the element $\mathbf{o}_i^h$ in the output sequence $\mathbf{O}^h = \{\mathbf{o}_1^h, \dots, \mathbf{o}_I^h\}$ is calculated by

$$\mathbf{o}_i^h = \textsc{Att}(\mathbf{q}_i^h, \mathbf{K}^h)\mathbf{V}^h \qquad \in \mathbb{R}^{\frac{d}{H}} \quad (2)$$

where $\textsc{Att}(\cdot)$ is an attention model (Bahdanau et al., 2015; Vaswani et al., 2017) that retrieves the keys $\mathbf{K}^h$ with the query $\mathbf{q}_i^h$. The final output representation $\mathbf{O}$ is the concatenation of outputs generated by multiple attention models:

$$\mathbf{O} = [\mathbf{O}^1, \dots, \mathbf{O}^H] \qquad \in \mathbb{R}^{I \times d} \quad (3)$$

3 Approach

As shown in Figure 1(a), the vanilla SANs use the query $\mathbf{q}_i^h$ to compute a categorical distribution over all elements from $\mathbf{K}^h$ (Equation 2). It may inherit the attention to neighboring information (Yu et al., 2018; Yang et al., 2018; Guo et al., 2019). In this work, we propose to model locality for SANs by restricting the model to attend to a local region via convolution operations (1D-CSANs, Figure 1(b)). Accordingly, it provides distance-aware information (e.g. phrasal patterns), which is complementary to the distance-agnostic dependencies modeled by the standard SANs (Section 3.1).

Moreover, the calculation of output $\mathbf{o}^h$ are restricted to the a single individual subspace, overlooking the richness of contexts and the dependencies among groups of features, which have proven beneficial to the feature learning (Ngiam et al., 2011; Wu and He, 2018). We thus propose to convolute the items in adjacent heads (2D-CSANs, Figure 1(c)). The proposed model is expected to improve performance through interacting linguistic properties across heads (Section 3.2).

3.1 Locality Modeling via 1D Convolution

For each query $\mathbf{q}_i^h$, we restrict its attention region (e.g., $\mathbf{K}^h = \{\mathbf{k}_1^h, \dots, \mathbf{k}_i^h, \dots, \mathbf{k}_I^h\}$) to a local scope with a fixed size $M + 1$ ($M \leq I$) centered at the position i:

$$\widehat{\mathbf{K}}^h = \{\mathbf{k}_{i-\frac{M}{2}}^h, \dots, \mathbf{k}_i^h, \dots, \mathbf{k}_{i+\frac{M}{2}}^h\} \quad (4)$$

$$\widehat{\mathbf{V}}^h = \{\mathbf{v}_{i-\frac{M}{2}}^h, \dots, \mathbf{v}_i^h, \dots, \mathbf{v}_{i+\frac{M}{2}}^h\} \quad (5)$$

Accordingly, the calculation of corresponding output in Equation (2) is modified as:

$$\mathbf{o}_i^h = \textsc{Att}(\mathbf{q}_i^h, \widehat{\mathbf{K}}^h)\widehat{\mathbf{V}}^h \quad (6)$$

As seen, SANs are only allowed to attend to the neighboring tokens (e.g., $\widehat{\mathbf{K}}^h$, $\widehat{\mathbf{V}}^h$), instead of all the tokens in the sequence (e.g., $\mathbf{K}^h$, $\mathbf{V}^h$).

The SAN-based models are generally implemented as multiple layers, in which higher layers tend to learn semantic information while lower layers capture surface and lexical information (Peters et al., 2018; Raganato and Tiedemann, 2018). Therefore, we merely apply locality modeling to the lower layers, which same to the configuration in Yu et al. (2018) and Yang et al. (2018). In this way, the representations are learned in a hierarchical fashion (Yang et al., 2017). That is, the distance-aware and local information extracted by the lower SAN layers, is expected to complement distance-agnostic and global information captured by the higher SAN layers.

3.2 Attention Interaction via 2D Convolution

Mutli-head mechanism allows different heads to capture distinct linguistic properties (Raganato and Tiedemann, 2018; Li et al., 2018), especially in diverse local contexts (Yang et al., 2018). We hypothesis that exploiting local properties across heads can further improve the performance of SANs. To this end, we expand the 1-dimensional window to a 2-dimensional area with the new dimension being the index of attention head. Suppose that the area size is $(N+1) \times (M+1)$ $(N \leq H)$, the keys and values in the area are:

$$\widetilde{\mathbf{K}}^h = \bigcup[\widehat{\mathbf{K}}^{h-\frac{N}{2}}, \dots, \widehat{\mathbf{K}}^h, \dots, \widehat{\mathbf{K}}^{h+\frac{N}{2}}] \quad (7)$$

$$\widetilde{\mathbf{V}}^h = \bigcup[\widehat{\mathbf{V}}^{h-\frac{N}{2}}, \dots, \widehat{\mathbf{V}}^h, \dots, \widehat{\mathbf{V}}^{h+\frac{N}{2}}] \quad (8)$$

where $\widehat{\mathbf{K}}^h, \widehat{\mathbf{V}}^h$ are elements in the h-th subspace, which are calculated by Equations 4 and 5 respectively. The union operation $\bigcup$ means combining the keys and values in different subspaces. The corresponding output is calculated as:

$$\mathbf{o}_i^h = \textsc{Att}(\mathbf{q}_i^h, \widetilde{\mathbf{K}}^h)\widetilde{\mathbf{V}}^h \quad (9)$$

The 2D convolution allows SANs to build relevance between elements across adjacent heads, thus flexibly extract local features from different subspaces rather than merely from an unique head.

The vanilla SAN models linearly aggregate features from different heads, and this procedure limits the extent of abstraction (Fukui et al., 2016; Li et al., 2019). Multiple sets of representations presented at feature learning time can further improve the expressivity of the learned features (Ngiam et al., 2011; Wu and He, 2018).

4 Related Work

Self-Attention Networks Recent studies have shown that SANs can be further improved by capturing complementary information. For example, Hao et al. (2019) complemented SANs with recurrence modeling, while Yang et al. (2019) modeled contextual information for SANs.

Concerning modeling locality for SANs, Yu et al. (2018) injected several CNN layers (Kim, 2014) to fuse local information, the output of which is fed to the subsequent SAN layer. Several researches proposed to revise the attention distribution with a parametric localness bias, and succeed on machine translation (Yang et al., 2018) and natural language inference (Guo et al., 2019). While both models introduce additional parameters, our approach is a more lightweight solution without introducing any new parameters. Closely related to this work, Shen et al. (2018a) applied a positional mask to encode temporal order, which only allows SANs to attend to the previous or following tokens in the sequence. In contrast, we employ a positional mask (i.e. the tokens outside the local window is masked as 0) to encode the distance-aware local information.

In the context of distance-aware SANs, Shaw et al. (2018) introduced relative position encoding to consider the relative distances between sequence elements. While they modeled locality from position embedding, we improve locality modeling from revising attention scope. To make a fair comparison, we re-implemented the above approaches under a same framework. Empirical results on machine translation tasks show the superiority of our approach in both translation quality and training efficiency.

Multi-Head Attention Multi-head attention mechanism (Vaswani et al., 2017) employs different attention heads to capture distinct features (Raganato and Tiedemann, 2018). Along this direction, Shen et al. (2018a) explicitly used multiple attention heads to model different dependencies of the same word pair, and Strubell et al. (2018) employed different attention heads to capture different linguistic features. Li et al. (2018) introduced disagreement regularizations to encourage the diversity among attention heads. Inspired by recent successes on fusing information across layers (Dou et al., 2018, 2019), Li et al. (2019) proposed to aggregate information captured by different attention heads. Based on these findings, we model interactions among attention heads to exploit the richness of local properties distributed in different heads.

5 Experiments

We conducted experiments with the Transformer model (Vaswani et al., 2017) on English⇒German (En⇒De), Chinese⇒English (Zh⇒En) and Japanese⇒English (Ja⇒En) translation tasks.

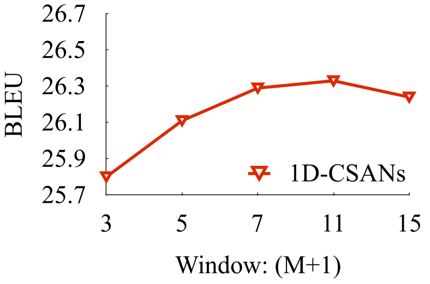
For the En⇒De and Zh⇒En tasks, the models were trained on widely-used WMT14 and WMT17 corpora, consisting of around 4.5 and 20.62 million sentence pairs, respectively. Concerning Ja⇒En, we used the first two sections of WAT17 corpus as the training data, which consists of 2M sentence pairs. To reduce the vocabulary size, all the data were tokenized and segmented into subword symbols using byte-pair encoding (Sennrich et al., 2016) with 32K merge operations. Following Shaw et al. (2018), we incorporated the proposed model into the encoder, which is a stack of 6 SAN layers. Prior studies revealed that modeling locality in lower layers can achieve better performance (Shen et al., 2018b; Yu et al., 2018; Yang et al., 2018), we applied our approach to the lowest three layers of the encoder. About configurations of NMT models, we used the *Base* and *Big* settings same as Vaswani et al. (2017), and all models were trained on 8 NVIDIA P40 GPUs with a batch of 4096 tokens.

5.1 Effects of Window/Area Size

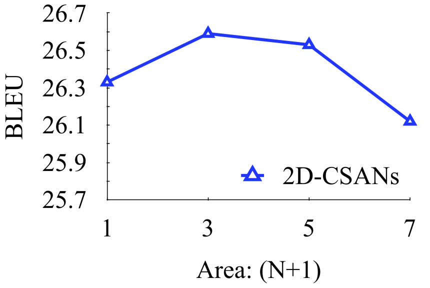
We first investigated the effects of window size (1D-CSANs) and area size (2D-CSANs) on En⇒De validation set, as plotted in Figure 2. For 1D-CSANs, the local size with 11 is superior to other settings. This is consistent with Luong et al. (2015) who found that 10 is the best window size in their local attention experiments. Then, we fixed the number of neighboring tokens being 11 and varied the number of heads. As seen, by considering the features across heads (i.e. > 1), 2D-CSANs further improve the translation quality. However, when the number of heads in attention goes up, the translation quality inversely drops. One possible reason is that the model still has the flexibility of learning a different distribution for each head with few interactions, while a large amount of interactions assumes more heads make “similar contributions” (Wu and He, 2018).

5.2 Accuracy of Phrase Translation

One intuition of our approach is to capture useful phrasal patterns via modeling locality. To evaluate the accuracy of phrase translations, we calculate the improvement of the proposed approaches over multiple granularities of n-grams, as shown in Figure 3. Both the two model variations consistently outperform the baseline on larger granularities, indicating that modeling locality can raise the ability of self-attention model on capturing the phrasal information. Furthermore, the dependencies among heads can be complementary to the localness modeling, which reveals the necessity of the interaction of features in different subspaces.



(a) 1D-CSANs



(b) 2D-CSANs

Figure 2: Effects of (a) window size on 1D-CSANs, and (b) attended head numbers on 2D-CSANs. For 2D-CSANs, the window size dimension is fixed to be 11.

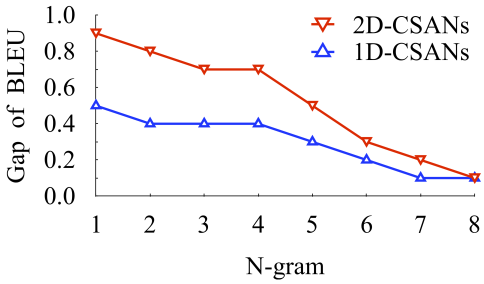


Figure 3: Performance improvement on different n-grams. “Gap of BLEU” denotes the improvement achieved by the proposed models over the baseline.

5.3 Comparison to Related Work

We re-implemented and compared several exiting works (Section 4) upon the same framework. Table 1 lists the results on the En⇒De translation task. As seen, all the models improve translation quality, reconfirming the necessity of modeling locality and distance information. Besides, our models outperform all the existing works, indicating the superiority of the proposed approaches. In particular, CSANs achieve better performance than

Model	Parameter	Speed	BLEU	△
Transformer-Base (Vaswani et al., 2017)	88.0M	1.28	27.31	-
+ Bi_Direct (Shen et al., 2018a)	+0.0M	-0.00	27.58	+0.27
+ Rel_Pos (Shaw et al., 2018)	+0.1M	-0.11	27.63	+0.32
+ Neighbor (Sperber et al., 2018)	+0.4M	-0.06	27.60	+0.29
+ Local_Hard (Luong et al., 2015)	+0.4M	-0.06	27.73	+0.42
+ Local_Soft (Yang et al., 2018)	+0.8M	-0.09	27.81	+0.50
+ Block (Shen et al., 2018b)	+6.0M	-0.33	27.59	+0.28
+ CNNs (Yu et al., 2018)	+42.6M	-0.54	27.70	+0.39
+ 1D-CSANs	+0.0M	-0.00	**27.86**	+0.55
+ 2D-CSANs	+0.0M	-0.06	**28.18**	+0.87

Table 1: Comparing with the existing approaches on WMT14 En⇒De translation task. For a fair comparison, we re-implemented the existing locality approaches under the same framework. “Parameter” denotes the number of model parameters (M = million) and “Speed” denotes the training speed (steps/second). “△” column denotes performance improvements over the Transformer baseline.

Model	WMT14 En⇒De		WMT17 Zh⇒En		WAT17 Ja⇒En	
	Speed	BLEU	Speed	BLEU	Speed	BLEU
Transformer-Base	1.28	27.31	1.21	24.13	1.33	28.10
+ CSANs	1.22	$28.18^{\Uparrow}$	1.16	$24.80^{\Uparrow}$	1.28	$28.50^{\uparrow}$
Transformer-Big	0.61	28.58	0.58	24.56	0.65	28.41
+ CSANs	0.50	28.74	0.48	$25.01^{\uparrow}$	0.55	$28.73^{\uparrow}$

Table 2: Experimental results on WMT14 En⇒De, WMT17 Zh⇒En and WAT17 Ja⇒En test sets. “Speed” denotes the training speed (steps/second). “↑ / ⇑” indicates statistically significant difference from the vanilla self-attention counterpart ($p < 0.05/0.01$), tested by bootstrap resampling (Koehn, 2004).

CNNs, revealing that extracting local features with dynamic weights is superior to assigning fixed parameters. Moreover, while most of the existing approaches (except for Shen et al. (2018a)) introduce new parameters, our methods are parameter-free and thus only marginally affect training efficiency.

5.4 Universality of The Proposed Model

To validate the universality of our approach on MT tasks, we evaluated the proposed approach on different language pairs and model settings. Table 2 lists the results on En⇒De, Zh⇒En and Ja⇒En translation tasks. As seen, our model consistently improves translation quality across language pairs, which demonstrates the effectiveness and universality of the proposed approach. It is encouraging to see that CSANs with *base* setting yields comparable performance with Transformer-Big.

6 Conclusion

In this paper, we propose a parameter-free convolutional self-attention model to enhance the feature extraction of neighboring elements across multiple heads. Empirical results of machine translation task on a variety of language pairs demonstrate the effectiveness and universality of the proposed methods. The extensive analyses suggest that: 1) modeling locality is beneficial to SANs; 2) interacting features across multiple heads at attention time can further improve the performance; and 3) to some extent, the dynamic weights are superior to their fixed counterpart (i.e. CSANs vs. CNNs) on local feature extraction. Moreover, it is interesting to validate the proposed model in other sequence modeling tasks.

Abstract

Neural network models for many NLP tasks have grown increasingly complex in recent years, making training and deployment more difficult. A number of recent papers have questioned the necessity of such architectures and found that well-executed, simpler models are quite effective. We show that this is also the case for document classification: in a large-scale reproducibility study of several recent neural models, we find that a simple BiLSTM architecture with appropriate regularization yields accuracy and F_1 that are either competitive or exceed the state of the art on four standard benchmark datasets. Surprisingly, our simple model is able to achieve these results *without* attention mechanisms. While these regularization techniques, borrowed from language modeling, are not novel, to our knowledge we are the first to apply them in this context. Our work provides an open-source platform and the foundation for future work in document classification.

1 Introduction

Recent developments in neural architectures for a wide range of NLP tasks can be characterized as a drive towards increasingly complex network components and modeling techniques. Worryingly, these new models are accompanied by smaller and smaller improvements in effectiveness on standard benchmark datasets, which leads us to wonder if observed improvements are "real". There is, however, ample evidence to the contrary. To provide a few examples: Melis et al. (2018) report that standard LSTM architectures outperform more recent models when properly tuned. Vaswani et al. (2017) show that sequence transduction using encoder–decoder networks with attention mechanisms work just as well with the attention module only, making most of the complex neural machinery unnecessary. Mohammed et al. (2018) show that simple RNN- and CNN-based models yield accuracies rivaling far more complex architectures in simple question answering over knowledge graphs.

Perhaps most damning are the indictments of Sculley et al. (2018), who lament the lack of empirical rigor in our field and cite even more examples where improvements can be attributed to far more mundane reasons (e.g., hyperparameter tuning) or are simply noise. Lipton and Steinhardt (2018) concur with these sentiments, adding that authors often use fancy mathematics to obfuscate or to impress (reviewers) rather than to clarify. Complex architectures are more difficult to train, more sensitive to hyperparameters, and brittle with respect to domains with different data characteristics—thus both exacerbating the "crisis of reproducibility" and making it difficult for practitioners to deploy networks that tackle real-world problems in production environments.

Like the papers cited above, we question the need for overly complex neural architectures, focusing on the problem of document classification. Starting with a large-scale reproducibility study of several recent neural models, we find that a simple bi-directional LSTM (BiLSTM) architecture with appropriate regularization yields accuracy and F_1 that are either competitive or exceed the state of the art on four standard benchmark datasets. As the closest comparison point, we find no benefit to the hierarchical modeling proposed by Yang et al. (2016) and we are able to achieve good classification results *without* attention mechanisms. While these regularization techniques, borrowed from language modeling, are not novel, we are to our knowledge the first to apply them in this context. Our work provides an open-source platform and the foundation for future work in document classification.

2 Background and Related Work

2.1 Document Classification

Over the last few years, deep neural networks have achieved the state of the art in document classification. One popular model, hierarchical attention network (HAN), uses word- and sentence-level attention in classifying documents (Yang et al., 2016). Although this model nicely captures the intuition that modeling word sequences in sentences should be handled separately from sentence-level discourse modeling, one wonders if such complex architectures are really necessary, especially given the size of training data available today.

An important variant of document classification is the multi-label, multi-class case. Liu et al. (2017) develop XML-CNNs for multi-label text classification, basing the architecture on KimCNN (Kim, 2014) with increased filter sizes and an additional fully-connected layer. They also incorporate dynamic adaptive max-pooling (Chen et al., 2015) instead of the vanilla max-pooling over time in KimCNN. The paper compares with CNN-based approaches for the multi-label task, but only reports precision and disregards recall. Yang et al. (2018) instead adopts encoder–decoder sequence generation models (SGMs) for generating multiple labels for each document. Similar to our critique of HAN, we opine against the high complexity of these multi-label approaches.

2.2 Regularizing RNNs

There have been attempts to extend dropout (Srivastava et al., 2014) from feedforward neural networks to recurrent ones. Unfortunately, direct application of dropout on the hidden units of an RNN empirically harms its ability to retain long-term information (Zaremba et al., 2014). Recently, however, Merity et al. (2018) successfully apply dropout-like techniques to regularize RNNs for language modeling, achieving competitive word-level perplexity on multiple datasets. Inspired by this development, we adopt two of their regularization techniques, embedding dropout and weight-dropped LSTMs, to our task of document classification.

Weight-dropped LSTM. LSTMs comprise eight total input–hidden and hidden–hidden weight matrices; in weight dropping, Merity et al. (2018) regularize the four hidden–hidden matrices with DropConnect (Wan et al., 2013). The operation is applied only once per sequence, using the same dropout mask across multiple timesteps. Conveniently, this allows practitioners to use fast, out-of-the-box LSTM implementations without affecting the RNN formulation or training performance.

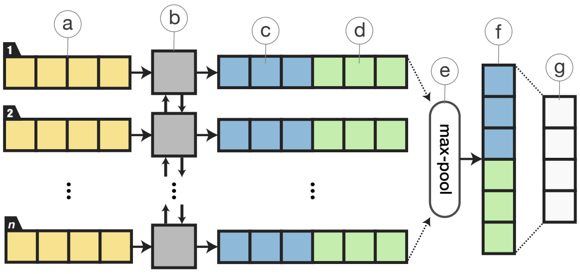

Figure 1: Illustration of the model architecture, where the labels are the following: (a) input word embeddings (b) BiLSTM (c, d) concatenated forward $h^f_{1:n}$ and backward $h^b_{1:n}$ hidden features (e) max-pooling over time (f) document feature vector (g) softmax or sigmoid output.

Embedding Dropout. Introduced in Gal and Ghahramani (2016) and successfully employed for neural language modeling (Merity et al., 2018), embedding dropout performs dropout on entire word embeddings, effectively removing some of the words at each training iteration. As a result, the technique conditions the model to be robust against missing input; for document classification, this discourages the model from relying on a small set of input words for prediction.

3 BiLSTM Model

We design our model to be minimalistic: First, we feed the word embeddings $\mathbf{w}_{1:n}$ of a document to a single-layer BiLSTM, extracting concatenated forward and backward word-level context vectors $\mathbf{h}_{1:n} = \mathbf{h}^f_{1:n} \oplus \mathbf{h}^b_{1:n}$. Subsequently, we max-pool $\mathbf{h}_{1:n}$ across time to yield document vector $\mathbf{d}$—see Figure 1, labels a–f. Finally, we feed $\mathbf{d}$ to a sigmoid or a softmax layer over the labels, depending on if the task type is multi-label or single-label classification (label g).

Contrary to prior art, our approach refrains from attention, hierarchical structure, and sequence generation, each of which increases model complexity. For one, hierarchical structure requires sentence-level tokenization and multiple RNNs. For another, sequence generation uses an encoder–decoder architecture, reducing computational parallelism. All three methods add depth to the model; our approach instead uses a single-layer BiLSTM with trivial max-pooling and concatenation operations, which makes for both simple implementation and resource-efficient inference.

4 Experimental Setup

We conduct a large-scale reproducibility study involving HAN, XML-CNN, KimCNN, and SGM. These are compared to our proposed model, referred to as LSTM_{reg}, as well as an ablated variant without regularization, denoted LSTM_{base}. The implementation of our model as well as from-scratch reimplementations of all the comparison models (except for SGM) are provided in our toolkit called Hedwig, which we make publicly available to serve as the foundation for future work.[1] In addition, we compare the neural approaches to logistic regression (LR) and support vector machines (SVMs). The LR model is trained using a one-vs-rest multi-label objective, while the SVM is trained with a linear kernel. Both of these methods use word-level tf–idf vectors of the documents as features.

All of our experiments are performed on Nvidia GTX 1080 and RTX 2080 Ti GPUs, with PyTorch 0.4.1 as the backend framework. We use Scikit-learn 0.19.2 for computing the tf–idf vectors and implementing LR and SVMs.

4.1 Datasets

We evaluate our models on the following four datasets: Reuters-21578, arXiv Abstract Paper dataset (AAPD), IMDB, and Yelp 2014. Reuters and AAPD are multi-label datasets, whereas IMDB and Yelp are single-label ones. For IMDB and Yelp, we use random sampling to split the dataset such that 80% is used for training, 10% for validation, and 10% for test. We use the standard ModApte splits (Apté et al., 1994) for the Reuters dataset, and author-defined splits for AAPD (Yang et al., 2018). We summarize the statistics of these datasets in Table 1.

Unfortunately, there is little consensus within the natural language processing community for choosing the splits of IMDB and Yelp 2014. Furthermore, they are often unreported in modeling papers, hence preventing direct comparison with past results. We are not able to find the exact splits Yang et al. (2016) use; for consistency, we use the same proportion the authors report, but of course this yields different samples in each split.

Dataset	C	N	W	S
Reuters	90	10,789	144.3	6.6
AAPD	54	55,840	167.3	1.0
IMDB	10	135,669	393.8	14.4
Yelp 2014	5	1,125,386	148.8	9.1

Table 1: Summary of the datasets. C denotes the number of classes in the dataset, N the number of samples, and W and S the average number of words and sentences per document, respectively.

For the multi-label datasets, we report the well-known micro-averaged F_1 score, which is the class-weighted harmonic mean between recall and precision. For the single-label datasets, we compare the models using accuracy.

4.2 Training and Hyperparameters

To ensure a fair comparison, we tune the hyperparameters for all baseline models. For HAN, we use a batch size of 32 across all the datasets, with a learning rate of 0.01 for Reuters and 0.001 for the rest. To train XML-CNN, we select a dynamic pooling window length of eight, a learning rate of 0.001, and 128 output channels, with batch sizes of 32 and 64 for single-label and multi-label datasets, respectively. For KimCNN, we use a batch size of 64 with a learning rate of 0.01. For training SGM on Reuters, we use the source code provided by the authors[2] and follow the same hyperparameters in their paper (Yang et al., 2018). For the LR and SVM models, we use the default set of hyperparameters in Scikit-learn.

For LSTM_{reg} and LSTM_{base}, we use the Adam optimizer with a learning rate of 0.01 on Reuters and 0.001 on the rest of the datasets, using batch sizes of 32 and 64 for multi-label and single-label tasks, respectively. For LSTM_{reg}, we also apply temporal averaging (TA): as shown in Kingma and Ba (2014), TA reduces both generalization error and stochastic noise in recent parameter estimates from stochastic approximation. We set the default TA exponential smoothing coefficient of β_{EMA} to 0.99. We choose 512 hidden units for the Bi-LSTM models, whose max-pooled output is regularized using a dropout rate of 0.5. We also regularize the input–hidden and hidden–hidden Bi-LSTM connections using embedding dropout and weight dropping, respectively, with dropout rates of 0.1 and 0.2.

Table 2: Results for each model on the validation and test sets; best values are bolded in blue. *Repl.* reports mean ± SD of five runs from our reimplementations; *Orig.* refers to point estimates from †Yang et al. (2018), ‡Yang et al. (2016), and ††Tang et al. (2015).

For our optimization objective, we use cross-entropy and binary cross-entropy loss for single-label and multi-label tasks, respectively. On all datasets and models, we use 300-dimensional word vectors (Mikolov et al., 2013) pre-trained on Google News. We train all neural models for 30 epochs with five random seeds, reporting the mean validation set scores and their corresponding test set results.

Toward Robust Baselines. Recently, reproducibility is becoming a growing concern for the NLP community (Crane, 2018). Indeed, very few of the papers that we consider in this study report validation set results, let alone run on multiple seeds. In order to address these issues, we report scores on both validation and test sets for our reimplementations; doing so is good practice, since it reinforces the validity of the experimental results and claims. We also provide the standard deviation of the scores across different seeds to demonstrate the stability of our results. This is in line with previous papers (Zhang and Wallace, 2017; Reimers and Gurevych, 2017; Crane, 2018) that emphasize reporting variance for robustness against potentially spurious conclusions.

5 Results and Discussion

We report the mean and standard deviation (SD) of the F_1 scores and accuracy for all five runs in Table 2. For HAN and KimCNN, we include results from the original papers to validate our reimplementation. We fail to replicate the reported results of SGM on AAPD using the authors' codebase and data splits.[3] As a result, we simply copy the value reported in Yang et al. (2018) in Table 2, row 8, which represents their maximum F_1 score. To verify the correctness of our HAN and KimCNN reimplementations, we compare the differences in F_1 and accuracy on the appropriate datasets. We attribute the small differences to using different dataset splits (see Section 4.1) and reporting mean values.

Baseline Comparison. We see that our simple LSTM$_{reg}$ model achieves state of the art on Reuters and IMDB (see Table 2, rows 9 and 10), establishing mean scores of 87.0 and 52.8 for F_1 score and accuracy on the test sets of Reuters and IMDB, respectively. This highlights the efficacy of proper regularization and optimization techniques for the task. We observe that LSTM$_{reg}$ consistently improves upon the performance of LSTM$_{base}$ across all of the tasks—see rows 9 and 10, where, on average, regularization yields increases of 1.5 and 0.5 points for F_1 score and accuracy, respectively.

A few of our LSTM$_{reg}$ runs attain state-of-the-art test F_1 scores on AAPD. However, in the interest of robustness, we report the mean value, as mentioned in Section 4.2. We also find the accuracy of LSTM$_{reg}$ and our reimplemented version of HAN on Yelp 2014 to be almost two points lower than the copied result of HAN (rows 6, 7, and 10) from Yang et al. (2016). On the other hand, both of the models surpass the original result by nearly two points for the IMDB dataset. We cannot rule out that these disparities are caused

---

[3] The authors did not answer our e-mails seeking assistance.

by the absence of any widely-accepted splits for evaluation on Yelp 2014 and IMDB (as opposed to model or implementation differences).

Interestingly, the non-neural LR and SVM baselines perform remarkably well. On Reuters, for example, the SVM beats many neural baselines, including our non-regularized LSTM_{base} (rows 2–9). On AAPD, the SVM either ties or beats the other models, losing only to SGM (rows 2–8). Compared to the SVM, the LR baseline appears better suited for the single-label datasets IMDB and Yelp 2014, where it achieves better accuracy than the SVM does.

6 Conclusions and Future Work

In this paper, we question the complexity of existing neural network architectures for document classification. To demonstrate the effectiveness of proper regularization and optimization, we apply embedding dropout, weight dropping, and temporal averaging when training a simple BiLSTM model, establishing either competitive or state-of-the-art results on multiple datasets.

One potential extension of this work is to conduct a comprehensive ablation study to determine the relative contribution of each of the regularization and optimization techniques. Furthermore, it would be interesting to compare these techniques to the recent line of research in deep language representation models, such as Embeddings from Language Models (ELMo; Peters et al., 2018) and pre-trained transformers (Devlin et al., 2018; Radford, 2018). Finally, the examined regularization and optimization methods deserve exploration in other NLP tasks as well.

Pre-trained Language Model Representations for Language Generation

Abstract

Pre-trained language model representations have been successful in a wide range of language understanding tasks. In this paper, we examine different strategies to integrate pre-trained representations into sequence to sequence models and apply it to neural machine translation and abstractive summarization. We find that pre-trained representations are most effective when added to the encoder network which slows inference by only 14%. Our experiments in machine translation show gains of up to 5.3 BLEU in a simulated resource-poor setup. While returns diminish with more labeled data, we still observe improvements when millions of sentence-pairs are available. Finally, on abstractive summarization we achieve a new state of the art on the full text version of CNN-DailyMail. [1]

1 Introduction

Pre-training of language models has been shown to provide large improvements for a range of language understanding tasks (Peters et al., 2018; Radford et al., 2018; Phang et al., 2018; Devlin et al., 2018). The key idea is to train a large generative model on vast corpora and use the resulting representations on tasks for which only limited amounts of labeled data is available. Pre-training of sequence to sequence models has been previously investigated for text classification (Dai and Le, 2015) but not for text generation. In neural machine translation, there has been work on transferring representations from high-resource language pairs to low-resource settings (Zoph et al., 2016).

In this paper, we apply pre-trained representations from language models to language generation tasks that can be modeled by sequence to sequence architectures. Previous work on integrating language models with sequence to sequence models focused on the decoder network and added language model representations right before the output of the decoder (Gulcehre et al., 2015). We extend their study by investigating several other strategies such as inputting ELMo-style representations (Peters et al., 2018) or fine-tuning the language model (§2).

Our experiments rely on strong transformer-based language models trained on up to six billion tokens (§3). We present a detailed study of various strategies in different simulated labeled training data scenarios and observe the largest improvements in low-resource settings but gains of over 1 BLEU are still possible when five million sentence-pairs are available. The most successful strategy to integrate pre-trained representations is as input to the encoder network (§4).

2 Strategies to add representations

We consider augmenting a standard sequence to sequence model with pre-trained representations following an ELMo-style regime (§2.1) as well as by fine-tuning the language model (§2.2).

2.1 ELMo augmentation

The ELMo approach of Peters et al. (2018) forms contextualized word embeddings based on language model representations without adjusting the actual language model parameters. Specifically, the ELMo module contains a set of parameters $\lambda_1 \dots \lambda_L, \gamma$ to form a linear combination of the L layers of the language model: ELMo = $\gamma \sum_{i=0}^{L} \frac{1}{Z} \exp(\lambda_i) \mathbf{h}^k$ where γ is a learned scalar, Z is a constant to normalize the $\exp(\lambda_i)$ to sum to one and $\mathbf{h}^k$ is the output of the k-th language model layer; the module also considers the input word embeddings of the language model. We also

Minneapolis, Minnesota, June 2 - June 7, 2019.

apply layer normalization (Ba et al., 2016) to each $\mathbf{h}^k$ before computing ELMo vectors.

We experiment with an ELMo module to input contextualized embeddings either to the encoder (SRC-ELMO) or the decoder (TGT-ELMO). This provides word representations specific to the current input sentence and these representations have been trained on much more data than is available for the text generation task.

2.2 Fine-tuning approach

Fine-tuning the pre-trained representations adjusts the language model parameters by the learning signal of the end-task (Radford et al., 2018; Devlin et al., 2018). We replace learned input word embeddings in the encoder network with the output of the language model (SRC-FT). Specifically, we use the language model representation of the layer before the softmax and feed it to the encoder. We also add dropout to the language model output. Tuning separate learning rates for the language model and the sequence to sequence model may lead to better performance but we leave this to future work. However, we do tune the number of encoder blocks N as we found this important to obtain good accuracy for this setting. We apply the same strategy to the decoder: we input language model representations to the decoder network and fine-tune the language model when training the sequence to sequence model (TGT-FT).

3 Experimental setup

3.1 Datasets

Pre-training. We train language models on two languages: One model is estimated on the German newscrawl distributed by WMT'18 comprising 260M sentences or 6B tokens. Another model is trained on the English newscrawl data comprising 193M sentences or 5B tokens. We learn a joint Byte-Pair-Encoding (BPE; Sennrich et al., 2016) vocabulary of 37K types on the German and English newscrawl and train the language models with this vocabulary.

Machine translation. We consider two benchmarks: Most experiments are run on the WMT'18 English-German (en-de) news translation task and we validate our findings on the WMT'18 English-Turkish (en-tr) news task. For WMT'18 English-German, the training corpus consists of all available bitext excluding the ParaCrawl corpus and we remove sentences longer than 250 tokens as well as sentence-pairs with a source/target length ratio exceeding 1.5. This results in 5.18M sentence pairs. We tokenize all data with the Moses tokenizer (Koehn et al., 2007) and apply the BPE vocabulary learned on the monolingual corpora.

For WMT'18 English-Turkish, we use all of the available bitext comprising 208K sentence-pairs without any filtering. We develop on newstest2017 and test on newstest2018. For en-tr we only experiment with adding representations to the encoder and therefore apply the language model vocabulary to the source side. For the target vocabulary we learn a BPE code with 32K merge operations on the Turkish side of the bitext. Both datasets are evaluated in terms of case-sensitive de-tokenized BLEU (Papineni et al., 2002; Post, 2018).[2]

Summarization. We consider the CNN-DailyMail abstractive document summarization task comprising over 280K news articles paired with multi-sentence summaries. CNN-DailyMail is a widely used dataset for abstractive text summarization. Following (See et al., 2017), we report results on the non-anonymized version of CNN-DailyMail rather than the entity-anonymized version (Hermann et al., 2015; Nallapati et al., 2016) because the language model was trained on full text. Articles are truncated to 400 tokens (See et al., 2017) and we use a BPE vocabulary of 32K types (Fan et al., 2017). We evaluate in terms of F1-Rouge, that is Rouge-1, Rouge-2 and Rouge-L (Lin, 2004).[3]

3.2 Language model pre-training

We consider two types of architectures: a bi-directional language model to augment the sequence to sequence encoder and a uni-directional model to augment the decoder. Both use self-attention (Vaswani et al., 2017) and the uni-directional model contains $N = 12$ transformer blocks, followed by a word classifier to predict the next word on the right. The bi-directional model solves a cloze-style token prediction task at training time (Baevski et al., 2019). The model consists of two towers, the *forward* tower operates left-to-right and the tower operating right-to-left as *backward* tower; each tower contains $N = 12$ trans-

[3] We use the following parameters for `ROUGE-1.5.5.pl`: -m -a -n 2

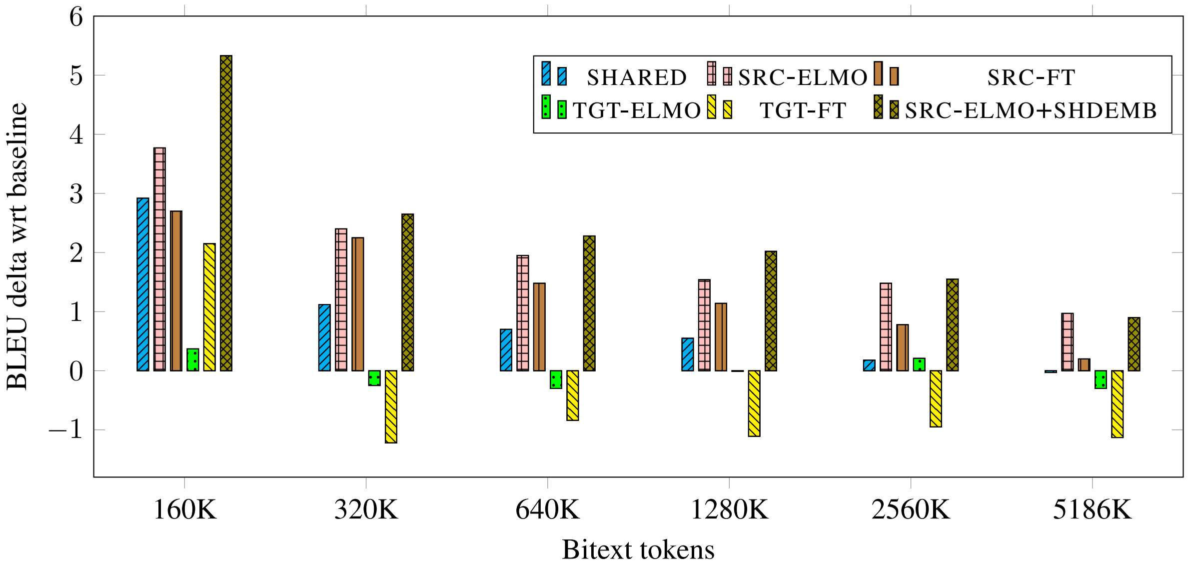

Figure 1: BLEU difference to a bitext-only baseline when adding pre-trained language model representations to a neural machine translation model in different simulated bitext settings. Results are based on averaging newstest2012-2017 of WMT English-German translation.

former blocks. The forward and backward representations are combined via a self-attention module and the output of this module is used to predict the token at position i. The model has access to the entire input surrounding the current target token. Models use the standard settings for the Big Transformer (Vaswani et al., 2017). The bi-directional model contains 353M parameters and the uni-directional model 190M parameters. Both models were trained for 1M steps using Nesterov's accelerated gradient (Sutskever et al., 2013) with momentum 0.99 following Baevski and Auli (2018). The learning rate is linearly warmed up from 10^{-7} to 1 for 16K steps and then annealed using a cosine learning rate schedule with a single phase to 0.0001 (Loshchilov and Hutter, 2016). We train on 32 Nvidia V100 SXM2 GPUs and use the NCCL2 library as well as the torch distributed package for inter-GPU communication. Training relies on 16-bit floating point operations (Ott et al., 2018) and it took six days for the bi-directional model and four days for the uni-directional model.

3.3 Sequence to sequence model

We use the transformer implementation of the fairseq toolkit (Ott et al., 2019). The WMT en-de and en-tr experiments are based on the Big Transformer sequence to sequence architecture with 6 blocks in the encoder and decoder. For abstractive summarization we use a base transformer model (Vaswani et al., 2017). We tune dropout values of between 0.1 and 0.4 on the validation set. Models are optimized with Adam (Kingma and Ba, 2015) using $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 1e - 8$ and we use the same learning rate schedule as Vaswani et al. (2017); we perform 10K-200K depending on bitext size. All models use label smoothing with a uniform prior distribution over the vocabulary $\epsilon = 0.1$ (Szegedy et al., 2015; Pereyra et al., 2017). We run experiments on 8 GPUs and generate translations with a beam of size 5.

4 Results

4.1 Machine translation

We first present a comparison of the various strategies in different simulated parallel corpus size settings. For each experiment, we tune the dropout applied to the language model representations, and we reduce the number of optimizer steps for smaller bitext setups as models converge faster; all other hyper-parameters are equal between setups. Our baseline is a Big Transformer model and we also consider a variant where we share token embeddings between the encoder and decoder (SHARED; Inan et al., 2016; Press & Wolf, 2016).

Figure 1 shows results averaged over six test sets relative to the baseline which does not share source and target embeddings (Appendix A shows a detailed breakdown). SHARED performs very well with little labeled data but the gains erode to practically zero in large bitext settings. Pre-trained

	160K	640K	5186K
baseline	21.4	33.1	40.1
SRC-ELMO	26.6	35.6	41.8
SRC-FT	24.3	34.9	40.8
TGT-ELMO	21.3	31.9	40.5
TGT-FT	24.2	31.4	38.8
SRC-ELMO+SHDEMB	29.0	36.2	41.8

Table 1: BLEU on newstest2018 of WMT English-German in three simulated bitext size scenarios.

	news2017	news2018
baseline	9.8	9.5
SRC-ELMO	12.0	11.3
SRC-ELMO+SHDEMB	12.9	11.8

Table 2: WMT English-Turkish translation results in terms of BLEU on newstest2017 (valid) and newstest2018 (test) with ELMo inputs to the encoder.

language model representations are most effective in low bitext setups. The best performing strategy is ELMo embeddings input to the encoder (SRC-ELMO). This improves the baseline by 3.8 BLEU in the 160K bitext setting and it still improves the 5.2M setting by over 1 BLEU.

We further improve SRC-ELMO by sharing learned word representations in the decoder by tying input and output embeddings (SRC-ELMO+SHDEMB). This configuration performs even better than SRC-ELMO with a gain of 5.3 BLEU in the 160K setup. Sharing decoder embeddings is equally applicable to SRC-FT. Language model representations are much less effective in the decoder: TGT-FT improves the 160K bitext setup but yields no improvements thereafter and TGT-ELMO performs even worse. We conjecture that pre-trained representations give much easier wins in the encoder. Table 1 shows additional results on newstest2018.

Pre-trained representations mostly impacts the training time of the sequence to sequence model (see Appendix B): SRC-ELMO slows throughput during training by about 5.3x and SRC-FT is even slower because of the need to backpropagate through the LM for fine-tuning (9.2x). However, inference is only 12-14% slower than the baseline when adding pre-trained embeddings to the encoder (SRC-ELMO, SRC-FT). This is because the LM computation can be paralelized for all input tokens. Inference is much slower when adding representations to the decoder because the LM needs to be invoked repeatedly. Our current implementation does not cache LM operations for the previous state and can be made much faster.

	ROUGE		
	1	2	L
Lead-3	40.34	17.70	36.57
See et al. (2017)	39.53	17.28	36.38
Gehrmann et al. (2018)	41.22	18.68	38.34
baseline	40.07	17.61	36.78
SRC-ELMO+SHDEMB	41.56	18.94	38.47

Table 3: Abstractive summarization results on CNN-DailyMail. ELMo inputs achieve a new state of the art.

The baseline uses a BPE vocabulary estimated on the language model corpora (§3). Appendix A shows that this vocabulary actually leads to sligtly better performance than a joint BPE code learned on the bitext as is usual.

Next, we validate our findings on the WMT'18 English-Turkish task for which the bitext is truly limited (208K sentence-pairs). We use the language model vocab for the the English side of the bitext and a BPE vocabulary learned on the Turkish side. Table 2 shows that ELMo embeddings for the encoder improve English-Turkish translation.

4.2 Abstractive summarization

Following See et al. (2017), we experiment on the non-anonymized version of CNN-DailyMail. When generating summaries, we follow standard practice of tuning the maximum output length and disallow repeating the same trigram (Paulus et al., 2017; Fan et al., 2017). For this task we train language model representations on the combination of newscrawl and the CNN-DailyMail training data. Table 3 shows that pre-trained embeddings can significantly improve on top of a strong baseline transformer. We also compare to Gehrmann et al. (2018) who use a task-specific architecture compared to our generic sequence to sequence baseline. Pre-trained representations are complementary to their method.

5 Conclusion

We presented an analysis of different strategies to add pre-trained language model representations to sequence to sequence models for neural machine translation and abstractive document summarization. Adding pre-trained representations is very effective for the encoder network and while returns diminish when more labeled data becomes available, we still observe improvements when millions of examples are available. In future research we will investigate ways to improve the decoder with pre-trained representations.

Pragmatically Informative Text Generation

Abstract

We improve the informativeness of models for conditional text generation using techniques from computational pragmatics. These techniques formulate language production as a game between speakers and listeners, in which a speaker should generate output text that a listener can use to correctly identify the original input that the text describes. While such approaches are widely used in cognitive science and grounded language learning, they have received less attention for more standard language generation tasks. We consider two pragmatic modeling methods for text generation: one where pragmatics is imposed by information preservation, and another where pragmatics is imposed by explicit modeling of distractors. We find that these methods improve the performance of strong existing systems for abstractive summarization and generation from structured meaning representations.

1 Introduction

Computational approaches to pragmatics cast language generation and interpretation as game-theoretic or Bayesian inference procedures (Golland et al., 2010; Frank and Goodman, 2012). While such approaches are capable of modeling a variety of pragmatic phenomena, their main application in natural language processing has been to improve the *informativeness* of generated text in grounded language learning problems (Monroe et al., 2018). In this paper, we show that pragmatic reasoning can be similarly used to improve performance in more traditional language generation tasks like generation from structured meaning representations (Figure 1) and summarization.

Our work builds on a line of learned Rational Speech Acts (RSA) models (Monroe and Potts, 2015; Andreas and Klein, 2016), in which generated strings are selected to optimize the behavior of an embedded listener model. The canonical presentation of the RSA framework (Frank and Goodman, 2012) is grounded in reference resolution: models of speakers attempt to describe referents in the presence of distractors, and models of listeners attempt to resolve descriptors to referents. Recent work has extended these models to more complex groundings, including images (Mao et al., 2015) and trajectories (Fried et al., 2018). The techniques used in these settings are similar, and the primary intuition of the RSA framework is preserved: from the speaker's perspective, a good description is one that picks out, as discriminatively as possible, the content the speaker intends for the listener to identify.

Input meaning representation (i):
Name[Fitzbillies], EatType[coffee shop], Food[English], PriceRange[cheap], CustomerRating[5 out of 5], Area[Riverside], FamilyFriendly[yes]

Human-written
A cheap coffee shop in riverside with a 5 out of 5 customer rating is Fitzbillies. Fitzbillies is family friendly and serves English food.

Base sequence-to-sequence model (S_0)
Fitzbillies is a family friendly coffee shop located near the river.

Distractor-based pragmatic system (S_1^D)
Fitzbillies is a family friendly coffee shop that serves English food. It is located in riverside area. It has a customer rating of 5 out of 5 and is cheap.

Reconstructor-based pragmatic system (S_1^R)
Fitzbillies is a family friendly coffee shop that serves cheap English food in the riverside area. It has a customer rating of 5 out of 5.

Figure 1: Example outputs of our systems on the E2E generation task. While a base sequence-to-sequence model (S_0, Sec. 2) fails to describe all attributes in the input meaning representation, both of our pragmatic systems (S_1^R, Sec. 3.1 and S_1^D, Sec. 3.2) and the human-written reference do.

Outside of grounding, cognitive modeling (Frank et al., 2009), and targeted analysis of linguistic phenomena (Orita et al., 2015), rational speech acts models have seen limited application in the natural language processing literature. In this work we show that they can be extended

Proceedings of NAACL-HLT 2019, pages 4060–4067
Minneapolis, Minnesota, June 2 - June 7, 2019.

to a distinct class of language generation problems that use as referents structured descriptions of lingustic content, or other natural language texts. In accordance with the maxim of quantity (Grice, 1970) or the Q-principle (Horn, 1984), pragmatic approaches naturally correct underinformativeness problems observed in state-of-the-art language generation systems (S_0 in Figure 1).

We present experiments on two language generation tasks: generation from meaning representations (Novikova et al., 2017) and summarization. For each task, we evaluate two models of pragmatics: the reconstructor-based model of Fried et al. (2018) and the distractor-based model of Cohn-Gordon et al. (2018). Both models improve performance on both tasks, increasing ROUGE scores by 0.2–0.5 points on the CNN/Daily Mail abstractive summarization dataset and BLEU scores by 2 points on the End-to-End (E2E) generation dataset, obtaining new state-of-the-art results.

2 Tasks

We formulate a conditional generation task as taking an input i from a space of possible inputs $\mathcal{I}$ (e.g., input sentences for abstractive summarization; meaning representations for structured generation) and producing an output o as a sequence of tokens $(o_1, \ldots, o_T)$. We build our pragmatic approaches on top of learned *base speaker* models S_0, which produce a probability distribution $S_0(o \mid i)$ over output text for a given input. We focus on two conditional generation tasks where the information in the input context should largely be preserved in the output text, and apply the pragmatic procedures outlined in Sec. 3 to each task. For these S_0 models we use systems from past work that are strong, but may still be underinformative relative to human reference outputs (e.g., Figure 1).

Meaning Representations Our first task is generation from structured meaning representations (MRs) containing attribute-value pairs (Novikova et al., 2017). An example is shown in Figure 1, where systems must generate a description of the restaurant with the specified attributes. We apply pragmatics to encourage output strings from which the input MR can be identified. For our S_0 model, we use a publicly-released neural generation system (Puzikov and Gurevych, 2018) that achieves comparable performance to the best published results in Dušek et al. (2018).

Abstractive Summarization Our second task is multi-sentence document summarization. There is a vast amount of past work on summarization (Nenkova and McKeown, 2011); recent neural models have used large datasets (e.g., Hermann et al. (2015)) to train models in both the extractive (Cheng and Lapata, 2016; Nallapati et al., 2017) and abstractive (Rush et al., 2015; See et al., 2017) settings. Among these works, we build on the recent abstractive neural summarization system of Chen and Bansal (2018). First, this system uses a sentence-level extractive model RNN-EXT to identify a sequence of salient sentences $i^{(1)}, \ldots i^{(P)}$ in each source document. Second, the system uses an abstractive model ABS to rewrite each $i^{(p)}$ into an output $o^{(p)}$, which are then concatenated to produce the final summary. We rely on the fixed RNN-EXT model to extract sentences as inputs in our pragmatic procedure, using ABS as our S_0 model and applying pragmatics to the $i^{(p)} \rightarrow o^{(p)}$ abstractive step.

3 Pragmatic Models

To produce informative outputs, we consider pragmatic methods that extend the *base speaker* models, S_0, using *listener* models, L, which produce a distribution $L(i \mid o)$ over possible inputs given an output. Listener models are used to derive *pragmatic speakers*, $S_1(o \mid i)$, which produce output that has a high probability of making a listener model L identify the correct input. There are a large space of possible choices for designing L and deriving S_1; we follow two lines of past work which we categorize as *reconstructor-based* and *distractor-based*. We tailor each of these pragmatic methods to both our two tasks by developing reconstructor models and methods of choosing distractors.

3.1 Reconstructor-Based Pragmatics

Pragmatic approaches in this category (Dušek and Jurčíček, 2016; Fried et al., 2018) rely on a *reconstructor listener* model L^R defined independently of the speaker. This listener model produces a distribution $L^R(i \mid o)$ over all possible input contexts $i \in \mathcal{I}$, given an output description o. We use sequence-to-sequence or structured classification models for L^R (described below), and train these models on the same data used to supervise the S_0 models.

The listener model and the base speaker model together define a *pragmatic speaker*, with output score given by:

$$S_1^R(o \mid i) = L^R(i \mid o)^\lambda \cdot S_0(o \mid i)^{1-\lambda} \quad (1)$$

where λ is a *rationality parameter* that controls how much the model optimizes for discriminative outputs (see Monroe et al. (2017) and Fried et al. (2018) for a discussion). We select an output text sequence o for a given input i by choosing the highest scoring output under Eq. 1 from a set of candidates obtained by beam search in $S_0(\cdot \mid i)$.

Meaning Representations We construct L^R for the meaning representation generation task as a multi-task, multi-class classifier, defining a distribution over possible values for each attribute. Each MR attribute has its own prediction layer and attention-based aggregation layer, which conditions on a basic encoding of o shared across all attributes. See Appendix A.1 for architecture details. We then define $L^R(i \mid o)$ as the joint probability of predicting all input MR attributes in i from o.

Summarization To construct L^R for summarization, we train an ABS model (of the type we use for S_0, Chen and Bansal (2018)) but in reverse, i.e., taking as input a sentence in the summary and producing a sentence in the source document. We train L^R on the same heuristically-extracted and aligned source document sentences used to train S_0 (Chen and Bansal, 2018).

3.2 Distractor-Based Pragmatics

Pragmatic approaches in this category (Frank and Goodman, 2012; Andreas and Klein, 2016; Vedantam et al., 2017; Cohn-Gordon et al., 2018) derive pragmatic behavior by producing outputs that distinguish the input i from an alternate *distractor* input (or inputs). We construct a distractor $\widetilde{\imath}$ for a given input i in a task-dependent way.[1]

We follow the approach of Cohn-Gordon et al. (2018), outlined briefly here. The base speakers we build on produce outputs incrementally, where the probability of o_t, the word output at time t, is conditioned on the input and the previously generated words: $S_0(o_t \mid i, o_{<t})$. Since the output is generated incrementally and there is no separate listener model that needs to condition on entire output decisions, the distractor-based approach is able to make pragmatic decisions at each word rather than choosing between entire output candidates (as in the reconstructor approaches).

The listener L^D and pragmatic speaker S_1^D are derived from the base speaker S_0 and a belief distribution $p_t(\cdot)$ maintained at each timestep t over the possible inputs $\mathcal{I}^D$:

$$L^D(i \mid o_{<t}) \propto S_0(o_{<t} \mid i) \cdot p_{t-1}(i) \quad (2)$$

$$S_1^D(o_t \mid i, o_{<t}) \propto L^D(i \mid o_{<t})^\alpha \cdot S_0(o_t \mid i, o_{<t}) \quad (3)$$

$$p_t(i) \propto S_0(o_t \mid i, o_{<t}) \cdot L^D(i \mid o_{<t}) \quad (4)$$

where α is again a rationality parameter, and the initial belief distribution $p_0(\cdot)$ is uniform, i.e., $p_0(i) = p_0(\widetilde{\imath}) = 0.5$. Eqs. 2 and 4 are normalized over the true input i and distractor $\widetilde{\imath}$; Eq. 3 is normalized over the output vocabulary. We construct an output text sequence for the pragmatic speaker S_1^D incrementally using beam search to approximately maximize Eq. 3.

Meaning Representations A distractor MR is automatically constructed for each input to be the most distinctive possible against the input. We construct this distractor by masking each present input attribute and replacing the value of each non-present attribute with the value that is most frequent for that attribute in the training data. For example, for the input MR in Figure 1, the distractor is NEAR[BURGER KING].

Summarization For each extracted input sentence $i^{(p)}$, we use the previous extracted sentence $i^{(p-1)}$ from the same document as the distractor input $\widetilde{\imath}$ (for the first sentence we do not use a distractor). This is intended to encourage outputs $o^{(p)}$ to contain distinctive information against other summaries produced within the same document.

4 Experiments

For each of our two conditional generation tasks we evaluate on a standard benchmark dataset, following past work by using automatic evaluation against human-produced reference text. We choose hyperparameters for our models (beam size, and parameters α and λ) to maximize task metrics on each dataset's development set; see Appendix A.2 for the settings used.[2]

---

[1] In tasks such as contrastive captioning or referring expression generation, these distractors are given; for the conditional generation task, we will show that pragmatic behavior can be obtained by constructing or selecting a single distractor that contrasts with the input i.

[2] Our code is publicly available at `https://github.com/sIncerass/prag_generation`.

System	BLEU	NIST	METEOR	R-L	CIDEr
T-Gen	65.93	8.61	44.83	68.50	2.23
Best Prev.	66.19†	8.61†	**45.29**‡	**70.83**$^\diamond$	2.27$^\bullet$
S_0	66.52	8.55	44.45	69.34	2.23
S_0 ×2	65.93	8.31	43.52	69.58	2.12
S_1^R	**68.60**	**8.73**	**45.25**	**70.82**	**2.37**
S_1^D	67.76	8.72	44.59	69.41	2.27

Table 1: Test results for the E2E generation task, in comparison to the T-Gen baseline (Dušek and Jurčíček, 2016) and the best results from the E2E challenge, reported by Dušek et al. (2018): †Juraska et al. (2018), ‡Puzikov and Gurevych (2018), $^\diamond$Zhang et al. (2018), and $^\bullet$Gong (2018). We bold our highest performing model on each metric, as well as previous work if it outperforms all of our models.

4.1 Meaning Representations

We evaluate on the E2E task of generation from meaning representations containing restaurant attributes (Novikova et al., 2017). We report the task's five automatic metrics: BLEU (Papineni et al., 2002), NIST (Doddington, 2002), METEOR (Lavie and Agarwal, 2007), ROUGE-L (Lin, 2004) and CIDEr (Vedantam et al., 2015).

Table 1 compares the performance of our base S_0 and pragmatic models to the baseline T-Gen system (Dušek and Jurčíček, 2016) and the *best previous* result from the 20 primary systems evaluated in the E2E challenge (Dušek et al., 2018). The systems obtaining these results encompass a range of approaches: a template system (Puzikov and Gurevych, 2018), a neural model (Zhang et al., 2018), models trained with reinforcement learning (Gong, 2018), and systems using ensembling and reranking (Juraska et al., 2018). To ensure that the benefit of the reconstructor-based pragmatic approach, which uses two models, is not due solely to a model combination effect, we also compare to an ensemble of two base models (S_0 ×2). This ensemble uses a weighted combination of scores of two independently-trained S_0 models, following Eq. 1 (with weights tuned on the development data).

Both of our pragmatic systems improve over the strong baseline S_0 system on all five metrics, with the largest improvements (2.1 BLEU, 0.2 NIST, 0.8 METEOR, 1.5 ROUGE-L, and 0.1 CIDEr) from the S_1^R model. This S_1^R model outperforms the previous best results obtained by any system in the E2E challenge on BLEU, NIST, and CIDEr, with comparable performance on METEOR and ROUGE-L.

System	R-1	R-2	R-L	METEOR
Extractive				
Lead-3	40.34	17.70	36.57	**22.21**
Inputs	38.93	18.23	35.90	**24.66**
Abstractive				
Best Previous	**41.69**†	**19.47**†	**39.08**‡	21.00$^\diamond$
S_0	40.88	17.80	38.54	20.38
S_0 ×2	40.76	17.88	38.46	19.88
S_1^R	41.23	18.07	38.76	20.57
S_1^D	**41.39**	**18.30**	**38.78**	**21.70**

Table 2: Test results for the non-anonymized CNN/Daily Mail summarization task. We compare to extractive baselines, and the best previous abstractive results of †Celikyilmaz et al. (2018), ‡Paulus et al. (2018) and $^\diamond$Chen and Bansal (2018). We bold our highest performing model on each metric, as well as previous work if it outperforms all of our models.

4.2 Abstractive Summarization

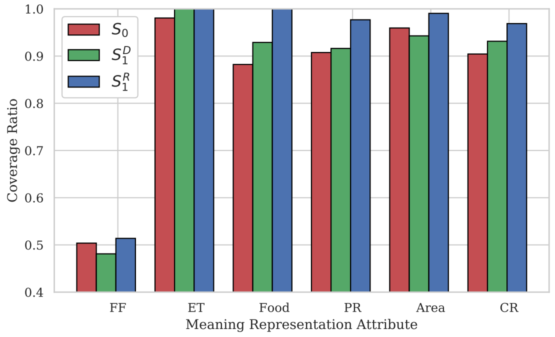
We evaluate on the CNN/Daily Mail summarization dataset (Hermann et al., 2015; Nallapati et al., 2016), using See et al.'s (2017) non-anonymized preprocessing. As in previous work (Chen and Bansal, 2018), we evaluate using ROUGE and METEOR.

Table 2 compares our pragmatic systems to the base S_0 model (with scores taken from Chen and Bansal (2018); we obtained comparable performance in our reproduction[3]), an ensemble of two of these base models, and the *best previous* abstractive summarization result for each metric on this dataset (Celikyilmaz et al., 2018; Paulus et al., 2018; Chen and Bansal, 2018). We also report two extractive baselines: *Lead-3*, which uses the first three sentences of the document as the summary (See et al., 2017), and *Inputs*, the concatenation of the extracted sentences used as inputs to our models (i.e., $i^{(1)}, \dots, i^{(P)}$).

The pragmatic methods obtain improvements of 0.2–0.5 in ROUGE scores and 0.2–1.8 METEOR over the base S_0 model, with the distractor-based approach S_1^D outperforming the reconstructor-based approach S_1^R. S_1^D is strong across all metrics, obtaining results competitive to the best previous abstractive systems.

---

[3] We use retrained versions of Chen and Bansal (2018)'s sentence extractor and abstractive S_0 models in all our experiments, as well as their n-gram reranking-based inference procedure, replacing scores from the base model S_0 with scores from S_1^R or S_1^D in the respective pragmatic procedures.



(a) Coverage ratios by attribute type for the base model S_0 and pragmatic models S_1^R and S_1^D. The pragmatic models typically improve coverage ratios across attribute types when compared to the base model.

		Coverage Ratio for Attribute					
		FF	ET	Food	PR	Area	CR
	S_0	0.50	0.98	0.88	0.91	0.96	0.90
Distractor Attr.	S_1^D-FF	0.57	1.00	0.92	0.90	0.95	0.95
	S_1^D-ET	0.47	1.00	0.96	0.92	0.96	0.95
	S_1^D-Food	0.45	1.00	1.00	0.93	0.95	0.94
	S_1^D-PR	0.51	1.00	0.90	0.98	0.93	0.92
	S_1^D-Area	0.47	1.00	0.93	0.91	0.98	0.93
	S_1^D-CR	0.45	1.00	0.91	0.90	0.91	0.95

(b) Coverage ratios by attribute type (columns) for the base model S_0, and for the pragmatic system S_1^D when constructing the distractor by masking the specified attribute (rows). Cell colors are the degree the coverage ratio increases (green) or decreases (red) relative to S_0.

Figure 2: Coverage ratios for the E2E task by attribute type, estimating how frequently the values for each attribute from the input meaning representations are mentioned in the output text.

5 Analysis

The base speaker S_0 model is often underinformative, e.g., for the E2E task failing to mention certain attributes of a MR, even though almost all the training examples incorporate all of them. To better understand the performance improvements from the pragmatic models for E2E, we compute a *coverage ratio* as a proxy measure of how well content in the input is preserved in the generated outputs. The coverage ratio for each attribute is the fraction of times there is an exact match between the text in the generated output and the attribute's value in the source MR (for instances where the attribute is specified).[4]

Figure 2(a) shows coverage ratio by attribute category for all models. The S_1^R model increases the coverage ratio when compared to S_0 across all attributes, showing that using the reconstruction model score to select outputs does lead to an increase in mentions for each attribute. Coverage ratios increase for S_1^D as well in four out of six categories, but the increase is typically less than that produced by S_1^R.

While S_1^D optimizes less explicitly for attribute mentions than S_1^R, it still provides a potential method to control generated outputs by choosing alternate distractors. Figure 2(b) shows coverage ratios for S_1^D when masking only a single attribute in the distractor. The highest coverage ratio for each attribute is usually obtained when masking that attribute in the distractor MR (entries on the main diagonal, underlined), in particular for FAMILYFRIENDLY (FF), FOOD, PRICERANGE (PR), and AREA. However, masking a single attribute sometimes results in decreasing the coverage ratio, and we also observe substantial increases from masking other attributes: e.g., masking either FAMILYFRIENDLY or CUSTOMERRATING (CR) produces an equal increase in coverage ratio for the CUSTOMERRATING attribute. This may reflect underlying correlations in the training data, as these two attributes have a small number of possible values (3 and 7, respectively).

6 Conclusion

Our results show that S_0 models from previous work, while strong, still imperfectly capture the behavior that people exhibit when generating text; and an explicit pragmatic modeling procedure can improve results. Both pragmatic methods evaluated in this paper encourage prediction of outputs that can be used to identify their inputs, either by reconstructing inputs in their entirety or distinguishing true inputs from distractors, so it is perhaps unsurprising that both methods produce similar improvements in performance. Future work might allow finer-grained modeling of the tradeoff between *under*- and *over*-informativity within the sequence generation pipeline (e.g., with a learned communication cost model) or explore applications of pragmatics for content selection earlier in the generation pipeline.

A Supplemental Material

A.1 Reconstructor Model Details

For the reconstructor-based speaker in the E2E task, we first follow the same data preprocessing steps as Puzikov and Gurevych (2018), which includes a delexicalization module that deals with sparsely occurring MR attributes (NAME, NEAR) by mapping such values to placeholder tokens.

MRs have only a few possible values for most attributes: six out of eight attributes have fewer than seven unique values, and the remaining two attributes (NAME, NEAR) are handled by our S_0 and S_1^D using delexicalized placeholders, following Puzikov and Gurevych (2018). In this way, the reconstructor only needs to predict the presence of these two attributes with a boolean variable, and other attributes with the corresponding categorical variable. We use a one layer bi-directional GRU (Cho et al., 2014) for the shared sentence encoder. We concatenate the latent vectors from both directions to construct a bi-directional encoded vector h_i for every single word vector d_i as:

$$\overrightarrow{h_i} = \overrightarrow{GRU}(d_i, h_{i-1}), \overleftarrow{h_i} = \overleftarrow{GRU}(d_i, h_{i+1})$$

$$h_i = [\overrightarrow{h_i}, \overleftarrow{h_i}], i \in [1, L]$$

Since not all words contribute equally to predicting each MR attribute, we thus use an attention mechanism (Bahdanau et al., 2014) to determine the importance of every single word. The aggregated sentence vector for task k is calculated by

$$a_i^{(k)} = \frac{exp(W_a^{(k)} h_i)}{\sum_{j=1}^{L} exp(W_a^{(k)} h_j)}, v^{(k)} = \sum_{i=1}^{L} a_i^{(k)} h_i,$$

The task-specific sentence representation is then used as input to k layers with softmax outputs, returning a probability vector $Y^{(k)}$ for each of the k MR attributes.

A.2 Hyperparameters

For structured generation, we use beam size 10, $\lambda = 0.4$, and $\alpha = 0.2$, tuned to maximize the normalized average of all five metrics on the development set.

For abstractive summarization, we use beam size 20, $\lambda = 0.9$, and $\alpha = 1.0$, tuned to maximize ROUGE-L on the development set.

Stochastic Wasserstein Autoencoder for Probabilistic Sentence Generation

Abstract

The variational autoencoder (VAE) imposes a probabilistic distribution (typically Gaussian) on the latent space and penalizes the Kullback–Leibler (KL) divergence between the posterior and prior. In NLP, VAEs are extremely difficult to train due to the problem of KL collapsing to zero. One has to implement various heuristics such as KL weight annealing and word dropout in a carefully engineered manner to successfully train a VAE for text. In this paper, we propose to use the Wasserstein autoencoder (WAE) for probabilistic sentence generation, where the encoder could be either stochastic or deterministic. We show theoretically and empirically that, in the original WAE, the stochastically encoded Gaussian distribution tends to become a Dirac-delta function, and we propose a variant of WAE that encourages the stochasticity of the encoder. Experimental results show that the latent space learned by WAE exhibits properties of continuity and smoothness as in VAEs, while simultaneously achieving much higher BLEU scores for sentence reconstruction.[1]

1 Introduction

Natural language sentence generation in the deep learning regime typically uses a recurrent neural network (RNN) to predict the most probable next word given previous words (Mikolov et al., 2010). Such RNN architecture can be further conditioned on some source information, for example, an input sentence, resulting in a sequence-to-sequence (Seq2Seq) model.

Traditionally, sentence generation is accomplished in a *deterministic* fashion, i.e., the model uses a deterministic neural network to encode an input sentence to some hidden representations, from which it then decodes an output sentence using another deterministic neural network.

Bowman et al. (2016) propose to use the variational autoencoder (VAE, Kingma and Welling, 2014) to map an input sentence to a probabilistic continuous latent space. VAE makes it possible to generate sentences from a distribution, which is desired in various applications. For example, in an open-domain dialog system, the information of an utterance and its response is not necessarily a one-to-one mapping, and multiple plausible responses could be suitable for a given input. Probabilistic sentence generation makes the dialog system more diversified and more meaningful (Serban et al., 2017; Bahuleyan et al., 2018). Besides, probabilistic modeling of the hidden representations serves as a way of posterior regularization (Zhang et al., 2016), facilitating interpolation (Bowman et al., 2016) and manipulation of the latent representation (Hu et al., 2017).

However, training VAEs in NLP is more difficult than the image domain (Kingma and Welling, 2014). The VAE training involves a reconstruction loss and a Kullback–Leibler (KL) divergence between the posterior and prior of the latent space. In NLP, the KL term tends to vanish to zero during training, leading to an ineffective latent space. Previous work has proposed various engineering tricks to alleviate this problem, including KL annealing and word dropout (Bowman et al., 2016).

In this paper, we address the difficulty of training VAE sentence generators by using a Wasserstein autoencoder (WAE, Tolstikhin et al., 2018). WAE modifies VAE in that it requires the integration of the posterior to be close to its prior, where the closeness is measured with empirical samples drawn from the distributions. In this way, the encoder could be either stochastic or deterministic, but the model still retains probabilistic properties.

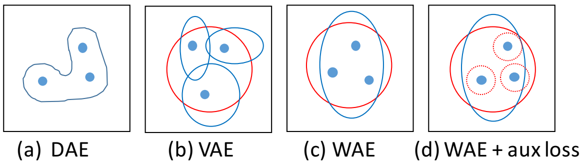

Figure 1: The latent space of the deterministic autoencoder (DAE), variational autoencoder (VAE), Wasserstein autoencoder (WAE), as well as WAE with by our KL penalty. Blue circles: Posterior or aggregated posterior distributions of data in the latent space. Red circles: Regularizations of the posterior.

Moreover, we show both theoretically and empirically that the stochastic Gaussian encoder in the original form tends to be a Dirac-delta function. We thus propose a WAE variant that encourages the encoder's stochasticity by penalizing an auxiliary KL term.

Experiments show that the sentences generated by WAE exhibit properties of continuity and smoothness as in VAE, while achieving a much higher reconstruction performance. Our proposed variant further encourages the stochasticity of the encoder. More importantly, WAE is robust to hyperparameters and much easier to train, without the need for KL annealing or word dropout as in VAE. In a dialog system, we demonstrate that WAEs are capable of generating better quality and more diverse sentences than VAE.

2 Probabilistic Sentence Generation

Base Model: Deterministic Autoencoder (DAE). DAE encodes an input sentence with a recurrent neural network (RNN) and then decodes the same sentence through another RNN.

For the encoder, the hidden state of the last word is represented as the latent space of the input sentence $\mathbf{x}$. The latent representation is denoted as $\boldsymbol{z}$. We feed $\boldsymbol{z}$ to the decoder RNN, which predicts one word at a time using a softmax layer, given by $p(\mathrm{x}_t|\boldsymbol{z}, \mathbf{x}_{<t})$.The training objective for DAE is the sequence-aggregated cross-entropy loss, given by

$$J = -\sum_{n=1}^{N}\sum_{t=1}^{|\mathbf{x}^{(n)}|}\log p(\mathrm{x}_t^{(n)}|\boldsymbol{z}^{(n)}, \mathbf{x}_{<t}^{(n)}) \qquad (1)$$

where superscript (n) indicates the nth data point among $1, \cdots, N$.

In DAE, the latent space is encoded and then decoded in a deterministic way, i.e., there is no probabilistic modeling of the hidden space. The hidden representations of data may be located on an arbitrary manifold (Figure 1a), which is not suitable for probabilistic generation.

Variational Autoencoder (VAE). VAE extends DAE by imposing a prior distribution $p(\boldsymbol{z})$ on the latent variable $\boldsymbol{z}$, which is typically set to the standard normal $\mathcal{N}(\mathbf{0}, \mathbf{I})$ (Kingma and Welling, 2014). Given an input sentence $\mathbf{x}$, we would like to model the posterior of $\boldsymbol{z}$ by another normal distribution, $q(\boldsymbol{z}|\mathbf{x}) = \mathcal{N}(\boldsymbol{\mu}_{\text{post}}, \operatorname{diag}\boldsymbol{\sigma}^2_{\text{post}})$, where $\boldsymbol{\mu}_{\text{post}}$ and $\boldsymbol{\sigma}^2_{\text{post}}$ are the outputs of the encoder.

In the training of VAE, $\boldsymbol{z}$ is sampled from $q(\boldsymbol{z}|\mathbf{x})$, and the training objective is to maximize a variational lower bound of the likelihood of data. This is equivalent to minimizing the (expected) reconstruction loss similar to (1), while being regularized by the KL divergence between $q(\boldsymbol{z}|\boldsymbol{x})$ and $p(\boldsymbol{z})$, given by

$$J = \sum_{n=1}^{N}\Big[-\underset{\boldsymbol{z}^{(n)}\sim q}{\mathbb{E}}\sum_{t=1}^{|\mathbf{x}^{(n)}|}\log p(\mathrm{x}_t^{(n)}|\boldsymbol{z}^{(n)}, \mathbf{x}_{<t}^{(n)}) + \lambda_{\text{VAE}}\cdot \mathrm{KL}(q(\boldsymbol{z}^{(n)}|\mathbf{x}^{(n)})\|p(\boldsymbol{z}))\Big] \qquad (2)$$

where in the expectation $\boldsymbol{z}^{(n)}$ is sampled from $q(\boldsymbol{z}|\mathbf{x}^{(n)})$ and λ_{VAE} is a hyperparameter balancing the two terms.

Since VAE penalizes the divergence of $\boldsymbol{z}$'s posterior from its prior, it serves as a way of posterior regularization, making it possible to generate sentences from the continuous latent space.

However, the two objectives in (2) are contradictory to each other, as argued by Tolstikhin et al. (2018). VAE pushes the posterior of $\boldsymbol{z}$, given any input $\mathbf{x}^{(n)}$, to be close to its prior, i.e., every blue ellipse in Figure 1b should be close to the red one. This makes perfect reconstruction impossible.

Further, VAE is difficult to train in NLP due to the problem of KL collapse, where the KL term tends to be zero, meaning that the encoder captures no information and the decoder learns an unconditioned language model. This phenomenon is observed in variational auto-regressive decoders using RNN. To alleviate this problem, existing tricks include KL annealing and word dropout (Bowman et al., 2016), but both require extensive engineering.

Wasserstein Autoencoder (WAE). An alternative way of posterior regularization is to impose a constraint that the *aggregated posterior* of $\boldsymbol{z}$ should be the same as its prior (Tolstikhin et al., 2018), i.e., $q(\boldsymbol{z}) \overset{\text{def}}{=} \sum_{\mathbf{x}} q(\boldsymbol{z}|\mathbf{x})p_{\mathcal{D}}(\mathbf{x}) \overset{\text{set}}{=} p(\boldsymbol{z})$, where $p_{\mathcal{D}}$ is the data distribution. This is also demonstrated in Figure 1c. By contrast, VAE requires that $q(\boldsymbol{z}|\mathbf{x})$ should be close to $p(\boldsymbol{z})$ for every input sentence $\mathbf{x}$.

For computational purposes, Tolstikhin et al. (2018) relax the above constraint by penalizing the Wasserstein distance between $q(\boldsymbol{z})$ and $p(\boldsymbol{z})$. In particular, it is computed by the Maximum Mean Discrepancy (MMD), defined as

$$\mathrm{MMD} = \left\| \int k(\boldsymbol{z},\cdot)\,\mathrm{d}P(\boldsymbol{z}) - \int k(\boldsymbol{z},\cdot)\,\mathrm{d}Q(\boldsymbol{z}) \right\|_{\mathcal{H}_k}$$

where $P(\boldsymbol{z})$ and $Q(\boldsymbol{z})$ are cumulative density functions. $\mathcal{H}_k$ refers to the reproducing kernel Hilbert space defined by the kernel k, which is often chosen as the inverse multiquadratic kernel $k(x,y) = \frac{C}{C+\|x-y\|_2^2}$ for high-dimensional Gaussians.

One advantage of the Wasserstein distance is that it can be estimated by empirical samples as

$$\widehat{\mathrm{MMD}} = \frac{1}{N(N-1)}\sum_{n\neq m} k(\boldsymbol{z}^{(n)},\boldsymbol{z}^{(m)}) + \frac{1}{N(N-1)}\sum_{n\neq m} k(\widetilde{\boldsymbol{z}}^{(n)},\widetilde{\boldsymbol{z}}^{(m)}) - \frac{1}{N^2}\sum_{n,m} k(\boldsymbol{z}^{(n)},\widetilde{\boldsymbol{z}}^{(m)}) \tag{3}$$

where $\widetilde{\boldsymbol{z}}^{(n)}$ is a sample from the prior $p(\boldsymbol{z})$, and $\boldsymbol{z}^{(n)}$ is a sample from the aggregated posterior $q(\boldsymbol{z})$, which is obtained by sampling $\mathbf{x}^{(n)}$ from the data distribution and then sampling $\boldsymbol{z}^{(n)}$ from $q(\boldsymbol{z}|\mathbf{x}^{(n)})$. In summary, the training objective of WAE is

$$J_{\mathrm{WAE}} = -\sum_{n=1}^{N}\sum_{t=1}^{|\mathbf{x}^{(n)}|}\log p(\mathrm{x}_t^{(n)}|\boldsymbol{z}^{(n)},\mathbf{x}_{<t}^{(n)}) + \lambda_{\mathrm{WAE}}\cdot\widehat{\mathrm{MMD}} \tag{4}$$

where λ_{WAE} balances the MMD penalty and the reconstruction loss.

Alternatively, the dual form (adversarial loss) can also be used for WAE (Zhao et al., 2018). In our preliminary experiments, we found MMD similar to but slightly better than the adversarial loss. The difference between our work and Zhao et al. (2018)—who extend the original WAE to sequence generation—is that we address the KL annealing problem of VAE and further analyze the stochasticity of WAE from a theoretical perspective, as follows.

WAE with Auxiliary Loss. In WAE, the aggregated posterior $q(\boldsymbol{z})$ involves an integration of data distribution, which allows using a deterministic function to encode $\boldsymbol{z}$ as $\boldsymbol{z} = \boldsymbol{f}_{\text{encode}}(\mathbf{x})$ as suggested by Tolstikhin et al. (2018). This would largely alleviate the training difficulties as in VAE, because backpropagating gradient into the encoder no longer involves a stochastic layer.

The stochasticity of the encoder, however, is still a desired property in some applications, for example, generating diverse responses in a dialog system. We show both theoretically and empirically that a *dangling* Gaussian stochastic encoder could possibly degrade to a deterministic one.

Theorem 1. *Suppose we have a Gaussian family $\mathcal{N}(\boldsymbol{\mu}, \operatorname{diag}\boldsymbol{\sigma}^2)$, where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ are parameters. The covariance is diagonal, meaning that the variables are independent. If the gradient of $\boldsymbol{\sigma}$ completely comes from sample gradient and $\boldsymbol{\sigma}$ is small at the beginning of training, then the Gaussian converges to a Dirac delta function with stochastic gradient descent, i.e., $\boldsymbol{\sigma} \to \mathbf{0}$. (See Appendix A for the proof.)* ☐

To alleviate this problem, we propose a simple heuristic that encourages the stochasticity of the encoder. In particular, we penalize, for every data point, a KL term between the predicted posterior $q(\boldsymbol{z}|\boldsymbol{x}) = \mathcal{N}(\boldsymbol{\mu}_{\text{post}}, \operatorname{diag}\boldsymbol{\sigma}_{\text{post}}^2)$ and a Gaussian with covariance $\mathbf{I}$ centered at the predicted mean, i.e., $\mathcal{N}(\boldsymbol{\mu}_{\text{post}}, \mathbf{I})$. This is shown in Figure 1d, where each posterior is encouraged to stretch with covariance $\mathbf{I}$. Formally, the loss is

$$J = J_{\text{rec}} + \lambda_{\text{WAE}}\cdot\widehat{\mathrm{MMD}} + \lambda_{\text{KL}}\sum\nolimits_n \mathrm{KL}\left(\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)}, \operatorname{diag}(\boldsymbol{\sigma}_{\text{post}}^{(n)})^2)\|\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)}, \mathbf{I})\right) \tag{5}$$

While our approach appears heuristic, the next theorem shows its theoretical justification.

Theorem 2. *Objective (5) is a relaxed optimization of the WAE loss (4) with a constraint on $\boldsymbol{\sigma}_{\text{post}}$. (See Appendix B for the proof.)* ☐

We will show empirically that such auxiliary loss enables us to generate smoother and more diverse sentences in WAE. It, however, does not suffer from KL collapse as in VAEs. The auxiliary KL loss that we define for stochastic WAE is computed against a target distribution $\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)}, \mathbf{I})$ for each data sample $\mathbf{x}^{(n)}$. Here, the predicted posterior mean itself is used in the target distribution.

	BLEU$^{\uparrow}$	**PPL**$^{\downarrow}$	**UniKL**$^{\downarrow}$	**Entropy**	**AvgLen**
Corpus	-	-	-	$\rightarrow 5.65$	$\rightarrow 9.6$
DAE	**86.35**	146.2	0.178	6.23	11.0
VAE (KL-annealed)	43.18	79.4	0.081	5.04	8.8
WAE-D $\lambda_{\text{WAE}}=3$	86.03	113.8	0.071	5.59	10.0
WAE-D $\lambda_{\text{WAE}}=10$	84.29	104.9	0.073	5.57	9.9
WAE-S $\lambda_{\text{KL}}=0.0$	75.66	115.2	0.069	**5.61**	9.9
WAE-S $\lambda_{\text{KL}}=0.01$	82.01	84.9	**0.058**	5.26	**9.4**
WAE-S $\lambda_{\text{KL}}=0.1$	47.63	**62.5**	0.150	4.65	8.7

Table 1: Results of SNLI-style sentence generation, where WAE is compared with DAE and VAE. **D** and **S** refer to the deterministic and stochastic encoders, respectively. $^{\uparrow/\downarrow}$The larger/lower, the better. For **Entropy** and **AvgLen**, the closer to corpus statistics, the better (indicated by the $\rightarrow$ arrow).

As a result, this KL term does not force the model to learn the same posterior for all data samples (as in VAE), and thus, the decoder does not degrade to an unconditioned language model.

3 Experiments

We evaluate WAE in sentence generation on the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) as well as dialog response generation. All models use single-layer RNN with long short term memory (LSTM) units for both the encoder and decoder. Appendix C details our experimental settings.

VAE training. VAE is notoriously difficult to train in the RNN setting. While different researchers have their own practice of training VAE, we follow our previous experience (Bahuleyan et al., 2018) and adopt the following tricks to stabilize the training: (1) λ_{VAE} was annealed in a $\mathrm{sigmoid}$ manner. We monitored the value of $\lambda \cdot \text{KL}$ and stop annealing once it reached its peak value, known as *peaking annealing*. (2) For word dropout, we started with no dropout, and gradually increased the dropout rate by 0.05 every epoch until it reached a value of 0.5. The effect of KL annealing is further analyzed in Appendix D.

3.1 SNLI Generation

The SNLI sentences are written by crowdsourcing human workers in an image captioning task. It is a massive corpus but with comparatively simple sentences (examples shown in Table 4). This task could be thought of as domain-specific sentence generation, analogous to hand written digit generation in computer vision.

In Table 1, we compare all methods in two aspects. (1) We evaluate by **BLEU** (Papineni et al., 2002) how an autoencoder preserves input information in a reconstruction task. (2) We also evaluate the quality of probabilistic sentence generation from the latent space. Although there is no probabilistic modeling of the latent space in DAE, we nevertheless draw samples from $\mathcal{N}(\mathbf{0}, \mathbf{I})$, which could serve as a non-informative prior. Perplexity (**PPL**) evaluates how fluent the generated sentences are. This is given by a third-party n-gram language model trained on the Wikipedia dataset. The unigram-KL (**UniKL**) evaluates if the word distribution of the generated sentences is close to that of the training corpus. Other surface metrics (entropy of the word distribution and average sentence length) also measure the similarity of the latent space generated sentence set to that of the corpus.

We see that DAE achieves the best BLEU score, which is not surprising because DAE directly optimizes the maximum likelihood of data as a surrogate of word prediction accuracy. Consequently, DAE performs poorly for probabilistic sentence generation as indicated by the other metrics.

VAE and WAE have additional penalties that depart from the goal of reconstruction. However, we see that WAEs, when trained with appropriate hyperparameters ($\lambda_{\text{WAE}}, \lambda_{\text{KL}}$), achieve close performance to DAE, outperforming VAE by 40 BLEU points. This is because VAE encodes each input's posterior to be close to the prior, from which it is impossible to perfectly reconstruct the data.

Comparing the deterministic and stochastic encoders in WAE, we observe the same trade-off between reconstruction and sampling. However, our proposed stochastic encoder, with $\lambda_{\text{KL}} = 0.1$ for WAE, consistently outperforms VAE in the contradictory metrics BLEU and PPL. The hyperparameters $\lambda_{\text{WAE}} = 10.0$ and $\lambda_{\text{KL}} = 0.01$ appear to have the best balance between reconstruction, sentence fluency, as well as similarity to the original corpus.

Moreover, all our WAEs are trained without annealing or word dropout. It is significantly simpler than training a VAE, whose KL annealing typically involves a number of engineering tricks, such as the time step when KL is included, the slope of annealing, and the stopping criterion for annealing.

	BLEU-2	BLEU-4	Entropy	Dist-1	Dist-2
Test Set	-	-	6.15	0.077	0.414
DED	3.96	0.85	5.55	0.044	0.275
VED	3.26	0.59	5.45	0.053	0.204
WED-D	**4.05**	**0.98**	5.53	0.042	0.272
WED-S	3.72	0.69	**5.59**	**0.066**	**0.309**

Table 2: Results on dialog generation, where VED/WED hyperparameters for each model were chosen by Table 1.

3.2 Dialog Generation

We extend WAE to an encoder-decoder framework (denoted by WED) and evaluate it on the DailyDialog corpus (Li et al., 2017).[2] We follow Bahuleyan et al. (2018), using the encoder to capture an utterance and the decoder to generate a reply.

Table 2 shows that WED with a deterministic encoder (WED-D) is better than the variational encoder-decoder (VED) in BLEU scores, but the generated sentences lack variety, which is measured by output entropy and the percentage of distinct unigrams and bigrams (Dist-1/Dist-2, Li et al., 2016), evaluated on the generated test set responses.

We then applied our stochastic encoder for WED and see that, equipped with our KL-penalized stochastic encoder, WED-S outperforms DED, VED, and WED-D in all diversity measures. WED-S also outperforms VED in generation quality, consistent with the results in Table 1.

4 Conclusion

In this paper, we address the difficulty of training VAE by using a Wasserstein autoencoder (WAE) for probabilistic sentence generation. WAE implementation can be carried out with either a deterministic encoder or a stochastic one. The deterministic version achieves high reconstruction performance, but lacks diversity for generation. The stochastic encoder in the original form may collapse to a Dirac delta function, shown by both a theorem and empirical results. We thus propose to encourage stochasticity by penalizing a heuristic KL loss for WAE, which turns out to be a relaxed optimization of the Wasserstein distance with a constraint on the posterior family.

We evaluated our model on both SNLI sentence generation and dialog systems. We see that WAE achieves high reconstruction performance as DAE, while retaining the probabilistic property as VAE. Our KL-penalty further improves the stochasticity of WAE, as we achieve the highest performance in all diversity measures.

Acknowledgments

We would like to acknowledge Yiping Song and Zhiliang Tian for their independent investigation on the DailyDialog corpus. We also thank Yanran Li, one of the authors who released DailyDialog, for discussion on this issue. This work was supported in part by the NSERC grant RGPIN-261439-2013 and an Amazon Research Award.

[2] In our pilot experiment, we obtained a BLEU-4 score of 6 by training a pure Seq2Seq model with LSTM units for 200 epochs, whereas Li et al. (2017) report 0.009 BLEU-4 and Luo et al. (2018) report 2.84 BLEU-4. Due to our unreasonably high performance, we investigated this in depth and found that the training and test sets of the DailyDialog corpus have overlaps. For the results reported in our paper, we have removed duplicate data in the test set, which is also available on our website (Footnote 1). To the best of our knowledge, we are the first to figure out the problem, which, unfortunately, makes comparison with previous work impossible.

A Proof of Theorem 1

Theorem 1. *Suppose we have a Gaussian family* $\mathcal{N}(\boldsymbol{\mu}, \operatorname{diag} \boldsymbol{\sigma}^2)$*, where* $\boldsymbol{\mu}$ *and* $\boldsymbol{\sigma}$ *are parameters. The covariance is diagonal, meaning that the variables are independent. If the gradient of* $\boldsymbol{\sigma}$ *completely comes from sample gradient and* $\boldsymbol{\sigma}$ *is small at the beginning of training, then the Gaussian converges to a Dirac delta function with stochastic gradient descent, i.e.,* $\boldsymbol{\sigma} \to \mathbf{0}$.

Proof. For the predicted posterior $\mathcal{N}(\boldsymbol{\mu}, \operatorname{diag} \boldsymbol{\sigma}^2)$ where all dimensions are independent, we consider a certain dimension, where the sample is $z_i \sim \mathcal{N}(\mu_i, \sigma_i^2)$.

We denote the gradient of J wrt to z_i at $z_i = \mu_i$ by $g_i \triangleq \frac{\partial J}{\partial z_i}\big|_{z_i=\mu_i}$. At a particular sample $z_i^{(j)}$ around μ_i, the gradient $g_i^{(j)}$ is

$$
\begin{aligned}
g_i^{(j)} &\triangleq \left.\frac{\partial J}{\partial z_i}\right|_{z_i=z_i^{(j)}} && (6)\\
&\approx g_i + \frac{\partial^2 J}{\partial \mu_i^2}(z_i^{(j)} - \mu_i) && (7)\\
&\triangleq g_i + k(z_i^{(j)} - \mu_i) && (8)\\
&= g_i + k(\mu_i + \epsilon^{(j)}\sigma_i - \mu_i) && (9)\\
&= g_i + k\sigma_i\epsilon^{(j)} && (10)
\end{aligned}
$$

where (7) is due to Taylor series approximation, if we assume σ_i^2 is small and thus $z_i^{(j)}$ is near μ_i. k denotes $\frac{\partial^2 J}{\partial \mu_i^2}$.

We compute the expected gradient wrt to σ_i for $\epsilon \sim \mathcal{N}(0, 1)$. The assumption of this theorem is that the gradient of μ_i and σ_i completely comes from the sample z_i. By the chain rule, we have

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{\epsilon^{(j)}\sim\mathcal{N}(0,1)}\left[\frac{\partial J}{\partial \sigma_i}\right] && (11)\\
=&\mathop{\mathbb{E}}_{\epsilon^{(j)}\sim\mathcal{N}(0,1)}\left[\frac{\partial J}{\partial z_i^{(j)}}\cdot\frac{\partial z_i^{(j)}}{\partial \sigma_i}\right] && (12)\\
=&\mathop{\mathbb{E}}_{\epsilon^{(j)}\sim\mathcal{N}(0,1)}\left[(g_i+k\sigma_i\epsilon^{(j)})\cdot\epsilon^{(j)}\right] && (13)\\
=&\mathop{\mathbb{E}}_{\epsilon^{(j)}\sim\mathcal{N}(0,1)}\left[g_i\epsilon_i^{(j)}+k\sigma_i(\epsilon^{(j)})^2\right] && (14)\\
=&k\sigma_i && (15)
\end{aligned}
$$

Notice that $k > 0$ if we are near a local optimum (locally convex).

In other words, the expected gradient of σ_i is proportional to σ_i. According to stochastic gradient descent (SGD), σ_i will converge to zero. ☐

The theorem assumes $\boldsymbol{\sigma}^2$ is small, compared with how J changes in the latent space. In practice, the encoded vectors of different samples may vary a lot, whereas if we sample different vectors from a certain predicted multi-variate Gaussian, we would generally obtain the same sentence. Therefore, J is kind of smooth in the latent space. The phenomenon can also be verified empirically by plotting the histogram of σ in WAE with a stochastic Gaussian encoder (Figure 2). We see that if the KL coefficient λ_{KL} is 0, meaning that the gradient of σ comes only from the samples, then most σ's collapse to 0.

Notice, however, that the theorem does not suggest a stochastic WAE and a deterministic WAE will yield exactly the same result, as their trajectories may be different.

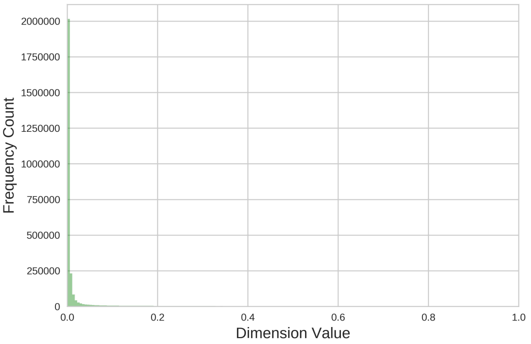
B Proof of Theorem 2

Theorem 2. *Objective (5) is a relaxed optimization of the WAE loss (4) with a constraint on* $\boldsymbol{\sigma}_{\text{post}}$.

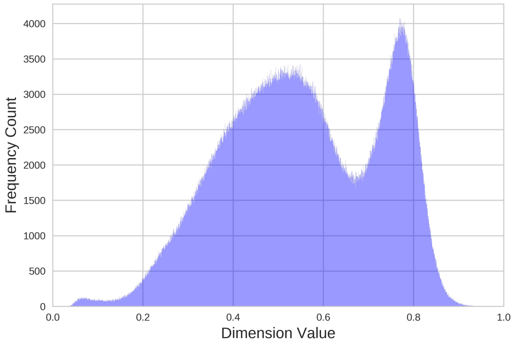
Proof. Objective (5) optimizes

$$
\begin{aligned}
J = &J_{\text{rec}} + \lambda_{\text{WAE}}\cdot\widehat{\text{MMD}}\\
&+\lambda_{\text{KL}}\sum\nolimits_n \text{KL}\left(\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)},\text{diag}(\boldsymbol{\sigma}_{\text{post}}^{(n)})^2)\|\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)},\mathbf{I})\right)
\end{aligned}
$$

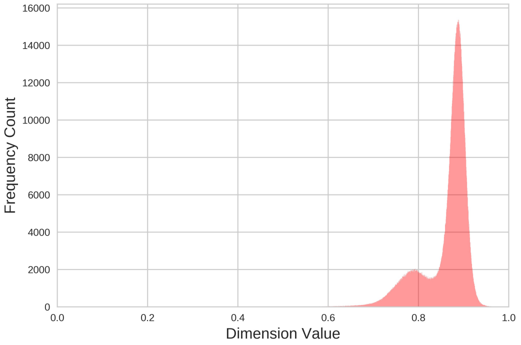
The first two terms are the WAE loss, whereas the last penalty relaxes the following optimization problem



(a) $\lambda_{\text{KL}} = 0$



(b) $\lambda_{\text{KL}} = 0.01$



(c) $\lambda_{\text{KL}} = 0.1$

Figure 2: The histograms of σ in the posterior of the WAE in the SNLI experiment. In the plot, there are 200 buckets in the range of $(0, 1)$.

$$
\begin{aligned}
&\text{minimize}\ \ J_{\text{rec}} + \lambda_{\text{WAE}}\cdot\widehat{\text{MMD}}\\
&\text{subject to}\\
&\sum\nolimits_n \text{KL}\left(\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)},\text{diag}(\boldsymbol{\sigma}_{\text{post}}^{(n)2}))\|\mathcal{N}(\boldsymbol{\mu}_{\text{post}}^{(n)},\mathbf{I})\right) < C
\end{aligned}
\tag{16}
$$

for some constant C.

As known, the KL divergence between two

Table 3: Experimental settings.

(univariant) Gaussian distributions is

$$\begin{aligned} &\mathrm{KL}(\mathcal{N}(\mu_1,\sigma_1)\|(\mathcal{N}(\mu_2,\sigma_2))) \\ &= \log\frac{\sigma_2}{\sigma_1} + \frac{\sigma_1^2+(\mu_1-\mu_2)^2}{2\sigma_2^2} - \frac{1}{2} \end{aligned} \tag{17}$$

The constraint in (16) is equivalent to

$$\sum_n\sum_i\left[-\log\sigma_i^{(n)} + \frac{1}{2}(\sigma_i^{(n)})^2\right] < C \tag{18}$$

In other words, our seemingly heuristic KL penalty optimizes the Wasserstein loss, while restricting the posterior family. □

C Implementation Details

All models were trained with the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. In all our experiments, we feed the sampled latent vector $\boldsymbol{z}$ to each time step of the decoder. Task-specific settings are listed in Table 3.

D VAE Training Difficulties

It is a common practice that training VAEs involves KL annealing and word dropout, which further consists of hacks for tuning hyperparameters. We conducted an experiment of training VAE without KL annealing. In Figure 3, we present the KL loss (weighted by λ_{VAE}) during the training process for different values of λ_{VAE}. The KL loss is believed to be an important diagnostic measure to indicate if the latent space is "variational" (Yang et al., 2017; Higgins et al., 2017; Burgess et al., 2017). We see that if the penalty is too large, KL simply collapses to zero ignoring the entire input, in the case of which, the decoder becomes an unconditioned language model. On the other hand, if the KL penalty is too small, the model tends to become more *deterministic* and the KL term does not play a role in the training. This is expected since in the limit of λ_{VAE} to 0, the model would probably ignore the KL term and becomes a deterministic autoencoder (shown also by Theorem 1).

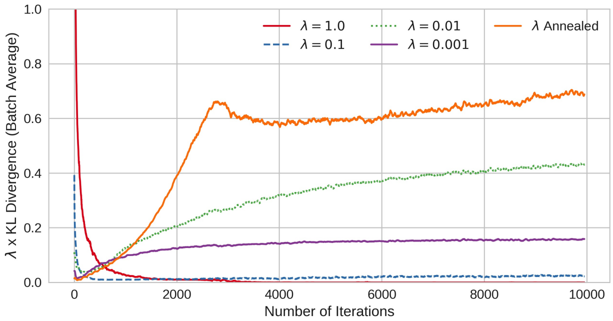

Figure 3: Learning curves of the KL term in the VAE loss function ($\lambda \cdot \mathrm{KL}$) for different values of λ, and the variant where λ is annealed.

The VAE with collapsed KL does not exhibit interesting properties such as random sampling for probabilistic sequence generation (Bowman et al., 2016). As seen in Table 4, the generated sentences by VAE without annealing are very close to each other. This is because VAE's encoder does not capture useful information in the latent space, which is simply ignored during the decoding phase. By sampling the latent space, we do not obtain varying sentences. The empirical evidence verifies our intuition.

A recent study (Xu and Durrett, 2018) propose to get rid of KL annealing by using the von Mises–Fisher (vMF) family of posterior and prior. In particular, they set the prior to the uniform distribution on a unit hypersphere, whereas the posterior family is normal distribution on the surface of the same sphere. They fix the standard deviation (parametrized by κ) of the posterior, so that their KL is a constant and annealing is not required. This, unfortunately, loses the privilege of learning uncertainty in the probabilistic modeling. Examples in Table 4 show that, while we have reproduced the reconstruction negative log-likelihood with vMF-VAE (the metric used in their paper), the generated sentences are of poor quality. As also suggested by Xu and Durrett (2018), if the posterior uncertainty in vMF is made learnable, it re-introduces the KL collapse problem, in which

case, the KL annealing is still needed.

By contrast, WAEs for sequence-to-sequence models are trained without any additional optimization strategies such as annealing. Even in our stochastic encoder, the KL penalty does not make WAE an unconditioned language model, because it does not force the encoded posterior to be the same for different input sentences.

E Qualitative Samples

Table 4 shows sentences generated by randomly sampling points in the latent space for different models, along with sample sentences from the training set. They provide a qualitative understanding of each model's performance.

Benchmarking Hierarchical Script Knowledge

Yonatan Bisk[1] **Jan Buys**[1] **Karl Pichotta**[*] **Yejin Choi**[1,2]

Abstract

Understanding procedural language requires reasoning about both hierarchical and temporal relations between events. For example, "boiling pasta" is a *sub-event* of "making a pasta dish", typically happens *before* "draining pasta," and *requires* the use of omitted tools (e.g. a strainer, sink...). While people are able to choose when and how to use abstract versus concrete instructions, the NLP community lacks corpora and tasks for evaluating if our models can do the same. In this paper, we introduce **KIDSCOOK**, a parallel script corpus, as well as a cloze task which matches video captions with missing procedural details. Experimental results show that state-of-the-art models struggle at this task, which requires inducing functional commonsense knowledge not explicitly stated in text.

1 Introduction

The level of detail used in natural language communication varies: descriptive or instructive text for experts may elide over details the reader can seamlessly infer, while text for more novice audiences may be more verbose. A given document typically adheres to a single level of verbosity suited to its presumed audience (Grice, 1975), so learning correspondences between abstract and detailed descriptions of similar concepts from text is a challenging problem.

Commonsense knowledge of how complex events decompose into stereotypical sequences of simpler events is a necessary component of a system that can automatically understand and reason about different types of discourse. Hierarchical correspondences between abstract and detailed representations of concepts and events were an important aspect of the original formulation of scripts for natural language understanding (Schank and Abelson, 1977; DeJong, 1981) but required hand-written data structures encoding world knowledge. However, the automatic induction of such commonsense knowledge from open-domain noisy text corpora remains an open problem (Chambers, 2013; Weber et al., 2018; Zellers et al., 2018). As a step towards solving this problem we consider textual descriptions of actions in a cooking domain.

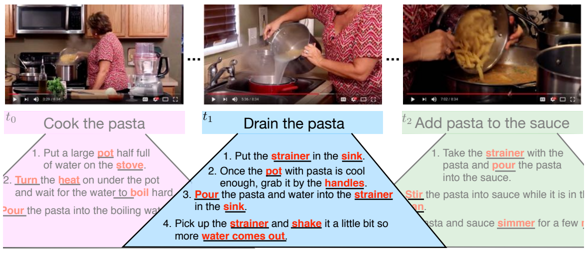

Figure 1: An example **KIDSCOOK** sequence with multiple types of hierarchy and abstraction: the example contains sequences of complex instructions, given both as sentences and sequences of simpler instructions.

We introduce a dataset, **KIDSCOOK**, targeted at exploring the automatic acquisition of correspondences between abstract and concrete descriptions of actions. The dataset consists of higher-level single-sentence imperative descriptions paired with lower-level descriptions with elided details included. Descriptions come from real grounded actions, built on top of the YouCookII video caption dataset (Zhou et al., 2017).

Figure 1 gives an example annotation from the dataset: the phrase "drain the pasta," presented to an annotator with its corresponding video clip, was annotated as corresponding to four constituent steps appropriate as instruction for a child. The constituent steps are "simpler" in the sense that they correspond to more atomic actions, but not necessarily in their linguistic complexity. We identify over 1,500 procedures and tools which **KIDSCOOK** makes explicit but are assumed as

Minneapolis, Minnesota, June 2 - June 7, 2019.

commonsense world knowledge by YouCookII.

The **KidsCook** dataset allows us to learn mappings between abstract and concrete descriptions via sequence-to-sequence prediction. We apply several standard neural sequence-to-sequence models; however, since these models do not expose explicit, interpretable correspondences between abstract and concrete descriptions, we also propose the application of neural transduction models which capture correspondences with latent hard alignment variables. We define a cloze-style evaluation to complement our dataset, in which models must predict the values of held-out tokens which target knowledge of tool usage, temporal ordering, and kitchen commonsense. We find that our neural transduction models are able to match the predictive power of traditional neural sequence models while providing interpretable alignments between abstract and concrete subsequences useful for our primary goal of analysis of implicit hierarchical script knowledge.

2 Data & Task

Our approach situates script learning as a case of grounding. For simplicity of exposition, let us assume there are three levels of abstraction to grounding: *abstract* → *concrete* → *motor control*. Most prior work in grounding treats language monolithically[1] and ignores the issue of audience. In practice, this means the task formulation or exposed API may implicitly bias the language to be more concrete. By viewing the task as purely linguistic, we have no API or robot that constrains our language; instead, we define our audience as children. By eliciting child-directed instructions, we collect concrete language capturing otherwise implicit world knowledge that a child would not know. Because annotators assume a smart and capable but uninformed listener, we posit this language corresponds closely to the most "concrete" form in which language naturally occurs.

2.1 Data Collection

We construct a task on Amazon's Mechanical Turk, where workers are asked to explain a video action caption to a child.[2] Every instruction is paired with the original YouTube video and YouCook caption so the annotator could see how the action was performed, rather than hallucinating additional details. All captions received three simplifications. The instructions ask users to focus on missing information and allow them up to five steps. Finally, we explicitly asked annotators to simplify complex actions (e.g. *dice*) that can be defined by a series of more basic actions (e.g. *cut*).

	Seqs	Tokens	Vocab	Avg Len YC	 **KC**
Train	8,125	307,573	3,573	10.0	37.9
Valid	1,014	36,830	1,479	8.8	36.3
Test	1,020	37,156	1,489	8.8	36.4

Table 1: **KidsCook** corpus statistics

Our **KidsCook** corpus statistics are shown in Table 1. In total we collected over 10K action sequences (~400K tokens). The average caption is approximately 4x longer than a YouCook caption. Most importantly 1,536 lemmas and 2,316 lexical types from **KidsCook**'s vocabulary do not appear in any of the original captions. This indicates that there are over 1,500 new concepts, tools, and procedures that were assumed by YouCookII but are now explicit in **KidsCook**.

2.2 Cloze Task

To investigate what new knowledge is being introduced and whether a model has captured it, we construct a cloze-style slot-filling task (Chambers, 2017; Hermann et al., 2015). We drop key content words from the concrete realization of an abstract instruction and ask the model to predict them. Several examples from the validation set are shown in Table 2. Correctly predicting the missing words requires knowledge of the manner of executing a task and the tools required.

To choose candidate words to drop, we only allow words that occur primarily in the concrete instructions. Additionally, we do not drop stop words, numbers, or words occurring fewer than five times. We do, however, drop units of measure (*cup*, *minute*, etc.). This ensures we create blanks whose answers are previously omitted concrete details. Relatedly, under this filter the answer to a blank is very rarely an ingredient, as our goal is not to memorize recipes, but to infer the tool knowledge necessary to execute them. In total, we whitelist ∼1,000 words that can be dropped to create blanks. We prefer longer blanks when available to give preference to compound nouns (e.g. *wire whisk*). Finally, we do not drop any words

---

[1] Notable exceptions include the hierarchical instructions of (Regneri et al., 2013) and (Bisk et al., 2016).

[2] Pay was calculated based on $15/hr and assuming workers took 1.5x as long to complete a task as the experimenters.

from the concrete sentence if they occur in the abstract description. This restriction eliminates any benefits that might have been achieved via models with copy mechanisms. Examples that do not meet our criteria are removed from the corpus.

3 Models

We investigate the utility of sequence-to-sequence models with attention (Bahdanau et al., 2015) to generate concrete realizations of abstract task descriptions. We hypothesize that models that learn explicit alignments are particularly amenable to interpretable analysis on the task. Therefore, in addition to using the global attention model of (Luong et al., 2015), we adapt the transducer model proposed by Yu et al. (2016), which uses learned latent discrete variables to model phrase-to-phrase alignments. In contrast to many standard neural models, this approach enables us to incorporate prior knowledge about the alignment structure, and to extract interpretable alignments between task phrases. Closely related architectures have been proposed for segmental sequence modeling (Wang et al., 2017) and phrase-based neural machine translation (Huang et al., 2018).

We train the transducer models using Viterbi EM (after doing marginal likelihood training for the initial iterations), as we found it gave higher predictive accuracy than marginal likelihood training only. Following Yu et al. (2016) we experiment with both a fixed alignment transition probability model and a transition model with a neural parameterization. Cloze task prediction is performed greedily.[3] At each slot the Viterbi alignment of the prefix of the sequence up to that slot is computed. See appendix 7 for model details.[4] We also evaluate the performance of a language modelling baseline and a seq2seq model without attention (Sutskever et al., 2014), to compare the effect of not modeling alignment at all.

We expect all the models to implicitly capture aspects of world knowledge. However, the discrete latent variable models provide Viterbi alignments over the training data, from which we can compile a look-up table with the extracted knowledge. In neural attention models, this knowledge is only weakly recoverable: extracting information requires hand tuning attention thresholds and there is no direct way to extract contiguous alignments for multi-word phrases.

4 Results

4.1 Evaluation Metrics

During generation, we provide the model with the number of words in each blank to be predicted. We consider two setups for evaluating examples with multiple blanks, both assuming that predictions are made left-to-right: Oracle, where the gold prediction of each blank is fed into the model to condition on for future predictions, and Greedy, where the model prediction is used for future predictions. We compute the proportion of exact word matches over each blank and the precision of the top $k = 5$ predictions for both setups. Additionally we compute the average surprisal of the gold prediction (conditioning on oracle predictions). The *surprisal* of a word (Attneave, 1959; Hale, 2001) is its negative log probability under the model: $-log(P(w_i|w_{1:i-1}))$. The higher the probability of the ground truth, the lower the model's "surprise" at seeing it in that context.

Finally, as a quantitative proxy for interpretability, we report the length of the transducer models' average Viterbi alignment span: our goal is a model which balances low average alignment lengths and high matching or ranking scores.

4.2 Cloze Task Results

We report results on the prediction task in Table 4. First we consider models trained only on our dataset: All the models that incorporate a notion of alignment do substantially better than those who

Table 4: Results on the Cloze prediction task (Match = Exact Match, Top-5 = Precision of Top 5 predictions, Surp = Surprisal). Transducer results are reported for models with unparameterized and parameterized (+ParamTran) alignment transition models. The **best** and *second best* results are emphasized.

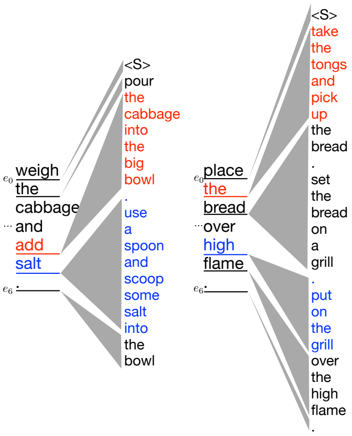

Figure 2: Example Viterbi alignments

do not. We see that our transducer model with fixed alignment transition probabilities performs best in terms of predictive accuracy (exact match and top-5 precision), while the seqseq model with attention is the next best in most comparisons. The model with parameterized transitions has the lowest surprisal though, as it is more confident about the alignment predictions it is making.

Using average alignment length to quantify whether the phrase alignments exhibit desirable structure, we see that the alignments found by the unparameterized transition model (average length 6.18) are significantly shorter than those of the parameterized model (average length 16.61). Investigation shows that the paramaterized model mostly learns degenerate alignments, aligning most of the concrete sequence to either the start or end of the abstract sentence. In contrast, qualitative analysis of the unparameterized transition model show that its alignments learn desirable correspondences (see Figure 2). Therefore among our proposed models (trained on in-domain data only) the transducer with unparameterized transitions satisfies our desiderata of displaying both good predictive power for word generation, and learning interpretable alignments.

Given the recent success of massively pretrained language models (Peters et al., 2018), we are interested if these approaches transfer to our cloze task. We evaluate the OpenAI GPT transformer language model (Radford et al., 2018) with and without fine-tuning.Without fine-tuning this model does slightly worse than our best domain-specific model. With fine-tuning, its accuracy is substantially higher, but it still suffers from the same fundamental limitations as our other models (see Table 5). The transformer (Vaswani et al., 2017) attention is multi-headed and multi-layered which prohibits direct interpretability.

5 Qualitative Analysis

We visualize alignments of our transduction model over two partial sequences in Fig. 2. This shows which hidden vector of the abstract sentence aligned to every region of the concrete sequence. Specifically, we see how tools like *the big bowl*, *spoon*, and *tongs* are introduced to facilitate the actions. There are also implications, e.g. that *high* indicates *grill*. For further analysis we extract alignments over the training corpus, linking each decoded phrase with the word from the encoding it used during generation. We then aggregate these tuples into a table which we can filter (based on our whitelist) and sort (with PMI). This process is imprecise as it discards the context in which the alignment occurs, but it nonetheless extracts many

`Abs`	shape each dough ball into a circle and add tomato sauce .

Table 5: Above is the output of OpenAI GPT when forced to greedily decode answers to blanks in validation.

of the phenomena we would hope to see (Table 3).

The left-hand side of the table shows words from the abstract YouCook annotations and corresponding phrases in the concrete annotation. For the righthand side we searched for common concrete terms that may be preceded or followed by other terms, and present the abstract terms they were most often generated by.

Finally, Table 5 shows three randomly chosen examples (from the validation set) of greedy decodings for slot filling with GPT fine-tuned on our dataset. These examples demonstrate that, first, there are cases where GPT is successful or produces a semantically valid answer (e.g. *fully* vs *completely*). Second, as is common with greedy decoding, the model can get stuck in a loop (e.g. *cut, cutting, cutting, ...*). Finally, note there are nonsensical cases where the model appears to have discarded the abstract context (e.g. *knife to add tomato sauce* or *freezer on a cold water*).

6 Related Work

Many script learning systems are based on event co-occurrence and language modeling in large text corpora, and can infer implicit events without creating explicit situation-specific frame structures (Chambers and Jurafsky, 2008; Rudinger et al., 2015; Pichotta and Mooney, 2016). Other systems induce situation-specific frames from text (Cheung et al., 2013; Balasubramanian et al., 2013). However, these methods do not explicitly target the commonsense correspondence between differing levels of detail of complex events.

Most relevant to this paper is the pioneering work of Regneri et al. (2013) as extended by Senina et al. (2014) and Rohrbach et al. (2014). These papers present the TACOS corpus, consisting of natural language descriptions of activities in videos paired with low-level activity labels. Senina et al. (2014) collect an additional level of multi-sentence annotations on the corpus, which allowing for video caption generation at multiple levels of detail. Rohrbach et al. (2014) describe a similar corpus of natural descriptions of composite actions, useful for activity recognition in video. These corpora differ in a number of important ways from **KIDSCOOK**; in particular, the language has somewhat limited complexity and "naturalness" when describing complex scenarios, a phenomenon also observed in the robotics literature (Scalise et al., 2018). Our data collection process avoids more formulaic language by eliciting "child-directed" descriptions.

7 Conclusion

We introduce a new hierarchical script learning dataset and cloze task in which models must learn commonsense world knowledge about tools, procedures and even basic physics to perform well. Our aim is to begin a conversation about abstraction in language, how it is modeled, and what is implicitly hidden. Our abstract and concrete instructions are grounded in the same videos yet differ dramatically due to their assumed audiences. We show that a neural transduction model produces interpretable alignments for analyzing these otherwise latent correlations and phenomena.

A Transducer Model

We briefly describe the model of Yu, Buys, and Blunsom (2016) and our minor modifications thereto.

A.1 Alignment with Latent Variables

We model the conditional probability of a concrete sequence y given abstract sequence x through a latent alignment variable a between x and y, which is a sequence of variables a_j, with $a_j = i$ signifying that y_j is aligned to x_i. The marginal probability of y given x is

$$p(y|x) = \sum_a p(y, a|x). \tag{1}$$

In the following, we use m to denote the length of x and n to denote the length of y. The model formulation restricts alignments to be monotonic, i.e. $a_{j+1} \geq a_j$ for all j.

The model factorizes over timesteps into alignment and word prediction probabilities, such that the word prediction at each timestep is informed by its alignment:

$$\begin{aligned} p(y, a|x) = \prod_j & p(a_j | a_{j-1}, x_{1:a_{j-1}}, y_{1:j-1}) \\ & \times p(y_j | a_j, x_{1:a_j}, y_{1:j-1}) \end{aligned} \tag{2}$$

The abstract and concrete sequences are both encoded with LSTM Recurrent Neural Networks (Hochreiter and Schmidhuber, 1997). In contrast to standard attention-based models, the aligned encoder representation is not fed into the decoder RNN state, but only used to make next word predictions. Due to the small size of the training data, words in both sequences are embedded using fixed GloVe embeddings (Pennington et al., 2014). The word emission probability is then defined as

$$p(y_j | a_j, x_{1:a_j}, y_{1:j-1}) = \text{softmax}(\text{MLP}(e_{a_j}, d_j)) \tag{3}$$

with e the encoder hidden states and d the decoder hidden states.

The alignment probability factorizes into *shift* and *emit* probabilities, where a *shift* action increments the alignment to the next word in the input sequence, and an *emit* action generates the next output word. We refer to these as *transition* probabilities. This formulation enables us to restrict the hard alignment to be monotonic.

We consider two parameterizations of this distribution. In the first, the probabilities are parameterized by the neural network, using the encoder and decoder hidden state in a similar manner to how the word emission probability was computed. The alignment probability at a given timestep is therefore parameterized as

$$\begin{aligned} p(a_j | a_{j-1}, x_{1:a_{j-1}}, y_{1:j-1}) &= p(\text{emit} | a_j, x_{1:a_j}, y_{1:j-1}) \\ & \times \prod_{i=a_{j-1}}^{a_j - 1} p(\text{shift} | i, x_{1:i}, y_{1:j-1}), \end{aligned} \tag{4}$$

where

$$p(\text{shift} | i, x_{1:i}, y_{1:j-1}) = \sigma(MLP(e_i, d_j)), \tag{5}$$

$$p(\text{emit} | i, x_{1:i}, y_{1:j-1}) = 1 - p(\text{shift} | i, x_{1:i}, y_{1:j-1}). \tag{6}$$

We also consider using the simpler, fixed alignment parameterization in Yu, Buys, and Blunsom (2016), where the transition probability is conditioned only on sequence length, not on x or y, and can therefore be estimated using the ratio between input and output sentence lengths. The alignment probabilities are not updated during training, and consequently the posterior distribution over the alignments is biased towards this prior, favoring alignments close to the diagonal.

The parameterized alignment model contains as special cases two degenerate solutions: (1) an unconditional language model and (2) a seq2seq model. These occur if the model performs all emits before shifting or all shifts before emitting, respectively. To prevent the creation of a language model we force the last output word to be aligned to the last word in the abstract sequence, similar to Yu et al. (2017). However, the parameterized transition model could still in practice revert to a pure sequence-to-sequence model.

A.2 Marginalization

Next we briefly describe the dynamic program used to marginalize over alignments during training and to find the most likely alignments of a given alignment during inference; we refer the reader to Yu, Buys, and Blunsom (2016) for a more thorough treatment.

The forward variable $\alpha_i(j)$ representing $p(y_{1:j}, a_j = i | x_{1:i})$ is recursively as

$$\begin{aligned} \alpha_i(j) &= p(y_j | i, x_{1:i}, y_{1:j-1}) \\ & \times \sum_{k=1}^{i} \alpha_k(j-1) p(a_j = i | k, x_{1:k}, y_{1:j-1}). \end{aligned} \tag{7}$$

The marginal likelihood objective is to train the model to optimize $\alpha_m(n) = p(y_{1:n}, a_n =$

$m|x_{1:m})$. The gradients are computed with automatic differentiation; as this is is equivalent to using the forward-backward algorithm to estimate the gradients (Eisner, 2016), only the forward algorithm has to be implemented.

To make the implementation GPU-efficient, we vectorize the computation of α. The computation iterates through decoding steps, each of which can be generated from an alignment to any of the encoder tokens. We can efficiently construct a transition matrix T, corresponding to all possible encoder states performing all possible shifts, and emission matrix E_j which is a gather by word index j.

To compute the forward probabilities at each timestep, the current forward probabilities are first multiplied by all possible transitions. A sum in logspace collapses all paths, and the emission (word generation) probabilities are multiplied to obtain the new forward probabilities. When fixed transition probabilities are used, T is precomputed.

A.3 Viterbi EM Training

Latent variable models can be trained either through directly optimizing the likelihood objective through gradient descent (as described above), or with the Expectation Maximization (EM) algorithm (Dempster et al., 1977), which alternates between calculating expectations over the values of the latent variables given the current parameters, and maximizing the expected complete data log likelihood given those expectations. We consider training our alignment model with Viterbi EM (Brown et al., 1993), also known as “hard” EM, where at each iteration the most likely assignment of the hidden variables (alignments) are found and the parameters are updated to optimize the log likelihood given those alignments. Viterbi EM has been shown to give superior performance to standard EM on unsupervised parsing (Spitkovsky et al., 2010), due to better convergence properties in practice by making the distribution more peaked.

We perform batched Viterbi EM training by computing the Viterbi alignments for a batch, and then performing a gradient step based on treating those alignments as observations.

We follow a two-stage training procedure: we first directly optimize the marginal likelihood with batched SGD to find a reasonable initial distribution over alignments, before switching to Viterbi EM training. Such a strategy has been shown to reduce the chance that the model will get stuck in local optima (Spitkovsky et al., 2011).

A.4 Inference

We apply the trained models to multiple inference problems to evaluate how well they are capturing script knowledge. The first is finding the most likely alignment given a pair of abstract and concrete sequences. We use the standard Viterbi algorithm, in which we replace the sum in equation (7) with $\max$, and keep track of the index corresponding to each value of α during the forward computation. The most likely alignment can then be traced back from $a_n = m$.

The second inference problem is slot-filling, for application to the cloze task. Given an abstract sentence and a partially-filled concrete sequence, we want to use the model to predict words to fill the given blanks. To make the prediction, we sample 5 candidate sequences by predicting words for each slot, in left-to-right order, and then choosing the sequence with the highest overall probability. Words are predicted by sampling with temperature 0.1, in order to peak the distribution while still allowing some diversity in the samples. The motivation for selecting the final output from multiple samples is that the original samples are biased, as they are only conditioned on the left context.

At the start of the prediction for each slot, the Viterbi alignment of the prefix of the sequence up to the start of that slot is re-predicted, independent of previous alignment predictions. Consequently alignment decisions can be revised, and the slot alignments are no longer constrained to be monotonic, which makes the slot prediction model more flexible. For the parameterized transition model, the slot alignment is predicted greedily by incrementing the last predicted alignment while the shift probability is greater than 0.5. The fixed transition model assumes that the alignment of the word preceding the slot is shared across the slot.

A Large-Scale Study of the Effects of Word Frequency and Predictability in Naturalistic Reading

Cory Shain
Department of Linguistics
The Ohio State University
`shain.3@osu.edu`

Abstract

A number of psycholinguistic studies have factorially manipulated words' contextual predictabilities and corpus frequencies and shown separable effects of each on measures of human sentence processing, a pattern which has been used to support distinct mechanisms underlying prediction on the one hand and lexical retrieval on the other. This paper examines the generalizability of this finding to more realistic conditions of sentence processing by studying effects of frequency and predictability in three large-scale naturalistic reading corpora. Results show significant effects of word frequency and predictability in isolation but no effect of frequency over and above predictability, and thus do not provide evidence of distinct mechanisms. The non-replication of separable effects in a naturalistic setting raises doubts about the existence of such a distinction in everyday sentence comprehension. Instead, these results are consistent with previous claims that apparent effects of frequency are underlyingly effects of predictability.

1 Introduction

Are there distinct effects of a word's frequency versus predictability in human sentence comprehension? Recent evidence implicates prediction as a major organizing principle in cognition (Bubic et al., 2010; Singer et al., 2018; Keller and Mrsic-Flogel, 2018), and psycholinguists have long studied the role of prediction in human sentence processing and its relation to other comprehension mechanisms (Marslen-Wilson, 1975; Kutas and Hillyard, 1984; MacDonald et al., 1994; Tanenhaus et al., 1995; Hale, 2001; Norris, 2006; Levy, 2008; Frank and Bod, 2011). Some prominent theories of word recognition claim that ease of lexical access is modulated by the strength of a word's representation in memory, independently of contextual factors that guide prediction (Seidenberg and McClelland, 1989; Coltheart et al., 2001; Harm and Seidenberg, 2004). Other theories hold that apparent effects of frequency are underlyingly effects of predictability (Norris, 2006; Levy, 2008; Rasmussen and Schuler, 2018).

A number of studies using constructed stimuli that factorially manipulate word frequency and predictability have found separable additive effects of each, suggesting distinct influences on lexical processing (see Staub, 2015 for a review). This paper examines the generalizability of these findings to typical sentence comprehension by searching for separable effects of frequency and *n*-gram predictability using deconvolutional time series regression (DTSR) models (Shain and Schuler, 2018) fitted to three large naturalistic reading corpora: Natural Stories (Futrell et al., 2018), Dundee (Kennedy et al., 2003), and UCL (Frank et al., 2013). While results show evidence of both frequency and predictability effects in isolation, they show no effect of frequency over predictability and thus do not support the existence of separable effects. They are instead consistent with either (1) an account of apparent frequency effects as epiphenomena of predictive processing (Norris, 2006; Levy, 2008) or (2) a more circumscribed role for frequency effects in naturalistic reading than constructed experiments suggest.

2 Background and Related Work

2.1 Frequency and Predictability in Human Sentence Processing

It has long been recognized that low-frequency words are harder to process (Inhoff and Rayner, 1986). For example, in a neutral context, the more frequent *bottle* should on average be processed more quickly than the less frequent *kettle*:

Proceedings of NAACL-HLT 2019, pages 4086–4094
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

(1) a. I have a **bottle**.
b. I have a **kettle**.

However, context can dramatically alter these patterns by changing words' predictability (Ehrlich and Rayner, 1981):

(2) a. the pot calling the **bottle** black
b. the pot calling the **kettle** black

Some models of word recognition (Seidenberg and McClelland, 1989; Coltheart et al., 2001; Harm and Seidenberg, 2004) posit a context-independent lexical retrieval mechanism, distinct from any mechanisms for predictive coding, with processing cost proportional to the strength of a word's representation in memory (a function of lexical frequency). Such a view predicts separable effects of frequency and predictability in human language comprehension. Other models (Hale, 2001; Norris, 2006; Levy, 2008; Rasmussen and Schuler, 2018) posit no such context-independent retrieval mechanism, and instead propose a unified comprehension mechanism that incrementally reallocates resources between possible interpretations of the unfolding sentence, with processing cost proportional to the amount of information (resource reallocation) contributed by each new word. Such a view predicts no separable effects of frequency and predictability because lexical frequencies are subsumed into the incremental probability model.

Consistently with the first hypothesis, previous studies have shown separable additive effects of frequency and predictability by factorially manipulating corpus frequency and cloze predictability (Rayner et al., 2004; Ashby et al., 2005; Gollan et al., 2011; Staub and Benatar, 2013, see Staub, 2015 for a review). However, cloze estimates poorly distinguish degrees of low contextual probability (Smith and Levy, 2013), and constructed stimuli, while affording direct control over linguistic variables, may fail to reflect the typical distributional characteristics of the language, lack context, and/or inadvertently trigger suspension of the usual processes of pragmatic inference due to the absence of an overarching discourse (Demberg and Keller, 2008; Hasson and Honey, 2012; Shain et al., 2018). It is therefore not yet clear whether frequency and predictability effects can be separated in a more realistic setting.

2.2 The Naturalistic Experimental Paradigm

Concerns about the ecological validity of constructed stimuli can be addressed by the use of naturalistic stimuli (e.g. stories, newspaper articles, persuasive pieces, etc.). Naturalistic experiments are therefore an important complement to constructed experiments in the study of cognitive processes (Hasson and Honey, 2012).

However, naturalistic experiments introduce their own challenges. Without the ability to factorially manipulate frequency and predictability, naturalistic studies must confront the natural collinearity between these two variables in ordinary language (Demberg and Keller, 2008). Furthermore, because naturalistic stimuli do not define a critical region of the stimulus, responses are generally modeled word-by-word (Demberg and Keller, 2008; Frank and Bod, 2011; Smith and Levy, 2013; van Schijndel and Schuler, 2015). It is standard psycholinguistic practice to do so through ablative likelihood ratio testing (LRT) of linear mixed effects regression (LMER) models (Bates et al., 2015) fitted to the dependent variable of interest (e.g. fixation duration) (Demberg and Keller, 2008; Frank and Bod, 2011; van Schijndel and Schuler, 2015; Shain et al., 2016). However, this approach has important disadvantages. First, naturalistic data constitute time series that may violate the independence assumptions of linear regression and therefore confound model interpretation and hypothesis testing (Baayen et al., 2017, 2018; Shain and Schuler, 2018). One major such confound is *temporal diffusion* (i.e. a lingering response to stimuli), which can be brought under statistical control through deconvolutional time series regression (DTSR) models that directly estimate temporal structure in the relationships between predictors and response (Shain and Schuler, 2018). Second, LRT implicitly evaluates on in-sample data, making it challenging to diagnose overfitting and to assess external validity (Vasishth et al., 2018). This can be addressed through out-of-sample non-parametric tests, such as the paired permutation test widely used in machine learning (Demšar, 2006).

3 Experimental Setup

This paper seeks to complement constructed stimulus experiments by searching for separable effects of frequency and predictability during naturalistic reading, using methods designed to ad-

	Effect estimate (log-ms)							
Corpus	SentPos	Trial	Rate	WordLen	SaccLen	PrevFix	Unigram	5-gram

UCL	-0.74

Table 2: Pearson's correlation between *5-gram surprisal* and *unigram log probability* by corpus.

dress the challenges of Section 2.2. The problem of temporal diffusion is addressed by using DTSR models rather than LMER (see Appendix A for implementation details). The problem of external validity is addressed by using held-out paired permutation testing rather than LRT, thus basing the hypothesis test directly on generalization error. The possibility that cloze probabilities are poor estimates of predictability for low-frequency words is addressed by operationalizing predictability as 5-gram surprisal generated by a large-vocabulary statistical language model. The natural collinearity of frequency and predictability is addressed through the use of large-scale data that should permit subtle differentiation of collinear effects. Taken together, the corpora examined in this study contain over one million fixations generated by 243 human subjects. Although there is a large-magnitude correlation between *unigram log probability* (frequency) and *5-gram surprisal* (predictability) in these corpora, as shown in Table 2, synthetic experiments show that DTSR can faithfully identify models from much smaller data than that used here, even when all predictors are correlated at the 0.75 level (Shain, 2018). Given the size of the data, failure to distinguish effects of frequency and predictability would raise doubts about the existence of such a separation in naturalistic reading.

3.1 Statistical Procedure

DTSR models are fitted separately to each of the Natural Stories (Futrell et al., 2018), Dundee (Kennedy et al., 2003), and UCL (Frank et al., 2013) corpora.[1] Following previous investigations of this question (Rayner et al., 2004; Ashby et al., 2005; Gollan et al., 2011, *inter alia*), frequency is estimated from corpus statistics — in this case, KenLM (Heafield et al., 2013) unigram models trained on the Gigaword 3 corpus (Graff and Cieri, 2003). Unlike previous studies using close estimates of predictability (Rayner et al., 2004; Ashby et al., 2005; Gollan et al., 2011, *inter alia*), predictability is statistically estimated, again using KenLM models (5-gram) trained on Gigaword 3. This is both because (1) cloze norming all words contained in thousands of naturalistic sentences is prohibitive and (2) statistical language models trained on large data can more reliably differentiate low probability continuations (Smith and Levy, 2013). Following recent work on prediction effects in naturalistic sentence comprehension (Demberg and Keller, 2008; Frank and Bod, 2011; Smith and Levy, 2013), predictability estimates are encoded as *surprisal* by negating the 5-gram log probabilities.

The models assume ShiftedGamma impulse response functions (Shain and Schuler, 2018, see Appendix A) for each of these variables, as well as for the nuisance variables *word length*, *saccade length* and an indicator variable for whether the previous word was fixated.[2] To capture trends in the response at different timescales, the mod-

---

[1] Natural Stories is a self-paced reading corpus containing 848,768 word fixations from 181 subjects reading narrative and informational texts. Dundee is an eye-tracking corpus containing 260,065 word fixations from 10 subjects reading newspaper editorials. UCL is an eye-tracking corpus containing 53,070 fixations from 42 subjects reading sentences taken from novels by amateur authors.

Although the sentences in UCL were randomized and presented in isolation — and therefore subject to some of the concerns about constructed stimuli raised in Section 2 — they are included here because the stimuli are naturally occurring rather than constructed for a particular experimental purpose. The UCL results replicate the overall pattern of significance (Table 3), and excluding them has no impact on the overall results.

[2] The variables *saccade length* and *previous was fixated* are only used for eye-tracking since they are not relevant to self-paced reading.

		Corpus

Table 3: Held-out paired permutation testing results, both pooled (left) and by corpus (right).

els also include linear effects for the word's index in the sentence (*sentence position*) and document (*trial*). Following Shain and Schuler (2018), in addition to the intercept, the models contain a convolved intercept (*rate*) designed to capture effects of stimulus timing. The response used in all corpora is log fixation duration (go-past for eye-tracking).[3] Outlier filtering is performed in each corpus following the procedures described in Shain and Schuler (2018).

Approximately half the data in each corpus is used for training, with the remaining half reserved for held-out evaluation. Models include by-subject random intercepts as well as by-subject random slopes and impulse response parameters for each predictor.[4] Held-out hypothesis testing uses a "diamond" ablative structure first ablating fixed effects for *5-gram surprisal* and *unigram log probability* individually and then ablating both. All random effects are retained in all models. Comparisons use paired permutation tests of the by-item losses on the evaluation set, pooling across all corpora.[5] Note that the non-parametric permutation test permits this pooling procedure to unify the models from all three corpora into a single test, since (unlike LRT) permutation testing supports out-of-sample comparison. Data processing was performed using the ModelBlocks toolchain (van Schijndel and Schuler, 2013), available at `https://github.com/modelblocks/modelblocks-release`. Model fitting was performed using the DTSR software library (Shain and Schuler, 2018), available at `https://github.com/coryshain/dtsr`. See the citations above for data access instructions.

4 Results

Effect estimates[6] from the full models are presented in Table 1 and pooled statistical comparisons are presented in the *Pooled* column of Table 3. If predictability and frequency effects are additive, all four comparisons in Table 3 should be significant. As shown, this is not the case. There is evidence that both frequency (*unigram log probability*) and predictability (*5-gram surprisal*) in isolation reliably index processing difficulty, as shown by the significance of both effects over the baseline. However, when the effects are compared to each other, predictability explains significantly more variance than frequency but not vice versa.

This general pattern of results further obtains for each corpus individually, as shown by the *Corpus* column breakdown in Table 3. One minor exception is that neither predictability nor frequency improves significantly over the other in Dundee.[7] The Dundee results are nevertheless consistent with an interpretation in which frequency and predictability do not index distinct processing phenomena and inconsistent with an interpretation in which they do. These results thus provide no evidence of separable frequency and predictability effects, whether the corpora are considered together or individually.

5 Discussion

As described in Section 4, results show no evidence of separable effects of frequency and predictability in naturalistic reading. One possible explanation for this outcome is that 5-gram surprisal tracks human prediction effort better than cloze probabilities, in part because cloze probabilities are less reliable for infrequent words. Although countervailing evidence exists in the literature (e.g. Smith and Levy, 2011 found effects of cloze but not *n*-gram probabilities in human read-

---

[3] The overall pattern of significance does not change when first-pass durations are used.

[4] By-word random intercepts are not included because of their potential to subsume frequency effects.

[5] To correct for different error variances, errors are rescaled by the joint standard deviation of the errors from the full and ablated models by corpus.

[6] The estimated impulse response functions that underlie these effect sizes are plotted in Appendix B.

[7] The *p*-value of 0.0105 observed for frequency over predictability does not achieve significance at the 0.05 level under 6-way Bonferroni correction (2 variables × 3 corpora).

ing times), in general this evidence is based on weak statistical competitors to cloze (e.g. Smith and Levy, 2011 used tri-grams). By contrast, recent trends in cognitive modeling point toward a correlation between the linguistic and psycholinguistic performance of language models, such that more powerful models with lower perplexity also tend to correlate more strongly with measures of cognitive effort (Goodkind and Bicknell, 2018; van Schijndel and Linzen, 2018). This suggests that apparent frequency effects may arise in part from poor estimates of predictability. Note that by using 5-gram surprisal rather than more powerful neural language models (Jozefowicz et al., 2016), the analysis described in this paper is conservative in its attribution of variance to predictability. The failure of frequency is thus all the more compelling, since replacing 5-gram surprisal with surprisals obtained from more powerful language models would be unlikely to increase the explanatory power of frequency.

Another potential explanation for the lack of separable effects of frequency and predictability is the use of naturalistic rather than constructed stimuli. Neuroscientific evidence shows that domain-general executive control regions activate during the processing of some artificially constructed language stimuli (Kaan and Swaab, 2002; Kuperberg et al., 2003; Novick et al., 2005; January et al., 2009) but fail to activate during the processing of naturalistic stimuli (Blank and Fedorenko, 2017). Such results have led some to argue that artificially constructed experimental stimuli may increase general cognitive load by coercing comprehension into problem solving, thereby engaging mechanisms that play little role in everyday sentence processing (Campbell and Tyler, 2018, Wehbe et al., in prep; Diashek et al., in prep). It is possible that the language comprehension mechanisms that implement linguistic prediction (Shain et al., under review) are relatively less engaged while domain general executive control mechanisms are relatively more engaged during the processing of constructed stimuli presented without context, perhaps suppressing the influence of preceding words on participants' reading behavior. Further investigation is needed in order to explore this hypothesis.

In any case, it is a statistical truism that negative results do not motivate acceptance of the null hypothesis. Thus, it is possible that frequency effects exist in naturalistic reading but are too small to be detected here. Nevertheless, the failure to find frequency effects in large naturalistic data indicates that any such effects are greatly attenuated in the processing of naturalistic texts in comparison to the processing of constructed stimuli, which circumscribes the importance that any such effects might have in driving comprehension effort during typical reading.

6 Conclusion

This paper explored whether effects of word frequency and predictability are distinguishable in naturalistic sentence processing. Despite the size of the combined dataset, results showed no evidence of separable effects in naturalistic reading, contrary to previous findings of separable effects in studies using constructed stimuli. This investigation thus shows no evidence of a distinct, context-independent lexical retrieval mechanism modulated by strength of memory representation (Seidenberg and McClelland, 1989; Coltheart et al., 2001; Harm and Seidenberg, 2004), and instead favors a view in which sentence processing effort is driven by a mechanism that incrementally reallocates resources between competing interpretations, subsuming any effects of raw lexical frequency (Norris, 2006; Levy, 2008; Rasmussen and Schuler, 2018). The discrepancy between constructed and naturalistic experimental settings presents a puzzle for our understanding of the mental processes that underlie human language comprehension, and is perhaps linked to recent evidence that artificially constructed linguistic stimuli can spuriously engage non-linguistic executive mechanisms by increasing general cognitive load as compared to naturalistic settings (Blank and Fedorenko, 2017; Campbell and Tyler, 2018). Further investigation into the precise sources of the discrepancy may shed new light on the interplay between prediction and memory in human sentence processing.

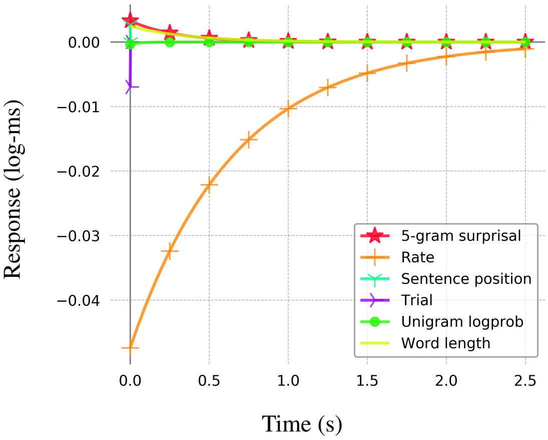

Figure 1: Natural Stories IRFs

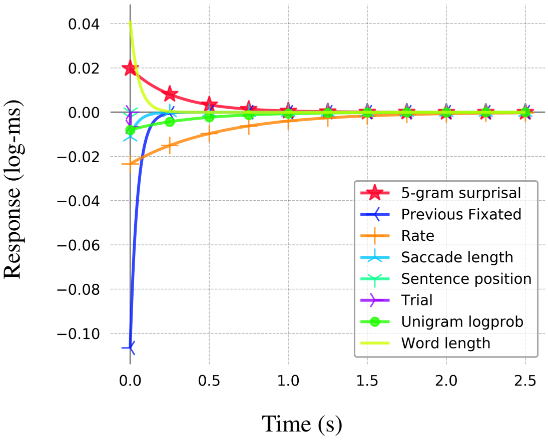

Figure 2: Dundee IRFs

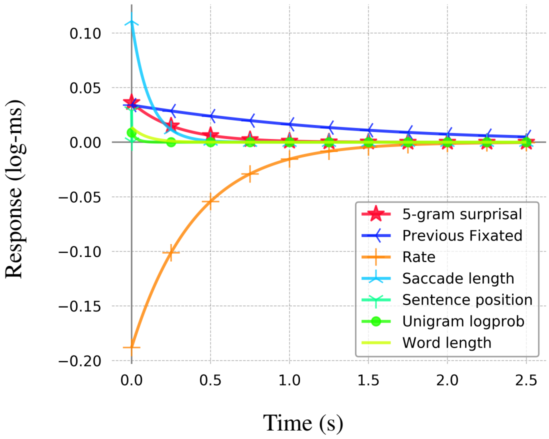

Figure 3: UCL IRFs

A DTSR Implementation

The deconvolutional time series regression (DTSR) models used in this paper were fitted using the code repository released by Shain and Schuler (2018), available at: `https://github.com/coryshain/dtsr`. Models used variational inference to fit the means and variances of independent normal posterior distributions over all model parameters assuming an improper uniform prior. Convolved predictors used the three-parameter ShiftedGamma impulse response function (IRF) kernel:

$$f(x; \alpha, \beta, \delta) = \frac{\beta^{\alpha}(x-\delta)^{\alpha-1}e^{-\beta(x-\delta)}}{\Gamma(\alpha)} \tag{1}$$

Posterior means for the IRF parameters were initialized at $\alpha = 2$, $\beta = 5$, and $\delta = -0.2$, which defines a decreasing IRF with peak centered at $t = 0$ that decays to near-zero within about 1s. Models were fitted using the Adam optimizer (Kingma and Ba, 2014) with Nesterov momentum (Nesterov, 1983; Dozat, 2016), a constant learning rate of 0.01, and minibatches of size 1024. For computational efficiency, histories were truncated at 128 timesteps. Prediction from the network used an exponential moving average of parameter iterates with a decay rate of 0.999, and models were evaluated using *maximum a posteriori* estimates obtained by setting all parameters to their posterior means.[8] Convergence was visually diagnosed.

---

[8] Since all parameters have independent normal distributions in the variational posterior, the law of large numbers guarantees that samples from the posterior converge in probability to the posterior mean.

B Impulse response shapes

For reference, estimated impulse response shapes by corpus are plotted in Figures 1–3. Plotted curves describe the estimated change in the response t seconds after having observed a unit impulse of each predictor. For example, in the Dundee estimates, observing a word with one standard deviation of *5-gram surprisal* (red curve) is expected to increase reading time by about 0.04 log-ms instantaneously, and by about 0.01 log-ms at a subsequent word observed 0.5s later. Positive IRFs (curves above 0) mean that predictors are estimated to increase reading time (and, by assumption, comprehension difficulty), and negative IRFs (curves below 0) mean that predictors are estimated to decrease reading time. For more detailed psycholinguistic interpretation of IRF estimates like these, see Shain and Schuler (2018).

Augmenting word2vec with Latent Dirichlet Allocation within a Clinical Application

Abstract

This paper presents three hybrid models that directly combine latent Dirichlet allocation and word embedding for distinguishing between speakers with and without Alzheimer's disease from transcripts of picture descriptions. Two of our models get F-scores over the current state-of-the-art using automatic methods on the DementiaBank dataset.

1 Introduction

Word embedding projects words into a lower-dimensional latent space that captures semantic and morphological information. Separately but related, the task of topic modelling also discovers latent semantic structures or *topics* in a corpus. Latent Dirichlet allocation (LDA) uses bag-of-words statistics to infer topics in an unsupervised manner. LDA considers each document to be a probability distribution over hidden topics, and each topic is a probability distribution over all words in the vocabulary, both with Dirichlet priors.

The inferred probabilities over learned latent topics of a given document (i.e., *topic vectors*) can be used along with a discriminative classifier, as in the work by Luo and Li (2014), but other approaches such as TF-IDF (Lan et al., 2005) easily outperform this model, like in the case of the *Reuters-21578* corpus (Lewis et al., 1987). Here, we hypothesize that creating a hybrid of LDA and word2vec (Mikolov et al., 2013b) models will produce discriminative features. We introduce three new variants of hybrid LDA-word2vec models, and investigate the effect of dropping the first component after principal component analysis (PCA). These models can be thought of as extending the conglomeration of topical embedding models. We incorporate topical information into our word2vec models by using the final state of the topic-word distribution in the LDA model during training.

1.1 Motivation and Related Work

Alzheimer's disease (AD) is a neurodegenerative disease that affects approximately 5.5 million Americans with annual costs of care up to $259B in the US, in 2017, alone (Alzheimer's Association et al., 2017). The existing state-of-the-art methods for detecting AD from speech used extensive feature engineering, some of which involved experienced clinicians. Fraser et al. (2016) investigated multiple linguistic and acoustic characteristics and obtained accuracies up to 81% with aggressive feature selection. Yancheva and Rudzicz (2016) use vector-space topic models, and achieved F-scores up to 74%. It is generally expensive to get sufficient labeled data for arbitrary pathological conditions.

In our experiments, we train our hybrid models on a normative dataset and apply them for classification on a clinical dataset. The goal of this project is to i) effectively augment word2vec with LDA for classification, and ii) to improve the accuracy of dementia detection using automatic methods.

2 Datasets

The **Wisconsin Longitudinal Study** (WLS) is a normative dataset where residents of Wisconsin perform the Cookie Theft picture description task (Goodglass and Barresi, 2000). The audio excerpts from the 2011 survey *(N = 1,366)* were converted to text using the Kaldi open source automatic speech recognition (ASR) engine (Povey et al., 2011), specifically using a bi-directional LSTM trained to the Fisher data set (Cieri et al., 2004).

DementiaBank (DB) is part of the TalkBank project (MacWhinney et al., 2011). Each participant was assigned to either the 'Dementia' group ($N = 167$) or the 'Control' group ($N = 97$). We use 240 samples from those in the 'Dementia'

	Fold 1	Fold 2	Fold 3	Fold 4	Fold 5	Total
CT	55	56	40	40	50	241
AD	56	54	70	70	60	310

Table 1: DB test-data distribution

group, and 233 from those in the ‘Control’ group. Each speech sample was recorded and manually transcribed at the word level following the CHAT protocol (MacWhinney, 1992). We use a 5−fold group cross-validation (CV) to split this dataset while ensuring that a particular participant does not occur in both the train and test splits. Table 1 presents the distribution of Control and Dementia groups in the test split for each fold.

WLS is used to train our LDA, word2vec and hybrid models that are then used to generate feature vectors on the DB dataset. The feature vectors on the train set are used to train a discriminative classifier (e.g., SVM), that is then used to do the AD/CT binary classification on the feature vectors of the test set. During training we filter out spaCy’s (Honnibal and Montani, 2017) list of stop words from our datasets. For our LDA models trained on ASR transcripts, we remove the *[UNK]* and *[NOISE]* tokens generated by Kaldi, as well as the *um* and *uh* tokens, as this improved downstream model performance.

3 Methods

3.1 Baselines

Once an **LDA** model is trained, it can be used to infer the topic distribution on a given document. We set the number of topics empirically to *K=5* and *K=25*.

We use a pre-trained **word2vec** model trained on the Google News Dataset (Mikolov et al., 2013a). We also train our own word vectors with 300 dimensions and window size of 2 to be consistent with the pre-trained variant. We represent a document by averaging the word embeddings for all the words in that document.

Third, **TF-IDF** is a common numerical statistic in information retrieval that measures the number of times a word occurs in a document, and through the entire corpus. We use a TF-IDF vector representation for each transcript for the top *1,000* words after preprocessing, learned on the train set.

Finally, since the goal of this paper is to create a hybrid of LDA and word2vec models, one of the simpler hybrid models – i.e., **concatenating** LDA probabilities with average word2vec representations – is the fourth baseline model.

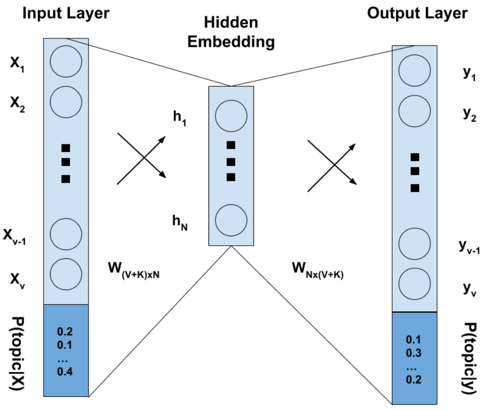

Figure 1: Neural representation of topical word2vec

3.2 Topic Vectors

We represent a topic vector as the *weighted* combination of the word2vec vectors of the words in the vocabulary. This represents every inferred *topic* as a real-valued vector, with the same dimensions as the word embedding. A topic vector for a given topic is defined as:

$$topic\_vector_D = \frac{\sum_{i=1}^{V} p_i W_i}{V} \tag{1}$$

where V is the vocabulary size of our corpus, p_i is the probability that a given word appears in the topic, from LDA, and W_i is the word2vec embedding of that word.

A document vector is given by:

$$avg\_topic\_vector_D = \frac{\sum_{i=1}^{K} p_i T_i}{K} \tag{2}$$

where T_i is the topic vector defined in Equation 1, K is the number of topics of the LDA model, and p_i is the inferred probability that a given document contains topic i.

3.3 Topical Embedding

To generate topical embeddings, we use the $P(word\,|\,topic)$ from LDA training as the ground truth of how words and topics are related to each other. We normalize that distribution, so that $\sum_{topics} P(topic\,|\,word) = 1$. This gives a topical representation for every word in the vocabulary.

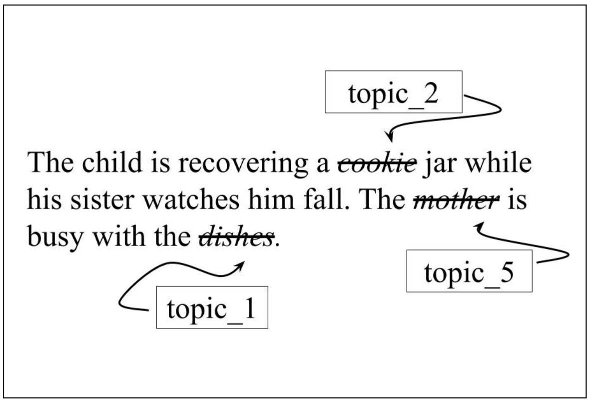

Figure 2: Example topic induction in the WLS corpus.

We concatenate this representation to the one-hot encoding of a given word to train a skip-gram word2vec model. Figure 1 shows a single pass of the word2vec training with this added information. There, X and Y are the concatenated representations of the input-output words determined by a context window, and h is an N-dimensional hidden layer. All the words and the topics are mapped to an N-dimensional embedding during inference. Our algorithm also skips the softmax layer at the output of a standard word2vec model, as our vectors are now a combination of one-hot encoding and dense probability matrices.

To get document representations, we use the average these modified word2vec embeddings. We also propose a new way of representing documents as seen in Figure 3 where we concatenate the average word2vec with the word2vec representation of the most prevalent topic in the document following LDA inference.

3.4 Topic-induced word2vec

Our final model involves inducing topics into the corpus itself. We represent every topic with the string *topic_i* where i is its topic number; e.g., topic 1 is *topic_1*, and topic 25 is *topic_25*. We also create a *sunk* topic character (analogous to *UNK* in vocabulary space) and set it to *topic_(K+1)*, where K is the number of topics in the LDA model.

We normalize $P(word\,|\,topic)$ to get $P(topic\,|\,word)$ (Section 3.3). With a probability of 0.5, set empirically, we replace a given word with the topic string for $\max(P(topic\,|\,word))$, provided the max value is ≥ 0.2. If this max value is < 0.2, the word is replaced with the sunk topic for that model.

Figure 2 shows an example of topic induction on a snapshot of an ASR transcript of WLS. This process is repeated $N = 10$ times and this augmented corpus is now run through a standard skip-gram word2vec model with dimensions set to 400 to accommodate the bigger corpus. The intuition behind this approach is that it allows words to learn how they occur around *topics* in a corpus and vice versa. Document representations follow the same format as in Section 3.3 and in Figure 3.

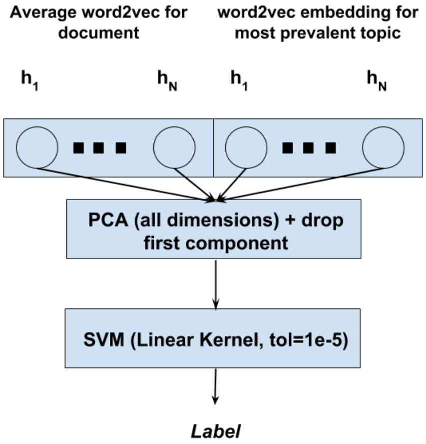

Figure 3: Setup for classification using hybrid models. The PCA step exists for models applying work described in Section 3.4.1.

3.4.1 PCA Update

Inspired by the work of Arora et al. (2016), we transform the features of our models with PCA, drop the first component, and input the result to the classifier, as it improves accuracy empirically.

Apart from the ablation study, all experiments use an SVM classifier with a linear kernel and tolerance set to 10^{-5}.

4 Results

4.1 DB Classification

We report the average of the F1 micro and F1 macro scores for the 5-folds for all baseline and proposed models. These results are presented in two parts in Tables 2 and 3.

The TF-IDF model sets a very strong baseline with an accuracy of 74.95%, which is already better than the automatic models of Yancheva and Rudzicz (2016) on the same data.

The 25-topic topical embedding model outperforms the TF-IDF baseline and gives accuracies of 75.32% when using the average word2vec approach. All topic-induced models beat the topical

F1 macro	74.97%	75.01%	73.32%	70.70%	74.98%	75.36%	**77.19%**	76.09%	**76.86%**	72.27%	**76.48%**	75%

Table 3: DB Classification results (Average 5-Fold F-scores): Part 2

embedding model, with the 25-topics variant giving an average accuracy of 77.5%.

To check if accuracies are statistically significant, we calculate our test statistic (Z) as follows:

$$Z = \frac{p_1 - p_2}{\sqrt{2\bar{p}(1-\bar{p})/n}} \tag{3}$$

where (p_1, p_2) are the proportions of samples correctly classified by the two classifiers respectively, n is the number of samples (which in our case is 551) and $\bar{p} = \frac{p_1+p_2}{2}$.

Augmenting word2vec models with topic information significantly improves accuracy in the topic-induced word2vec model ($p = 0.0227$) when compared to the vanilla-trained word2vec model. This change is not significant in the topical embedding model ($p = 0.152$).

4.2 Evaluation of Different Classifiers

Using the the 25-topic topic-induced word2vec, we consider other discriminative classifiers. As seen in Table 4, the linear SVM model gives the best accuracy of 77.5%, though all other models perform similarly, with accuracies upwards of 70%. There is no statistically significant difference between using an SVM vs. a LR ($p = 0.569$) or a gradient boosting classifier ($p = 0.094$).

Discriminative Classifier	**F1 micro**	**F1 macro**
SVM w/ linear kernel	**77.50%**	**77.19%**
Logistic Regression (LR)	76.05%	75.51%
Random Forest	71.13%	69.97%
Gradient Boosting Classifier	73.14%	72.39%

Table 4: DB: Discriminative Classifiers on Topic-induced LDA-25 model

5 Discussions

Although the topic distributions of the LDA models were not distinctive enough in themselves, they capture subtle differences between the AD and CT patients *missed* by the vanilla word2vec models. Simple concatenation of this distribution to the document increases the accuracy by 2.72% ($p = 0.31$).

Topic vectors on their own do not provide much generative potential for this clinical data set, as representing a document as a single point in space, after going through two layers of contraction, removes information relevant to classification.

Our novel topic-induced model performs the best among our proposed models, with an accuracy of 77.5% on a 5-fold split of the DB dataset. To put this in perspective, Yancheva and Rudzicz (2016)'s automatic vector-space topic models achieved 74% on the same data set, albeit with a slightly different setup. Applying PCA to the features does not have a significant trend.

6 Limitations and Future Work

Both of our proposed topic-induced and topical embedding models could benefit from using corpus-level word probability priors during normalization, and we intend on experimenting with those in the future. Work needs to be done to directly compare the performance of our models to the topical models proposed by (Liu et al., 2015), given that both kinds of models fall in the same universe. Finally, while we get promising results on a clinical application, the generalizability of these methods needs to be studied on other text classification tasks.

7 Conclusions

In this paper, we show the utility of augmenting word2vec with LDA-induced topics. We present three models, two of which outperform vanilla word2vec and LDA models for a clinical binary text classification task. Going forward, we will test this model on other tasks, diagnostic and otherwise, to see its generalizability. This can provide a starting point for clinical classification problems where labeled data may be scarce.

Abstract

While idiosyncrasies of the Chinese classifier system have been a richly studied topic among linguists (Adams and Conklin, 1973; Erbaugh, 1986; Lakoff, 1986), not much work has been done to quantify them with statistical methods. In this paper, we introduce an information-theoretic approach to measuring idiosyncrasy; we examine how much the uncertainty in Mandarin Chinese classifiers can be reduced by knowing semantic information about the nouns that the classifiers modify. Using the empirical distribution of classifiers from the parsed Chinese Gigaword corpus (Graff et al., 2005), we compute the mutual information (in bits) between the distribution over classifiers and distributions over other linguistic quantities. We investigate whether semantic classes of nouns and adjectives differ in how much they reduce uncertainty in classifier choice, and find that it is not fully idiosyncratic; while there are no obvious trends for the majority of semantic classes, shape nouns reduce uncertainty in classifier choice the most.

1 Introduction

Many of the world's languages make use of **numeral classifiers** (Aikhenvald, 2000). While theoretical debate still rages on the function of numeral classifiers (Krifka, 1995; Ahrens and Huang, 1996; Cheng et al., 1998; Chierchia, 1998; Li, 2000; Nisbett, 2004; Bale and Coon, 2014), it is generally accepted that they need to be present for nouns to be modified by numerals, quantifiers, demonstratives, or other qualifiers (Li and Thompson, 1981, 104). In Mandarin Chinese, for instance, the phrase *one person* translates as 一个人 (*yī gè rén*); the classifier 个 (*gè*) has no clear translation in English, yet, nevertheless, it is necessary to place it between the numeral 一 (*yī*) and the word for person 人 (*rén*).

There are hundreds of numeral classifiers in the Mandarin lexicon (Po-Ching and Rimmington, 2015, Table 1 gives some canonical examples), and classifier choices are often argued to be based on inherent, possibly universal, semantic properties associated with the noun, such as shape (Kuo and Sera, 2009; Zhang and Jiang, 2016). Indeed, in a summary article, Tai (1994) writes: "Chinese classifier systems are cognitively based, rather than arbitrary systems of classification." If classifier choice were solely based on conceptual features of a given noun, then we might expect it to be nearly determinate—like gender-marking on nouns in German, Slavic, or Romance languages (Erbaugh, 1986, 400)—and perhaps even fixed for all of a given noun's synonyms.

Classifier	**Pīnyīn**	**Semantic Class**
个	*gè*	objects, general-purpose
件	*jiàn*	matters
头	*tóu*	domesticated animals
只	*zhī*	general animals
张	*zhāng*	flat objects
条	*tiáo*	long, narrow objects
项	*xiàng*	items, projects
道	*dào*	orders, roads, projections
匹	*pǐ*	horses, cloth
顿	*dùn*	meals

Table 1: Examples of Mandarin classifiers. Classifiers' simplified Mandarin Chinese characters (1st column), *pīnyīn* pronunciations (2nd column), and commonly modified noun types (3rd column) are listed.

However, selecting which classifers go with nouns in practice is an idiosyncratic process, often with several grammatical options (see Table 2 for two examples). Moreover, knowing what a noun means doesn't always mean you can guess the classifier. For example, most nouns referring to animals, such as 驴 (*lǘ*, *donkey*) or 羊 (*yáng*, *goat*), use the classifier 只 (*zhī*). However, horses

Classifier	$p(C \mid N = \text{人士})$	$p(C \mid N = \text{工程})$
位 (*wèi*)	**0.4838**	0.0058
名 (*míng*)	**0.3586**	0.0088
个 (*gè*)	0.0205	0.0486
批 (*pī*)	0.0128	0.0060
项 (*xiàng*)	0.0063	**0.4077**
期 (*qī*)	0.0002	**0.2570**
Everything else	0.1178	0.2661

Table 2: Empirical distribution of selected classifiers over two nouns: 人士 (*rén shì, people*) and 工程 (*gōng chéng, project*). Most of the probability mass is allocated to only a few classifiers for both nouns (bolded).

cannot use 只 (*zhī*), despite being semantically similar to goats and donkeys, and instead must appear with 匹 (*pǐ*). Conversely, knowing which particular subset of noun meaning is reflected in the classifer also doesn't mean that you can use that classifier with any noun that seems to have the right semantics. For example, classifier 条 (*tiáo*) can be used with nouns referring to long and narrow objects, like rivers, snakes, fish, pants, and certain breeds of dogs—but never cats, regardless of how long and narrow they might be! In general, classifiers carve up the semantic space in a very idiosyncratic manner that is neither fully arbitrary, nor fully predictable from semantic features.

Given this, we can ask: precisely *how* idiosyncratic is the Mandarin Chinese classifier system? For a given noun, how predictable is the set of classifiers that can be grammatically employed? For instance, had we not known that the Mandarin word for horse 马 (*mǎ*) predominantly takes the classifier 匹 (*pǐ*), how likely would we have been to guess it over the much more common animal classifier 只 (*zhī*)? Is it more important to know that a noun is 马 (*mǎ*) or simply that the noun is an animal noun? We address these questions by computing how much the uncertainty in the distribution over classifiers can be reduced by knowing information about nouns and noun semantics. We quantify this notion of classifier idiosyncrasy by calculating the mutual information between classifiers and nouns, and also between classifiers and several sets that are relevant to noun meaning (i.e., categories of noun senses, sets of noun synonyms, adjectives, and categories of adjective senses). Our results yield concrete, quantitative measures of idiosyncrasy in bits, that can supplement existing hand-annotated, intuition-based approaches that organize Mandarin classifiers into an ontology.

Why investigate the idiosyncrasy of the Mandarin Chinese classifier system? How idiosyncratic or predictable natural language is has captivated researchers since Shannon (1951) originally proposed the question in the context of printed English text. Indeed, looking at predictability directly relates to the complexity of language—a fundamental question in linguistics (Newmeyer and Preston, 2014; Dingemanse et al., 2015)—which has also been claimed to have consequences learnability and processing. For example, how hard it is for a learner to master irregularity, say, in the English past tense (Rumelhart and McClelland, 1987; Pinker and Prince, 1994; Pinker and Ullman, 2002; Kirov and Cotterell, 2018) might be affected by predictability, and highly predictable noun-adjacent words, such as gender affixes in German and prenominal adjectives in English, are also shown to confer online processing advantages (Dye et al., 2016, 2017, 2018). Within the Chinese classifier system itself, the very common, general-purpose classifier 个 (*gè*) is acquired by children earlier than rarer, more semantically rich ones (Hu, 1993). General classifiers are also found to occur more often in corpora with nouns that are less predictable in context (i.e., nouns with high *surprisal*; Hale 2001) (Zhan and Levy, 2018), providing initial evidence that predictability likely plays a role in classifier-noun pairing more generally. Furthermore, providing classifiers improves participants' recall of nouns in laboratory experiments (Zhang and Schmitt, 1998; Gao and Malt, 2009) (but see Huang and Chen 2014)—but, it isn't known whether classifiers do so by modulating noun predictability.

2 Quantifying Classifier Idiosyncrasy

We take an information-theoretic approach to statistically quantify the idiosyncrasy of the Mandarin Chinese classifier system, and measure the uncertainty (entropy) reduction—or **mutual information** (MI) (Cover and Thomas, 2012)—between classifiers and other linguistic quantities, like nouns or adjectives. Intuitively, MI lets us directly measure classifier "idiosyncrasy", because it tells us how much information (in bits) about a classifier we can get by observing another linguistic quantity. If classifiers were completely independent from other quantities, knowing them would give us no information about classifier choice.

Notation. Let C be a classifier-valued random variable with range $\mathcal{C}$, the set of Mandarin Chinese classifiers. Let X be a second random variable, which models a second linguistic quantity, with range $\mathcal{X}$. Mutual information (MI) is defined as

$$I(C;X) \equiv H(C) - H(C \mid X) \tag{1a}$$

$$= \sum_{c \in \mathcal{C}, x \in \mathcal{X}} p(c,x) \log \frac{p(c,x)}{p(c)p(x)} \tag{1b}$$

Let $\mathcal{N}$ and $\mathcal{A}$ denote the sets of nouns and adjectives, respectively, with N and A be noun- and adjective-valued random variables, respectively. Let $\mathcal{N}_i$ and $\mathcal{A}_i$ denote the sets of nouns and adjectives in i^{th} *SemCor supersense category* for nouns (Tsvetkov et al., 2015) and adjectives (Tsvetkov et al., 2014), respectively, with their random variables being N_i and A_i, respectively. Let $\mathcal{S}$ be the set of all English WordNet (Miller, 1998) senses of nouns, with S be the WordNet sense-valued random variable. Given the formula above and any choice for $X \in \{N, A, N_i, A_i, S\}$, we can calculate the mutual information between classifiers and other relevant linguistic quantities.

2.1 MI between Classifiers and Nouns

Mutual information between classifiers and nouns ($I(C;N)$) shows how much uncertainty (i.e., entropy) in classifiers can be reduced once we know the noun, and vice versa. Because only a few classifiers are suitable to modify a given noun (again, see Table 2) and the entropy of classifiers for a given noun is predicted to be close to zero, MI between classifiers and nouns is expected to be high.

2.2 MI Between Classifiers and Adjectives

The distribution over adjectives that modify a noun in a large corpus give us a language-internal peek into a word's lexical semantics. Moreover, adjectives have been found to increase the predictability of nouns (Dye et al., 2018), so we ask whether they might affect classifier predictability too. We compute MI between classifiers and adjectives ($I(C;A)$) that modify the same nouns to investigate their relationship. If both adjectives and classifiers track comparable portions of the noun's semantics, we expect $I(C;A)$ to be significantly greater than zero, which implies mutual dependence between classifier C and adjective A.

2.3 MI between Classifiers and Noun Supersenses

To uncover which nouns are able to reduce the uncertainty in classifiers more, we divide them into 26 *SemCor supersense categories* (Tsvetkov et al., 2015), and then compute $I(C;N_i)$ ($i \in \{1, 2, ..., 26\}$) for each supersense category. The supersense categories (e.g., *animal, plant, person, artifact*, etc.) provide a semantic classification system for English nouns. Since there are no known supersense categories for Mandarin, we need to translate Chinese nouns into English to perform our analysis. We use *SemCor supersense categories* instead of WordNet hypernyms because different "basic levels" for each noun make it difficult to determine the "correct" category for each noun.

2.4 MI between Classifiers and Adjective Supersenses

We translated and divided the adjectives into 12 *supersense categories* (Tsvetkov et al., 2014), and compute mutual information $I(C;A_i)$ ($i \in \{1, 2, ..., 12\}$) for each category separately to determine which categories have more mutual dependence on classifiers. Adjective supersenses are defined as categories describing certain properties of nouns. For example, adjectives in MIND category describe intelligence and awareness, while those in the PERCEPTION category focus on, e.g., color, brightness, and taste. Examining the distribution over adjectives is a language-specific measure of *noun* meaning, albeit an imperfect one, because only certain adjectives modify any given noun.

2.5 MI between Classifiers and Noun Synsets

We also compute the mutual information $I(C;S)$ between classifiers and nouns' WordNet (Miller, 1998) synonym sets (**synsets**), assuming that each synset is independent. For nouns with multiple synsets, we assume that all synsets are equally probable for simplicity. If classifiers are fully semantically determined, then knowing a noun's synsets should enable one to know the appropriate classifier(s), resulting in high MI. If classifiers are largely idiosyncratic, then noun synsets should have lower MI with classifiers. We do not use WordNet to attempt to capture word polysemy here.

3 Data and Experiments

Data Provenance. We apply an existing neural Mandarin word segmenter (Cai et al., 2017) to the Chinese Gigaword corpus (Graff et al., 2005), and then feed the segmented corpus to a neural dependency parser, using Google's pretrained Parsey Uni-

$H(C)$	$H(C \mid N)$	$I(C;N)$	$H(C \mid S)$	$I(C;S)$	$H(C \mid A)$	$I(C;A)$
5.61	0.66	4.95	4.14	1.47	3.53	2.08

Table 3: Mutual information between classifiers and nouns $I(C;N)$, noun senses $I(C;S)$, and adjectives $I(C;A)$, is compared to their entropies.

versal model on Mandarin.[1] The model is trained on Universal Dependencies datasets v1.3.[2] We extract classifier-noun pairs and adjective-classifier-noun triples from sentences, where the adjective and the classifier modify the same noun—this is easily determined from the parse. We also record the tuple counts, and use them to compute an empirical distribution over classifiers that modify nouns, and noun-adjective pairs, respectively.

Data Preprocessing. Since no annotated supersense list exists for Mandarin, we first use CC-CEDICT[3] as a Mandarin Chinese-to-English dictionary to translate nouns and adjectives into English. Acknowledging that translating might introduce noise, we subsequently categorize our words into different senses using the SemCor supersense data for nouns (Miller et al., 1993; Tsvetkov et al., 2015), and adjectives (Tsvetkov et al., 2014). After that, we calculate the mutual information under each noun, and adjective supersense.

Modeling Assumptions. As this contribution is the first to investigate classifier predictability, we make several simplifying assumptions. Extracting distributions over classifiers from a large corpus, as we do, *ignores* sentential context, which means we ignore the fact that some nouns (i.e., relational nouns, like *māmā*, *Mom*) are more likely to be found in verb frames or other constructions where classifiers are not needed. We also ignore singular-plural, which might affect classifier choice, and the mass-count distinction (Cheng et al., 1998; Bale and Coon, 2014), to the extent that it is not encoded in noun superset categories (e.g., *substance* includes mass nouns).

We also assume that every classifier-noun or classifier-adjective pairing we extract is equally acceptable to native speakers. However, it's possible that native speakers differ in either their knowledge of classifier-noun distributions or confidence in particular combinations. Whether and how such human knowledge interacts with our calculations would be an interesting future avenue.

4 Results and Analysis

4.1 MI between Classifiers and Nouns, Noun Synsets, and Adjectives

Table 3 shows MI between classifiers and other linguistic quantities. As we can see, $I(C;N) > I(C;A) > I(C;S)$. As expected, knowing the noun greatly reduces classifier uncertainty; the noun and classifier have high MI (4.95 bits). Classifier MI with noun synsets (1.47 bits) is not comparable to with nouns (4.95 bits), suggesting that knowing a synset does not greatly reduce classifier uncertainty, leaving $>{}^{3}\!/_{5}$ of the entropy unaccounted for. We also see that adjectives (2.08 bits) reduce the uncertainty in classifiers more than noun synsets (1.47 bits), but less than nouns (4.95 bits).

4.2 MI between Classifiers and Noun Supersenses

Noun supersense results are in Figure 1. Natural categories are helpful, but are far from completely predictive of the classifier distribution: knowing that a noun is a *plant* helps, but cannot account for about ${}^{1}\!/_{3}$ of the original entropy for the distribution over classifiers, and knowing that a noun is a *location* leaves $>{}^{1}\!/_{2}$ unexplained. The three supersenses with highest $I(C;N)$ are *body*, *artifact*, and *shape*. Of particular interest is the *shape* category. Knowing that a noun refers to a shape (e.g., 角度; *jiǎo dù*, *angle*), makes the choice of classifier relatively predictable. This result sheds new light on psychological findings that Mandarin speakers are more likely to classify words as similar based on shape than English speakers (Kuo and Sera, 2009), by uncovering a possible role for information structure in shape-based choice. It also accords with Chien et al. (2003) and Li et al. (2010, 216) that show that children as young as three know classifiers often delineate categories of objects with similar shapes.

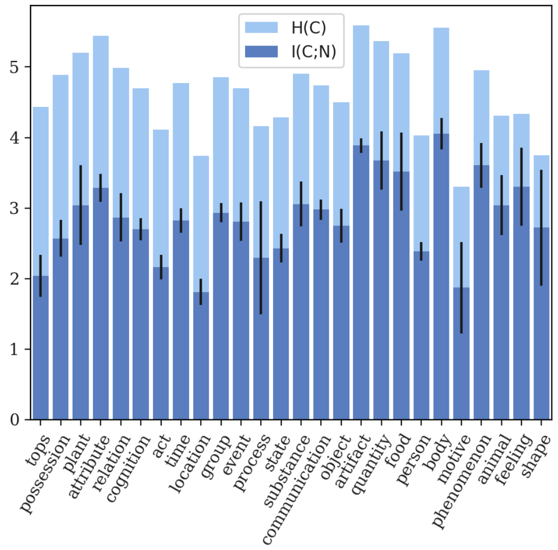

Figure 1: Mutual information between classifiers and nouns (dark blue), and classifier entropy (light & dark blue) plotted with $H(C \mid N) = H(C) - I(C;N)$ (light blue) decreasing from left. Error bars denote bootstrapped 95% confidence interval of $I(C;N)$.

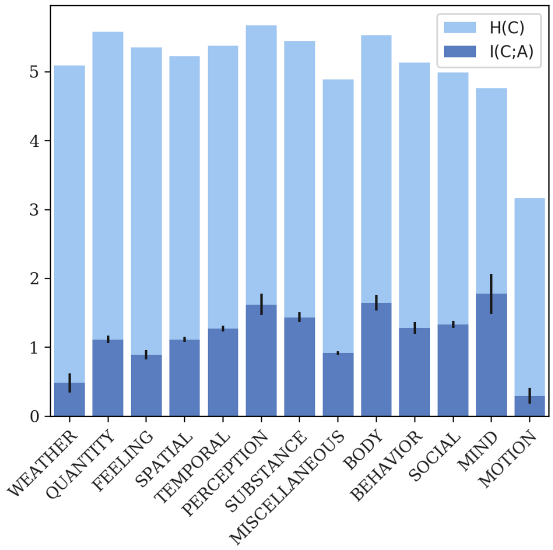

Figure 2: Mutual information between classifiers and adjectives (dark blue), and classifier entropy (light & dark blue) plotted with $H(C \mid A) = H(C) - I(C;A)$ (light blue) decreasing from left. Error bars denote bootstrapped 95% confidence interval of $I(C;A)$.

4.3 MI between Classifiers and Adjectives Supersenses

Adjective supersense results are in Figure 2. Interestingly, the top three senses that have the highest mutual information between their adjectives and classifiers—MIND, BODY (constitution, appearance) and PERCEPTION—are all involved with people's subjective views. With respect to Kuo and Sera (2009), adjectives from the SPATIAL sense pick out shape nouns in our results. Although it does not make it into the top three, MI for the SPATIAL sense is still significant.

5 Conclusion

While classifier choice is known to be idiosyncratic, no extant study has precisely quantified this. To do so, we measure the mutual information between classifiers and other linguistic quantities, and find that classifiers are highly mutually dependent on nouns, but are less mutually dependent on adjectives and noun synsets. Furthermore, knowing which noun or adjective supersense a word comes from helps, often significantly, but still leaves much of the original entropy in the classifier distribution unexplained, providing quantitative support for the notion that classifier choice is largely idiosyncratic. Although the amount of mutual dependence is highly variable across the semantic classes we investigate, we find that knowing a noun refers to a shape reduces uncertainty in classifier choice more than knowing it falls into any other semantic class, arguing for a role for information structure in Mandarin speakers' reliance on shape (Kuo and Sera, 2009). This result might have implications for second language pedagogy, adducing additional, tentative evidence in favor of collocational approaches to teaching classifiers (Zhang and Lu, 2013) that encourages memorizing classifiers and nouns together. Investigating classifiers might also provide cognitive scientific insights into conceptual categorization (Lakoff, 1986)—often considered crucial for language use (Ungerer, 1996; Taylor, 2002; Croft and Cruse, 2004). Studies like this one opens up avenues for comparisons with other phenomena long argued to be idiosyncratic, such as grammatical gender, or declension class.

Abstract

Fine-tuning neural networks is widely used to transfer valuable knowledge from high-resource to low-resource domains. In a standard fine-tuning scheme, source and target problems are trained using the same architecture. Although capable of adapting to new domains, pre-trained units struggle with learning uncommon target-specific patterns. In this paper, we propose to augment the target-network with normalised, weighted and randomly initialised units that beget a better adaptation while maintaining the valuable source knowledge. Our experiments on POS tagging of social media texts (Tweets domain) demonstrate that our method achieves state-of-the-art performances on 3 commonly used datasets.

1 Introduction

POS tagging is a sequence labelling problem, that consists on assigning to each sentence' word, its disambiguated POS tag (*e.g.*, Pronoun, Noun) in the phrasal context in which the word is used. Such information is useful for higher-level applications, such as machine-translation (Niehues and Cho, 2017) or cross-lingual information retrieval (Semmar et al., 2006, 2008).

One of the best approaches for POS tagging of social media text (Meftah et al., 2018a), is transfer-learning, which relies on a neural-network learned on a *source-dataset* with sufficient annotated data, then further adapted to the problem of interest (*target-dataset*). While this approach is known to be very effective (Zennaki et al., 2019), because it takes benefit from pre-trained neurons, it has one main drawback by design. Indeed, it has been shown in computer-vision (Zhou et al., 2018a) that, when fine-tuning on scenes a model pre-trained on objects, it is the neuron firing on the *white dog* object that became highly sensitive to the *white waterfall* scene. Simply said, pre-trained neurons are *biased* by what they have learned in the source-dataset. This is also the case on NLP (see experiments). Consequently, pre-trained units struggle with learning patterns specific to the target-dataset (*e.g.*, "wanna" or "gonna" in the Tweets domain). This last is non-desirable, since it has been shown recently (Zhou et al., 2018b) that such specific units are important for performance. To overcome this drawback, one can propose to take benefit from randomly initialised units, that are by design non-biased. However, it is common to face small target-datasets that contain too few data to learn such neurons from scratch. Hence, in such setting, it is hard to learn random units that fire on specific patterns and generalise well.

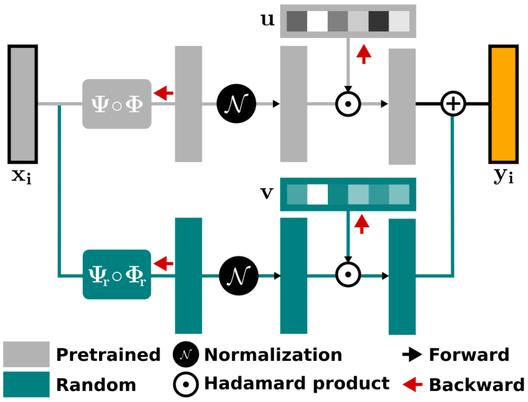

Figure 1: Given a word representation x_i, a BiLSTM (Φ) models the sequence, and a FC layer (Ψ) performs classification. In standard fine-tuning, the units are pre-trained on a large source-dataset then adapted to the target one. In this work, we propose to add randomly initialised units (green branch) and jointly adapt them with pre-trained ones (gray branch). An element-wise sum is further applied to merge the two branches. Before merging, we balance the different behaviours of pre-trained and random units, using an independent normalisation ($\mathcal{N}$). Finally we let the network learn which of pre-trained or random neurons are more suited for every class, by adding learnable weighting vectors (u and v initialised with 1-values) on the FC layers.

In this article, we propose a hybrid method that takes benefit from both worlds, without their drawbacks. It consists in augmenting the source-

Proceedings of NAACL-HLT 2019, pages 4107–4112
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

network (set of pre-trained units) with randomly initialised units and jointly learn them. We call our method **PretRand** (**Pret**rained and **Rand**om units) and illustrate it in Fig. 1. The main difficulty is forcing the network to consider random units, because they have different behaviours than pre-trained ones. Indeed, while these last strongly fire discriminatively on many words, these first do not fire on any word at the initial stage of fine-tuning. Therefore, random units do *not* significantly contribute to the computation of gradients and are thus slowly updated. To overcome this problem, we proposed to independently normalise pre-trained and random layers. This last balances their range of activations and thus forces the network to consider them, both. Last but not least, we do not know which of pre-trained and random units are the best for every class-predictor, thus we propose to learn weighting vectors on top of each branch.

Evaluation was carried on 3 POS tagging Tweets datasets in a transfer-learning setting. Our method outperforms SOTA methods and significantly surpasses fairly comparable baselines.

2 Proposed Method: PretRand

2.1 Base Model

Given an input sentence $S = [w_1, \ldots, w_n]$ of n successive tokens w_i, the goal of a POS tagger is to predict the POS-tag $c_i \in \mathcal{C}$ of every w_i, with $\mathcal{C} \in \mathbb{R}^C$ being the tag-set. Hence, for our base model, we used a common sequence labelling model which first, computes for each token w_i, a word-level embedding (denoted $\boldsymbol{\Upsilon}_\mathbf{w}$) and character-level embedding using biLSTM encoder ($\boldsymbol{\Upsilon}_\mathbf{c}$), and concatenates them to get a final representation x_i. Second, it feeds the later representation into a biLSTM features extractor (denoted $\boldsymbol{\Phi}$) that outputs a hidden representation, that is itself fed into a fully-connected (FC) layer (denoted $\boldsymbol{\Psi}$) for classification. Formally, given w_i, the logits are obtained using: $\hat{y}_{w_i} = \boldsymbol{\Psi} \circ \boldsymbol{\Phi} \circ \boldsymbol{\Upsilon}(w_i)$, with $\boldsymbol{\Upsilon}$ being the concatenation of the output of $\boldsymbol{\Upsilon}_\mathbf{c}$ and $\boldsymbol{\Upsilon}_\mathbf{w}$ for w_i. In a standard fine-tuning scheme (Meftah et al., 2018b), $\boldsymbol{\Upsilon}$ and $\boldsymbol{\Phi}$ are pre-trained on the *source-task* and $\boldsymbol{\Psi}$ is randomly initialised. Then, the three modules are further jointly trained on the *target-task* by minimising a Softmax Cross-Entropy (SCE) loss using the SGD algorithm.

2.2 Adding Random Branch

As mentioned in the introduction, pre-trained neurons are biased by design, thus limited. This motivated our proposal to augment the pre-trained branch with additional random units (as illustrated in Fig. 1). To do so, theoretically one can add the new units in any layer of the base model. However in practice, we have to make a trade-off between performances and the number of parameters (model complexity). Thus, given that deep layers are more task-specific than shallow ones (Peters et al., 2018; Mou et al., 2016), and that word embeddings (shallow layers) contain the majority of parameters, we choose to expand only the top layers. With this choice, we desirably increase the complexity of the model only by $1.02\times$ compared to the base one. In terms of the layers expanded, we specifically add k units to $\boldsymbol{\Phi}$ resulting in an extra biLSTM layer: $\boldsymbol{\Phi}_\mathbf{r}$ (r for rand); and C units in $\boldsymbol{\Psi}$ resulting in an extra FC layer: $\boldsymbol{\Psi}_\mathbf{r}$. Hence, for every w_i, the additional random branch predicts class-probabilities following: $\hat{y}^r_{w_i} = \boldsymbol{\Psi}_\mathbf{r} \circ \boldsymbol{\Phi}_\mathbf{r}(x_i)$ (with $x_i = \boldsymbol{\Upsilon}(w_i)$). Note that, having two FC layers obviously outputs two predictions per class (one from the pre-trained FC $\hat{y}^p_{w_i}$ and one from the random $\hat{y}^r_{w_i}$), that thus need to be merged. Hence, to get the final predictions, we simply apply an element-wise sum between the output of both branches: $\hat{y}_{w_i} = \hat{y}^p_{w_i} \oplus \hat{y}^r_{w_i}$. As in the classical scheme, SCE is minimised but here, both branches are trained jointly.

2.3 Independent Normalisation

Nevertheless, while at the initial stage of fine-tuning, the pre-trained units are strongly firing on many words, the random ones are firing very weakly. As stated in some computer-vision works (Liu et al., 2015; Tamaazousti et al., 2018), the later setting causes an absorption of the weights, outputs and thus gradients of the random units by the pre-trained ones, which thus makes them useless at the end. We encountered the same problem with textual data on the POS-tagging problem. Indeed, as illustrated in the left plot of Fig.2, at the end of training, the distribution of the random units' weights is still absorbed (closer to zero) by that of the pre-trained ones.

To prompt the two classifiers to work cooperatively, we normalise (using an ℓ_p-norm) both of them independently before merging them. Formally, we apply $\boldsymbol{\mathcal{N}}_p(x) = \frac{x}{||x||_p}$ on $\hat{y}^p_{w_i}$ and $\hat{y}^r_{w_i}$. The normalisation is desirably solving the weights absorption problem since at the end of the training, the distributions of the pre-trained and random weights become very similar (right of Fig. 2).

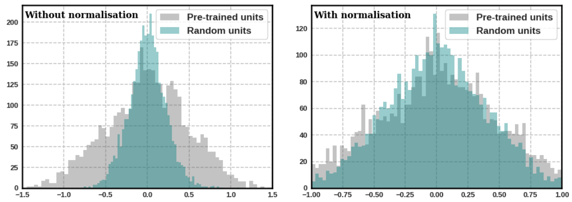

Figure 2: Distributions of learned weight-values for the randomly initialised (green) and pre-trained (gray) fully-connected layers after joint training. Left: without normalisation, right: with normalisation.

Furthermore, we have observed that despite the normalisation, the performances of the pre-trained classifiers were still much better than the randomly initialised ones. Thus, to make them more competitive, we propose to start with optimising only the randomly initialised units while freezing the pre-trained ones, then, launch the joint training. This is called random++ in the following.

2.4 Learnable Weighting Vectors

Back to the extra predictor (FC layer of random branch), it is important to note that both branches are equally important for making a decision for every class, *i.e.,* no weight is applied on the dimensions of $\hat{y}^p_{w_i}$ and $\hat{y}^r_{w_i}$. However, this latter is sub-optimal since we, a priori, do not know which kind of units (random or pre-trained) is better for making a decision. Consequently, we propose to weight the contribution of the predictions for each class. For this end, instead of simply performing an element-wise sum between the random and pre-trained predictions, we first *weight* each of them with learnable weighting vectors, then compute a Hadamard product with their associated normalised predictions; the learnable vectors $u \in \mathbb{R}^C$ and $v \in \mathbb{R}^C$, respectively corresponding to the pre-trained and random branch, are initialised with 1-values and are learned by SGD. Formally, the final predictions are computed following: $\hat{y}_{w_i} = u \odot \boldsymbol{\mathcal{N}}_p(\hat{y}^p_{w_i}) \oplus v \odot \boldsymbol{\mathcal{N}}_p(\hat{y}^r_{w_i})$.

3 Experiments

3.1 Implementation Details

In the word-level embeddings, tokens are lower-cased while the character-level component still retains access to the capitalisation information. We set the character embedding dimension at 50, the dimension of hidden states of the character-level biLSTM at 100 and used 300-dimensional word-level embeddings. The latter were pre-loaded from publicly available Glove pre-trained vectors on 42 billions words from a web crawling and containing 1.9M words (Pennington et al., 2014). Note that, these embeddings are also updated during fine-tuning. For biLSTM (token-level feature extractor), we set the number of units of the pre-trained branch to 200 and experimented our approach with k added random-units, with $k \in \{50, 100, 150, 200\}$. For the normalisation, we used ℓ_2-norm. Finally, in all experiments, training was performed using SGD with momentum and mini-batches of 8 sentences. Evidently, all the hyperparameters have been cross-validated.

Test	2,291	7,707	19,112

Table 1: Number of tokens in every used dataset.

3.2 Datasets

For the source-dataset, we used the Wall Street Journal (**WSJ**) part of Penn-Tree-Bank (PTB), a large English dataset containing 1.2M+ tokens from the newswire domain annotated with the PTB tag-set. Regarding the target-datasets, we used three Tweets datasets: **TPoS** (Ritter et al., 2011), annotated with 40 tags ; **ARK** (Owoputi et al., 2013) containing 25 coarse tags; and the recent **TweeBank** (Liu et al., 2018) containing 17 tags (PTB universal tag-set). The number of tokens in the datasets are given in Table 1.

3.3 Comparison Methods

To assess the POS tagging performances of our PretRand model, we compared it to 5 baselines: **Random-200** and **Random-400**: randomly initialised neural model with 200 and 400 biLSTM's units; **Fine-tuning**: pre-trained neural model, fine-tuned with the standard scheme; **Ensemble (2 rand)**: averaging the predictions of two base models randomly initialised and learned independently (with different random initialisation) on Tweets datasets; and **Ensemble (1 pret + 1 rand)**: same as the previous but with one pre-trained on WSJ and the other randomly initialised.

We also compared it to the 3 best SOTA methods: Derczynski et al. (2013) (GATE) is a model based on HMMs with a set of normalisation rules, external dictionaries and lexical features. They experiment it on TPoS, with WSJ and 32K tokens from the NPS IRC corpus. They also used 1.5M additional training tokens annotated by vote-constrained bootstrapping (GATE-bootstrap). Owoputi et al. (2013) proposed a model based on first-order Maximum Entropy

Markov Model (MEMM) with greedy decoding and using brown clustering and careful hand-engineered features. Recently, Gui et al. (2017) proposed TPANN that uses adversarial training to leverage huge amounts of unlabelled Tweets.

3.4 Results

From the results given in Table 2, one can first see that our approach outperforms the SOTA and baseline methods on all the datasets. More interestingly, PretRand significantly outperforms the popular fine-tuning baseline by +1.4% absolute point on average and is better on all classes (see per-class improvement on Fig. 4). PretRand also outperforms the challenging Ensemble Model by a large margin (+2.2%), while using much less parameters. This clearly highlights the difference of our method with ensemble methods and the importance of having a shared word representation as well as our normalisation and weighting learnable vectors during training. A key asset of PretRand, is that it uses only 0.02% more parameters compared to the fine-tuning baseline.

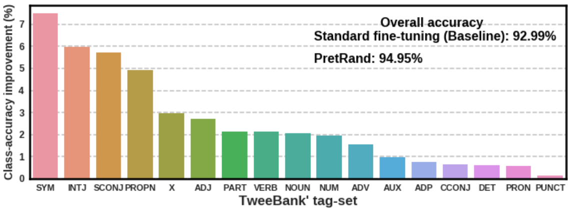

Figure 4: Sorted class-accuracy improvement (%) on TweeBank of PretRand compared to fine-tuning.

An interesting experiment is to evaluate the gain of performance of PretRand compared to fine-tuning, according different target-datasets' sizes. From the results in Fig. 3, PretRand has desirably a bigger gain with bigger *target-task* datasets, which clearly means that the more target training-data, the more interesting our method will be.

To assess the contribution of different components of PretRand, we performed an ablation study. Specifically, we successively ablated the main components of PretRand, namely, the learnable vectors (learnVect), the longer training for random units (random++) and the normalisation (ℓ_2-norm). From the results in Table 3, we can observe that the performances are only marginally better than standard fine-tuning when ablating the three components from PretRand. More importantly, adding each of them successively, makes the performances significantly better, which highlights the importance of every component.

4 Analysis

Bias when fine-tuning pre-trained units

Here our goal is to highlight that as in (Zhou et al., 2018a), pre-trained units can be biased in

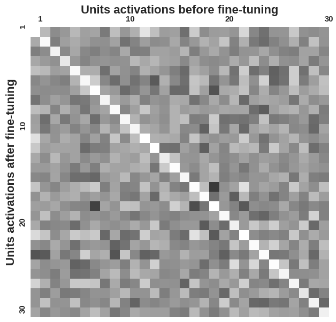

Figure 5: Correlation between units' activations before fine-tuning (columns) and after fine-tuning (rows).

the standard fine-tuning scheme. To do so, we follow (Tamaazousti et al., 2017) and analyse the units of **Φ** (biLSTM layer) *before* and *after* fine-tuning. Specifically, we compute the Pearson's correlation between all the units of the layer before and after fine-tuning. Here, a unit is represented by the random variable being the concatenation of its output activations from all the validation samples of the TweeBank dataset. From the resulting correlation matrix illustrated in Fig. 5, one can clearly observe the white diagonal, highlighting the fact that, every unit after fine-tuning is more correlated with itself before fine-tuning than with any other unit. This clearly confirms our initial motivation that pre-trained units are highly biased to what they have learned in the source-dataset, making them limited to learn patterns specific to the target-dataset.

Additionally, we visualise in Fig. 6 a concrete example of a biased neuron when transferring from newswire to Tweets domain. Specifically, we show the top-10 words activating unit-169 of **Φ** (from the standard fine-tuning baseline), *before* fine-tuning (at this stage, the model is trained on the source-dataset WSJ) and *during fine-tuning* on the TweeBank dataset. We can observe that this unit is highly sensitive to proper nouns (*e.g.*, *George* and *Washington*) before fine-tuning, and to words with capitalised first-letter whether the word is a proper noun or not (*e.g.*, *Man* and *Father*) during fine-tuning on TweeBank dataset. Indeed, we found that most of tokens with upper-cased first letter are mistakenly predicted as proper nouns (*PROPN*) in the standard fine-tuning scheme. In fact, in standard English, inside sentences, only proper nouns start with upper-cased letter thus fine-tuning the pre-trained model fails to slough this pattern which is not always respected in Tweets.

Figure 7: Top-10 words activating unit-99 of the random branch of PretRand, before and during training.

Unique units emerge in random branch

Finally, we highlight the ability of randomly initialised units to learn patterns specific to the target-dataset and not learned by the pre-trained ones because of their bias problem. To do so, we visualise unique units – *i.e.*, random units having a correlation lower than 0.4 with pre-trained ones – emerging in the random branch. While only one shown in Fig. 7, many unique units have been learned by the random branch of our PretRand model: 37.5% of the 200 random units have correlation lower than 0.4 with the pre-trained ones. Regarding unit-99, it is highly discriminative to tokens *"na"*, *"ta"* and *"n't"*. Indeed, in TweeBank, words like *"gonna"* (going to) are tokenized into two tokens: *"gon"* and *"na"*, with the later annotated as a *particle* and the former as a *verb*. Importantly, not even one unit from the standard fine-tuning scheme has been found firing on the same important and target-dataset specific pattern.

5 Conclusion

In this paper, we introduced a method to improve fine-tuning using 3 main ideas: adding random units and jointly learn them with pre-trained ones; normalising the activations of both to balance their different behaviours; applying learnable weights on both predictors to let the network learn which of random or pre-trained one is better for every class. We have demonstrated its effectiveness on domain adaptation from newswire domain to three commonly used Tweets-datasets for POS tagging.

Show Some Love to Your n-grams: A Bit of Progress and Stronger n-gram Language Modeling Baselines

Ehsan Shareghi, Daniela Gerz, Ivan Vulić, Anna Korhonen
Language Technology Lab, DTAL, University of Cambridge
`{es776, dsg40, iv250, alk23}@cam.ac.uk`

Abstract

In recent years neural language models (LMs) have set state-of-the-art performance for several benchmarking datasets. While the reasons for their success and their computational demand are well-documented, a comparison between neural models and more recent developments in n-gram models is neglected. In this paper, we examine the recent progress in n-gram literature, running experiments on 50 languages covering all morphological language families. Experimental results illustrate that a simple extension of Modified Kneser-Ney outperforms an LSTM language model on 42 languages while a word-level Bayesian n-gram LM (Shareghi et al., 2017) outperforms the character-aware neural model (Kim et al., 2016) on average across all languages, and its extension which explicitly injects linguistic knowledge (Gerz et al., 2018a) on 8 languages. Further experiments on larger Europarl datasets for 3 languages indicate that neural architectures are able to outperform computationally much cheaper n-gram models: n-gram training is up to $15,000\times$ quicker. Our experiments illustrate that standalone n-gram models lend themselves as natural choices for resource-lean or morphologically rich languages, while the recent progress has significantly improved their accuracy.

1 Introduction

Statistical language models (LMs) are the pivot for several natural language processing tasks where a model trained on a text corpus is required to assign a probability to a given sequence $w_1 w_2 ... w_N$ (denoted by w_1^N). This probability indicates how likely is for w_1^N to belong to the corpus and is decomposed into conditional probabilities of words given their preceding contexts as $P(w_1^N) = \prod_{i=1}^{N} P(w_i|w_1^{i-1})$.

In n-gram LMs the unbounded conditional probabilities $P(w_i|w_1^{i-1})$ are approximated by imposing a finite-order Markov assumption, $P(w_i|w_1^{i-1}) \approx P(w_i|w_{i-n+1}^{i-1})$. Several smoothing techniques address the statistical sparsity issue for computing the conditional probabilities (Kneser and Ney, 1995; Chen and Goodman, 1999; Teh, 2006; Shareghi et al., 2016a), while others avoided the above approximation with unbounded hierarchical nonparametric Bayesian frameworks (Wood et al., 2011; Shareghi et al., 2017).

Alternatively, neural LMs compute $P(w_i|w_1^{i-1})$ via recurrent neural units which, in theory, are capable of encoding an unbounded context w_1^{i-1}. In recent years, neural LMs have become the prominent class of language modeling and have established state-of-the-art results on almost all sufficiently large benchmarks (Melis et al., 2018; Yang et al., 2018). While outperforming n-grams in terms of predictive accuracy, the computational shortcomings of neural LMs are well-documented: Training neural LMs is computationally expensive to the point that running experiments on large data ($\geq$ a few GiBs) is beyond the reach of academic research to this date (Chen et al., 2016; Patwary et al., 2018; Puri et al., 2018).[1] Similarly, querying is slower for neural LMs due to the required matrix-based operations, whereas most of the widely used n-gram LM toolkits rely on a few hash lookups and much cheaper scalar-based operations (Liu et al., 2018; Tang and Lin, 2018).

Nonetheless, it has been shown that the best predictive performance is still achieved by combining the two models via a basic interpolation or a mixture model (Jozefowicz et al., 2016; Neubig and Dyer, 2016): this indicates that the progress in n-gram LM should eventually be reflected in improving the

---

[1] For instance, n-gram LMs could be trained on 32GiB of data on a single CPU with ~32GiB of RAM in half a day (Shareghi et al., 2016b). A ballpark estimate for neural LMs, based on Puri et al. (2018), requires 26 Tesla V100 16GB GPUs to finish within the same amount of time while its financial cost is at least 100× higher.

Proceedings of NAACL-HLT 2019, pages 4113–4118
Minneapolis, Minnesota, June 2 - June 7, 2019.

state-of-the-art performance. Inspired by this, in this paper we shed new light on the most notable recent progress in n-gram statistical LMs which improves their predictive accuracy.

We demonstrate that under a recent massively multilingual experimental setup of Gerz et al. (2018a), more recent extensions of Kneser-Ney family of n-gram LMs (Shareghi et al., 2016a, 2017) are highly competitive with neural LMs. More specifically, we experiment on 50 languages from different morphological families, and illustrate that a word-level Bayesian n-gram LM (Shareghi et al., 2017) outperforms the character-level informed neural counterpart (Kim et al., 2016) on average, and its linguistically informed variant (Gerz et al., 2018a) on 8 languages. On larger Europarl datasets we find that n-gram models cannot reach the performance peaks of computationally much more expensive neural models, but a 2× decrease in perplexity comes at the cost of 15,000× longer training time. Our work reveals that recent n-gram LMs should be used as strong baselines, especially in resource-lean LM data and for morphologically rich languages.

Additionally, n-gram LMs offer a stringent way of dealing with Out-of-Vocabulary (OOVs) and rare words in a *full vocabulary* setting without relying on any pruning (Heafield, 2013). However, in neural LMs this remains an open question (Kawakami et al., 2017; Kim et al., 2016; Cotterell et al., 2018), while a common practice is pruning the training corpus and imposing *closed vocabulary* assumption (Mikolov et al., 2010) where rare words at training and unseen words at test are treated as an UNK token. We provide the mathematical underpinnings of n-gram models and highlight how this popular treatment works in favor of neural LMs (in comparative studies), and enforces n-gram LMs to perform much worse than their full potential.

2 n-gram Language Models: Smoothing

We now provide an overview of established smoothing techniques for n-gram LMs and their recent extensions. Smoothing is typically achieved by interpolation, where the probability of seeing a word w_i after a context w_{i-n+1}^{i-1} $P(w_i|w_{i-n+1}^{i-1}, \Theta)$ is smoothed by its probability after a shorter context, w_{i-n+2}^{i-1}, and follows the following general form:

$$\beta(w_i|w_{i-n+1}^{i-1},\Theta)+\gamma(w_{i-n+1}^{i-1},\Theta)P(w_i|w_{i-n+2}^{i-1},\Theta). \tag{1}$$

	$\beta(w_i \mid w_{i-n+1}^{i-1}, \Theta)$	Θ
KN	$\frac{\left[c(w_{i-n+1}^{i})-D_n\right]^+}{c(w_{i-n+1}^{i-1})}$	D_n
MKN	$\frac{\left[c(w_{i-n+1}^{i})-D_n^{c(w_{i-n+1}^{i})}\right]^+}{c(w_{i-n+1}^{i-1})}$	$D_n^{i\in\{1,2,3+\}}$
GKN	$\frac{\left[c(w_{i-n+1}^{i})-D_n^{c(w_{i-n+1}^{i})}\right]^+}{c(w_{i-n+1}^{i-1})}$	$D_n^{i\in\{1,...,10+\}}$
BKN	$\frac{\left[c(w_{i-n+1}^{i})-D_{w_{i-n+1}}t_{w_{i-n+1}}^{w_i}\right]^+}{c(w_{i-n+1}^{i-1})+\theta_{w_{i-n+1}}}$	$D_{w_{i-n+1}}, \theta_{w_{i-n+1}}, t_{w_{i-n+1}}^{w_i}$

Table 1: Top-level interpolation for n-gram LMs smoothings and its parameters, and $[x]^+ \overset{\text{def}}{=} \max\{x, 0\}$.

The term $\beta(\cdot)$ represents the existing mass for the n-gram (e.g. via maximum likelihood estimation), γ is the weight used for redistributing the preserved mass (e.g. via discounting), and Θ are the parameters of the smoothing technique. The recursion stops at the unigram level where the conditioning context is empty. The recursion at lower levels relies on different quantities (e.g. pseudo-counts) but for brevity we focus on the top level of recursion and only the first term, $\beta(w_i|w_{i-n+1}^{i-1}, \Theta)$, which suffices to highlight the key differences between smoothing techniques (see Table 1).

Kneser-Ney (KN). The key parameters of KN (Kneser and Ney, 1995) are the k-gram specific discounts D_k which control the amount of preserved and redistributed mass at kth level of recursion. While learning the discounts (on held-out data) is a possibility, the following estimation is shown to work well in practice:

$$D_k = 1 - 2\frac{n_2(k)}{n_1(k)}.\frac{n_1(k)}{n_1(k) + 2n_2(k)}. \tag{2}$$

It captures the characteristics of different k-gram orders by looking at the number of unique k-grams which occurred once, $n_1(k)$, or twice, $n_2(k)$ in the training data, defined as follows:

$$n_j(k) = \begin{cases} |\{\alpha \text{ s.t. } |\alpha|=k, c(\alpha)=j\}|, & \text{if } k=n \\ \left|\left\{\alpha \text{ s.t. } |\alpha|=k, N_{1+}(\bullet\alpha)=j\right\}\right|, & \text{if } k<n \end{cases} \tag{3}$$

where $N_{1+}(\bullet\alpha) = |\{w : c(w\alpha) > 0\}|$, and is referred to as a form of pseudo-count, and $c(\alpha)$ denotes the frequency of sequence α. KN considers one discount value at each level of recursion and the discounts are bounded, $0 \leq D_k < 1$.

Modified Kneser-Ney (MKN). Similarly, Modified Kneser-Ney (Chen and Goodman, 1999) is defined with modifications applied to the discounting mechanism in order to make them sensitive to the *existing* mass j. The discounts are estimated as:

$$D_k^j = \begin{cases} 0, & \text{if } j = 0 \\ j-(j+1)\frac{n_{j+1}(k)}{n_j(k)} \frac{n_1(k)}{n_1(k)+2n_2(k)}, & \text{if } j < \mathcal{B} \\ \mathcal{B}-(\mathcal{B}+1)\frac{n_4(k)}{n_3(k)} \cdot \frac{n_1(k)}{n_1(k)+2n_2(k)}, & \text{if } j \geq \mathcal{B} \end{cases} \quad (4)$$

where $n_j(k)$ is defined in Eq. (3), and $\mathcal{B} = 3$. This leads to three discount parameters $\{D_k^1, D_k^2, D_k^{3+}\}$ for each recursion level, and allows for discount values to be as large as $c(w_{i-n+1}^i)$. MKN is widely accepted as the state-of-the-art n-gram LM and is very frequently confused with KN in the literature.

Generalized Modified Kneser-Ney (GKN). In conditions where statistical sparsity is more severe a more refined approach to model the distributions is necessary. Motivated by this, Shareghi et al. (2016a) provided the mathematical proof (based on leave-one-out log-likelihood) of the discount bounds used in MKN and proposed a natural extension of its discount binning to $\mathcal{B} = 10$. This was shown to be effective for further perplexity reduction in out-of-domain setting where OOV ratio is naturally high.

Bayesian Kneser-Ney (BKN). The Bayesian generalization of KN is the Hierarchical Pitman-Yor Process (HPYP) language model (Teh, 2006). This can be interpreted as a richer parameterization of KN and MKN, where the additional parameters (introduced shortly) allow the model to have more flexibility in capturing the desired distribution.

The Pitman-Yor Process (Pitman et al., 1997), $\text{PYP}(D, \theta, H)$, is a distribution defined over probability vectors (each draw from a PYP is a multinomial distribution) and has three parameters: a base probability vector H which is the expected value of a draw from a PYP, the concentration parameter $-D < \theta$ which controls the variation of draws from a PYP around H, and the discount parameter $0 \leq D < 1$ which allows the drawn vectors to capture the power-law behavior.

In the LM context, given a sequence of words w_{i-n+1}, a draw from a PYP is a multinomial distribution over the words following this sequence, denoted by $G_{w_{i-n+1}}$. This distribution can be captured by a vector of two counts $\{t_{w_{i-n+1}}^{w_i}, n_{w_{i-n+1}}^{w_i}\}^{w_i \in \sigma}$ which defines a partitioning arrangement of $G_{w_{i-n+1}}$, while different partitioning correspond to different multinomial draws from PYP. Here, $n_{i-n+1}^{w_i}$ is the total number of evidence [2] for word w_i after the context w_{i-n+1}, $t_{i-n+1}^{w_i}$ is the total number of partitions dedicated to w_i constrained by $0 \leq t_{i-n+1}^{w_i} \leq n_{i-n+1}^{w_i}$, and σ is the vocabulary.

The HPYP ties PYP distributions through their base and offers the statistical mean to smooth over infinitely long contexts (Wood et al., 2011). For instance, $\text{PYP}(D_u, \theta_u, \text{PYP}(D_{\pi(u)}, \theta_{\pi(u)}, H))$ is a two-level HPYP where a draw from a *child* distribution u, is smoothed by a draw from its *parent* $\pi(u)$. Here, $\pi(u)$ is u with its most earliest word dropped (e.g., $u = abc$, $\pi(u) = bc$).

KN can be seen as a special case for BKN, when the concentration is 0, and $\{t_{w_{i-n+1}}^{w_i}{=}1\}^{w_i \in \sigma}$. BKN can be considered as a richer parameterization of MKN: The product $D_{w_{i-n+1}} t_{w_{i-n+1}}^{w_i}$ (see Table 1) allows ≥ 1 discounting, simulating the discount range of MKN, while an additional parameter $\theta_{w_{i-n+1}}$ permits further adjustments of the distribution. BKN is shown to outperform MKN (Shareghi et al., 2017) but relies on expensive parameter sampling.

Out-of-Vocabulary (OOV). To complete the definitions we now explain how unseen words or contexts are handled during the computation without resorting to pruning or closed vocabulary setting. This treatment is the same for both non-Bayesian and Bayesian methods described in this paper. Let us consider the generic interpolation form of Eq. (1) and the maximum likelihood estimation of the $\beta(.)$ term (hence Θ is dropped) in the top level of the interpolation, $\beta(w_i|w_{i-n+1}^{i-1}) = \frac{c(w_{i-n+1}^i)}{c(w_{i-n+1}^{i-1})}$. Regardless of the level of interpolation and the paradigm used for computing the $\beta(.)$ term, $\beta(.)$ and $\gamma(.)$ always share the same denominator (normalizing factor).

An unseen word can appear as the target word w_i, which results in $\beta(.) = 0$ as $c(w_{i-n+1}^i) = 0$. It can also appear as a part of the prediction context w_{i-n+1}^{i-1} in which case both the $\beta(.)$ and $\gamma(.)$ terms will be undefined (and ignored) as the denominator $c(w_{i-n+1}^{i-1}) = 0$. This procedure is applied to all levels of interpolation without loss of generality, and as can be seen it only relies on the basic mathematical property of the involved computations rather than any other presumptions about data preprocessing or vocabulary. [3]

---

[2] This is equal to $c(w_{i-n+1}^i)$ at the top level of recursion, hence not mentioned as a part of Θ in Table 1.

[3] See Shareghi (2017) for a comprehensive explanation of the models covered in this section.

Table 2: Data Statistics and Perplexity scores. OOV denotes the percentage of unseen words at test time. For detailed data stats see (Gerz et al., 2018a). Suit symbols denote morphological types: ◇ Isolating, ♡ Fusional, ♠ Agglutinative, ♣ Introflexive. Color coded shapes denote comparative performance: ‡ is outperformed by LSTM, † outperforms CNN, § outperforms AP.

3 Experiments and Results

As our main large-scale experiment we use a typologically diverse set of 50 languages. These LM datasets cover many languages which are challenging in terms of data size, as well as the type-token ratio. In a less challenging setup, we experiment on 3 languages with larger training data from the Europarl (Koehn, 2005) to compare the two classes of LMs based on perplexity reduction and training time. For full data statistics, actual sampling of languages and data curation see Gerz et al. (2018a,b).

The common practice of setting a frequency threshold and mapping training data unigrams ($(k = 1)$-gram) to an UNK token degrades the performance of n-gram LMs by discarding a range of discount parameters: e.g., using threshold (< 3) results in $n_1(1), n_2(1) = 0$, both included in Eq. (2) and Eq. (4), increases the average perplexity score of 5-gram KN in our experiments by 11%. Motivated by its significance, we base our comparison on reported results by Gerz et al. (2018a): they deal with the task in the full vocabulary setting (Adams et al., 2017) with word-level predictions, and follow a relatively comparable treatment of unseen words with both n-gram and neural LM families (although not identical) at test time without enforcing any threshold over the training data.

The benchmarked neural LMs include three models with word-level predictions: a standard LSTM (Zaremba et al., 2014), a Char-CNN-LSTM (denoted as CNN) (Kim et al., 2016) which incorporates character-level information in the input, and the Attract-Preserve model (denoted as AP) (Gerz et al., 2018a) which injects further subword-level information. All benchmarked n-gram LMs are 5-grams, with the exception of BKN which is an ∞-gram model trained via 5 samples[4] following the recipe of Shareghi et al. (2017). GKN results are based on $\mathcal{B} = 5$, tuned on a development set.

Results and Discussion. The main results on the 50-languages benchmark are summarized in Table 2. The results for the more recent n-gram LMs indicate that these n-gram models are highly competitive with neural LMs in this challenging resource-lean setup.[5] For instance, for 26/50 languages all n-gram models outperform a regular LSTM, while GKN and BKN extend the lead to 42/50

---

[4] Marginal improvements achieved with more sampling.

[5] The size of each dataset is ≈ 40K sentences, which is at the level of the standard Penn Treebank dataset often used for LM evaluation in English (Marcus et al., 1993).

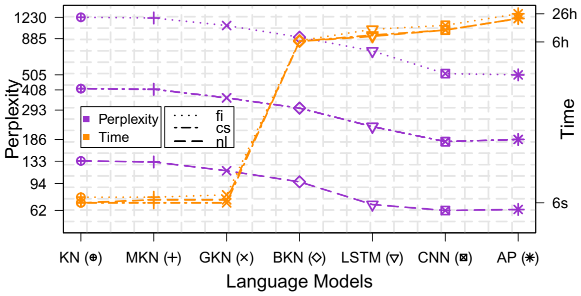

Figure 1: Time-Perplexity for *n*-gram and neural LMs across 3 languages fi, cs, nl. Timings done on a single core of AMD Ryzen 1900X for *n*-grams, and on a Nvidia TITAN X Pascal GPU for neural models.

and 48/50 languages, respectively. For certain morphologically rich languages (e.g., Tamil, Mongolian, Hebrew), the *n*-gram LMs are able to outscore even character-aware neural LMs. On average we observe *n*-grams succeed, especially the BKN model, for introflexive and agglutinative languages which are known to have productive morphological systems: as reported in Table 2, they have the higher OOV ratio compared to the other language families. Overall, the best performing *n*-gram model, BKN, outperforms both the LSTM (42% reduction in perplexity) and CNN models (3% reduction in perplexity), while falling behind AP by 8%.

These results highlight that *n*-gram models can serve as strong baselines for such morphologically rich languages with high OOV rates and type-to-token ratios, which are especially problematic in scarce data setups. Additionally, they suggest that more sophisticated *n*-gram variants such as GKN or BKN should be used to provide adequate comparison points with *n*-gram LMs than the commonly used KN or MKN.

As expected, experiments on 10× larger Europarl datasets for 3 languages show that neural models outperform *n*-gram models in less challenging data-intensive scenarios. However, training on large datasets comes at the expense of training efficiency for neural models: e.g., according to Figure 1 training non-Bayesian *n*-grams is around 15,000× quicker than training neural models. We leave a full-fledged investigation on the relation of training corpus size and efficacy of *n*-gram vs. neural LM training for future work. In addition, motivated by these preliminary insights, we advocate investing further efforts in future work into coupling the ideas behind *n*-gram and neural LMs towards improved language modeling.

4 Conclusion

We provided an overview of previous work and very recent progress in *n*-gram LMs. The recent developments, when tested on a challenging set of 50 languages, demonstrated superior or highly competitive performance compared with neural LMs, while being substantially cheaper to train. We also shed light on a common issue in the experimental setups, concerning OOV or rare words handling, when comparing *n*-grams and neural LMs.

While being non-trivial, investigating any correlation between cheap-to-compute heuristics (e.g., basic data statistics) and the choice of the most suitable model for a given dataset is worth exploring. Also, motivated by our findings, we will work on utilizing continuous space representations as side information in sampling the parameters of BKN, i.e. similar to Zhao et al. (2018), which potentially can reduce the gap between BKN and neural models.

Abstract

Lemmatization aims to reduce the sparse data problem by relating the inflected forms of a word to its dictionary form. Using context can help, both for unseen and ambiguous words. Yet most context-sensitive approaches require full lemma-annotated sentences for training, which may be scarce or unavailable in low-resource languages. In addition (as shown here), in a low-resource setting, a lemmatizer can learn more from n labeled examples of distinct words (types) than from n (contiguous) labeled tokens, since the latter contain far fewer distinct types. To combine the efficiency of type-based learning with the benefits of context, we propose a way to train a context-sensitive lemmatizer with little or no labeled corpus data, using inflection tables from the UniMorph project and raw text examples from Wikipedia that provide sentence contexts for the unambiguous UniMorph examples. Despite these being unambiguous examples, the model successfully generalizes from them, leading to improved results (both overall, and especially on unseen words) in comparison to a baseline that does not use context.

1 Introduction

Many lemmatizers work on isolated wordforms (Wicentowski, 2002; Dreyer et al., 2008; Rastogi et al., 2016; Makarov and Clematide, 2018b,a). Lemmatizing in context can improve accuracy on ambiguous and unseen words (Bergmanis and Goldwater, 2018), but most systems for context-sensitive lemmatization must train on complete sentences labeled with POS and/or morphological tags as well as lemmas, and have only been tested with 20k-300k training tokens (Chrupała et al., 2008; Müller et al., 2015; Chakrabarty et al., 2017).[1]

Intuitively, though, sentence-annotated data is inefficient for training a lemmatizer, especially in low-resource settings. Training on (say) 1000 word types will provide far more information about a language's morphology than training on 1000 contiguous tokens, where fewer types are represented. As noted above, sentence data can help with ambiguous and unseen words, but we show here that when data is scarce, this effect is small relative to the benefit of seeing more word types.[2] Motivated by this result, we propose a training data augmentation method that combines the efficiency of type-based learning and the expressive power of a context-sensitive model.[3] We use *Lematus* (Bergmanis and Goldwater, 2018), a state-of-the-art lemmatizer that learns from lemma-annotated words in their N-character contexts. No predictions about surrounding words are used, so fully annotated training sentences are not needed. We exploit this fact by combining two sources of training data: 1k lemma-annotated types (with contexts) from the Universal Dependency Treebank (UDT) v2.2[4] (Nivre et al., 2017), plus examples obtained by finding *unambiguous* word-lemma pairs in inflection tables from the Universal Morphology (UM) project[5] and collecting sentence contexts for them from Wikipedia. Although these examples are noisy and biased, we show that they improve lemmatization accuracy in experiments on 10 languages, and that the use of context helps, both overall and especially on unseen words.

2 Method

Lematus (Bergmanis and Goldwater, 2018) is a neural sequence-to-sequence model with attention

---

[1] The smallest of these corpora contains 20k tokens of Bengali annotated only with lemmas, which Chakrabarty et al. (2017) reported took around two person months to create.

[2] Garrette et al. (2013) found the same for POS tagging.

Minneapolis, Minnesota, June 2 - June 7, 2019.

inspired by the re-inflection model of Kann and Schütze (2016), which won the 2016 SIGMORPHON shared task (Cotterell et al., 2016). It is built using the Nematus machine translation toolkit,[6] which uses the architecture of Sennrich et al. (2017): a 2-layer bidirectional GRU encoder and a 2-layer decoder with a conditional GRU (Sennrich et al., 2017) in the first layer and a GRU in the second layer.

Lematus takes as input a character sequence representing the wordform in its N-character context, and outputs the characters of the lemma. Special input symbols are used to represent the left and right boundary of the target wordform (`<lc>`, `<rc>`) and other word boundaries (`<s>`). For example, if $N = 15$, the system trained on Latvian would be expected to produce the characters of the lemma *ceļš* (meaning *road*) given input such as:

```
s a k a <s> p a š v a l d ī b u
<lc> c e ļ u <rc>
u n <s> i e l u <s> r e ģ i s t r
```

When $N = 0$ (**Lematus 0-ch**), no context is used, making Lematus 0-ch comparable to other systems that do not model context (Dreyer et al., 2008; Rastogi et al., 2016; Makarov and Clematide, 2018b,a). In our experiments we use both Lematus 0-ch and **Lematus 20-ch** (20 characters of context), which was the best-performing system reported by Bergmanis and Goldwater (2018).

2.1 Data Augmentation

Our data augmentation method uses UM inflection tables and creates additional training examples by finding Wikipedia sentences that use the inflected wordforms in context, pairing them with their lemma as shown in the inflection table. However, we cannot use all the words in the tables because some of them are ambiguous: for example, Figure 1 shows that the form `ceļi` could be lemmatized either as `ceļš` or `celis`. Since we don't know which would be correct for any particular Wikipedia example, we only collect examples for forms which are unambiguous according to the UM tables. However, this method is only as good as the coverage of the UM tables. For example, if UM doesn't include a table for the Latvian verb *celt*, then the underlined forms in Table 1 would be incorrectly labeled as unambiguous.

	noun: `ceļš`		**noun: `celis`**	
	SG	**PL**	**SG**	**PL**
NOM	ceļš	~~ceļi~~	celis	~~ceļi~~
GEN	~~ceļa~~	~~ceļu~~	~~ceļa~~	~~ceļu~~
DAT	ceļam	~~ceļiem~~	celim	~~ceļiem~~
ACC	ceļu	~~ceļus~~	celi	~~ceļus~~
INS	ceļu	~~ceļiem~~	celi	~~ceļiem~~
LOC	ceļā	~~ceļos~~	celī	~~ceļos~~
VOC	ceļ	~~ceļi~~	celi	~~ceļi~~

Table 1: Example UM inflection tables for Latvian nouns *ceļš* (*road*) and *celis* (*knee*). The ~~crossed out forms~~ are examples of evidently ambiguous forms that are not used for data augmentation because of being shared by the two lemmas. The underlined forms appear unambiguous in this toy example but actually conflict with inflections of the verb *celt* (*to lift*).

There are several other issues with this method that could potentially limit its usefulness. First, the UM tables only include verbs, nouns and adjectives, whereas we test the system on UDT data, which includes all parts of speech. Second, by excluding ambiguous forms, we may be restricting the added examples to a non-representative subset of the potential inflections, or the system may simply ignore the context because it isn't needed for these examples. Finally, there are some annotation differences between UM and UDT.[7] Despite all of these issues, however, we show below that the added examples and their contexts do actually help.

3 Experimental Setup

Baselines and Training Parameters We use four baselines: (1) **Lemming**[8] (Müller et al., 2015) is a context-sensitive system that uses log-linear models to jointly tag and lemmatize the data, and is trained on sentences annotated with both lemmas and POS tags. (2) The hard monotonic attention model (**HMAM**)[9] (Makarov and Clematide, 2018b) is a neural sequence-to-sequence model with a hard attention mechanism that advances through the sequence monotonically. It is trained on word-lemma pairs (without context)

---

[6] Code for Nematus: `https://github.com/EdinburghNLP/nematus`, Code for Lematus: `https://bitbucket.org/tomsbergmanis/lematus.git`

[7] Recent efforts to unify the two resources have mostly focused on validating dataset schema (McCarthy et al., 2018), leaving conflicts in word lemmas unresolved. We estimated (by counting types that are unambiguous in each dataset but have different lemmas across them) that annotation inconsistencies affect up to 1% of types in the languages we used.

[8] `http://cistern.cis.lmu.de/lemming`

[9] `https://github.com/ZurichNLP/coling2018-neural-transition-based-morphology`

with character-level alignments learned in a preprocessing step using an alignment model, and it has proved to be competitive in low resource scenarios. (3) Our naive **Baseline** outputs the most frequent lemma (or one lemma at random from the options that are equally frequent) for words observed in training. For unseen words it outputs the wordform itself. (4) We also try a baseline data augmentation approach (**AE Aug Baseline**) inspired by Bergmanis et al. (2017) and Kann and Schütze (2017), who showed that adding training examples where the network simply learns to auto-encode corpus words can improve morphological inflection results in low-resource settings. The AE Aug Baseline is a variant of Lematus 0-ch which augments the UDT lemmatization examples by auto-encoding the inflected forms of the UM examples (i.e., it just treats them as corpus words). Comparing AE Aug Baseline to Lematus 0-ch augmented with UM lemma-inflection examples tells us whether using the UM lemma information helps more than simply auto-encoding more inflected examples.

To train the models we use the default settings for Lemming and the suggested lemmatization parameters for HMAM. We mainly follow the hyperparameters used by Bergmanis and Goldwater (2018) for Lematus; details are in Appendix B.

Languages and Training Data We conduct preliminary experiments on five development languages: Estonian, Finnish, Latvian, Polish, and Russian. In our final experiments we also add Bulgarian, Czech, Romanian, Swedish and Turkish. We vary the amount and type of training data (types vs. tokens, UDT only, UM only, or UDT plus up to 10k UM examples), as described in Section 4.

To obtain N UM-based training examples, we select the first N unambiguous UM types (with their sentence contexts) from shuffled Wikipedia sentences. For experiments with $j > 1$ examples per type, we first find all UM types with at least j sentence contexts in Wikipedia and then choose the N distinct types and their j contexts uniformly at random.

Evaluation To evaluate models' ability to lemmatize wordforms in their sentence context we follow Bergmanis and Goldwater (2018) and use the full UDT development and test sets. Unlike Bergmanis and Goldwater (2018) who reported token level lemmatization exact match accuracy, we report *type-level* micro averaged lemmatization exact match accuracy. This measure better reflects improvements on unseen words, which tend to be rare but are more important (since a most-frequent-lemma baseline does very well on seen words, as shown by Bergmanis and Goldwater (2018)).

		Ambig.	**Unseen**	**All**
Tokens	*Baseline*	41.0	26.6	31.0
	Lemming	38.2	48.3	50.6
	HMAM	41.4	50.2	52.1
	Lematus 0-ch	39.9	43.7	46.8
	Lematus 20-ch	38.4	42.8	45.8
Types	*Baseline*	45.0	26.6	32.4
	Lemming	N/A	N/A	N/A
	HMAM	41.8	53.7	56.3
	Lematus 0-ch	42.5	53.7	55.1
	Lematus 20-ch	43.1	51.7	54.9

Table 2: Average type level lemmatization exact match accuracy on five development languages in type and token based training data scenarios. Colour-scale is computed over the whole *Ambig.* column and over all but *Baseline* rows for the other columns.

We separately report performance on unseen and ambiguous tokens. For a fair comparison across scenarios with different training sets, we count as unseen only words that are not ambiguous and are absent from *all* training sets/scenarios introduced in Section 4. Due to the small training sets, between 70-90% of dev set types are classed as unseen in each language. We define a type as ambiguous if the empirical entropy over its lemmas is greater than 0.1 in the full original UDT training splits.[10] According to this measure, only 1.2-5.3% of dev set types are classed as ambiguous in each language.

Significance Testing All systems are trained and tested on ten languages. To test for statistically significant differences between the results of two systems we use a Monte Carlo method: for each set of results (i.e. a set of 10 numerical values) we generate 10000 random samples, where each sample swaps the results of the two systems for each language with a probability of 0.5. We then obtain a p-value as the proportion of samples for which the difference on average was at least as large as the difference observed in our experiments.

4 Experiments, Results, and Discussion

Types vs. Tokens and Context in Very Low Resource Settings We compare training on the first

---

[10] This measure, *adjusted ambiguity*, was defined by Kirefu (2018), who noticed that many frequent wordforms appear to have multiple lemmas due to annotation errors. The adjusted ambiguity filters out these cases.

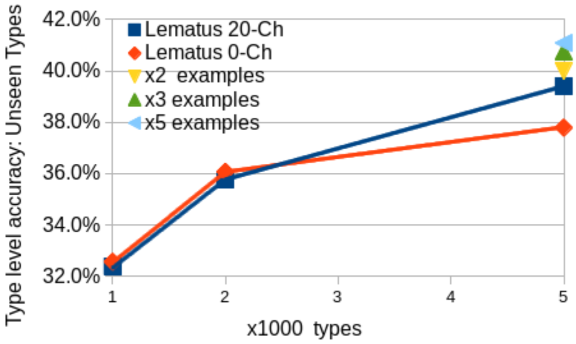

Figure 1: Average type level lemmatization exact match accuracy on unseen words of five development languages. X-axis: thousands of types in training data.

1k tokens vs. first 1k distinct types of the UDT training sets. Table 2 shows that if only 1k examples are available, using types is clearly better for all systems. Although Lematus does relatively poorly on the token data, it benefits the most from switching to types, putting it on par with HMAM and suggesting is it likely to benefit more from additional type data. Lemming requires token-based data, but does worse than HMAM (a context-free method) in the token-based setting, and we also see no benefit from context in comparing Lematus 20-ch vs Lematus 0-ch. So overall, in this very low-resource scenario with no data augmentation, context does not appear to help.

Using UM + Wikipedia Only We now try training only on UM + Wikipedia examples, rather than examples from UDT. We use 1k, 2k or 5k unambiguous types from UM with a single example context from Wikipedia for each. With 5k types we also try adding more example contexts (2, 3, or 5 examples for each type).

Figure 1 presents the results (for unseen words only). As with the UDT experiments, there is little difference between Lematus 20-ch and Lematus 0-ch in the smallest data setting. However, when the number of training types increases to 5k, the benefits of context begin to show, with Lematus 20-ch yielding a 1.6% statistically significant ($p < 0.001$) improvement over Lematus 0-ch. The results for increasing the number of examples per type are numerically higher than the one-example case, but the differences are not statistically significant.

It is worth noting that the accuracy even with 5k UM types is considerably lower than the accuracy of the model trained on only 1k UDT types (see Table 2). We believe this discrepancy is due to the issues of biased/incomplete data noted above.

	DEVELOPMENT			TEST
	Ambig.	*Unseen*	*All*	*All*
	1k UDT types (No augmentation)			
Baseline	**49.1**	30.8	36.7	-
HMAM	46.3	**58.9**†‡	**61.5**†‡	**62.6**†‡
Lematus 0-ch	46.5	55.0	58.5	59.1‡
Lematus 20-ch	45.0	54.3	57.7	57.7
	1k UDT types + 1k UM types			
Baseline	45.9	30.8	38.4	-
AE Aug Baseline	45.6	57.5	60.4	60.8
HMAM	45.9	60.2	64.2	64.3
Lematus 0-ch	46.6	59.0	63.4	63.6
Lematus 20-ch	**49.8***	**61.7***†	**65.5***†	**65.3**†
	1k UDT types + 5k UM types			
Baseline	**55.4***†‡	30.7	41.7	-
AE Aug Baseline	46.0	58.8	61.3	61.6
HMAM	46.7	60.8	65.7	65.7
Lematus 0-ch	46.2	61.5	66.1	66.4
Lematus 20-ch	48.6	**65.4***†	**69.2***†	**69.5** *†
	1k UDT types + 10k UM types			
Baseline	**54.9***†	31.2	43.5	-
AE Aug Baseline	46.3	58.6	61.2	61.7
HMAM	45.4	60.8	65.5	65.3
Lematus 0-ch	45.5	62.1	66.4	66.4
Lematus 20-ch	49.5*	**66.7***†	**70.6***†	**70.9***†

Table 3: Average lemmatization accuracy for all 10 languages, trained on 1k UDT types (No aug.), or 1k UDT plus 1k, 5k, or 10k UM types with contexts from Wikipedia. The numerically highest scores in each data setting are bold; *, †, and ‡ indicate statistically significant improvements over HMAM (Makarov and Clematide, 2018b), Lematus 0-ch and 20-ch, respectively (all $p < 0.05$; see text for details). Colour-scale is computed over the whole *Ambig.* column and over all but *Baseline* rows for the other columns.

For example, we analyzed the Latvian data and found that the available tables for nouns, verbs, and adjectives give rise to 78 paradigm slots. The 17 POS tags in UDT give rise to about 10 times as many paradigm slots, although only 448 are present in the unseen words of the dev set. Of these, 197 are represented amongst the 1k UDT training types, whereas only 25 are included in the 1k UM training types. As a result, about 72% of the unseen types of dev set have no representative of their paradigm slot in 1k types of UM, whereas this figure is only 17% for the 1k types of UDT.

Data Augmentation Although UM + Wikipedia examples alone are not sufficient to train a good lemmatizer, they might improve a low-resource baseline trained on UDT data. To see, we augmented the 1k UDT types with 1k, 5k or 10k UM

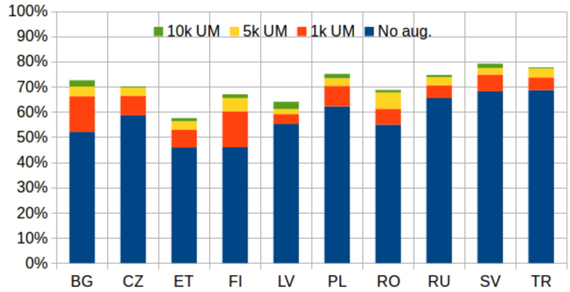

Figure 2: Lematus 20-ch lemmatization accuracy for each language on all types in the dev sets.

types with contexts from Wikipedia.

Table 3 summarizes the results, showing that despite the lower quality of the UM + Wikipedia examples, using them improves results of all systems, and more so with more examples. Improvements are especially strong for unseen types, which constitute more than 70% of types in the dev set. Furthermore, the benefit of the additional UM examples is above and beyond the effect of auto-encoding (AE Aug Baseline) for all systems in all data scenarios.

Considering the two context-free models, HMAM does better on the un-augmented 1k UDT data, but (as predicted by our results above) it benefits less from data augmentation than does Lematus 0-ch, so with added data they are statistically equivalent ($p = 0.07$ on the test set with 10k UM).

More importantly, Lematus 20-ch begins to outperform the context-free models with as few as 1k UM + Wikipedia examples, and the difference increases with more examples, eventually reaching over 4% better on the test set than the next best model (Lematus 0-ch) when 10k UM + Wikipedia examples are used ($p < 0.001$) This indicates that the system can learn useful contextual cues even from unambiguous training examples.

Finally, Figure 2 gives a breakdown of Lematus 20-ch dev set accuracy for individual languages, showing that data augmentation helps consistently, although results suggest diminishing returns.

Data Augmentation in Medium Resource Setting To examine the extent to which augmented data can help in the medium resource setting of 10k continuous tokens of UDT used in previous work, we follow Bergmanis and Goldwater (2018) and train Lematus 20-ch models for all ten languages using the first 10k tokens of UDT and compare them with models trained on 10k tokens of UDT augmented with 10k UM types. To provide a better comparison of our results, we report both the type and the token level development set accuracy. First of all, Table 4 shows that training on 10k continuous tokens of UDT yields a token level accuracy that is about 8% higher than when using the 1k types of UDT augmented with 10k UM types—the best-performing data augmentation systems (see Table 3). Again, we believe this performance gap is due to the issues with the biased/incomplete data noted above. For example, we analyzed errors that were unique to the model trained on the Latvian augmented data and found that 41% of the errors were due to wrongly lemmatized words other than nouns, verbs, and adjectives—the three POSs with available inflection tables in UM. For instance, improperly lemmatized pronouns amounted to 14% of the errors on the Latvian dev set. Table 4 also shows that UM examples with Wikipedia contexts benefit lemmatization not only in the low but also the medium resource setting, yielding statistically significant type and token level accuracy gains over models trained on 10k UDT continuous tokens alone (for both Unseen and All $p < 0.001$).

Type accuracy:	**Ambig.**	**Unseen**	**All**
1k UDT+10k UM	49.5	66.7	70.6
10k UDT tok.	59.6	71.4	76.6
10k UDT tok.+10k UM	**60.8**	**75.1**	**80.1**
Token accuracy:	**Ambig.**	**Uns.**	**All**
1k UDT+10k UM	55.5	66.5	77.0
10k UDT tok.	**72.4**	72.5	85.3
10k UDT tok.+10k UM	72.3	**75.3**	**87.3**

Table 4: Lematus 20-ch average lemmatization type and token accuracy for all 10 languages, trained on 1k UDT types, 1k UDT augmented with 10k UM types, 10k UDT continuous tokens, or 10k UDT continuous tokens augmented with 10k UM types. Unless specified otherwise data consists of distinct types.

5 Conclusion

We proposed a training data augmentation method that combines the efficiency of type-based learning and the expressive power of a context-sensitive lemmatization model. The proposed method uses Wikipedia sentences to provide contextualized examples for unambiguous inflection-lemma pairs from UniMorph tables. These examples are noisy and biased, but nevertheless they improve lemmatization accuracy on all ten languages both in low (1k) and medium (10k) resource settings. In particular, we showed that context is helpful, both overall and especially on unseen words—the first work we know of to demonstrate improvements from context in a very low-resource setting.

A Lematus Training

Lematus is implemented using the *Nematus* machine translation toolkit[11]. We use default training parameters of Lematus as specified by Bergmanis and Goldwater (2018) except for early stopping with patience (Prechelt, 1998) which we increase to 20. Similar to Bergmanis and Goldwater (2018) we use the first epochs as a burn-in period, after which we validate the current model by its lemmatization exact match accuracy on the *first 3k instances* of development set and save this model if it performs better than the previous best model. We choose a burn-in period of 20 and validation interval of 5 epochs for models that we train on datasets up to 2k instances and a burn-in period of 10 and validation interval of 2 epochs for others. As we work with considerably smaller datasets than Bergmanis and Goldwater (2018) we reduce the effective model size and increase the rate of convergence by tying the input embeddings of the encoder, the decoder and the softmax output embeddings (Press and Wolf, 2017).

B Data Preparation

Wikipedia database dumps contain XML structured articles that are formatted using the *wikitext* markup language. To obtain wordforms in their sentence context we 1) use *WikiExtractor*[12] to extract plain text from Wikipedia database dumps, followed by scripts from *Moses* statistical machine translation system[13] (Koehn et al., 2007) to 2) split text into sentences (*split-sentences.perl*), and 3) extract separate tokens (*tokenizer.perl*). Finally, we shuffle the extracted sentences to encourage homogeneous type distribution across the entire text.

A Structural Probe for Finding Syntax in Word Representations

Abstract

Recent work has improved our ability to detect linguistic knowledge in word representations. However, current methods for detecting syntactic knowledge do not test whether syntax trees are represented in their entirety. In this work, we propose a *structural probe*, which evaluates whether syntax trees are embedded in a linear transformation of a neural network's word representation space. The probe identifies a linear transformation under which squared L2 distance encodes the distance between words in the parse tree, and one in which squared L2 norm encodes depth in the parse tree. Using our probe, we show that such transformations exist for both ELMo and BERT but not in baselines, providing evidence that entire syntax trees are embedded implicitly in deep models' vector geometry.

1 Introduction

As pretrained deep models that build contextualized representations of language continue to provide gains on NLP benchmarks, understanding what they learn is increasingly important. To this end, probing methods are designed to evaluate the extent to which representations of language encode particular knowledge of interest, like part-of-speech (Belinkov et al., 2017), morphology (Peters et al., 2018a), or sentence length (Adi et al., 2017). Such methods work by specifying a *probe* (Conneau et al., 2018; Hupkes et al., 2018), a supervised model for finding information in a representation.

Of particular interest, both for linguistics and for building better models, is whether deep models' representations encode syntax (Linzen, 2018). Despite recent work (Kuncoro et al., 2018; Peters et al., 2018b; Tenney et al., 2019), open questions remain as to whether deep contextual models encode entire parse trees in their word representations.

In this work, we propose a *structural probe*, a simple model which tests whether syntax trees are consistently embedded in a linear transformation of a neural network's word representation space. Tree structure is embedded if the transformed space has the property that squared L2 distance between two words' vectors corresponds to the number of edges between the words in the parse tree. To reconstruct edge directions, we hypothesize a linear transformation under which the squared L2 norm corresponds to the depth of the word in the parse tree. Our probe uses supervision to find the transformations under which these properties are best approximated for each model. If such transformations exist, they define inner products on the original space under which squared distances and norms encode syntax trees – even though the models being probed were never given trees as input or supervised to reconstruct them. This is a structural property of the word representation space, akin to vector offsets encoding word analogies (Mikolov et al., 2013). Using our probe, we conduct a targeted case study, showing that ELMo (Peters et al., 2018a) and BERT (Devlin et al., 2019) representations embed parse trees with high consistency in contrast to baselines, and in a low-rank space.[1]

In summary, we contribute a simple structural probe for finding syntax in word representations (§2), and experiments providing insights into and examples of how a low-rank transformation recovers parse trees from ELMo and BERT representations (§3,4). Finally, we discuss our probe and limitations in the context of recent work (§5).

2 Methods

Our goal is to design a simple method for testing whether a neural network embeds each sentence's

Minneapolis, Minnesota, June 2 - June 7, 2019.

dependency parse tree in its contextual word representations – a structural hypothesis. Under a reasonable definition, to embed a graph is to learn a vector representation of each node such that geometry in the vector space—distances and norms—approximates geometry in the graph (Hamilton et al., 2017). Intuitively, why do parse tree distances and depths matter to syntax? The distance metric—the path length between each pair of words—recovers the tree T simply by identifying that nodes u, v with distance $d_T(u, v) = 1$ are neighbors. The node with greater norm—depth in the tree—is the child. Beyond this identity, the distance metric explains hierarchical behavior. For example, the ability to perform the classic hierarchy test of subject-verb number agreeement (Linzen et al., 2016) in the presence of "attractors" can be explained as the verb (V) being closer in the tree to its subject (S) than to any of the attractor nouns:

Intuitively, if a neural network embeds parse trees, it likely will not use its entire representation space to do so, since it needs to encode many kinds of information. Our probe learns a linear transformation of a word representation space such that the transformed space embeds parse trees across all sentences. This can be interpreted as finding the part of the representation space that is used to encode syntax; equivalently, it is finding the distance on the original space that best fits the tree metrics.

2.1 The structural probe

In this section we provide a description of our proposed structural probe, first discussing the distance formulation. Let $\mathcal{M}$ be a model that takes in a sequence of n words $w^\ell_{1:n}$ and produces a sequence of vector representations $\mathbf{h}^\ell_{1:n}$, where ℓ identifies the sentence. Starting with the dot product, recall that we can define a family of inner products, $\mathbf{h}^T A \mathbf{h}$, parameterized by any positive semi-definite, symmetric matrix $A \in \mathbb{S}^{m\times m}_{+}$. Equivalently, we can view this as specifying a linear transformation $B \in \mathbb{R}^{k\times m}$, such that $A = B^T B$. The inner product is then $(B\mathbf{h})^T(B\mathbf{h})$, the norm of $\mathbf{h}$ once transformed by B. Every inner product corresponds to a distance metric. Thus, our family of squared distances is defined as:

$$d_B(\mathbf{h}^\ell_i, \mathbf{h}^\ell_j)^2 = \left(B(\mathbf{h}^\ell_i - \mathbf{h}^\ell_j)\right)^T \left(B(\mathbf{h}^\ell_i - \mathbf{h}^\ell_j)\right) \tag{1}$$

where i, j index the word in the sentence.[2] The parameters of our probe are exactly the matrix B, which we train to recreate the tree distance between all pairs of words (w^ℓ_i, w^ℓ_j) in all sentences T^ℓ in the training set of a parsed corpus. Specifically, we approximate through gradient descent:

$$\min_B \sum_\ell \frac{1}{|s^\ell|^2} \sum_{i,j} \left| d_{T^\ell}(w^\ell_i, w^\ell_j) - d_B(\mathbf{h}^\ell_i, \mathbf{h}^\ell_j)^2 \right|$$

where $|s^\ell|$ is the length of the sentence; we normalize by the square since each sentence has $|s^\ell|^2$ word pairs.

2.2 Properties of the structural probe

Because our structural probe defines a valid distance metric, we get a few nice properties for free. The simplest is that distances are guaranteed nonnegative and symmetric, which fits our probing task. Perhaps most importantly, the probe tests the concrete claim that there exists an inner product on the representation space whose squared distance—a global property of the space—encodes syntax tree distance. This means that the model not only encodes which word is governed by which other word, but each word's proximity to every other word in the syntax tree.[3] This is a claim about the structure of the representation space, akin to the claim that analogies are encoded as vector-offsets in uncontextualized word embeddings (Mikolov et al., 2013). One benefit of this is the ability to query the nature of this structure: for example, the dimensionality of the transformed space (§ 4.1).

2.3 Tree depth structural probes

The second tree property we consider is the *parse depth* $\|w_i\|$ of a word w_i, defined as the number of edges in the parse tree between w_i and the root of the tree. This property is naturally represented as a norm – it imposes a total order on the words in the sentence. We wish to probe to see if there exists a squared norm on the word representation

---

[2] As noted in Eqn 1, in practice, we find that approximating the parse tree distance and norms with the *squared* vector distances and norms consistently performs better. Because a distance metric and its square encode exactly the same parse trees, we use the squared distance throughout this paper. Also strictly, since A is not positive definite, the inner product is indefinite, and the distance a pseudometric. Further discussion can be found in our appendix.

[3] Probing for distance instead of headedness also helps avoid somewhat arbitrary decisions regarding PP headedness, the DP hypothesis, and auxiliaries, letting the representation "disagree" on these while still encoding roughly the same global structure. See Section 5 for more discussion.

Method	Distance UUAS	Distance DSpr.	Depth Root%	Depth NSpr.
Linear	48.9	0.58	2.9	0.27
ELMo0	26.8	0.44	54.3	0.56
Decay0	51.7	0.61	54.3	0.56
Proj0	59.8	0.73	64.4	0.75
ELMo1	77.0	0.83	86.5	0.87
BERTbase7	79.8	0.85	88.0	0.87
BERTlarge15	**82.5**	0.86	89.4	0.88
BERTlarge16	81.7	**0.87**	**90.1**	**0.89**

Table 1: Results of structural probes on the PTB WSJ test set; baselines in the top half, models hypothesized to encode syntax in the bottom half. For the distance probes, we show the Undirected Unlabeled Attachment Score (UUAS) as well as the average Spearman correlation of true to predicted distances, DSpr. For the norm probes, we show the root prediction accuracy and the average Spearman correlation of true to predicted norms, NSpr.

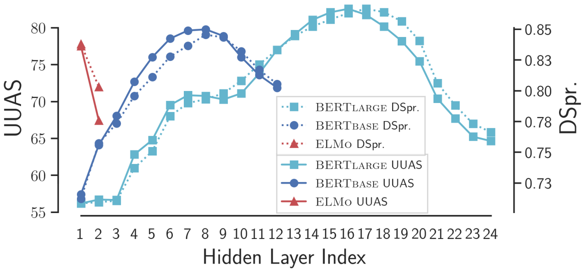

Figure 1: Parse distance UUAS and distance Spearman correlation across the BERT and ELMo model layers.

space that encodes this tree norm. We replace the vector distance function $d_B(\mathbf{h}_i, \mathbf{h}_j)$ with the squared vector norm $\|\mathbf{h}_i\|_B^2$, replacing Equation 1 with $\|\mathbf{h}_i\|_A = (B\mathbf{h}_i)^T(B\mathbf{h}_i)$ and training B to recreate $\|w_i\|$. Like the distance probe, this norm formulation makes a concrete claim about the structure of the vector space.

3 Experiments

Using our probe, we evaluate whether representations from ELMo and BERT, two popular English models pre-trained on language modeling-like objectives, embed parse trees according to our structural hypothesis. Unless otherwise specified, we permit the linear transformation B to be potentially full-rank (i.e., B is square.) Later, we explore what rank of transformation is actually necessary for encoding syntax (§ 4.1).

Representation models We use the 5.5B-word pre-trained ELMo weights for all ELMo representations, and both BERT-base (cased) and BERT-large (cased). The representations we evaluate are denoted ELMoK, BERTbaseK, BERTlargeK, where K indexes the hidden layer of the corresponding model. All ELMo and BERT-large layers are dimensionality 1024; BERT-base layers are dimensionality 768.

Data We probe models for their ability to capture the Stanford Dependencies formalism (de Marneffe et al., 2006), claiming that capturing most aspects of the formalism implies an understanding of English syntactic structure. To this end, we obtain fixed word representations for sentences of the parsing train/dev/test splits of the Penn Treebank (Marcus et al., 1993), with no pre-processing.[4]

Baselines Our baselines should encode features useful for training a parser, but not be capable of parsing themselves, to provide points of comparison against ELMo and BERT. They are as follows:

Linear : The tree resulting from the assumption that English parse trees form a left-to-right chain. A model that encodes the positions of words should be able to meet this baseline.

ELMo0 : Strong character-level word embeddings with no contextual information. As these representations lack even position information, we should be completely unable to find syntax trees embedded.

Decay0 : Assigns each word a weighted average of all ELMo0 embeddings in the sentence. The weight assigned to each word decays exponentially as $\frac{1}{2^d}$, where d is the linear distance between the words.

Proj0 : Contextualizes the ELMo0 embeddings with a randomly initialized BiLSTM layer of dimensionality identical to ELMo (1024), a surprisingly strong baseline for contextualization (Conneau et al., 2018).

3.1 Tree distance evaluation metrics

We evaluate models on how well the predicted distances between all pairs of words reconstruct gold parse trees and correlate with the parse trees' distance metrics. To evaluate tree reconstruction, we take each test sentence's predicted parse tree distances and compute the minimum spanning tree. We evaluate the predicted tree on undirected

---

[4] Since BERT constructs subword representations, we align subword vectors with gold Penn Treebank tokens, and assign each token the average of its subword representation. This thus represents a lower-bound on BERT's performance.

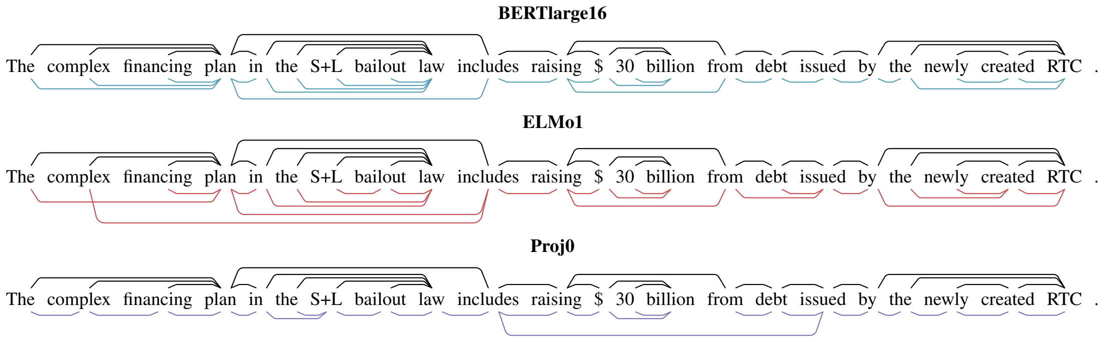

Figure 2: Minimum spanning trees resultant from predicted squared distances on BERTLARGE16 and ELMO1 compared to the best baseline, PROJ0. Black edges are the gold parse, above each sentence; blue are BERTLARGE16, red are ELMO1, and purple are PROJ0.

attachment score (UUAS)—the percent of undirected edges placed correctly—against the gold tree. For distance correlation, we compute the Spearman correlation between true and predicted distances for each word in each sentence. We average these correlations between all sentences of a fixed length, and report the macro average across sentence lengths 5–50 as the "distance Spearman (DSpr.)" metric.[5]

3.2 Tree depth evaluation metrics

We evaluate models on their ability to recreate the order of words specified by their depth in the parse tree. We report the Spearman correlation betwen the true depth ordering and the predicted ordering, averaging first between sentences of the same length, and then across sentence lengths 5–50, as the "norm Spearman (NSpr.)". We also evaluate models' ability to identify the root of the sentence as the least deep, as the "root%".[6]

4 Results

We report the results of parse distance probes and parse depth probes in Table 1. We first confirm that our probe can't simply "learn to parse" on top of any informative representation, unlike parser-based probes (Peters et al., 2018b). In particular, ELMO0 and DECAY0 fail to substantially outperform a right-branching-tree oracle that encodes the linear sequence of words. PROJ0, which has all of the representational capacity of ELMO1 but none of the training, performs the best among the baselines. Upon inspection, we found that our probe on PROJ0 improves over the linear hypothesis with mostly simple deviations from linearity, as visualized in Figure 2.

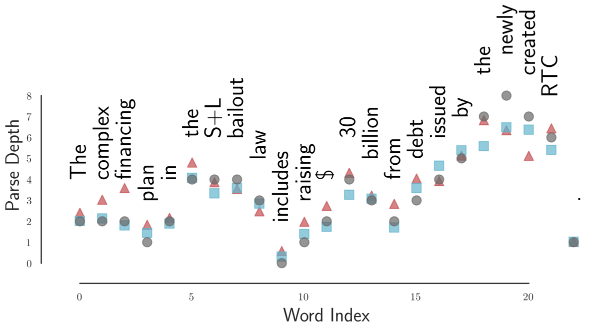

Figure 3: Parse tree depth according to the gold tree (black, circle) and the norm probes (squared) on ELMO1 (red, triangle) and BERTLARGE16 (blue, square).

We find surprisingly robust syntax embedded in each of ELMo and BERT according to our probes. Figure 2 shows the surprising extent to which a minimum spanning tree on predicted distances recovers the dependency parse structure in both ELMo and BERT. As we note however, the distance metric itself is a global notion; all pairs of words are trained to know their distance – not just which word is their head; Figure 4 demonstrates the rich structure of the true parse distance metric recovered by the predicted distances. Figure 3 demonstrates the surprising extent to which the depth in the tree is encoded by vector norm after the probe transformation. Between models, we find consistently that BERTLARGE performs better than BERTBASE, which performs better than ELMO.[7] We also find, as in Peters et al. (2018b), a clear difference in syntactic information between layers; Figure 1 reports the performance

---

[5] The 5–50 range is chosen to avoid simple short sentences as well as sentences so long as to be rare in the test data.

[6] In UUAS and "root%" evaluations, we ignore all punctuation tokens, as is standard.

[7] It is worthwhile to note that our hypotheses were developed while analyzing LSTM models like ELMo, and applied without modification on the self-attention based BERT models.

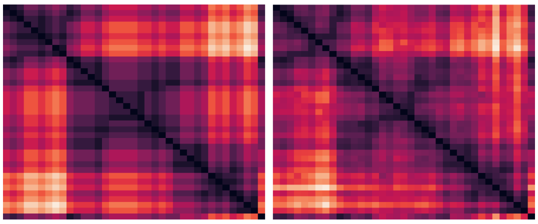

Figure 4: (left) Matrix representing gold tree distances between all pairs of words in a sentence, whose linear order runs top-to-bottom and left-to-right. Darker colors indicate close words, lighter indicate far. (right) The same distances as embedded by BERTLARGE16 (squared). More detailed graphs available in the Appendix.

of probes trained on each layer of each system.

4.1 Analysis of linear transformation rank

With the result that there exists syntax-encoding vector structure in both ELMo and BERT, it is natural to ask how compactly syntactic information is encoded in the vector space. We find that in both models, the effective rank of linear transformation required is surprisingly low. We train structural probes of varying k, that is, specifying a matrix $B \in \mathbb{R}^{k \times m}$ such that the transformed vector $B\mathbf{h}$ is in $\mathbb{R}^k$. As shown in Figure 5, increasing k beyond 64 or 128 leads to no further gains in parsing accuracy. Intuitively, larger k means a more expressive probing model, and a larger fraction of the representational capacity of the model being devoted to syntax. We also note with curiosity that the three models we consider all seem to require transformations of approximately the same rank; we leave exploration of this to exciting future work.

5 Discussion & Conclusion

Recent work has analyzed model behavior to determine if a model understands hierarchy and other linguistic phenomena (Linzen, 2018; Gulordava et al., 2018; Kuncoro et al., 2018; Linzen and Leonard, 2018; van Schijndel and Linzen, 2018; Tang et al., 2018; Futrell et al., 2018). Our work extends the literature on linguistic probes, found at least in (Peters et al., 2018b; Belinkov et al., 2017; Blevins et al., 2018; Hupkes et al., 2018). Conneau et al. (2018) present a task similar to our parse depth prediction, where a sentence representation vector is asked to classify the maximum parse depth ever achieved in the sentence. Tenney et al. (2019) evaluates a complementary task to ours, training probes to learn the *labels* on structures when the gold structures themselves are given. Peters et al. (2018b) evaluates the extent to which constituency trees can be extracted from hidden states, but uses a probe of considerable complexity, making less concrete hypotheses about how the information is encoded.

Probing tasks and limitations Our reviewers rightfully noted that one might just probe for headedness, as in a bilinear graph-based dependency parser. More broadly, a deep neural network probe of some kind is almost certain to achieve higher parsing accuracies than our method. Our task and probe construction are designed not to test for some notion of syntactic knowledge broadly construed, but instead for an extremely strict notion where all pairs of words know their syntactic distance, and this information is a global structural property of the vector space. However, this study is limited to testing that hypothesis, and we foresee future probing tasks which make other tradeoffs between probe complexity, probe task, and hypotheses tested.

In summary, through our structural probes we demonstrate that the structure of syntax trees emerges through properly defined distances and norms on two deep models' word representation spaces. Beyond this actionable insight, we suggest our probe may be useful for testing the existence of different types of graph structures on any neural representation of language, an exciting avenue for future work.

6 Acknowledgements

We would like to acknowledge Urvashi Khandelwal and Tatsunori B. Hashimoto for formative advice in early stages, Abigail See, Kevin Clark, Siva Reddy, Drew A. Hudson, and Roma Patel for helpful comments on drafts, and Percy Liang, for guidance on rank experiments. We would also like to thank the reviewers, whose helpful comments led to increased clarity and extra experiments. This research was supported by a gift from Tencent.

A Appendix: Implementation Details

A.1 Squared L2 distance vs. L2 distance

In Section 2.2, we note that while our distance probe specifies a distance metric, we recreate it with a squared vector distance; likewise, while our norm probe specifies a norm, we recreate it with a squared vector norm. We found this to be important for recreating the exact parse tree distances and norms. This does mean that in order to recreate the exact scalar values of the parse tree structures, we need to use the squared vector quantities. This may be problematic, since for example squared distance doesn't obey the triangle inequality, whereas a valid distance metric does.

However, we note that in terms of the graph structures encoded, distance and squared distance are identical. After training with the squared vector distance, we can square-root the predicted quantities to achieve a distance metric. The relative ordering between all pairs of words will be unchanged; the same tree is encoded either way, and none of our quantitative metrics will change; however, the exact scalar distances will differ from the true tree distances.

This raises a question for future work as to why squared distance works better than distance, and beyond that, what function of the L2 distance (or perhaps, what L^p distance) would best encode tree distances. It is possibly related to the gradients of the loss with respect to the function of the distance, as well as how amenable the function is to matching the exact scalar values of the tree distances.

A.2 Probe training details

All probes are trained to minimize L1 loss of the predicted squared distance or squared norm w.r.t. the true distance or norm. Optimization is performed using the Adam optimizer (Kingma and Ba, 2014) initialized at learning rate 0.001, with $\beta_1 = .9, \beta_2 = .999, \epsilon = 10^{-8}$. Probes are trained to convergence, up to 40 epochs, with a batch size of 20. For depth probes, loss is summed over all predictions in a sentence, normalized by the length of the sentence, and then summed over all sentences in a batch before a gradient step is taken. For distance probes, normalization is performed by the square of the length of the sentence. At each epoch, dev loss is computed; if the dev loss does not achieve a new minimum, the optimizer is reset (no momentum terms are kept) with an initial learning rate multiplied by 0.1. All models were implemented in both DyNet (Neubig et al., 2017), and in PyTorch (Paszke et al., 2017).

B Appendix: Extra examples

In this section we provide additional examples of model behavior, including baseline model behavior, across parse distance prediction and parse depth prediction. In Figure 6 and Figure 7, we present a single sentence with dependency trees as extracted from many of our models and baselines. In Figure 8, we present tree depth predictions on a complex sentence from ELMO1, BERTLARGE16, and our baseline PROJ0. Finally, in Figure 9, we present gold parse distances and predicted squared parse distances between all pairs of words in large, high-resolution format.

Abstract

This paper seeks to model human language by the mathematical framework of quantum physics. With the well-designed mathematical formulations in quantum physics, this framework unifies different linguistic units in a single complex-valued vector space, e.g. words as particles in quantum states and sentences as mixed systems. A complex-valued network is built to implement this framework for semantic matching. With well-constrained complex-valued components, the network admits interpretations to explicit physical meanings. The proposed complex-valued network for matching (CNM)[1] achieves comparable performances to strong CNN and RNN baselines on two benchmarking question answering (QA) datasets.

1 Introduction

There is a growing concern on the interpretability of neural networks. Along with the increasing power of neural networks comes the challenge of interpreting the numerical representation of network components into human-understandable language. Lipton (2018) points out two important factors for a model to be interpretable, namely *post-hoc interpretability* and *transparency*. The former refers to explanations of why a model works after it is executed, while the latter concerns self-explainability of components through some mechanisms in the designing phase of the model.

We seek inspirations from quantum physics to build transparent and post-hoc interpretable networks for modeling human language. The emerging research field of cognition suggests that there exist quantum-like phenomena in human cognition (Aerts and Sozzo, 2014), especially language understanding (Bruza et al., 2008). Intuitively, a sentence can be treated as a physical system with multiple words (like particles), and these words are usually polysemous (superposed) and correlated (entangled) with each other. Motivated by these existing works, we aim to investigate the following Research Question (RQ).

RQ1*: Is it possible to model human language with the mathematical framework of quantum physics?*

Towards this question, we build a novel quantum-theoretic framework for modeling language, in an attempt to capture the quantumness in the cognitive aspect of human language. The framework models different linguistic units as quantum states with the adoption of quantum probability (QP), which is the mathematical framework of quantum physics that models uncertainly on a uniform *Semantic Hilbert Space* (SHS).

Complex values are crucial in the mathematical framework of characterizing quantum physics. In order to preserve physical properties, the linguistic units have to be represented as complex vectors or matrices. This naturally gives rise to another research question:

RQ2*: Can we benefit from the complex-valued representation of human language in a real natural language processing (NLP) scenario?*

To this end, we formulate a linguistic unit as a complex-valued vector, and link its length and direction to different physical meanings: the length represents the relative weight of the word while the direction is viewed as a superposition state. The superposition state is further represented in an amplitude-phase manner, with amplitudes corresponding to the lexical meaning and phases implicitly reflecting the higher-level semantic aspects such as polarity, ambiguity or emotion.

In order to evaluate the above framework, we implement it as a complex-valued network (CNM) for semantic matching. The network is applied to the question answering task, which is the most

typical matching task that aims at selecting the best answer for a question from a pool of candidates. In order to facilitate local matching with n-grams of a sentence pair, we design a local matching scheme in CNM. Most of State-of-the-art QA models are mainly based on Convolution Neural Network (CNN), Recurrent Neural Network (RNN) and many variants thereof (Wang and Nyberg, 2015; Yang et al., 2016; Hu et al., 2014; Tan et al., 2015). However, with opaque structures of convolutional kernels and recurrent cells, these models are hard to understand for humans. We argue that our model is advantageous in terms of interpretability.

Our proposed CNM is transparent in that it is designed in alignment with quantum physics. Experiments on benchmarking QA datasets show that CNM has comparable performance to strong CNN and RNN baselines, whilst admitting post-hoc interpretations to human-understandable language. We therefore answer RQ1 by claiming that it is possible to model human language with the proposed quantum-theoretical framework in this paper. Furthermore, an ablation study shows that the complex-valued word embedding performs better than its real counterpart, which allows us to answer RQ2 by claiming that we benefit from the complex-valued representation of natural language on the QA task.

2 Background

Here we briefly introduce quantum probability and discuss a relevant work on quantum-inspired framework for QA.

2.1 Quantum Probability

Quantum probability provides a sound explanation for the phenomena and concepts of quantum mechanics, by formulating events as subspaces in a vector space with projective geometry.

2.1.1 Quantum Superposition

Quantum Superposition is one of the fundamental concepts in Quantum Physics, which describes the uncertainty of a single particle. In the micro world, a particle like a photon can be in multiple mutual-exclusive basis states simultaneously with a probability distribution. In a two-dimensional example, two basis vectors are denoted as $|0\rangle$ and $|1\rangle$[2]. *Superposition* is implemented to model a general state which is a linear combination of basis vectors with complex-valued weights such that

$$|\phi\rangle = \alpha_0 |0\rangle + \alpha_1 |1\rangle , \qquad (1)$$

where α_0 and α_1 are complex scalars satisfying $0 \leq |\alpha_0|^2 \leq 1, 0 \leq |\alpha_1|^2 \leq 1$ and $|\alpha_0|^2 + |\alpha_1|^2 = 1$. It follows that $|\phi\rangle$ is defined over the complex field. When α_0 and α_1 are non-zero values, the state $|\phi\rangle$ is said to be a superposition of the states $|0\rangle$ and $|1\rangle$, and the scalars α_0 and α_1 denote the probability amplitudes of the superposition.

2.1.2 Measurement

The uncertainty of an ensemble system with multiple particles is encapsulated as a mixed state, represented by a positive semi-definite matrix with unitary trace called *density matrix*: $\rho = \sum_i^m |\phi_i\rangle \langle\phi_i|$, where $\{|\phi_i\rangle\}_{i=0}^m$ are pure states like Eq. 1. In order to infer the probabilistic properties of ρ in the state space, Gleason's theorem (Gleason, 1957; Hughes, 1992) is used to calculate probability to observe x through projection measurements $|x\rangle \langle x|$ that is a rank-one projector denoted as a outer product of $|x\rangle$.

$$p_x(\rho) = \langle x| \rho |x\rangle = tr(\rho |x\rangle \langle x|) \qquad (2)$$

The measured probability $p_x(\rho)$ is a non-negative real-valued scalar, since both ρ and $|x\rangle \langle x|$ are Hermitian. The unitary trace property guarantees $\sum_{x \in X} p_x(\rho) = 1$ for X being a set of orthogonal basis states.

2.2 Neural Network based Quantum-like Language Model (NNQLM)

Based on the density matrices representation for documents in information retrieval (Van Rijsbergen, 2004; Sordoni et al., 2013), Zhang et al. (2018a) built a neural network with density matrix for question answering. This Neural Network based Quantum Language Model (NNQLM) embeds a word as a unit vector and a sentence as a real-valued density matrix. The distance between a pair of density matrices is obtained by extracting features of their matrix multiplication in two ways: NNQLM-I directly takes the trace of the resulting matrix, while NNQLM-II applies convolutional structures on top of the matrix to determine whether the pair of sentences match or not.

NNQLM is limited in that it does not make proper use of the full potential of probabilistic

---

[2] We here adopt the widely used Dirac notations in quantum probability, in which a *unit* vector $\vec{\mu}$ and its transpose $\vec{\mu}^T$ are denoted as a ket $|u\rangle$ and a bra $\langle u|$ respectively.

property of a density matrices.By treating density matrices as ordinary real vectors (NNQLM-I) or matrices (NNQLM-II), the full potential with complex-valued formulations is largely ignored. Meanwhile, adding convolutional layers on top of a density matrix is more of an empirical workaround than an implementation of a theoretical framework.

In contrast, a complex-valued matching network is built on top of a quantum-theoretical framework for natural language. In particular, an indirect way to measure the distance between two density matrices through trainable measurement operations, which makes advantage of the probabilistic properties of density matrices and also provides flexible matching score driven by training data.

3 Semantic Hilbert Space

Here we introduce the Semantic Hilbert Space $\mathcal{H}$ defined on a complex vector space $\mathcal{C}^n$, and three different linguistic units, namely sememes, words and word combinations on the space. The concept of semantic measurement is introduced at last.

Sememes. We assume $\mathcal{H}$ is spanned by the set of orthogonal basis states $\{|e_j\rangle\}_{j=1}^n$ for *sememes*, which are the minimum semantic units of word meanings in language universals (Goddard and Wierzbicka, 1994). The unit state $|e_j\rangle$ can be seen as a one-hot vector, i.e., the j-th element in $|e_j\rangle$ is one while other elements are zero, in order to obtain a set of orthogonal unit states. Semantic units with larger granularities are based on the set of sememe basis.

Words. Words are composed of sememes in superposition. Each word w is a superposition over all sememes $\{|e_j\rangle\}_{j=1}^n$, or equivalently a unit-length vector on $\mathcal{H}$:

$$|w\rangle = \sum_{j=1}^{n} r_j e^{i\phi_j} |e_j\rangle, \tag{3}$$

i is the imaginary number with $i^2 = -1$. In the above expression, $\{r_j\}_{j=1}^n$ are non-negative real-valued amplitudes satisfying $\sum_{j=1}^n {r_j}^2$ =1 and $\phi_j \in [-\pi, \pi]$ are the corresponding complex phases. In comparison to Eq. 1, $\{r_j e^{i\phi_j}\}_{j=0}^n$ are the polar form representation of the complex-valued scalars $\{\alpha_j\}_{j=0}^1$.

Word Combinations. We view a combination of words (e.g. phrase, n-gram, sentence or document) as a mixed system composed of individual words, and its representation is computed as follows:

$$\rho = \sum_{j}^{m} \frac{1}{m} |w_j\rangle \langle w_j|, \tag{4}$$

where m is the number of words and $|w_j\rangle$ is word superposition state in Eq. 3, allowing multiple occurrences. Eq. 4 produces a density matrix ρ for semantic composition of words. It also describes a non-classical distribution over the set of sememes: the complex-valued off-diagonal elements describes the correlations between sememes, while the diagonal entries (guaranteed to be real by its original property) correspond to a standard probability distribution. The off-diagonal elements provide our framework some potentials to model the possible interactions between the basic sememe basis, which was usually considered mutually independent with each other.

Semantic Measurements. The high-level features of a sequence of words are extracted through measurements on its mixed state. Given a density matrix ρ of a mixed state, a rank-one projector P, which is the outer product of a unit complex vector, i.e. $P = |x\rangle \langle x|$, is applied as a measurement projector. It is worth mentioning that $|x\rangle$ could be any pure state in this Hilbert space (not only limited to a specific word w). The measured probability is computed by Gleason‘s Theorem in Eq. 2.

4 Complex-valued Network for Matching

We implemented an end-to-end network for matching on the Semantic Hilbert Space. Fig. 1 shows the overall structure of the proposed Complex-valued Network for Matching (CNM). Each component of the network is further discussed in this section.

4.1 Complex-valued Embedding

On the Semantic Hilbert Space, each word w is embedded as a complex-valued vector $\vec{w}$. Here we link its length and direction to different physical meanings: the length of a vector represents the relative weight of the word while the vector direction is viewed as a superposition state. Each word w adopts a normalization into a superposition state $|w\rangle$ and a word-dependent weight $\pi(w)$:

$$|w\rangle = \frac{\vec{w}}{||\vec{w}||}, \;\; \pi(w) = ||\vec{w}||, \tag{5}$$

where $||\vec{w}||$ denotes the 2-norm length of $\vec{w}$. $\pi(w)$ is used to compute the relative weight of a word in

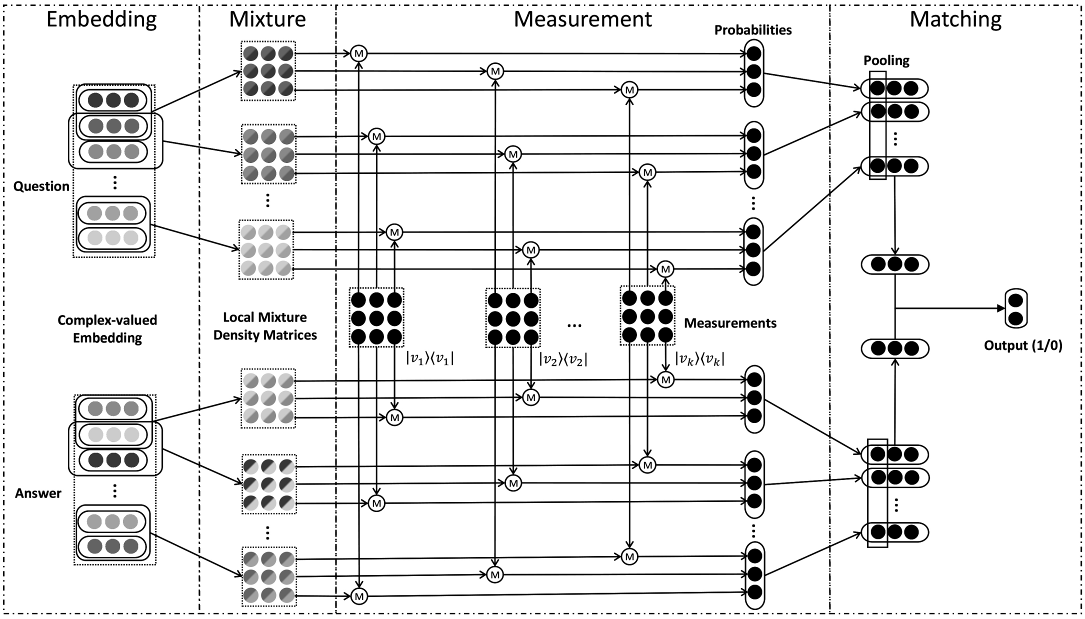

Figure 1: Architecture of Complex-valued Network for Matching. Ⓜ refers to the measurement operation in Eq. 2.

a local context window, which we will elaborate in Section 4.2.

4.2 Sentence Modeling with Local Mixture Scheme

A sentence is modeled as a combination of individual words in it. NNQLM (Zhang et al., 2018a) models a sentence as a *global mixture* of all words, which implicitly assumes a global interaction among all sentence words. This seems to be unreasonable in practice, especially for a long text segment such as a paragraph or a document, where the interaction between the first word and the last word is often negligible. Therefore, we address this limitation by proposing a *local mixture* of words, which tends to capture the semantic relations between neighboring words and undermine the long-range word dependencies. As is shown in Fig. 2, a sliding window is applied and a density matrix is constructed for a local window of length l (e.g. 3). Therefore, a sentence is composed of a sequence of density matrices for l-grams.

The representation of a local l-gram window is obtained by an improved approach over Eq. 4. In Eq. 4, each word is assigned with the same weight, which does not hold from an empirical point of view. In this study, we take the $L2$-norm of the word vector as the relative weight in a local context window for a specific word, which could be updated during training. To some extent, $L2$-norm is a measure of semantic richness of a word, i.e. the longer the vector the richer the meaning. The

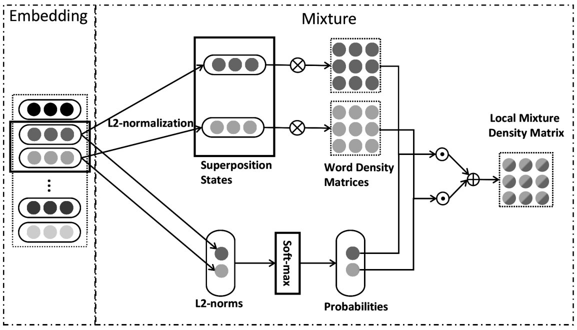

Figure 2: Architecture of local mixture component. A sliding window in the black color is applied to the sentence, generating a local mixture density matrix for each local window of length l. ⊙ means that a matrix multiplies a number with each element. ⊗ denotes the outer product of a vector with itself.

density matrix of an l-gram is computed as follows:

$$\rho = \sum_{i}^{l} p(w_i) \, |w_i\rangle \, \langle w_i|, \tag{6}$$

where the relative importance of each word $p(w_i)$ in an l-gram is the soft-max normalized word-dependent weight: $p(w_i) = \frac{e^{\pi(w_i)}}{\sum_j^l e^{\pi(w_j)}}$, where $\pi(w_i)$ is the word-dependent weight. By converting word-dependent weights to a probability distribution, a legal density matrix is produced, because $\sum_i^l p(w_i) = 1$ gives $tr(\rho) = 1$. Moreover, the weight of a word also depends on its neighboring words in a local context.

4.3 Matching of Question and Answer

In quantum information, there have been works trying to estimate a quantum state from the results of a series of measurements (Řeháček et al., 2001; Lvovsky, 2004). Inspired by these works, we introduce trainable measurements to extract density matrix features and match a pair of sentences.

Suppose a pair of sentences with length L are represented as two sets of density matrices $\{\rho_{1j}\}_{j=1}^{L}$ and $\{\rho_{2j}\}_{j=1}^{L}$ respectively. The same set of K semantic measurement operators $\{|v_k\rangle\}_{k=1}^{K}$ are applied to both sets, producing a pair of k-by-L probability matrix p^1 and p^2, where $p_{jk}^1 = \langle v_k| \rho_{1j} |v_k\rangle$ and $p_{jk}^2 = \langle v_k| \rho_{2j} |v_k\rangle$ for $k \in \{1, ..., K\}$ and $j \in \{1, ..., L\}$. A classical vector-based distances between p^1 and p^2 can be computed as the matching score of the sentence pair. By involving a set of semantic measurements, the properties of density matrix are taken into consideration in computing the density matrix distance.

We believe that this way of computing density matrix distance is both theoretically sound and applicable in practice. The trace inner product of density matrices (Zhang et al., 2018a) breaks the basic axioms of metric, namely the non-negativity, identity of indiscernibles and triangle inequality. The CNN-based feature extraction (Zhang et al., 2018a) for density matrix multiplication loses the property of density matrix as a probability distribution. Nielsen and Chuang (2010) introduced three measures namely trace distance, fidelity, and VN-divergence. However, it is computationally costly to compute these metrics and propagate the loss in an end-to-end training framework.

We set the measurements to be trainable so that the matching of question and answering can be integrated into the whole neural network, and identify the discriminative semantic measurements in a data-driven manner. From the perspective of linear discriminant analysis (LDA) (Fisher, 1936), this approach is intended to find a group of finite discriminative projection directions for a better division of different classes, but in a more sound framework inspired by quantum probability with complex-valued values. From an empirical point of view, the data-driven measurements make it flexible to match two sentences.

5 Experiments

5.1 Datasets and Evaluation Metrics

The experiments were conducted on two benchmarking question answering datasets for question answering (QA), namely TREC QA (Voorhees and Tice, 2000) and WikiQA (Yang et al., 2015). TREC QA is a standard QA dataset in the Text REtrieval Conference (TREC). WikiQA is released by Microsoft Research on open domain question answering. On both datasets, the task is to select the most appropriate answer from the candidate answers for a question, which requires a ranking of candidate answers. After removing the questions with no correct answers, the statistics of the cleaned datasets are given in the Tab. 1. Two common rank-based metrics, namely mean average precision (MAP) and mean reciprocal rank (MRR), are used to measure the performance of models.

5.2 Experiment Details

5.2.1 Baselines

We conduct a comprehensive comparison across a wide range of models. On TREC QA the experimented models include Bigram-CNN (Yu et al., 2014), three-layered Long Short-term Memory (LSTM) in combination with BM25 (LSTM-3L-BM25) (Wang and Nyberg, 2015), attention-based neural matching model (aNMM) (Yang et al., 2016), Multi-perspective CNN (MP-CNN) (He et al., 2015), CNTN (Qiu and Huang, 2015), attention-based LSTM+CNN model (LSTM-CNN-attn) (Tang et al., 2015) and pairwise word interaction modeling (PWIM) (He and Lin, 2016). On WikiQA dataset, we involve the following models into comparison: Bigram-CNN (Yu et al., 2014), CNN with word count information (CNN-Cnt) (Yang et al., 2015), QA-BILSTM (Santos et al., 2016), BILSTM with attentive pooling (AP-BILSTM) (Santos et al., 2016), and LSTM with attention (LSTM-attn) (Miao et al., 2015). On both datasets, we report the results of quantum language model (Sordoni et al., 2013) and two models NNQLM-I, NNQLM-II by (Zhang et al., 2018a) for comparison.

5.2.2 Parameter Settings

The parameters in the network are $\Theta = \{R, \Phi, \{|v_i\rangle\}_{i=1}^{k}\}$, in which R and Φ denote the lookup tables for amplitudes and complex phases of each word, and $\{|v_i\rangle\}_{i=1}^{k}$ denotes the set of semantic measurements. We use 50-dimension complex word embedding. The amplitudes are initialized with 50-dimension Glove vectors (Pennington et al., 2014) and L2-norm regularized during training. The phases are randomly initialized under a normal distribution of $[-\pi, \pi]$. The semantic measurements $\{|v_i\rangle\}_{i=1}^{k}\}$ are initialized with orthogonal real-valued one-hot vectors, and each measurement is constrained to be of unit length during training. We perform max pooling over the sentence dimension on the measurement probability matrices, resulting in a k-dim vector for both a question and an answer. We concatenate the vectors for $l = 1, 2, 3, 4$ for questions and answers, and the larger size of windows are also tried. We will use a longer sliding window in datasets with longer sentences. The cosine similarity is used as the distance metric of measured probabilities. We use triplet hinge loss and set the margin $\alpha = 0.1$. A dropout layer is built over the embedding layer and measurement probabilities with a dropout rate of 0.9.

A grid search is conducted over the parameter pools to explore the best parameters. The parameters under exploration include $\{0.01, 0.05, 0.1\}$ for the learning rate, $\{1e-5, 1e-6, 1e-7, 1e-8\}$ for the L2-normalization of complex word embeddings, $\{8, 16, 32\}$ for batch size, and $\{50, 100, 300, 500\}$ for the number of semantic measurements.

5.2.3 Parameter Scale

The proposed CNM has a limited scale of parameters. Apart from the complex word embeddings which are $|V| \times 2n$ by size, the only set of parameters are $\{|v_i\rangle\}_{i=1}^{k}$ which is $k \times 2n$, with $|V|, k, n$ being the vocabulary size, number of semantic measurements and the embedding dimension, respectively. In comparison, a single-layered CNN has at least $l \times k \times n$ additional parameters with l being the filter width, while a single-layered LSTM is $4 \times k \times (k + n)$ by the minimum parameter scale. Although we use both amplitude part and phase part for word embedding, lower dimensions of embedding are adopted, namely 50, with the comparable performance.

Table 3: Experiment Results on WikiQA Dataset.The best performed values for each dataset are in bold.

Therefore, our network scales better than the advanced models on the CNN or LSTM basis.

5.3 Experiment Results

Tab. 2 and 3 show the experiment results on TREC QA and WikiQA respectively, where bold values are the best performances out of all models. Our model achieves 3 best performances out of the 4 metrics on TREC QA and WikiQA, and performs slightly worse than the best-performed models on the remaining metric. This illustrates the effectiveness of our proposed model from a general perspective.

Specifically, CNM outperforms most CNN and LSTM-based models, which have more complicated structures and a relatively larger parameters scale. Also, CNM performs better than existing quantum-inspired QA models, QLM and NNQLM on both datasets, which means that the quantum theoretical framework gives rise to better performs model. Moreover, a significant improvement over NNQLM-1 is observed on these two datasets, supporting our claim that the trace inner product is not an effective distance metric of two density matrices.

Setting	MAP	MRR
FastText-MaxPool	0.6659 (0.1042↓)	0.7152 (0.1439↓)
CNM-Real	0.7112 (0.0589↓)	0.7922 (0.0659↓)

CNM-trace-inner-product	0.6952 (0.0749↓)	0.7688 (0.0903↓)
CNM	0.7701	0.8591

Table 4: Ablation Test. The values in parenthesis are the performance differences between the model and CNM.

5.4 Ablation Test

An ablation test is conducted to examine the influence of each component on our proposed CNM. The following models are implemented in the ablation test. *FastText-MaxPool* adopt max pooling over word-embedding, just like FastText (Joulin et al., 2016). *CNM-Real* replaces word embeddings and measurements with their real counterparts. *CNM-Global-Mixture* adopts a global mixture of the whole sentence, in which a sentence is represented as a single density matrix, leading to a probability vector for the measurement result. *CNM-trace-inner-product* replaces the trainable measurements with trace inner product like NNQLM.

For the real-valued models, we replace the embedding with double size of dimension, in order to eliminate the impact of the parameter scale on the performance. Due to limited space, we only report the ablation test result on TREC QA, and WikiQA has similar trends. The test results in Tab. 4 demonstrate that each component plays a crucial role in the CNM model. In particular, the comparison with CNM-Real and FastText-MaxPool shows the effectiveness of introducing complex-valued components, the increase in performance over CNM-Global-Mixture reveals the superiority of local mixture, and the comparison with CNM-trace-inner-product confirms the usefulness of trainable measurements.

6 Discussions

This section aims to investigate the proposed research questions mentioned in Sec 1. For RQ1, we explain the physical meaning of each component in term of the transparency (Sec. 6.1), and design some case studies for the post-hoc interpretability (Sec. 6.2). For RQ2, we argue that the complex-valued representation can model different aspects of semantics and naturally address the non-linear semantic compositionality, as discussed in Sec. 6.3.

Table 6: Selected learned important words in TREC QA. All words are converted to lower cases.

6.1 Transparency

CNM aims to unify many semantic units with different granularity e.g. sememes, words, phrases (or N-gram) and document in a single complex-valued vector space, as shown in Tab. 5. In particular, we formulate atomic sememes as a group of complete orthogonal basis states and words as superposition states over them. A linguistic unit with larger-granularity e.g. a word phrase or a sentence is represented as a mixed system over the words (with a density matrix, i.e. a positive semi-definite matrix with unit trace).

More importantly, trainable projection measurements are used to extract high-level representation for a word phrase or a sentence. Each measurement is also directly embedded in this unified Hilbert space, as a specific unit state (like words), thus making it easily understood by the neighbor words near this specific state. The corresponding trainable components in state-of-art neural network architectures, namely, kernels in CNN and cells in RNN, are represented as arbitrary real-valued without any constraints, lead to difficulty to be understood.

6.2 Post-hoc Interpretability

The post-hoc Interpretability is shown in three groups of case studies, namely word weight scheme, matching pattern, and discriminative semantic measurements.

6.2.1 Word Weighting Scheme

Tab. 6 shows the words selected from the top-50 most important words as well as top-50 unimpor-

Table 7: The matching patterns for specific sentence pairs in TREC QA. The darker the color, the bigger the word weight is. [and] denotes the possible border of the current sliding windows.

tant ones. The importance of words is based on the L2-norm of its learned amplitude embedding according to Eq. 5. It is consistent with the intuition that, the important words are more about specific topics or discriminative nouns, while the unimportant words include meaningless numbers or super-high frequency words. Note that some special form (e.g. plural form in the last row) of words are also identified as unimportant words, since we commonly did not stem the words.

6.2.2 Matching Pattern

Tab. 7 shows the match schema with local sliding windows. In a local context window, we visualize the relative weights (i.e. the weights after normalized by *softmax*) for each word with darkness degrees. The table illustrates that our model is capable of identifying true matched local windows of a sentence pair. Even some words are replaced with similar forms (e.g. commit and committing in the last case) or meanings (e.g. change and new in the fourth case), it could be robust to get a relatively high matching score. From an empirical point of view, our model outperforms other models in situations where specific matching pattern are crucial to the sentence meaning, such as when two sentences share some unordered bag-of-word combinations. To some extent, it is robust up to replacement of words with similar ones in the Semantic Hilbert Space.

6.2.3 Discriminative Semantic Measurements

The semantic measurements are performed through rank-one projectors $\{|x\rangle \langle x|\}$. From a classical point of view, each projector is associated with a superposition of fundamental sememes, which is not necessarily linked to a particular word. Since the similarity metric in the Semantic Hilbert Space can be used to indicate semantic relatedness, we rely on the nearby words of the learned measurement projectors to understand what they may refer to.

Essentially, we identified the 10 most similar words to a measurement based on the cosine similarity metric. Tab. 8 shows part of the most similar words of 5 measurements, which are randomly chosen from the total number of k=10 trainable measurements for the TREC QA dataset. It can be seen that the first three selected measurements were about positions, movement verbs, and people’s names, while the rest were about the topic of history and rebellion respectively. Even though a clear explanation of the measurements is not available, we are still able to roughly understand the meaning of the measurements in the proposed data-driven approach.

	Selected neighborhood words for a measurement vector

4	historically, 19th-century, genetic, hatchback
5	missile, exile, rebellion, darkness

Table 8: Selected learned measurements for TREC QA. They were selected according to nearest words for a measurement vector in Semantic Hilbert Space.

6.3 Complex-valued Representation

In CNM, each word is naturally embedded as a complex vector, composed of a complex phase part, a unit amplitude part, and a scalar-valued length. We argue that the amplitude part (i.e. the squared root of a probabilistic weight), corresponds to the classical word embedding with the lexical meaning, while the phase part implicitly reflects the higher-level semantic aspect e.g. polarity, ambiguity or emotion. The scalar-valued length is considered as the relative weight in a mixed system. The ablation study in Sec. 5.4 confirms that the complex-valued word embedding performs better than the real word embedding, which indicates that we benefit from the complex-valued embedding on the QA task.

From a mathematical point of view, complex-valued word embedding and other complex-valued components forms a new Hilbert vector space for modelling language, with a new definitions of addition and multiplication, as well as a new inner product operation. For instance, addition in the word meaning combination is defined as

$$\begin{aligned} z = & z_1 + z_2 = r_1 e^{i\theta_1} + r_2 e^{i\theta_2} \\ = & \sqrt{r_1^2 + r_2^2 + 2r_1 r_2 \cos(\theta_2 - \theta_1)} \\ & \times e^{i \arctan\left(\frac{r_1 \sin(\theta_1) + r_2 \sin(\theta_2)}{r_1 \cos(\theta_1) + r_2 \cos(\theta_2)}\right)} \end{aligned} \quad (7)$$

where z_1 and z_2 are the values for the corresponding element for two different word vectors $|w_1\rangle$ and $|w_2\rangle$ respectively. Both the amplitudes and complex phases of z are added with a nonlinear combination of phases and amplitudes of z_1 and z_2. A classical linear addition gives $\hat{z} = r_1 + r_2$, which can be viewed as a degenerating case of the complex-valued addition with the phase information being removed ($\theta_1 = \theta_2 = 0$ in the example).

7 Conclusions and Future Work

Towards the interpretable matching issue, we propose two research questions to investigate the possibility of language modelling with quantum mathematical framework. To this end, we design a new framework to model all the linguistic units in a unified Hilbert space with well-defined mathematical constraints and explicit physical meaning. We implement the above framework with neural network and then demonstrate its effectiveness in question answering (QA) task. Due to the well-designed components, our model is advantageous with its interpretability in term of transparency and post-hoc interpretability, and also shows its potential to use complex-valued components in NLP.

Despite the effectiveness of the current network, we would like to further explore the phase part in complex-valued word embedding to directly link to concrete semantics such as word sentiment or word position. Another possible direction is to borrow other quantum concepts to capture the interaction and non-interaction between word semantics, such as the *Fock Space* (Sozzo, 2014) which considers both interacting and non-interacting entities in different Hilbert Spaces. Furthermore, a deeper and robust quantum-inspired neural architecture in a higher-dimension Hilbert space like (Zhang et al., 2018b) is also worth to be investigated for achieving stronger performances with better explanatory power.

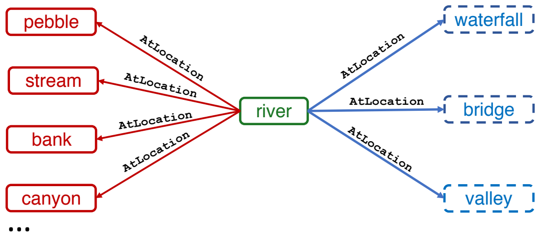
Abstract

When answering a question, people often draw upon their rich world knowledge in addition to the particular context. Recent work has focused primarily on answering questions given some relevant document or context, and required very little general background. To investigate question answering with prior knowledge, we present COMMONSENSEQA: a challenging new dataset for commonsense question answering. To capture common sense beyond associations, we extract from CONCEPTNET (Speer et al., 2017) multiple target concepts that have the same semantic relation to a single source concept. Crowd-workers are asked to author multiple-choice questions that mention the source concept and discriminate in turn between each of the target concepts. This encourages workers to create questions with complex semantics that often require prior knowledge. We create 12,247 questions through this procedure and demonstrate the difficulty of our task with a large number of strong baselines. Our best baseline is based on BERT-large (Devlin et al., 2018) and obtains 56% accuracy, well below human performance, which is 89%.

1 Introduction

When humans answer questions, they capitalize on their common sense and background knowledge about spatial relations, causes and effects, scientific facts and social conventions. For instance, given the question *"Where was Simon when he heard the lawn mower?"*, one can infer that the lawn mower is close to Simon, and that it is probably outdoors and situated at street level. This type of knowledge seems trivial for humans, but is still out of the reach of current natural language understanding (NLU) systems.

a) Sample ConceptNet for specific subgraphs



b) Crowd source corresponding natural language questions and two additional distractors

*Where on a **river** can you hold a cup upright to catch water on a sunny day?*
✓ waterfall, ✗ bridge, ✗ valley, ✗ *pebble*, ✗ **mountain**

*Where can I stand on a **river** to see water falling without getting wet?*
✗ waterfall, ✓ bridge, ✗ valley, ✗ *stream*, ✗ **bottom**

*I'm crossing the **river**, my feet are wet but my body is dry, where am I?*
✗ waterfall, ✗ bridge, ✓ valley, ✗ *bank*, ✗ **island**

Figure 1: (a) A source concept ('river') and three target concepts (dashed) are sampled from CONCEPTNET (b) Crowd-workers generate three questions, each having one of the target concepts for its answer (✓), while the other two targets are not (✗). Then, for each question, workers choose an additional distractor from CONCEPTNET (in italics), and author one themselves (in bold).

Work on Question Answering (QA) has mostly focused on answering factoid questions, where the answer can be found in a given context with little need for commonsense knowledge (Hermann et al., 2015; Rajpurkar et al., 2016; Nguyen et al., 2016; Joshi et al., 2017). Small benchmarks such as the Winograd Scheme Challenge (Levesque, 2011) and COPA (Roemmele et al., 2011), targeted common sense more directly, but have been difficult to collect at scale.

Recently, efforts have been invested in developing large-scale datasets for commonsense reasoning. In SWAG (Zellers et al., 2018b), given a textual description of an event, a probable subsequent event needs to be inferred. However, it

---

Proceedings of NAACL-HLT 2019, pages 4149–4158
Minneapolis, Minnesota, June 2 - June 7, 2019.

has been quickly realized that models trained on large amounts of unlabeled data (Devlin et al., 2018) capture well this type of information and performance on SWAG is already at human level. VCR (Zellers et al., 2018a) is another very recent attempt that focuses on the visual aspects of common sense. Such new attempts highlight the breadth of commonsense phenomena, and make it evident that research on common sense has only scratched the surface. Thus, there is need for datasets and models that will further our understanding of what is captured by current NLU models, and what are the main lacunae.

In this work, we present COMMONSENSEQA, a new dataset focusing on commonsense question answering, based on knowledge encoded in CONCEPTNET (Speer et al., 2017). We propose a method for generating commonsense questions at scale by asking crowd workers to author questions that describe the relation between concepts from CONCEPTNET (Figure 1). A crowd worker observes a source concept (*'River'* in Figure 1) and three target concepts (*'Waterfall'*, *'Bridge'*, *'Valley'*) that are all related by the same CONCEPTNET relation (`AtLocation`). The worker then authors three questions, one per target concept, such that only that particular target concept is the answer, while the other two distractor concepts are not. This primes the workers to add commonsense knowledge to the question, that separates the target concept from the distractors. Finally, for each question, the worker chooses one additional distractor from CONCEPTNET, and authors another distractor manually. Thus, in total, five candidate answers accompany each question.

Because questions are generated freely by workers, they often require background knowledge that is trivial to humans but is seldom explicitly reported on the web due to reporting bias (Gordon and Van Durme, 2013). Thus, questions in COMMONSENSEQA have a different nature compared to prior QA benchmarks, where questions are authored given an input text.

Using our method, we collected 12,247 commonsense questions. We present an analysis that illustrates the uniqueness of the gathered questions compared to prior work, and the types of commonsense skills that are required for tackling it. We extensively evaluate models on COMMONSENSEQA, experimenting with pre-trained models, fine-tuned models, and reading comprehension (RC) models that utilize web snippets extracted from Google search on top of the question itself. We find that fine-tuning BERT-LARGE (Devlin et al., 2018) on COMMONSENSEQA obtains the best performance, reaching an accuracy of 55.9%. This is substantially lower than human performance, which is 88.9%.

To summarize, our contributions are:

1. A new QA dataset centered around common sense, containing 12,247 examples.
2. A new method for generating commonsense questions at scale from CONCEPTNET.
3. An empirical evaluation of state-of-the-art NLU models on COMMONSENSEQA, showing that humans substantially outperform current models.

The dataset can be downloaded from `www.tau-nlp.org/commonsenseqa`. The code for all our baselines is available at `github.com/jonathanherzig/commonsenseqa`.

2 Related Work

Machine common sense, or the knowledge of and ability to reason about an open ended world, has long been acknowledged as a critical component for natural language understanding. Early work sought programs that could reason about an environment in natural language (McCarthy, 1959), or leverage a world-model for deeper language understanding (Winograd, 1972). Many commonsense representations and inference procedures have been explored (McCarthy and Hayes, 1969; Kowalski and Sergot, 1986) and large-scale commonsense knowledge-bases have been developed (Lenat, 1995; Speer et al., 2017). However, evaluating the degree of common sense possessed by a machine remains difficult.

One important benchmark, the Winograd Schema Challenge (Levesque, 2011), asks models to correctly solve paired instances of coreference resolution. While the Winograd Schema Challenge remains a tough dataset, the difficulty of generating examples has led to only a small available collection of 150 examples. The Choice of Plausible Alternatives (COPA) is a similarly important but small dataset consisting of 500 development and 500 test questions (Roemmele et al., 2011). Each question asks which of two alternatives best reflects a cause or effect relation to the premise. For both datasets, scalability is an issue when evaluating modern modeling approaches.

With the recent adoption of crowdsourcing, several larger datasets have emerged, focusing on predicting relations between situations or events in natural language. JHU Ordinal Commonsense Inference requests a label from 1-5 for the plausibility that one situation entails another (Zhang et al., 2017). The Story Cloze Test (also referred to as ROC Stories) pits ground-truth endings to stories against implausible false ones (Mostafazadeh et al., 2016). Interpolating these approaches, Situations with Adversarial Generations (SWAG), asks models to choose the correct description of what happens next after an initial event (Zellers et al., 2018b). LM-based techniques achieve very high performance on the Story Cloze Test and SWAG by fine-tuning a pre-trained LM on the target task (Radford et al., 2018; Devlin et al., 2018).

Investigations of commonsense datasets, and of natural language datasets more generally, have revealed the difficulty in creating benchmarks that measure the understanding of a program rather than its ability to take advantage of distributional biases, and to model the annotation process (Gururangan et al., 2018; Poliak et al., 2018). Annotation artifacts in the Story Cloze Test, for example, allow models to achieve high performance while only looking at the proposed endings and ignoring the stories (Schwartz et al., 2017; Cai et al., 2017). Thus, the development of benchmarks for common sense remains a difficult challenge.

Researchers have also investigated question answering that utilizes common sense. Science questions often require common sense, and have recently received attention (Clark et al., 2018; Mihaylov et al., 2018; Ostermann et al., 2018); however, they also need specialized scientific knowledge. In contrast to these efforts, our work studies common sense without requiring additional information. SQUABU created a small hand-curated test of common sense and science questions (Davis, 2016), which are difficult for current techniques to solve. In this work, we create similarly well-crafted questions but at a larger scale.

3 Dataset Generation

Our goal is to develop a method for generating questions that can be easily answered by humans without context, and require commonsense knowledge. We generate multiple-choice questions in a process that comprises the following steps:

1. We extract subgraphs from ConceptNet, each with one source concept and three target concepts.
2. We ask crowdsourcing workers to author three questions per subgraph (one per target concept), to add two additional distractors per question, and to verify questions' quality.
3. We add textual context to each question by querying a search engine and retrieving web snippets.

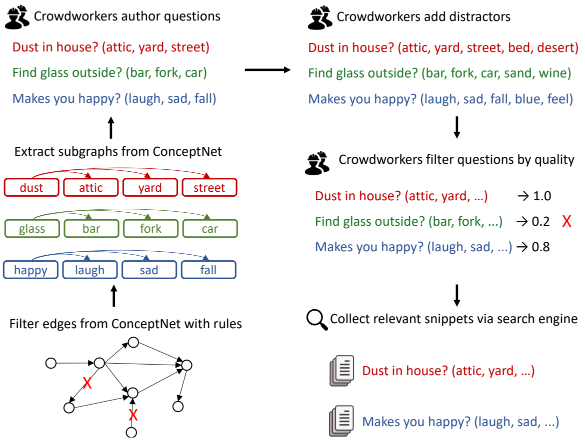

Figure 2: CommonsenseQA generation process. The input is ConceptNet knowledge base, and the output is a set of multiple-choice questions with corresponding relevant context (snippets).

The entire data generation process is summarized in Figure 2. We now elaborate on each of the steps:

Extraction from ConceptNet ConceptNet is a graph knowledge-base $G \subseteq \mathcal{C} \times \mathcal{R} \times \mathcal{C}$, where the nodes $\mathcal{C}$ represent natural language concepts, and edges $\mathcal{R}$ represent commonsense relations. Triplets (c_1, r, c_2) carry commonsense knowledge such as '(*gambler*, `CapableOf`, *lose money*)'. ConceptNet contains 32 million triplets. To select a subset of triplets for crowdsourcing we take the following steps:

1. We filter triplets with general relations (e.g., `RelatedTo`) or relations that are already well-explored in NLP (e.g., `IsA`). In total we use 22 relations.
2. We filter triplets where one of the concepts is more than four words or not in English.
3. We filter triplets where the edit distance between c_1 and c_2 is too low.

This results in a set of 236,208 triplets (q, r, a), where we call the first concept the *question concept* and the second concept the *answer concept*.

We aim to generate questions that contain the question concept and where the answer is the answer concept. To create multiple-choice questions we need to choose *distractors* for each question. Sampling distractors at random from CONCEPTNET is a bad solution, as such distractors are easy to eliminate using simple surface clues.

To remedy this, we propose to create *question sets*: for each question concept q and relation r we group three different triplets $\{(q, r, a_1), (q, r, a_2), (q, r, a_3)\}$ (see Figure 1). This generates three answer concepts that are semantically similar and have a similar relation to the question concept q. This primes crowd workers to formulate questions that require background knowledge about the concepts in order to answer the question.

The above procedure generates approximately 130,000 triplets (43,000 question sets), for which we can potentially generate questions.

Crowdsourcing questions We used Amazon Mechanical Turk (AMT) workers to generate and validate commonsense questions.

AMT workers saw, for every question set, the question concept and three answer concepts. They were asked to formulate three questions, where all questions contain the question concept. Each question should have as an answer one of the answer concepts, but not the other two. To discourage workers from providing simple surface clues for the answer, they were instructed to avoid using words that have a strong relation to the answer concept, for example, not to use the word *'open'* when the answer is *'door'*.

Formulating questions for our task is non-trivial. Thus, we only accept annotators for which at least 75% of the questions they formulate pass the verification process described below.

Adding additional distractors To make the task more difficult, we ask crowd-workers to add two additional incorrect answers to each formulated question. One distractor is selected from a set of answer concepts with the same relation to the question concept in CONCEPTNET (Figure 1, in red). The second distractor is formulated manually by the workers themselves (Figure 1, in purple). Workers were encouraged to formulate a distractor that would seem plausible or related to the question but easy for humans to dismiss as incorrect. In total, each formulated question is accompanied with five candidate answers, including one correct answer and four distractors.

Measurement	Value
# CONCEPTNET distinct question nodes	2,254
# CONCEPTNET distinct answer nodes	12,094
# CONCEPTNET distinct nodes	12,107
# CONCEPTNET distinct relation lables	22
average question length (tokens)	13.41
long questions (more than 20 tokens)	10.3%
average answer length (tokens)	1.5
# answers with more than 1 token	44%
# of distinct words in questions	14,754
# of distinct words in answers	4,911

Table 1: Key statistics for COMMONSENSEQA

Verifying questions quality We train a disjoint group of workers to verify the generated questions. Verifiers annotate a question as unanswerable, or choose the right answer. Each question is verified by 2 workers, and only questions verified by at least one worker that answered correctly are used. This processes filters out 15% of the questions.

Adding textual context To examine whether web text is useful for answering commonsense questions, we add textual information to each question in the following way: We issue a web query to Google search for every question and candidate answer, concatenating the answer to the question, e.g., *'What does a parent tell their child to do after they've played with a lot of toys? + "clean room"'*. We take the first 100 result snippets for each of the five answer candidates, yielding a context of 500 snippets per question. Using this context, we can investigate the performance of reading comprehension (RC) models on COMMONSENSEQA.

Overall, we generated 12,247 final examples, from a total of 16,242 that were formulated. The total cost per question is $0.33. Table 1 describes the key statistics of COMMONSENSEQA.

4 Dataset Analysis

CONCEPTNET concepts and relations COMMONSENSEQA builds on CONCEPTNET, which contains *concepts* such as `dog`, `house`, or `row boat`, connected by *relations* such as `Causes`, `CapableOf`, or `Antonym`. The top-5 question concepts in COMMONSENSEQA are *'Person'* (3.1%), *'People'* (2.0%), *'Human'* (0.7%), *'Water'* (0.5%) and *'Cat'* (0.5%). In addition, we present the main relations along with the percentage of questions generated from them in Table 2. It's

Relation	**Formulated question example**	%
`AtLocation`	*Where would I not want a fox?* **A.** hen house, **B.** england, **C.** mountains, **D.** ...	47.3
`Causes`	*What is the hopeful result of going to see a play?* **A.** being entertained, **B.** meet, **C.** sit, **D.** ...	17.3
`CapableOf`	*Why would a person put flowers in a room with dirty gym socks?* **A.** smell good, **B.** many colors, **C.** continue to grow , **D.** ...	9.4
`Antonym`	*Someone who had a very bad flight might be given a trip in this to make up for it?* **A.** first class, **B.** reputable, **C.** propitious , **D.** ...	8.5
`HasSubevent`	*How does a person begin to attract another person for reproducing?* **A.** kiss, **B.** genetic mutation, **C.** have sex , **D.** ...	3.6
`HasPrerequisite`	*If I am tilting a drink toward my face, what should I do before the liquid spills over?* **A.** open mouth, **B.** eat first, **C.** use glass , **D.** ...	3.3
`CausesDesire`	*What do parents encourage kids to do when they experience boredom?* **A.** read book, **B.** sleep, **C.** travel , **D.** ...	2.1
`Desires`	*What do all humans want to experience in their own home?* **A.** feel comfortable, **B.** work hard, **C.** fall in love , **D.** ...	1.7
`PartOf`	*What would someone wear to protect themselves from a cannon?* **A.** body armor, **B.** tank, **C.** hat , **D.** ...	1.6
`HasProperty`	*What is a reason to pay your television bill?* **A.** legal, **B.** obsolete, **C.** entertaining , **D.** ...	1.2

Table 2: Top CONCEPTNET relations in COMMONSENSEQA, along with their frequency in the data and an example question. The first answer (**A**) is the correct answer

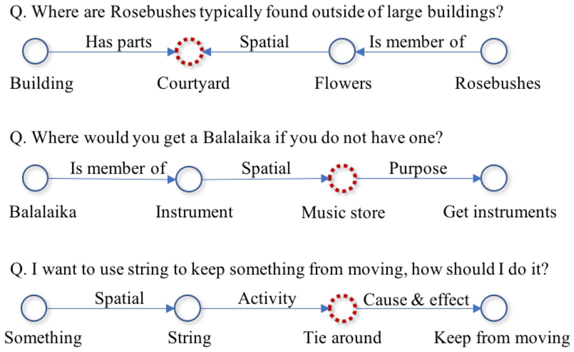

Figure 3: Examples of manually-annotated questions, with the required skills needed to arrive at the answers (red circles). Skills are labeled edges, and concepts are nodes.

Category	Definition	%
Spatial	Concept A appears near Concept B	41
Cause & Effect	Concept A causes Concept B	23
Has parts	Concept A contains Concept B as one of its parts	23
Is member of	Concept A belongs to the larger class of Concept B	17
Purpose	Concept A is the purpose of Concept B	18
Social	It is a social convention that Concept A correlates with Concept B	15
Activity	Concept A is an activity performed in the context of Concept B	8
Definition	Concept A is a definition of Concept B	6
Preconditions	Concept A must hold true in order for Concept B to take place	3

Table 3: Skills and their frequency in the sampled data. As each example can be annotated with multiple skills, the total frequency does not sum to 100%.

worth noting that since question formulators were not shown the CONCEPTNET relation, they often asked questions that probe other relationships between the concepts. For example, the question *"What do **audiences** clap for?"* was generated from the `AtLocation` relation, but focuses on social conventions instead.

Question formulation Question formulators were instructed to create questions with high language variation. 122 formulators contributed to question generation. However, 10 workers formulated more than 85% of the questions.

We analyzed the distribution of first and second words in the formulated questions along with example questions. Figure 4 presents the breakdown. Interestingly, only 44% of the first words are WH-words. In about 5% of the questions, formulators used first names to create a context story, and in 7% they used the word *"if"* to present a hypothetical question. This suggests high variability in the question language.

Commonsense Skills To analyze the types of commonsense knowledge needed to correctly answer questions in COMMONSENSEQA, we randomly sampled 100 examples from the development set and performed the following analysis.

For each question, we explicitly annotated the types of commonsense skills that a human uses to answer the question. We allow multiple commonsense skills per questions, with an average of 1.75 skills per question. Figure 3 provides three example annotations. Each annotation contains a node for the answer concept, and other nodes for concepts that appear in the question or latent concepts. Labeled edges describe the commonsense skill that relates the two nodes. We defined commonsense skills based on the analysis of LoBue and Yates (2011), with slight modifications to accommodate the phenomena in our data. Table 3 presents the skill categories we used, their definition and their frequency in the analyzed examples.

5 Baseline Models

Our goal is to collect a dataset of commonsense questions that are easy for humans, but hard for current NLU models. To evaluate this, we experiment with multiple baselines. Table 4 summarizes the various baseline types and characterizes them based on (a) whether training is done on COMMONSENSEQA or the model is fully pre-trained,

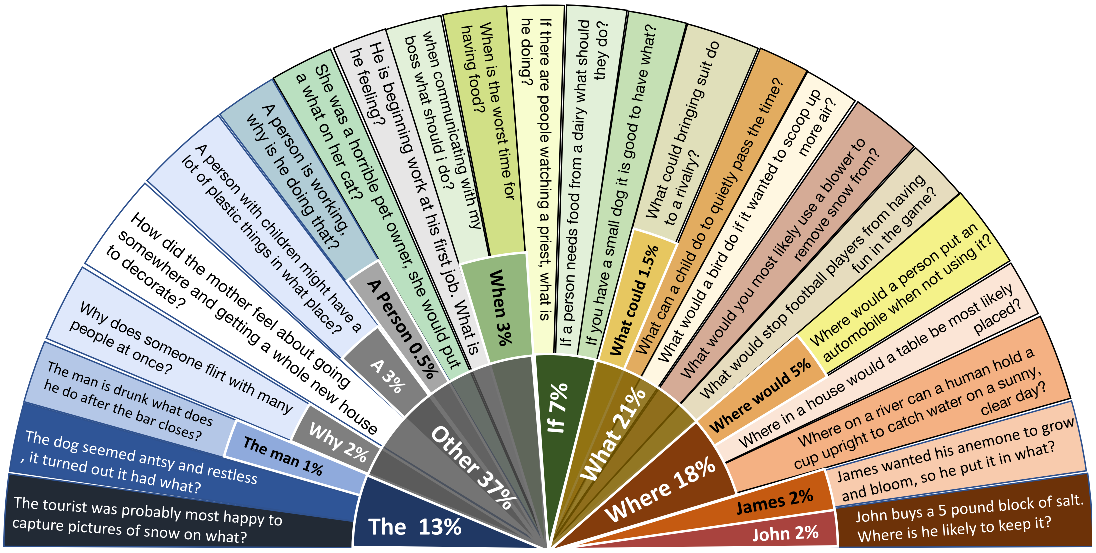

Figure 4: Distribution of the first and second words in questions. The inner part displays words and their frequency and the outer part provides example questions.

Model	Training	Context
VECSIM	✗	✗
LM1B	✗	✗
QABILINEAR	✓	✗
QACOMPARE	✓	✗
ESIM	✓	✗
GPT	✓	✗
BERT	✓	✗
BIDAF++	✓	✓

Table 4: Baseline models along with their characteristics. *Training* states whether the model was trained on COMMONSENSEQA, or was only trained a different dataset. *Context* states whether the model uses extra context as input.

and (b) whether context (web snippets) is used. We now elaborate on the different baselines.

a VECSIM A model that chooses the answer with highest cosine similarity to the question, where the question and answers are represented by an average of pre-trained word embeddings.

b LM1B Inspired by Trinh and Le (2018), we employ a large language model (LM) from Jozefowicz et al. (2016), which was pre-trained on the One Billion Words Benchmark (Chelba et al., 2013). We use this model in two variations. In the first (LM1B-CONCAT), we simply concatenate each answer to the question. In the second (LM1B-REP), we first cluster questions according to their first two words. Then, we recognize five high-frequency prefixes that cover 35% of the development set (e.g., *"what is"*). We rephrase questions that fit into one of these prefixes as a declarative sentence that contains the answer. E.g., we rephrase *"What is usually next to a door?"* and the candidate answer *"wall"* to *"Wall is usually next to a door"*. For questions that do not start with the above prefixes, we concatenate the answer as in LM1B-CONCAT. In both variations we return the answer with highest LM probability.

c QABILINEAR This model, propsed by Yu et al. (2014) for QA, scores an answer a_i with a bilinear model: $qWa_i^\top$, where the question q and answers a_i are the average pre-trained word embeddings and W is a learned parameter matrix. A softmax layer over the candidate answers is used to train the model with cross-entropy loss.

d QACOMPARE This model is similar to an NLI model from Liu et al. (2016). The model represents the interaction between the question q and a candidate answer a_i as: $h = \text{relu}([q; a_i; q \odot a_i; q - a_i]W_1 + b_1)$, where ';' denotes concatenation and $\odot$ is element-wise product. Then, the model predicts an answer score using a feed forward layer: $hW_2 + b_2$. Average pre-trained embeddings and softmax are used to train the model.

e ESIM We use ESIM, a strong NLI model (Chen et al., 2016). Similar to Zellers et al. (2018b), we change the output layer size to the number of candidate answers, and apply softmax to train with cross-entropy loss.

f BIDAF++ A state-of-the-art RC model, that uses the retrieved Google web snippets (Section 3) as context. We augment BIDAF (Seo et al., 2016) with a self-attention layer and ELMo representations (Peters et al., 2018; Huang et al., 2018). To adapt to the multiple-choice setting, we choose the answer with highest model probability.

g GENERATIVE PRE-TRAINED TRANSFORMER (GPT) Radford et al. (2018) proposed a method for adapting pre-trained LMs to perform a wide range of tasks. We applied their model to COMMONSENSEQA by encoding each question and its candidate answers as a series of delimiter-separated sequences. For example, the question *"If you needed a lamp to do your work, where would you put it?"*, and the candidate answer *"bedroom"* would become "`[start]` *If ... ?* `[sep]` *bedroom* `[end]`". The hidden representations over each `[end]` token are converted to logits by a linear transformation and passed through a softmax to produce final probabilities for the answers. We used the same pre-trained LM and hyper-parameters for fine-tuning as Radford et al. (2018) on ROC Stories, except with a batch size of 10.

h BERT Similarly to the GPT, BERT fine-tunes a language model and currently holds state-of-the-art across a broad range of tasks (Devlin et al., 2018). BERT uses a masked language modeling objective, which predicts missing words masked from unlabeled text. To apply BERT to COMMONSENSEQA, we linearize each question-answer pair into a delimiter-separated sequence (i.e., "`[CLS]` *If ... ?* `[SEP]` *bedroom* `[SEP]`") then fine-tune the pre-trained weights from uncased BERT-LARGE.[1] Similarly to the GPT, the hidden representations over each `[CLS]` token are run through a softmax layer to create the predictions. We used the same hyper-parameters as Devlin et al. (2018) for SWAG.

6 Experiments

Experimental Setup We split the data into a training/development/test set with an 80/10/10 split. We perform two types of splits: (a) *random split* – where questions are split uniformly at random, and (b) *question concept split* – where each of the three sets have disjoint question concepts. We empirically find (see below) that a random split is harder for models that learn from COMMONSENSEQA, because the same question concept appears in the training set and development/test set with different answer concepts, and networks that memorize might fail in such a scenario. Since the random split is harder, we consider it the primary split of COMMONSENSEQA.

We evaluate all models on the test set using accuracy (proportion of examples for which prediction is correct), and tune hyper-parameters for all trained models on the development set. To understand the difficulty of the task, we add a SANITY mode, where we replace the hard distractors (that share a relation with the question concept and one formulated by a worker) with random CONCEPTNET distractors. We expect a reasonable baseline to perform much better in this mode.

For pre-trained word embeddings we consider 300d GloVe embeddings (Pennington et al., 2014) and 300d Numberbatch CONCEPTNET node embeddings (Speer et al., 2017), which are kept fixed at training time. We also combine ESIM with 1024d ELMo contextual representations, which are also fixed during training.

Human Evaluation To test human accuracy, we created a separate task for which we did not use a qualification test, nor used AMT master workers. We sampled 100 random questions and for each question gathered answers from five workers that were not involved in question generation. Humans obtain 88.9% accuracy, taking a majority vote for each question.

Results Table 5 presents test set results for all models and setups.

The best baselines are BERT-LARGE and GPT with an accuracy of 55.9% and 45.5%, respectively, on the random split (63.6% and 55.5%, respectively, on the question concept split). This is well below human accuracy, demonstrating that the benchmark is much easier for humans. Nevertheless, this result is much higher than random (20%), showing the ability of language models to store large amounts of information related to commonsense knowledge.

The top part of Table 5 describes untrained models. We observe that performance is higher than random, but still quite low. The middle part describes models that were trained on COMMONSENSEQA, where BERT-LARGE obtains best performance, as mentioned above. ESIM models follow BERT-LARGE and GPT, and obtain much lower performance. We note that ELMo representations did not improve performance compared to GloVe embeddings, possibly because we were un-

Table 5: Test set accuracy for all models.

Category	**Formulated question example**	**Correct answer**	**Distractor**	**Accuracy**	**%**
Surface clues	*If someone laughs after surprising them they have a good sense of what?* *How might a automobile get off a freeway?*	**humor** **exit ramp**	laughter driveway	77.7	35%
Negation / Antonym	*Where would you store a pillow case that is not in use?* *Where might the stapler be if I cannot find it?*	drawer desk drawer	**bedroom** **desktop**	42.8	7%
Factoid knowledge	*How many hours are in a day?* *What geographic area is a lizard likely to be?*	twenty four west texas	**week** **ball stopped**	38.4	13%
Bad granularity	*Where is a well used toy car likely to be found?* *Where may you be if you're buying pork chops at a corner shop?*	child's room iowa	**own home** **town**	35.4	31%
Conjunction	*What can you use to store a book while traveling?* *On a hot day what can you do to enjoy something cool and sweet?*	suitcase eat ice cream	**library of congress** **fresh cake**	23.8	23%

Table 6: BERT-large baseline analysis. For each category we provide two examples, the correct answer, one distractor, model accuracy and frequency in the dataset. The predicted answer is in bold.

able to improve performance by back-propagating into the representations themselves (as we do in BERT-large and GPT). The bottom part shows results for BiDAF++ that uses web snippets as context. We observe that using snippets does not lead to high performance, hinting that they do not carry a lot of useful information.

Performance on the random split is five points lower than the question concept split on average across all trained models. We hypothesize that this is because having questions in the development/test set that share a question concept with the training set, but have a different answer, creates difficulty for networks that memorize the relation between a question concept and an answer.

Lastly, all SANITY models that were trained on CommonsenseQA achieve very high performance (92% for BERT-large), showing that selecting difficult distractors is crucial.

Baseline analysis To understand the performance of BERT-large, we analyzed 100 examples from the development set (Table 6). We labeled examples with categories (possibly more than one per example) and then computed the average accuracy of the model for each category.

We found that the model does well (77.7% accuracy) on examples where surface clues hint to the correct answer. Examples that involve negation or understanding antonyms have lower accuracy (42.8%), similarly to examples that require factoid knowledge (38.4%). Accuracy is particularly low in questions where the correct answer has finer granularity compared to one of the distractors (35.4%), and in cases where the correct answer needs to meet a conjunction of conditions, and the distractor meets only one of them (23.8%).

Learning Curves To extrapolate how current models might perform with more data, we evaluated BERT-large on the development set, training with varying amounts of data. The resulting learning curves are plotted in figure 5. For each training set size, hyper-parameters were identical to section 5, except the number of epochs was varied to keep the number of mini-batches during training constant. To deal with learning instabilities, each data point is the best of 3 runs. We observe that the accuracy of BERT-large is expected to be roughly 75% assuming 100k examples, still sub-

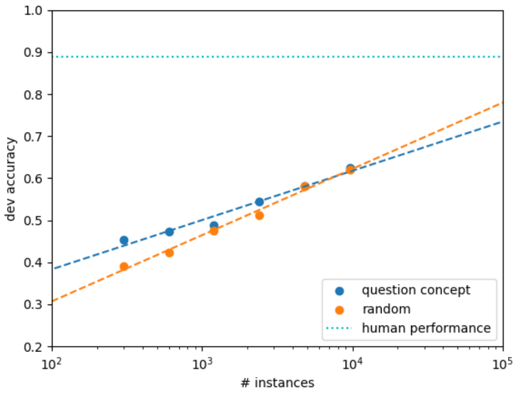

Figure 5: Development accuracy for BERT-LARGE trained with varying amounts of data.

stantially lower than human performance.

7 Conclusion

We present COMMONSENSEQA, a new QA dataset that contains 12,247 examples and aims to test commonsense knowledge. We describe a process for generating difficult questions at scale using CONCEPTNET, perform a detailed analysis of the dataset, which elucidates the unique properties of our dataset, and extensively evaluate on a strong suite of baselines. We find that the best model is a pre-trained LM tuned for our task and obtains 55.9% accuracy, dozens of points lower than human accuracy. We hope that this dataset facilitates future work in incorporating commonsense knowledge into NLU systems.

Abstract

Current work on multimodal machine translation (MMT) has suggested that the visual modality is either unnecessary or only marginally beneficial. We posit that this is a consequence of the very simple, short and repetitive sentences used in the only available dataset for the task (Multi30K), rendering the source text sufficient as context. In the general case, however, we believe that it is possible to combine visual and textual information in order to ground translations. In this paper we probe the contribution of the visual modality to state-of-the-art MMT models by conducting a systematic analysis where we partially deprive the models from source-side textual context. Our results show that under limited textual context, models are capable of leveraging the visual input to generate better translations. This contradicts the current belief that MMT models disregard the visual modality because of either the quality of the image features or the way they are integrated into the model.

1 Introduction

Multimodal Machine Translation (MMT) aims at designing better translation systems which take into account auxiliary inputs such as images. Initially organized as a shared task within the First Conference on Machine Translation (WMT16) (Specia et al., 2016), MMT has so far been studied using the Multi30K dataset (Elliott et al., 2016), a multilingual extension of Flickr30K (Young et al., 2014) with translations of the English image descriptions into German, French and Czech (Elliott et al., 2017; Barrault et al., 2018).

The three editions of the shared task have seen many exciting approaches that can be broadly categorized as follows: (i) multimodal attention using convolutional features (Caglayan et al., 2016; Calixto et al., 2016; Libovický and Helcl, 2017; Helcl et al., 2018) (ii) cross-modal interactions with spatially-unaware global features (Calixto and Liu, 2017; Ma et al., 2017; Caglayan et al., 2017a; Madhyastha et al., 2017) and (iii) the integration of regional features from object detection networks (Huang et al., 2016; Grönroos et al., 2018). Nevertheless, the conclusion about the contribution of the visual modality is still unclear: Grönroos et al. (2018) consider their multimodal gains "modest" and attribute the largest gain to the usage of external parallel corpora. Lala et al. (2018) observe that their multimodal word-sense disambiguation approach is not significantly different than the monomodal counterpart. The organizers of the latest edition of the shared task concluded that the multimodal integration schemes explored so far resulted in marginal changes in terms of automatic metrics and human evaluation (Barrault et al., 2018). In a similar vein, Elliott (2018) demonstrated that MMT models can translate without significant performance losses even in the presence of features from unrelated images.

These empirical findings seem to indicate that images are ignored by the models and hint at the fact that this is due to representation or modeling limitations. We conjecture that the most plausible reason for the linguistic dominance is that – at least in Multi30K – the source text is sufficient to perform the translation, eventually preventing the visual information from intervening in the learning process. To investigate this hypothesis, we introduce several input degradation regimes (Section 2) and revisit state-of-the-art MMT models (Section 3) to assess their behavior under degraded regimes. We further probe the visual sensitivity by deliberately feeding features from unrelated images. Our results (Section 4) show that MMT models successfully exploit the visual modality when the linguistic context is scarce, but indeed tend to be less sensitive to this modality when exposed to complete sentences.

Proceedings of NAACL-HLT 2019, pages 4159–4170
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Input Degradation

In this section we propose several degradations to the input language modality to simulate conditions where sentences may miss crucial information. We denote a set of translation pairs by $\mathcal{D}$ and indicate degraded variants with subscripts. Both the training and the test sets are degraded.

Color Deprivation. We consistently replace *source* words that refer to colors with a special token `[v]` ($\mathcal{D}_{\text{C}}$ in Table 1). Our hypothesis is that a monomodal system will have to rely on source-side contextual information and biases, while a multimodal architecture could potentially capitalize on color information extracted by exploiting the image and thus obtain better performance. This affects 3.3% and 3.1% of the words in the training and the test set, respectively.

Entity Masking. The Flickr30K dataset, from which Multi30K is derived, has also been extended with coreference chains to tag mentions of *visually depictable* entities in image descriptions (Plummer et al., 2015). We use these to mask out the head nouns in the *source* sentences ($\mathcal{D}_{\text{N}}$ in Table 1). This affects 26.2% of the words in both the training and the test set. We hypothesize that a multimodal system should heavily rely on the images to infer the missing parts.

Progressive Masking. A *progressively* degraded variant $\mathcal{D}_k$ replaces all but the first k tokens of *source* sentences with `[v]`. Unlike the color deprivation and entity masking, masking out suffixes does not guarantee systematic removal of visual context, but rather simulates an increasingly low-resource scenario. Overall, we form 16 degraded variants $\mathcal{D}_k$ (Table 1) where $k \in \{0, 2, \ldots, 30\}$. We stop at $\mathcal{D}_{30}$ since 99.8% of the sentences in Multi30K are shorter than 30 words with an average sentence length of 12 words. $\mathcal{D}_0$ – where the only remaining information is the source sentence length – is an interesting case from two perspectives: a neural machine translation (NMT) model trained on it resembles a target language model, while an MMT model becomes an image captioner with access to "expected length information".

Visual Sensitivity. Inspired by Elliott (2018), we experiment with *incongruent decoding* in order to understand how sensitive the multimodal systems are to the visual modality. This is achieved by explicitly violating the test-time semantic congruence across modalities. Specifically, we feed the visual features in *reverse* sample order to break image-sentence alignments. Consequently, a model capable of integrating the visual modality would likely deteriorate in terms of metrics.

$\mathcal{D}$	**a**	**lady**	**in**	**a**	**blue**	**dress**	**singing**
$\mathcal{D}_{\text{C}}$	a	lady	in	a	`[v]`	dress	singing
$\mathcal{D}_{\text{N}}$	a	`[v]`	in	a	blue	`[v]`	singing
$\mathcal{D}_4$	a	lady	in	a	`[v]`	`[v]`	`[v]`
$\mathcal{D}_2$	a	lady	`[v]`	`[v]`	`[v]`	`[v]`	`[v]`
$\mathcal{D}_0$	`[v]`	`[v]`	`[v]`	`[v]`	`[v]`	`[v]`	`[v]`

Table 1: An example of the proposed input degradation schemes: $\mathcal{D}$ is the original sentence.

3 Experimental Setup

Dataset. We conduct experiments on the English→French part of Multi30K. The models are trained on the concatenation of the *train* and *val* sets (30K sentences) whereas *test2016 (dev)* and *test2017 (test)* are used for early-stopping and model evaluation, respectively. For *entity masking*, we revert to the default Flickr30K splits and perform the model evaluation on *test2016*, since *test2017* is not annotated for entities. We use word-level vocabularies of 9,951 English and 11,216 French words. We use Moses (Koehn et al., 2007) scripts to lowercase, normalize and tokenize the sentences with hyphen splitting. The hyphens are stitched back prior to evaluation.

Visual Features. We use a ResNet-50 CNN (He et al., 2016) trained on ImageNet (Deng et al., 2009) as image encoder. Prior to feature extraction, we center and standardize the images using ImageNet statistics, resize the shortest edge to 256 pixels and take a center crop of size 256x256. We extract spatial features of size 2048x8x8 from the final convolutional layer and apply L_2 normalization along the depth dimension (Caglayan et al., 2018). For the non-attentive model, we use the 2048-dimensional global average pooled version (pool5) of the above convolutional features.

Models. Our baseline NMT is an attentive model (Bahdanau et al., 2014) with a 2-layer bidirectional GRU encoder (Cho et al., 2014) and a 2-layer conditional GRU decoder (Sennrich et al., 2017). The second layer of the decoder receives the output of the attention layer as input.

	$\mathcal{D}$	$\mathcal{D}_{\mathrm{C}}$
NMT	70.6 ± 0.5	68.4 ± 0.1
INIT	70.7 ± 0.2	$\mathbf{68.9} \pm 0.1$
HIER	70.9 ± 0.3	$\mathbf{69.0} \pm 0.3$
DIRECT	70.9 ± 0.2	$\mathbf{68.8} \pm 0.3$

Table 2: Baseline and color-deprivation METEOR scores: bold systems are significantly different from the NMT system within the same column (p-value ≤ 0.03).

For the MMT model, we explore the basic multimodal attention (DIRECT) (Caglayan et al., 2016) and its hierarchical (HIER) extension (Libovický and Helcl, 2017). The former linearly projects the concatenation of textual and visual context vectors to obtain the multimodal context vector, while the latter replaces the concatenation with another attention layer. Finally, we also experiment with encoder-decoder initialization (INIT) (Calixto and Liu, 2017; Caglayan et al., 2017a) where we initialize both the encoder and the decoder using a non-linear transformation of the pool5 features.

Hyperparameters. The encoder and decoder GRUs have 400 hidden units and are initialized with 0 except the multimodal INIT system. All embeddings are 200-dimensional and the decoder embeddings are tied (Press and Wolf, 2016). A dropout of 0.4 and 0.5 is applied on source embeddings and encoder/decoder outputs, respectively (Srivastava et al., 2014). The weights are decayed with a factor of $1e{-}5$. We use ADAM (Kingma and Ba, 2014) with a learning rate of $4e{-}4$ and mini-batches of 64 samples. The gradients are clipped if the total norm exceeds 1 (Pascanu et al., 2013). The training is early-stopped if *dev* set METEOR (Denkowski and Lavie, 2014) does not improve for ten epochs. All experiments are conducted with *nmtpytorch*[1] (Caglayan et al., 2017b).

4 Results

We train all systems three times each with different random initialization in order to perform significance testing with *multeval* (Clark et al., 2011). Throughout the section, we always report the mean over three runs (and the standard deviation) of the considered metrics. We decode the translations with a beam size of 12.

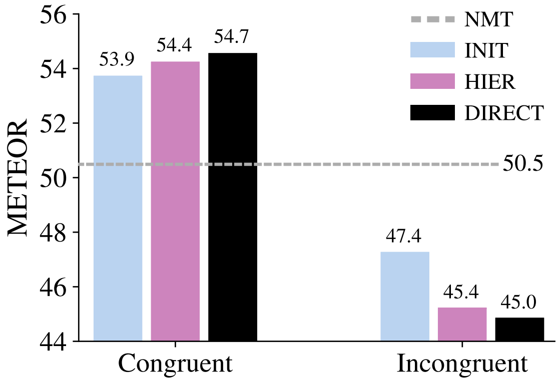

Figure 1: Entity masking: all masked MMT models are significantly better than the masked NMT (dashed). Incongruent decoding severely worsens all systems. The vanilla NMT baseline is 75.9[2].

We first present *test2017* METEOR scores for the baseline NMT and MMT systems, when trained on the full dataset $\mathcal{D}$ (Table 2). The first column indicates that, although MMT models perform slightly better on average, they are not significantly better than the baseline NMT. We now introduce and discuss the results obtained under the proposed degradation schemes. Please refer to Table 5 and the appendix for qualitative examples.

4.1 Color Deprivation

Unlike the inconclusive results for $\mathcal{D}$, we observe that all MMT models are significantly better than NMT when color deprivation is applied ($\mathcal{D}_{\mathrm{C}}$ in Table 2). If we further focus on the subset of the test set subjected to color deprivation (247 sentences), the gain increases to 1.6 METEOR for HIER. For the latter subset, we also computed the average color accuracy per sentence and found that the attentive models are 12% better than the NMT (32.5→44.5) whereas the INIT model only brings 4% (32.5→36.5) improvement. This shows that more complex MMT models are better at integrating visual information to perform better.

4.2 Entity Masking

The gains are much more prominent with entity masking, where the degradation occurs at a larger scale: Attentive MMT models show up to 4.2 METEOR improvement over NMT (Figure 1). We observed a large performance drop with *incongruent decoding*, suggesting that the visual modality is

---

[1] `github.com/lium-lst/nmtpytorch`

[2] Since entity masking uses Flickr30K splits (Section 3) rather than our splits, the scores are not comparable to those from other experiments in this paper.

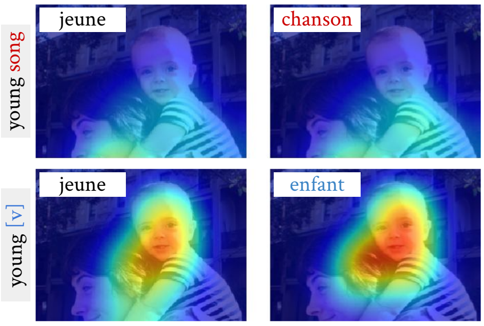

Figure 2: Baseline MMT (top) translates the misspelled "son" while the masked MMT (bottom) correctly produces "enfant" (child) by focusing on the image.

	+ Gain (↓ Incongruence Drop)		
	INIT	HIER	DIRECT
Czech	+1.4 (↓ 2.9)	+1.7 (↓ 3.5)	+1.7 (↓ 4.1)
German	+2.1 (↓ 4.7)	+2.5 (↓ 5.9)	+2.7 (↓ 6.5)
French	+3.4 (↓ 6.5)	+3.9 (↓ 9.0)	+4.2 (↓ 9.7)

Table 3: *Entity masking* results across three languages: all MMT models perform significantly better than their NMT counterparts (p-value ≤ 0.01). The incongruence drop applies on top of the MMT score.

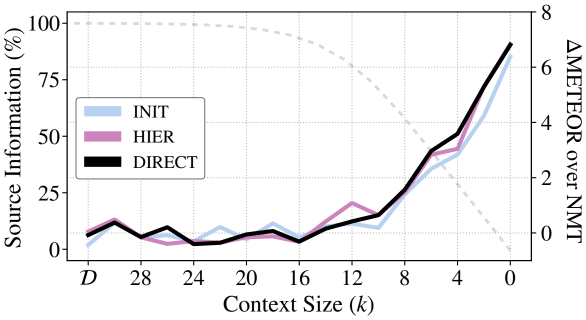

Figure 3: Multimodal gain in absolute METEOR for *progressive masking*: the dashed gray curve indicates the percentage of non-masked words in the training set.

	$\mathcal{D}_4$	$\mathcal{D}_6$	$\mathcal{D}_{12}$	$\mathcal{D}_{20}$	$\mathcal{D}$
DIRECT	**32.3**	**42.2**	**64.5**	**70.1**	**70.9**
Incongruent Dec.	↓ 6.4	↓ 5.5	↓ 1.4	↓ 0.7	↓ 0.7
Blinding	↓ 3.9	↓ 2.9	↓ 0.4	↓ 0.5	↓ 0.3
NMT	↓ 3.7	↓ 2.6	↓ 0.6	↓ 0.2	↓ 0.3

Table 4: The impact of incongruent decoding for *progressive masking*: all METEOR differences are against the DIRECT model. The blinded systems are both trained and decoded using incongruent features.

now much more important than previously demonstrated (Elliott, 2018). A comparison of attention maps produced by the baseline and masked MMT models reveals that the attention weights are more consistent in the latter. An interesting example is given in Figure 2 where the masked MMT model attends to the correct region of the image and successfully translates a dropped word that was otherwise a spelling mistake ("son"→"song").

Czech and German. In order to understand whether the above observations are also consistent across different languages, we extend the *entity masking* experiments to German and Czech parts of Multi30K. Table 3 shows the gain of each MMT system with respect to the NMT model and the subsequent drop caused by incongruent decoding[3]. First, we see that the multimodal benefits clearly hold for German and Czech, although the gains are lower than for French[4]. Second, when we compute the average drop from using incongruent images across all languages, we see how conservative the INIT system is (↓ 4.7) compared to HIER (↓ 6.1) and DIRECT (↓ 6.8). This raises a follow-up question as to whether the hidden state initialization eventually loses its impact throughout the recurrence where, as a consequence, the only modality processed is the text.

4.3 Progressive Masking

Finally, we discuss the results of the progressive masking experiments for French. Figure 3 clearly shows that as the sentences are progressively degraded, all MMT systems are able to leverage the visual modality. When the multimodal task becomes image captioning at $k{=}0$, MMT models improve over the language-model counterpart by $\sim$7 METEOR. Further qualitative examples show that the systems perform surprisingly well by producing visually plausible sentences (see Table 5 and the Appendix).

To get a sense of the visual sensitivity, we pick the DIRECT models trained on four degraded variants and perform *incongruent decoding*. We notice that as the amount of linguistic information increases, the gap narrows down: the MMT system gradually becomes less perplexed by the incongruence or, put in other words, less sensitive to the visual modality (Table 4).

---

[3] For example, the INIT system for French (Figure 1) surpasses the baseline (50.5) by reaching 53.9 (+3.4), which ends up at 47.4 (↓ 6.5) after incongruent decoding.

[4] This is probably due to the morphological richness of DE and CS which is suboptimally handled by word-level MT.

	`SRC`:	an older woman in `[v] [v] [v] [v] [v] [v] [v] [v] [v] [v] [v]`
	`NMT`:	une femme âgée avec un t-shirt blanc et des lunettes de soleil est assise sur un banc
		(an older woman with a white t-shirt and sunglasses is sitting on a bank)
	`MMT`:	une femme âgée en **maillot de bain rose** est assise sur un **rocher au bord de l'eau**
		(an older woman with a pink swimsuit is sitting on a rock at the seaside)
	`REF`:	une femme âgée **en bikini** bronze sur **un rocher au bord de l'océan**
		(an older woman in bikini is tanning on a rock at the edge of the ocean)
	`SRC`:	a young `[v]` in `[v]` holding a tennis `[v]`
	`NMT`:	un jeune garçon en bleu tenant une raquette de tennis
		(a young boy in blue holding a tennis racket)
	`MMT`:	**une** jeune **femme** en **blanc** tenant une raquette de tennis
	`REF`:	**une** jeune **femme** en **blanc** tenant une raquette de tennis
		(a young girl in white holding a tennis racket)
	`SRC`:	little girl covering her face with a `[v]` towel
	`NMT`:	une petite fille couvrant son visage avec une serviette blanche
		(a little girl covering her face with a white towel)
	`MMT`:	une petite fille couvrant son visage avec une serviette **bleue**
	`REF`:	une petite fille couvrant son visage avec une serviette **bleue**
		(a little girl covering her face with a blue towel)

Table 5: Qualitative examples from progressive masking, entity masking and color deprivation, respectively. Underlined and bold words highlight the bad and good lexical choices. MMT is an attentive system.

We then conduct a contrastive "blinding" experiment where the DIRECT models are not only fed with incongruent features at decoding time but also trained with them from scratch. The results suggest that the blinded models learn to ignore the visual modality. In fact, their performance is equivalent to NMT models.

5 Discussion and Conclusions

We presented an in-depth study on the potential contribution of images for multimodal machine translation. Specifically, we analysed the behavior of state-of-the-art MMT models under several degradation schemes in the Multi30K dataset, in order to reveal and understand the impact of textual predominance. Our results show that the models explored are able to integrate the visual modality if the available modalities are complementary rather than redundant. In the latter case, the primary modality (text) sufficient to accomplish the task. This dominance effect corroborates the seminal work of Colavita (1974) in Psychophysics where it has been demonstrated that visual stimuli dominate over the auditory stimuli when humans are asked to perform a simple audiovisual discrimination task. Our investigation using source degradation also suggests that visual grounding can increase the robustness of machine translation systems by mitigating input noise such as errors in the source text. In the future, we would like to devise models that can learn when and how to integrate multiple modalities by taking care of the complementary and redundant aspects of them in an intelligent way.

Acknowledgments

This work is a follow-up on the research efforts conducted within the "Grounded sequence-to-sequence transduction" team of the JSALT 2018 Workshop. We would like to thank Jindřich Libovický for contributing the hierarchical attention to *nmtpytorch* during the workshop. We also thank the reviewers for their valuable comments.

BERT: Pre-training of Deep Bidirectional Transformers for Language Understanding

Jacob Devlin **Ming-Wei Chang** **Kenton Lee** **Kristina Toutanova**
Google AI Language
`{jacobdevlin,mingweichang,kentonl,kristout}@google.com`

Abstract

We introduce a new language representation model called **BERT**, which stands for **B**idirectional **E**ncoder **R**epresentations from **T**ransformers. Unlike recent language representation models (Peters et al., 2018a; Radford et al., 2018), BERT is designed to pretrain deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers. As a result, the pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, without substantial task-specific architecture modifications.

BERT is conceptually simple and empirically powerful. It obtains new state-of-the-art results on eleven natural language processing tasks, including pushing the GLUE score to 80.5% (7.7% point absolute improvement), MultiNLI accuracy to 86.7% (4.6% absolute improvement), SQuAD v1.1 question answering Test F1 to 93.2 (1.5 point absolute improvement) and SQuAD v2.0 Test F1 to 83.1 (5.1 point absolute improvement).

1 Introduction

Language model pre-training has been shown to be effective for improving many natural language processing tasks (Dai and Le, 2015; Peters et al., 2018a; Radford et al., 2018; Howard and Ruder, 2018). These include sentence-level tasks such as natural language inference (Bowman et al., 2015; Williams et al., 2018) and paraphrasing (Dolan and Brockett, 2005), which aim to predict the relationships between sentences by analyzing them holistically, as well as token-level tasks such as named entity recognition and question answering, where models are required to produce fine-grained output at the token level (Tjong Kim Sang and De Meulder, 2003; Rajpurkar et al., 2016).

There are two existing strategies for applying pre-trained language representations to downstream tasks: *feature-based* and *fine-tuning*. The feature-based approach, such as ELMo (Peters et al., 2018a), uses task-specific architectures that include the pre-trained representations as additional features. The fine-tuning approach, such as the Generative Pre-trained Transformer (OpenAI GPT) (Radford et al., 2018), introduces minimal task-specific parameters, and is trained on the downstream tasks by simply fine-tuning *all* pretrained parameters. The two approaches share the same objective function during pre-training, where they use unidirectional language models to learn general language representations.

We argue that current techniques restrict the power of the pre-trained representations, especially for the fine-tuning approaches. The major limitation is that standard language models are unidirectional, and this limits the choice of architectures that can be used during pre-training. For example, in OpenAI GPT, the authors use a left-to-right architecture, where every token can only attend to previous tokens in the self-attention layers of the Transformer (Vaswani et al., 2017). Such restrictions are sub-optimal for sentence-level tasks, and could be very harmful when applying fine-tuning based approaches to token-level tasks such as question answering, where it is crucial to incorporate context from both directions.

In this paper, we improve the fine-tuning based approaches by proposing BERT: **B**idirectional **E**ncoder **R**epresentations from **T**ransformers. BERT alleviates the previously mentioned unidirectionality constraint by using a "masked language model" (MLM) pre-training objective, inspired by the Cloze task (Taylor, 1953). The masked language model randomly masks some of the tokens from the input, and the objective is to predict the original vocabulary id of the masked

Proceedings of NAACL-HLT 2019, pages 4171–4186
Minneapolis, Minnesota, June 2 - June 7, 2019.

word based only on its context. Unlike left-to-right language model pre-training, the MLM objective enables the representation to fuse the left and the right context, which allows us to pre-train a deep bidirectional Transformer. In addition to the masked language model, we also use a "next sentence prediction" task that jointly pre-trains text-pair representations. The contributions of our paper are as follows:

- We demonstrate the importance of bidirectional pre-training for language representations. Unlike Radford et al. (2018), which uses unidirectional language models for pre-training, BERT uses masked language models to enable pre-trained deep bidirectional representations. This is also in contrast to Peters et al. (2018a), which uses a shallow concatenation of independently trained left-to-right and right-to-left LMs.
- We show that pre-trained representations reduce the need for many heavily-engineered task-specific architectures. BERT is the first fine-tuning based representation model that achieves state-of-the-art performance on a large suite of sentence-level *and* token-level tasks, outperforming many task-specific architectures.
- BERT advances the state of the art for eleven NLP tasks. The code and pre-trained models are available at `https://github.com/google-research/bert`.

2 Related Work

There is a long history of pre-training general language representations, and we briefly review the most widely-used approaches in this section.

2.1 Unsupervised Feature-based Approaches

Learning widely applicable representations of words has been an active area of research for decades, including non-neural (Brown et al., 1992; Ando and Zhang, 2005; Blitzer et al., 2006) and neural (Mikolov et al., 2013; Pennington et al., 2014) methods. Pre-trained word embeddings are an integral part of modern NLP systems, offering significant improvements over embeddings learned from scratch (Turian et al., 2010). To pre-train word embedding vectors, left-to-right language modeling objectives have been used (Mnih and Hinton, 2009), as well as objectives to discriminate correct from incorrect words in left and right context (Mikolov et al., 2013).

These approaches have been generalized to coarser granularities, such as sentence embeddings (Kiros et al., 2015; Logeswaran and Lee, 2018) or paragraph embeddings (Le and Mikolov, 2014). To train sentence representations, prior work has used objectives to rank candidate next sentences (Jernite et al., 2017; Logeswaran and Lee, 2018), left-to-right generation of next sentence words given a representation of the previous sentence (Kiros et al., 2015), or denoising auto-encoder derived objectives (Hill et al., 2016).

ELMo and its predecessor (Peters et al., 2017, 2018a) generalize traditional word embedding research along a different dimension. They extract *context-sensitive* features from a left-to-right and a right-to-left language model. The contextual representation of each token is the concatenation of the left-to-right and right-to-left representations. When integrating contextual word embeddings with existing task-specific architectures, ELMo advances the state of the art for several major NLP benchmarks (Peters et al., 2018a) including question answering (Rajpurkar et al., 2016), sentiment analysis (Socher et al., 2013), and named entity recognition (Tjong Kim Sang and De Meulder, 2003). Melamud et al. (2016) proposed learning contextual representations through a task to predict a single word from both left and right context using LSTMs. Similar to ELMo, their model is feature-based and not deeply bidirectional. Fedus et al. (2018) shows that the cloze task can be used to improve the robustness of text generation models.

2.2 Unsupervised Fine-tuning Approaches

As with the feature-based approaches, the first works in this direction only pre-trained word embedding parameters from unlabeled text (Collobert and Weston, 2008).

More recently, sentence or document encoders which produce contextual token representations have been pre-trained from unlabeled text and fine-tuned for a supervised downstream task (Dai and Le, 2015; Howard and Ruder, 2018; Radford et al., 2018). The advantage of these approaches is that few parameters need to be learned from scratch. At least partly due to this advantage, OpenAI GPT (Radford et al., 2018) achieved previously state-of-the-art results on many sentence-level tasks from the GLUE benchmark (Wang et al., 2018a). Left-to-right language model-

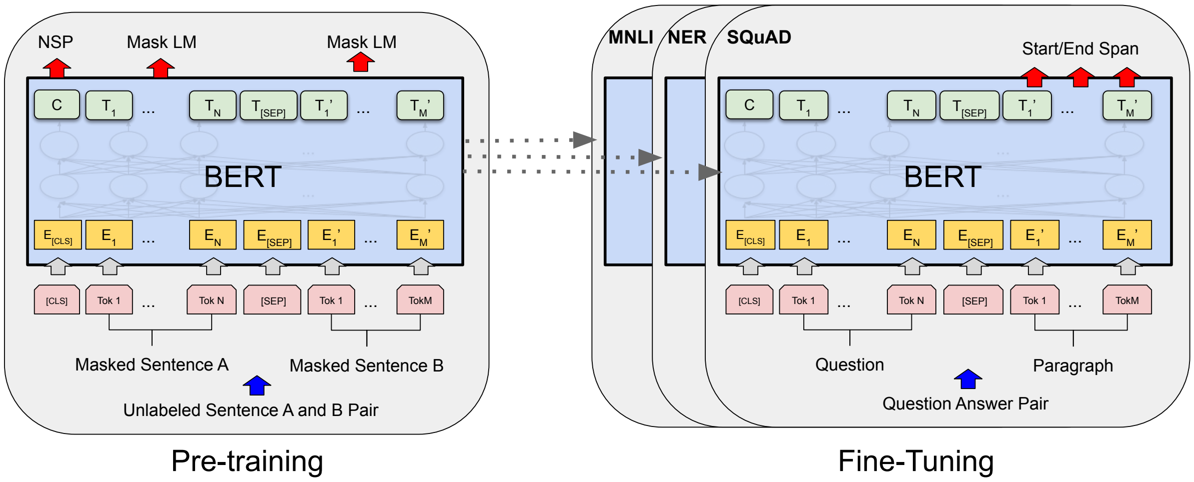

Figure 1: Overall pre-training and fine-tuning procedures for BERT. Apart from output layers, the same architectures are used in both pre-training and fine-tuning. The same pre-trained model parameters are used to initialize models for different down-stream tasks. During fine-tuning, all parameters are fine-tuned. `[CLS]` is a special symbol added in front of every input example, and `[SEP]` is a special separator token (e.g. separating questions/answers).

ing and auto-encoder objectives have been used for pre-training such models (Howard and Ruder, 2018; Radford et al., 2018; Dai and Le, 2015).

2.3 Transfer Learning from Supervised Data

There has also been work showing effective transfer from supervised tasks with large datasets, such as natural language inference (Conneau et al., 2017) and machine translation (McCann et al., 2017). Computer vision research has also demonstrated the importance of transfer learning from large pre-trained models, where an effective recipe is to fine-tune models pre-trained with ImageNet (Deng et al., 2009; Yosinski et al., 2014).

3 BERT

We introduce BERT and its detailed implementation in this section. There are two steps in our framework: *pre-training* and *fine-tuning*. During pre-training, the model is trained on unlabeled data over different pre-training tasks. For fine-tuning, the BERT model is first initialized with the pre-trained parameters, and all of the parameters are fine-tuned using labeled data from the downstream tasks. Each downstream task has separate fine-tuned models, even though they are initialized with the same pre-trained parameters. The question-answering example in Figure 1 will serve as a running example for this section.

A distinctive feature of BERT is its unified architecture across different tasks. There is minimal difference between the pre-trained architecture and the final downstream architecture.

Model Architecture BERT's model architecture is a multi-layer bidirectional Transformer encoder based on the original implementation described in Vaswani et al. (2017) and released in the `tensor2tensor` library.[1] Because the use of Transformers has become common and our implementation is almost identical to the original, we will omit an exhaustive background description of the model architecture and refer readers to Vaswani et al. (2017) as well as excellent guides such as "The Annotated Transformer."[2]

In this work, we denote the number of layers (i.e., Transformer blocks) as L, the hidden size as H, and the number of self-attention heads as A.[3] We primarily report results on two model sizes: **BERT$_{\text{BASE}}$** (L=12, H=768, A=12, Total Parameters=110M) and **BERT$_{\text{LARGE}}$** (L=24, H=1024, A=16, Total Parameters=340M).

BERT$_{\text{BASE}}$ was chosen to have the same model size as OpenAI GPT for comparison purposes. Critically, however, the BERT Transformer uses bidirectional self-attention, while the GPT Transformer uses constrained self-attention where every token can only attend to context to its left.[4]

---

[1] https://github.com/tensorflow/tensor2tensor

[2] http://nlp.seas.harvard.edu/2018/04/03/attention.html

[3] In all cases we set the feed-forward/filter size to be $4H$, i.e., 3072 for the $H = 768$ and 4096 for the $H = 1024$.

[4] We note that in the literature the bidirectional Trans-

Input/Output Representations To make BERT handle a variety of down-stream tasks, our input representation is able to unambiguously represent both a single sentence and a pair of sentences (e.g., ⟨ Question, Answer ⟩) in one token sequence. Throughout this work, a "sentence" can be an arbitrary span of contiguous text, rather than an actual linguistic sentence. A "sequence" refers to the input token sequence to BERT, which may be a single sentence or two sentences packed together.

We use WordPiece embeddings (Wu et al., 2016) with a 30,000 token vocabulary. The first token of every sequence is always a special classification token (`[CLS]`). The final hidden state corresponding to this token is used as the aggregate sequence representation for classification tasks. Sentence pairs are packed together into a single sequence. We differentiate the sentences in two ways. First, we separate them with a special token (`[SEP]`). Second, we add a learned embedding to every token indicating whether it belongs to sentence `A` or sentence `B`. As shown in Figure 1, we denote input embedding as E, the final hidden vector of the special `[CLS]` token as $C \in \mathbb{R}^H$, and the final hidden vector for the i^{th} input token as $T_i \in \mathbb{R}^H$.

For a given token, its input representation is constructed by summing the corresponding token, segment, and position embeddings. A visualization of this construction can be seen in Figure 2.

3.1 Pre-training BERT

Unlike Peters et al. (2018a) and Radford et al. (2018), we do not use traditional left-to-right or right-to-left language models to pre-train BERT. Instead, we pre-train BERT using two unsupervised tasks, described in this section. This step is presented in the left part of Figure 1.

Task #1: Masked LM Intuitively, it is reasonable to believe that a deep bidirectional model is strictly more powerful than either a left-to-right model or the shallow concatenation of a left-to-right and a right-to-left model. Unfortunately, standard conditional language models can only be trained left-to-right *or* right-to-left, since bidirectional conditioning would allow each word to indirectly "see itself", and the model could trivially predict the target word in a multi-layered context.

In order to train a deep bidirectional representation, we simply mask some percentage of the input tokens at random, and then predict those masked tokens. We refer to this procedure as a "masked LM" (MLM), although it is often referred to as a *Cloze* task in the literature (Taylor, 1953). In this case, the final hidden vectors corresponding to the mask tokens are fed into an output softmax over the vocabulary, as in a standard LM. In all of our experiments, we mask 15% of all WordPiece tokens in each sequence at random. In contrast to denoising auto-encoders (Vincent et al., 2008), we only predict the masked words rather than reconstructing the entire input.

Although this allows us to obtain a bidirectional pre-trained model, a downside is that we are creating a mismatch between pre-training and fine-tuning, since the `[MASK]` token does not appear during fine-tuning. To mitigate this, we do not always replace "masked" words with the actual `[MASK]` token. The training data generator chooses 15% of the token positions at random for prediction. If the i-th token is chosen, we replace the i-th token with (1) the `[MASK]` token 80% of the time (2) a random token 10% of the time (3) the unchanged i-th token 10% of the time. Then, T_i will be used to predict the original token with cross entropy loss. We compare variations of this procedure in Appendix C.2.

Task #2: Next Sentence Prediction (NSP) Many important downstream tasks such as Question Answering (QA) and Natural Language Inference (NLI) are based on understanding the *relationship* between two sentences, which is not directly captured by language modeling. In order to train a model that understands sentence relationships, we pre-train for a binarized *next sentence prediction* task that can be trivially generated from any monolingual corpus. Specifically, when choosing the sentences `A` and `B` for each pre-training example, 50% of the time `B` is the actual next sentence that follows `A` (labeled as `IsNext`), and 50% of the time it is a random sentence from the corpus (labeled as `NotNext`). As we show in Figure 1, C is used for next sentence prediction (NSP).[5] Despite its simplicity, we demonstrate in Section 5.1 that pre-training towards this task is very beneficial to both QA and NLI. [6]

---

former is often referred to as a "Transformer encoder" while the left-context-only version is referred to as a "Transformer decoder" since it can be used for text generation.

[5] The final model achieves 97%-98% accuracy on NSP.

[6] The vector C is not a meaningful sentence representation without fine-tuning, since it was trained with NSP.

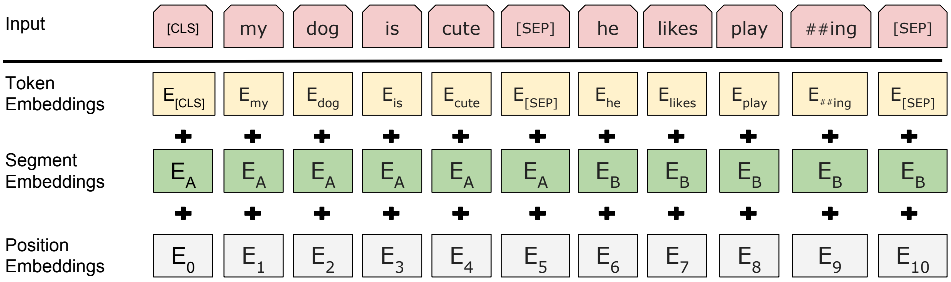

Figure 2: BERT input representation. The input embeddings are the sum of the token embeddings, the segmentation embeddings and the position embeddings.

The NSP task is closely related to representation-learning objectives used in Jernite et al. (2017) and Logeswaran and Lee (2018). However, in prior work, only sentence embeddings are transferred to down-stream tasks, where BERT transfers all parameters to initialize end-task model parameters.

Pre-training data The pre-training procedure largely follows the existing literature on language model pre-training. For the pre-training corpus we use the BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words). For Wikipedia we extract only the text passages and ignore lists, tables, and headers. It is critical to use a document-level corpus rather than a shuffled sentence-level corpus such as the Billion Word Benchmark (Chelba et al., 2013) in order to extract long contiguous sequences.

3.2 Fine-tuning BERT

Fine-tuning is straightforward since the self-attention mechanism in the Transformer allows BERT to model many downstream tasks—whether they involve single text or text pairs—by swapping out the appropriate inputs and outputs. For applications involving text pairs, a common pattern is to independently encode text pairs before applying bidirectional cross attention, such as Parikh et al. (2016); Seo et al. (2017). BERT instead uses the self-attention mechanism to unify these two stages, as encoding a concatenated text pair with self-attention effectively includes *bidirectional* cross attention between two sentences.

For each task, we simply plug in the task-specific inputs and outputs into BERT and fine-tune all the parameters end-to-end. At the input, sentence `A` and sentence `B` from pre-training are analogous to (1) sentence pairs in paraphrasing, (2) hypothesis-premise pairs in entailment, (3) question-passage pairs in question answering, and (4) a degenerate text-$\varnothing$ pair in text classification or sequence tagging. At the output, the token representations are fed into an output layer for token-level tasks, such as sequence tagging or question answering, and the `[CLS]` representation is fed into an output layer for classification, such as entailment or sentiment analysis.

Compared to pre-training, fine-tuning is relatively inexpensive. All of the results in the paper can be replicated in at most 1 hour on a single Cloud TPU, or a few hours on a GPU, starting from the exact same pre-trained model.[7] We describe the task-specific details in the corresponding subsections of Section 4. More details can be found in Appendix A.5.

4 Experiments

In this section, we present BERT fine-tuning results on 11 NLP tasks.

4.1 GLUE

The General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018a) is a collection of diverse natural language understanding tasks. Detailed descriptions of GLUE datasets are included in Appendix B.1.

To fine-tune on GLUE, we represent the input sequence (for single sentence or sentence pairs) as described in Section 3, and use the final hidden vector $C \in \mathbb{R}^H$ corresponding to the first input token (`[CLS]`) as the aggregate representation. The only new parameters introduced during fine-tuning are classification layer weights $W \in \mathbb{R}^{K \times H}$, where K is the number of labels. We compute a standard classification loss with C and W, i.e., $\log(\mathrm{softmax}(CW^T))$.

---

[7] For example, the BERT SQuAD model can be trained in around 30 minutes on a single Cloud TPU to achieve a Dev F1 score of 91.0%.

[8] See (10) in `https://gluebenchmark.com/faq`.

System	MNLI-(m/mm)	QQP	QNLI	SST-2	CoLA	STS-B	MRPC	RTE	**Average**
	392k	363k	108k	67k	8.5k	5.7k	3.5k	2.5k	-
Pre-OpenAI SOTA	80.6/80.1	66.1	82.3	93.2	35.0	81.0	86.0	61.7	74.0
BiLSTM+ELMo+Attn	76.4/76.1	64.8	79.8	90.4	36.0	73.3	84.9	56.8	71.0
OpenAI GPT	82.1/81.4	70.3	87.4	91.3	45.4	80.0	82.3	56.0	75.1
BERT$_{\text{BASE}}$	84.6/83.4	71.2	90.5	93.5	52.1	85.8	88.9	66.4	79.6
BERT$_{\text{LARGE}}$	**86.7/85.9**	**72.1**	**92.7**	**94.9**	**60.5**	**86.5**	**89.3**	**70.1**	**82.1**

Table 1: GLUE Test results, scored by the evaluation server (`https://gluebenchmark.com/leaderboard`). The number below each task denotes the number of training examples. The "Average" column is slightly different than the official GLUE score, since we exclude the problematic WNLI set.[8] BERT and OpenAI GPT are single-model, single task. F1 scores are reported for QQP and MRPC, Spearman correlations are reported for STS-B, and accuracy scores are reported for the other tasks. We exclude entries that use BERT as one of their components.

We use a batch size of 32 and fine-tune for 3 epochs over the data for all GLUE tasks. For each task, we selected the best fine-tuning learning rate (among 5e-5, 4e-5, 3e-5, and 2e-5) on the Dev set. Additionally, for BERT$_{\text{LARGE}}$ we found that fine-tuning was sometimes unstable on small datasets, so we ran several random restarts and selected the best model on the Dev set. With random restarts, we use the same pre-trained checkpoint but perform different fine-tuning data shuffling and classifier layer initialization.[9]

Results are presented in Table 1. Both BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ outperform all systems on all tasks by a substantial margin, obtaining 4.5% and 7.0% respective average accuracy improvement over the prior state of the art. Note that BERT$_{\text{BASE}}$ and OpenAI GPT are nearly identical in terms of model architecture apart from the attention masking. For the largest and most widely reported GLUE task, MNLI, BERT obtains a 4.6% absolute accuracy improvement. On the official GLUE leaderboard[10], BERT$_{\text{LARGE}}$ obtains a score of 80.5, compared to OpenAI GPT, which obtains 72.8 as of the date of writing.

We find that BERT$_{\text{LARGE}}$ significantly outperforms BERT$_{\text{BASE}}$ across all tasks, especially those with very little training data. The effect of model size is explored more thoroughly in Section 5.2.

4.2 SQuAD v1.1

The Stanford Question Answering Dataset (SQuAD v1.1) is a collection of 100k crowd-sourced question/answer pairs (Rajpurkar et al., 2016). Given a question and a passage from Wikipedia containing the answer, the task is to predict the answer text span in the passage.

As shown in Figure 1, in the question answering task, we represent the input question and passage as a single packed sequence, with the question using the `A` embedding and the passage using the `B` embedding. We only introduce a start vector $S \in \mathbb{R}^H$ and an end vector $E \in \mathbb{R}^H$ during fine-tuning. The probability of word i being the start of the answer span is computed as a dot product between T_i and S followed by a softmax over all of the words in the paragraph: $P_i = \frac{e^{S \cdot T_i}}{\sum_j e^{S \cdot T_j}}$. The analogous formula is used for the end of the answer span. The score of a candidate span from position i to position j is defined as $S{\cdot}T_i + E{\cdot}T_j$, and the maximum scoring span where $j \geq i$ is used as a prediction. The training objective is the sum of the log-likelihoods of the correct start and end positions. We fine-tune for 3 epochs with a learning rate of 5e-5 and a batch size of 32.

Table 2 shows top leaderboard entries as well as results from top published systems (Seo et al., 2017; Clark and Gardner, 2018; Peters et al., 2018a; Hu et al., 2018). The top results from the SQuAD leaderboard do not have up-to-date public system descriptions available,[11] and are allowed to use any public data when training their systems. We therefore use modest data augmentation in our system by first fine-tuning on TriviaQA (Joshi et al., 2017) befor fine-tuning on SQuAD.

Our best performing system outperforms the top leaderboard system by +1.5 F1 in ensembling and +1.3 F1 as a single system. In fact, our single BERT model outperforms the top ensemble system in terms of F1 score. Without TriviaQA fine-

tuning data, we only lose 0.1-0.4 F1, still outperforming all existing systems by a wide margin.[12]

4.3 SQuAD v2.0

The SQuAD 2.0 task extends the SQuAD 1.1 problem definition by allowing for the possibility that no short answer exists in the provided paragraph, making the problem more realistic.

We use a simple approach to extend the SQuAD v1.1 BERT model for this task. We treat questions that do not have an answer as having an answer span with start and end at the `[CLS]` token. The probability space for the start and end answer span positions is extended to include the position of the `[CLS]` token. For prediction, we compare the score of the no-answer span: $s_{\mathtt{null}} = S{\cdot}C + E{\cdot}C$ to the score of the best non-null span $\hat{s_{i,j}}$ = $\mathtt{max}_{j \geq i} S{\cdot}T_i + E{\cdot}T_j$. We predict a non-null answer when $\hat{s_{i,j}} > s_{\mathtt{null}} + \tau$, where the threshold τ is selected on the dev set to maximize F1. We did not use TriviaQA data for this model. We fine-tuned for 2 epochs with a learning rate of 5e-5 and a batch size of 48.

Table 4: SWAG Dev and Test accuracies. †Human performance is measured with 100 samples, as reported in the SWAG paper.

The results compared to prior leaderboard entries and top published work (Sun et al., 2018; Wang et al., 2018b) are shown in Table 3, excluding systems that use BERT as one of their components. We observe a +5.1 F1 improvement over the previous best system.

4.4 SWAG

The Situations With Adversarial Generations (SWAG) dataset contains 113k sentence-pair completion examples that evaluate grounded commonsense inference (Zellers et al., 2018). Given a sentence, the task is to choose the most plausible continuation among four choices.

When fine-tuning on the SWAG dataset, we construct four input sequences, each containing the concatenation of the given sentence (sentence `A`) and a possible continuation (sentence `B`). The only task-specific parameters introduced is a vector whose dot product with the `[CLS]` token representation C denotes a score for each choice which is normalized with a softmax layer.

We fine-tune the model for 3 epochs with a learning rate of 2e-5 and a batch size of 16. Results are presented in Table 4. BERT$_{\text{LARGE}}$ outperforms the authors' baseline ESIM+ELMo system by +27.1% and OpenAI GPT by 8.3%.

5 Ablation Studies

In this section, we perform ablation experiments over a number of facets of BERT in order to better understand their relative importance. Additional

---

Tasks	Dev Set MNLI-m (Acc)	QNLI (Acc)	MRPC (Acc)	SST-2 (Acc)	SQuAD (F1)
$\text{BERT}_{\text{BASE}}$	84.4	88.4	86.7	92.7	88.5
No NSP	83.9	84.9	86.5	92.6	87.9
LTR & No NSP	82.1	84.3	77.5	92.1	77.8
+ BiLSTM	82.1	84.1	75.7	91.6	84.9

Table 5: Ablation over the pre-training tasks using the $\text{BERT}_{\text{BASE}}$ architecture. "No NSP" is trained without the next sentence prediction task. "LTR & No NSP" is trained as a left-to-right LM without the next sentence prediction, like OpenAI GPT. "+ BiLSTM" adds a randomly initialized BiLSTM on top of the "LTR + No NSP" model during fine-tuning.

ablation studies can be found in Appendix C.

5.1 Effect of Pre-training Tasks

We demonstrate the importance of the deep bidirectionality of BERT by evaluating two pre-training objectives using exactly the same pre-training data, fine-tuning scheme, and hyperparameters as $\text{BERT}_{\text{BASE}}$:

No NSP: A bidirectional model which is trained using the "masked LM" (MLM) but without the "next sentence prediction" (NSP) task.

LTR & No NSP: A left-context-only model which is trained using a standard Left-to-Right (LTR) LM, rather than an MLM. The left-only constraint was also applied at fine-tuning, because removing it introduced a pre-train/fine-tune mismatch that degraded downstream performance. Additionally, this model was pre-trained without the NSP task. This is directly comparable to OpenAI GPT, but using our larger training dataset, our input representation, and our fine-tuning scheme.

We first examine the impact brought by the NSP task. In Table 5, we show that removing NSP hurts performance significantly on QNLI, MNLI, and SQuAD 1.1. Next, we evaluate the impact of training bidirectional representations by comparing "No NSP" to "LTR & No NSP". The LTR model performs worse than the MLM model on all tasks, with large drops on MRPC and SQuAD.

For SQuAD it is intuitively clear that a LTR model will perform poorly at token predictions, since the token-level hidden states have no right-side context. In order to make a good faith attempt at strengthening the LTR system, we added a randomly initialized BiLSTM on top. This does significantly improve results on SQuAD, but the results are still far worse than those of the pre-trained bidirectional models. The BiLSTM hurts performance on the GLUE tasks.

We recognize that it would also be possible to train separate LTR and RTL models and represent each token as the concatenation of the two models, as ELMo does. However: (a) this is twice as expensive as a single bidirectional model; (b) this is non-intuitive for tasks like QA, since the RTL model would not be able to condition the answer on the question; (c) this it is strictly less powerful than a deep bidirectional model, since it can use both left and right context at every layer.

5.2 Effect of Model Size

In this section, we explore the effect of model size on fine-tuning task accuracy. We trained a number of BERT models with a differing number of layers, hidden units, and attention heads, while otherwise using the same hyperparameters and training procedure as described previously.

Results on selected GLUE tasks are shown in Table 6. In this table, we report the average Dev Set accuracy from 5 random restarts of fine-tuning. We can see that larger models lead to a strict accuracy improvement across all four datasets, even for MRPC which only has 3,600 labeled training examples, and is substantially different from the pre-training tasks. It is also perhaps surprising that we are able to achieve such significant improvements on top of models which are already quite large relative to the existing literature. For example, the largest Transformer explored in Vaswani et al. (2017) is (L=6, H=1024, A=16) with 100M parameters for the encoder, and the largest Transformer we have found in the literature is (L=64, H=512, A=2) with 235M parameters (Al-Rfou et al., 2018). By contrast, $\text{BERT}_{\text{BASE}}$ contains 110M parameters and $\text{BERT}_{\text{LARGE}}$ contains 340M parameters.

It has long been known that increasing the model size will lead to continual improvements on large-scale tasks such as machine translation and language modeling, which is demonstrated by the LM perplexity of held-out training data shown in Table 6. However, we believe that this is the first work to demonstrate convincingly that scaling to extreme model sizes also leads to large improvements on very small scale tasks, provided that the model has been sufficiently pre-trained. Peters et al. (2018b) presented mixed results on the downstream task impact of increasing the pre-trained bi-LM size from two to four layers and Melamud et al. (2016) mentioned in passing that increasing hidden dimension size from 200 to 600 helped, but increasing further to 1,000 did not bring further improvements. Both of these prior works used a feature-based approach — we hypothesize that when the model is fine-tuned directly on the downstream tasks and uses only a very small number of randomly initialized additional parameters, the task-specific models can benefit from the larger, more expressive pre-trained representations even when downstream task data is very small.

5.3 Feature-based Approach with BERT

All of the BERT results presented so far have used the fine-tuning approach, where a simple classification layer is added to the pre-trained model, and all parameters are jointly fine-tuned on a downstream task. However, the feature-based approach, where fixed features are extracted from the pre-trained model, has certain advantages. First, not all tasks can be easily represented by a Transformer encoder architecture, and therefore require a task-specific model architecture to be added. Second, there are major computational benefits to pre-compute an expensive representation of the training data once and then run many experiments with cheaper models on top of this representation.

In this section, we compare the two approaches by applying BERT to the CoNLL-2003 Named Entity Recognition (NER) task (Tjong Kim Sang and De Meulder, 2003). In the input to BERT, we use a case-preserving WordPiece model, and we include the maximal document context provided by the data. Following standard practice, we formulate this as a tagging task but do not use a CRF layer in the output. We use the representation of the first sub-token as the input to the token-level classifier over the NER label set.

Hyperparams				Dev Set Accuracy		
#L	#H	#A	LM (ppl)	MNLI-m	MRPC	SST-2
3	768	12	5.84	77.9	79.8	88.4
6	768	3	5.24	80.6	82.2	90.7
6	768	12	4.68	81.9	84.8	91.3
12	768	12	3.99	84.4	86.7	92.9
12	1024	16	3.54	85.7	86.9	93.3
24	1024	16	3.23	86.6	87.8	93.7

Table 6: Ablation over BERT model size. #L = the number of layers; #H = hidden size; #A = number of attention heads. "LM (ppl)" is the masked LM perplexity of held-out training data.

System	Dev F1	Test F1
ELMo (Peters et al., 2018a)	95.7	92.2
CVT (Clark et al., 2018)	-	92.6
CSE (Akbik et al., 2018)	-	**93.1**
Fine-tuning approach		
BERT$_{\text{LARGE}}$	96.6	92.8
BERT$_{\text{BASE}}$	96.4	92.4
Feature-based approach (BERT$_{\text{BASE}}$)		
Embeddings	91.0	-
Second-to-Last Hidden	95.6	-
Last Hidden	94.9	-
Weighted Sum Last Four Hidden	95.9	-
Concat Last Four Hidden	96.1	-
Weighted Sum All 12 Layers	95.5	-

Table 7: CoNLL-2003 Named Entity Recognition results. Hyperparameters were selected using the Dev set. The reported Dev and Test scores are averaged over 5 random restarts using those hyperparameters.

To ablate the fine-tuning approach, we apply the feature-based approach by extracting the activations from one or more layers *without* fine-tuning any parameters of BERT. These contextual embeddings are used as input to a randomly initialized two-layer 768-dimensional BiLSTM before the classification layer.

Results are presented in Table 7. BERT$_{\text{LARGE}}$ performs competitively with state-of-the-art methods. The best performing method concatenates the token representations from the top four hidden layers of the pre-trained Transformer, which is only 0.3 F1 behind fine-tuning the entire model. This demonstrates that BERT is effective for both fine-tuning and feature-based approaches.

6 Conclusion

Recent empirical improvements due to transfer learning with language models have demonstrated that rich, unsupervised pre-training is an integral part of many language understanding systems. In particular, these results enable even low-resource tasks to benefit from deep unidirectional architectures. Our major contribution is further generalizing these findings to deep *bidirectional* architectures, allowing the same pre-trained model to successfully tackle a broad set of NLP tasks.

Appendix for "BERT: Pre-training of Deep Bidirectional Transformers for Language Understanding"

We organize the appendix into three sections:

- Additional implementation details for BERT are presented in Appendix A;
- Additional details for our experiments are presented in Appendix B; and
- Additional ablation studies are presented in Appendix C.

  We present additional ablation studies for BERT including:
  - Effect of Number of Training Steps; and
  - Ablation for Different Masking Procedures.

A Additional Details for BERT

A.1 Illustration of the Pre-training Tasks

We provide examples of the pre-training tasks in the following.

Masked LM and the Masking Procedure Assuming the unlabeled sentence is `my dog is hairy`, and during the random masking procedure we chose the 4-th token (which corresponding to `hairy`), our masking procedure can be further illustrated by

- 80% of the time: Replace the word with the `[MASK]` token, e.g., `my dog is hairy` → `my dog is [MASK]`
- 10% of the time: Replace the word with a random word, e.g., `my dog is hairy` → `my dog is apple`
- 10% of the time: Keep the word unchanged, e.g., `my dog is hairy` → `my dog is hairy`. The purpose of this is to bias the representation towards the actual observed word.

The advantage of this procedure is that the Transformer encoder does not know which words it will be asked to predict or which have been replaced by random words, so it is forced to keep a distributional contextual representation of *every* input token. Additionally, because random replacement only occurs for 1.5% of all tokens (i.e., 10% of 15%), this does not seem to harm the model's language understanding capability. In Section C.2, we evaluate the impact this procedure.

Compared to standard langauge model training, the masked LM only make predictions on 15% of tokens in each batch, which suggests that more pre-training steps may be required for the model

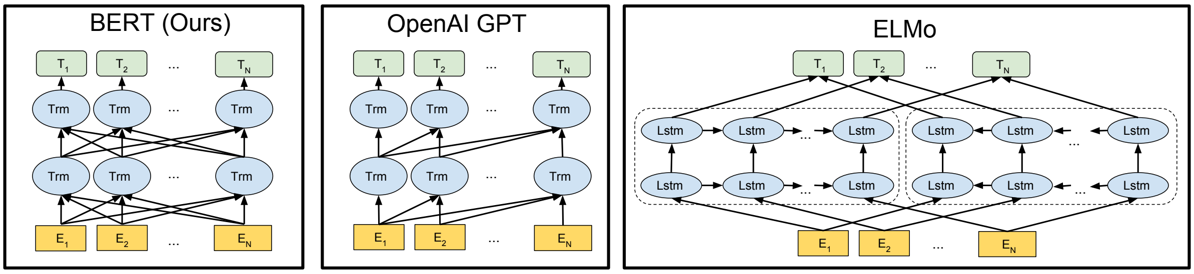

Figure 3: Differences in pre-training model architectures. BERT uses a bidirectional Transformer. OpenAI GPT uses a left-to-right Transformer. ELMo uses the concatenation of independently trained left-to-right and right-to-left LSTMs to generate features for downstream tasks. Among the three, only BERT representations are jointly conditioned on both left and right context in all layers. In addition to the architecture differences, BERT and OpenAI GPT are fine-tuning approaches, while ELMo is a feature-based approach.

to converge. In Section C.1 we demonstrate that MLM does converge marginally slower than a left-to-right model (which predicts every token), but the empirical improvements of the MLM model far outweigh the increased training cost.

Next Sentence Prediction The next sentence prediction task can be illustrated in the following examples.

Input = `[CLS] the man went to [MASK] store [SEP]`
`he bought a gallon [MASK] milk [SEP]`
Label = `IsNext`

Input = `[CLS] the man [MASK] to the store [SEP]`
`penguin [MASK] are flight ##less birds [SEP]`
Label = `NotNext`

A.2 Pre-training Procedure

To generate each training input sequence, we sample two spans of text from the corpus, which we refer to as "sentences" even though they are typically much longer than single sentences (but can be shorter also). The first sentence receives the `A` embedding and the second receives the `B` embedding. 50% of the time `B` is the actual next sentence that follows `A` and 50% of the time it is a random sentence, which is done for the "next sentence prediction" task. They are sampled such that the combined length is $\leq$ 512 tokens. The LM masking is applied after WordPiece tokenization with a uniform masking rate of 15%, and no special consideration given to partial word pieces.

We train with batch size of 256 sequences (256 sequences * 512 tokens = 128,000 tokens/batch) for 1,000,000 steps, which is approximately 40 epochs over the 3.3 billion word corpus. We use Adam with learning rate of 1e-4, $\beta_1 = 0.9$, $\beta_2 = 0.999$, L2 weight decay of 0.01, learning rate warmup over the first 10,000 steps, and linear decay of the learning rate. We use a dropout probability of 0.1 on all layers. We use a `gelu` activation (Hendrycks and Gimpel, 2016) rather than the standard `relu`, following OpenAI GPT. The training loss is the sum of the mean masked LM likelihood and the mean next sentence prediction likelihood.

Training of $\mathrm{BERT}_{\mathrm{BASE}}$ was performed on 4 Cloud TPUs in Pod configuration (16 TPU chips total).[13] Training of $\mathrm{BERT}_{\mathrm{LARGE}}$ was performed on 16 Cloud TPUs (64 TPU chips total). Each pretraining took 4 days to complete.

Longer sequences are disproportionately expensive because attention is quadratic to the sequence length. To speed up pretraing in our experiments, we pre-train the model with sequence length of 128 for 90% of the steps. Then, we train the rest 10% of the steps of sequence of 512 to learn the positional embeddings.

A.3 Fine-tuning Procedure

For fine-tuning, most model hyperparameters are the same as in pre-training, with the exception of the batch size, learning rate, and number of training epochs. The dropout probability was always kept at 0.1. The optimal hyperparameter values are task-specific, but we found the following range of possible values to work well across all tasks:

- **Batch size**: 16, 32

---

[13] https://cloudplatform.googleblog.com/2018/06/Cloud-TPU-now-offers-preemptible-pricing-and-global-availability.html

- **Learning rate (Adam)**: 5e-5, 3e-5, 2e-5
- **Number of epochs**: 2, 3, 4

We also observed that large data sets (e.g., 100k+ labeled training examples) were far less sensitive to hyperparameter choice than small data sets. Fine-tuning is typically very fast, so it is reasonable to simply run an exhaustive search over the above parameters and choose the model that performs best on the development set.

A.4 Comparison of BERT, ELMo ,and OpenAI GPT

Here we studies the differences in recent popular representation learning models including ELMo, OpenAI GPT and BERT. The comparisons between the model architectures are shown visually in Figure 3. Note that in addition to the architecture differences, BERT and OpenAI GPT are fine-tuning approaches, while ELMo is a feature-based approach.

The most comparable existing pre-training method to BERT is OpenAI GPT, which trains a left-to-right Transformer LM on a large text corpus. In fact, many of the design decisions in BERT were intentionally made to make it as close to GPT as possible so that the two methods could be minimally compared. The core argument of this work is that the bi-directionality and the two pre-training tasks presented in Section 3.1 account for the majority of the empirical improvements, but we do note that there are several other differences between how BERT and GPT were trained:

- GPT is trained on the BooksCorpus (800M words); BERT is trained on the BooksCorpus (800M words) and Wikipedia (2,500M words).
- GPT uses a sentence separator (`[SEP]`) and classifier token (`[CLS]`) which are only introduced at fine-tuning time; BERT learns `[SEP]`, `[CLS]` and sentence `A`/`B` embeddings during pre-training.
- GPT was trained for 1M steps with a batch size of 32,000 words; BERT was trained for 1M steps with a batch size of 128,000 words.
- GPT used the same learning rate of 5e-5 for all fine-tuning experiments; BERT chooses a task-specific fine-tuning learning rate which performs the best on the development set.

To isolate the effect of these differences, we perform ablation experiments in Section 5.1 which demonstrate that the majority of the improvements are in fact coming from the two pre-training tasks and the bidirectionality they enable.

A.5 Illustrations of Fine-tuning on Different Tasks

The illustration of fine-tuning BERT on different tasks can be seen in Figure 4. Our task-specific models are formed by incorporating BERT with one additional output layer, so a minimal number of parameters need to be learned from scratch. Among the tasks, (a) and (b) are sequence-level tasks while (c) and (d) are token-level tasks. In the figure, E represents the input embedding, T_i represents the contextual representation of token i, `[CLS]` is the special symbol for classification output, and `[SEP]` is the special symbol to separate non-consecutive token sequences.

B Detailed Experimental Setup

B.1 Detailed Descriptions for the GLUE Benchmark Experiments.

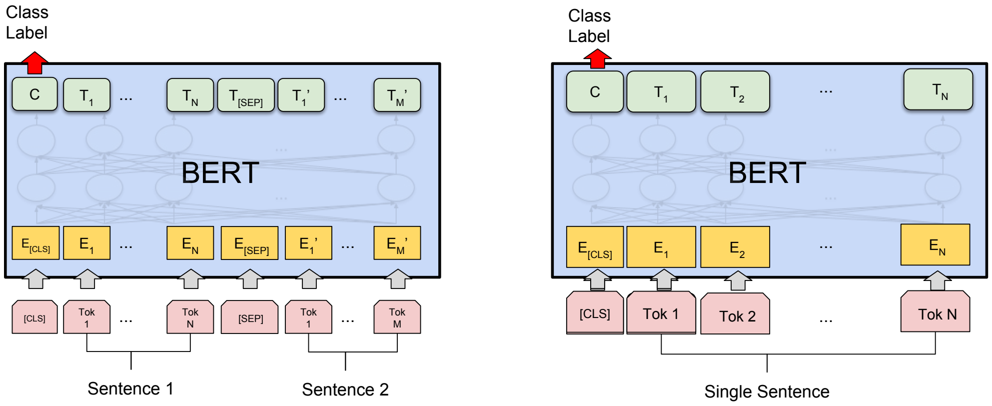
The GLUE benchmark includes the following datasets, the descriptions of which were originally summarized in Wang et al. (2018a):

MNLI Multi-Genre Natural Language Inference is a large-scale, crowdsourced entailment classification task (Williams et al., 2018). Given a pair of sentences, the goal is to predict whether the second sentence is an *entailment*, *contradiction*, or *neutral* with respect to the first one.

QQP Quora Question Pairs is a binary classification task where the goal is to determine if two questions asked on Quora are semantically equivalent (Chen et al., 2018).

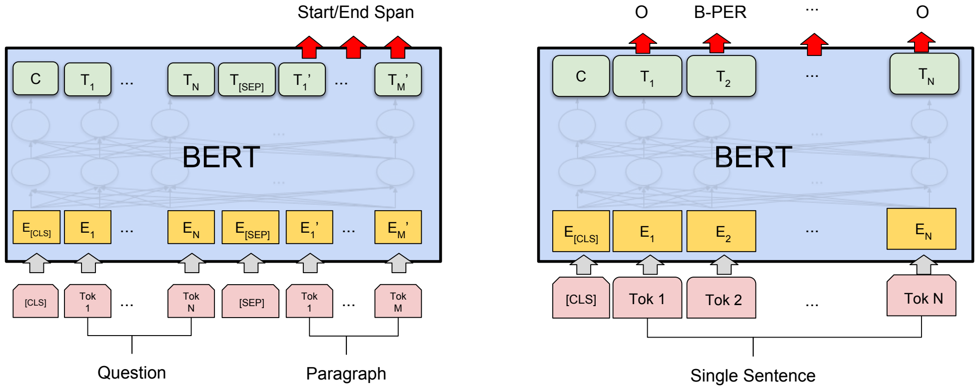
QNLI Question Natural Language Inference is a version of the Stanford Question Answering Dataset (Rajpurkar et al., 2016) which has been converted to a binary classification task (Wang et al., 2018a). The positive examples are (question, sentence) pairs which do contain the correct answer, and the negative examples are (question, sentence) from the same paragraph which do not contain the answer.

SST-2 The Stanford Sentiment Treebank is a binary single-sentence classification task consisting of sentences extracted from movie reviews



(a) Sentence Pair Classification Tasks: MNLI, QQP, QNLI, STS-B, MRPC, RTE, SWAG

(b) Single Sentence Classification Tasks: SST-2, CoLA



(c) Question Answering Tasks: SQuAD v1.1

(d) Single Sentence Tagging Tasks: CoNLL-2003 NER

Figure 4: Illustrations of Fine-tuning BERT on Different Tasks.

with human annotations of their sentiment (Socher et al., 2013).

CoLA The Corpus of Linguistic Acceptability is a binary single-sentence classification task, where the goal is to predict whether an English sentence is linguistically “acceptable” or not (Warstadt et al., 2018).

STS-B The Semantic Textual Similarity Benchmark is a collection of sentence pairs drawn from news headlines and other sources (Cer et al., 2017). They were annotated with a score from 1 to 5 denoting how similar the two sentences are in terms of semantic meaning.

MRPC Microsoft Research Paraphrase Corpus consists of sentence pairs automatically extracted from online news sources, with human annotations for whether the sentences in the pair are semantically equivalent (Dolan and Brockett, 2005).

RTE Recognizing Textual Entailment is a binary entailment task similar to MNLI, but with much less training data (Bentivogli et al., 2009).[14]

WNLI Winograd NLI is a small natural language inference dataset (Levesque et al., 2011). The GLUE webpage notes that there are issues with the construction of this dataset, [15] and every trained system that’s been submitted to GLUE has performed worse than the 65.1 baseline accuracy of predicting the majority class. We therefore exclude this set to be fair to OpenAI GPT. For our GLUE submission, we always predicted the majority class.

---

[14] Note that we only report single-task fine-tuning results in this paper. A multitask fine-tuning approach could potentially push the performance even further. For example, we did observe substantial improvements on RTE from multitask training with MNLI.

[15] `https://gluebenchmark.com/faq`

C Additional Ablation Studies

C.1 Effect of Number of Training Steps

Figure 5 presents MNLI Dev accuracy after fine-tuning from a checkpoint that has been pre-trained for k steps. This allows us to answer the following questions:

1. Question: Does BERT really need such a large amount of pre-training (128,000 words/batch * 1,000,000 steps) to achieve high fine-tuning accuracy?
   Answer: Yes, BERT$_{\text{BASE}}$ achieves almost 1.0% additional accuracy on MNLI when trained on 1M steps compared to 500k steps.

2. Question: Does MLM pre-training converge slower than LTR pre-training, since only 15% of words are predicted in each batch rather than every word?
   Answer: The MLM model does converge slightly slower than the LTR model. However, in terms of absolute accuracy the MLM model begins to outperform the LTR model almost immediately.

C.2 Ablation for Different Masking Procedures

In Section 3.1, we mention that BERT uses a mixed strategy for masking the target tokens when pre-training with the masked language model (MLM) objective. The following is an ablation study to evaluate the effect of different masking strategies.

Note that the purpose of the masking strategies is to reduce the mismatch between pre-training and fine-tuning, as the `[MASK]` symbol never appears during the fine-tuning stage. We report the Dev results for both MNLI and NER. For NER, we report both fine-tuning and feature-based approaches, as we expect the mismatch will be amplified for the feature-based approach as the model will not have the chance to adjust the representations.

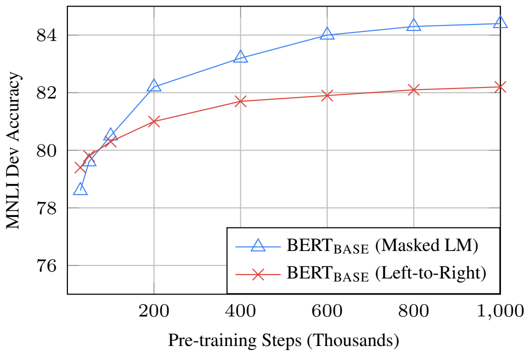


Figure 5: Ablation over number of training steps. This shows the MNLI accuracy after fine-tuning, starting from model parameters that have been pre-trained for k steps. The x-axis is the value of k.

Masking Rates			Dev Set Results		
Mask	Same	Rnd	MNLI	NER	
			Fine-tune	Fine-tune	Feature-based
80%	10%	10%	84.2	95.4	94.9
100%	0%	0%	84.3	94.9	94.0
80%	0%	20%	84.1	95.2	94.6
80%	20%	0%	84.4	95.2	94.7
0%	20%	80%	83.7	94.8	94.6
0%	0%	100%	83.6	94.9	94.6

Table 8: Ablation over different masking strategies.

The results are presented in Table 8. In the table, Mask means that we replace the target token with the `[MASK]` symbol for MLM; Same means that we keep the target token as is; Rnd means that we replace the target token with another random token.

The numbers in the left part of the table represent the probabilities of the specific strategies used during MLM pre-training (BERT uses 80%, 10%, 10%). The right part of the paper represents the Dev set results. For the feature-based approach, we concatenate the last 4 layers of BERT as the features, which was shown to be the best approach in Section 5.3.

From the table it can be seen that fine-tuning is surprisingly robust to different masking strategies. However, as expected, using only the Mask strategy was problematic when applying the feature-based approach to NER. Interestingly, using only the Rnd strategy performs much worse than our strategy as well.

Abstract

There is a growing body of work that proposes methods for mitigating bias in machine learning systems. These methods typically rely on access to protected attributes such as race, gender, or age. However, this raises two significant challenges: (1) protected attributes may not be available or it may not be legal to use them, and (2) it is often desirable to simultaneously consider multiple protected attributes, as well as their intersections. In the context of mitigating bias in occupation classification, we propose a method for discouraging correlation between the predicted probability of an individual's true occupation and a word embedding of their name. This method leverages the societal biases that are encoded in word embeddings, eliminating the need for access to protected attributes. Crucially, it only requires access to individuals' names at training time and not at deployment time. We evaluate two variations of our proposed method using a large-scale dataset of online biographies. We find that both variations simultaneously reduce race and gender biases, with almost no reduction in the classifier's overall true positive rate.

1 Introduction

In recent years, the performance of machine learning systems has improved substantially, leading to the widespread use of machine learning in many domains, including high-stakes domains such as healthcare, employment, and criminal justice (Chalfin et al., 2016; Miotto et al., 2017; Chouldechova, 2017). This increased prevalence has led many people to ask the question, "accurate, but for whom?" (Chouldechova and G'Sell, 2017).

When the performance of a machine learning system differs substantially for different groups of people, a number of concerns arise (Barocas and Selbst, 2016; Kim, 2016). First and foremost, there is a risk that the deployment of such a method may harm already marginalized groups and widen existing inequalities. Recent work highlights this concern in the context of online recruiting and automated hiring (De-Arteaga et al., 2019). When predicting an individual's occupation from their online biography, the authors show that if occupation-specific gender gaps in true positive rates are correlated with existing gender imbalances in those occupations, then those imbalances will be compounded over time—a phenomenon sometimes referred to as the "leaky pipeline." Second, the correlations that lead to performance differences between groups are often irrelevant. For example, while an occupation classifier should predict a higher probability of software engineer if an individual's biography mentions coding experience, there is no good reason for it to predict a lower probability of software engineer if the biography also mentions softball.

Prompted by such concerns about bias in machine learning systems, there is a growing body of work on fairness in machine learning.

"What's in a name? That which we call a rose by any other name would smell as sweet." – *William Shakespeare, Romeo and Juliet.*

Proceedings of NAACL-HLT 2019, pages 4187–4195
Minneapolis, Minnesota, June 2 - June 7, 2019.

Some of the foundational papers in this area highlighted the limitations of trying to mitigate bias using methods that are "unaware" of protected attributes such as race, gender, or age (e.g., Dwork et al., 2012). As a result, subsequent work has primarily focused on introducing fairness constraints, defined in terms of protected attributes, that reduce incentives to rely on undesirable correlations (e.g., Hardt et al., 2016; Zhang et al., 2018). This approach is particularly useful if similar performance can be achieved by slightly different means—i.e., fairness constraints may aid in model selection if there are many near-optima.

In practice, though, any approach that relies on protected attributes may stand at odds with anti-discrimination law, which limits the use of protected attributes in domains such as employment and education, even for the purpose of mitigating bias. And, in other domains, protected attributes are often not available (Holstein et al., 2019). Moreover, even when they are, it is usually desirable to simultaneously consider multiple protected attributes, as well as their intersections. For example, Buolamwini (2017) showed that commercial gender classifiers have higher error rates for women with darker skin tones than for either women or people with darker skin tones overall.

We propose a method for reducing bias in machine learning classifiers without relying on protected attributes. In the context of occupation classification, this method discourages a classifier from learning a correlation between the predicted probability of an individual's occupation and a word embedding of their name. Intuitively, the probability of an individual's occupation should not depend on their name—nor on any protected attributes that may be inferred from it. We present two variations of our method—i.e., two loss functions that enforce this constraint—and show that they simultaneously reduce both race and gender biases with little reduction in classifier accuracy. Although we are motivated by the need to mitigate bias in online recruiting and automated hiring, our method can be applied in any domain where individuals' names are available at training time.

Instead of relying on protected attributes, our method leverages the societal biases that are encoded in word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017). In particular, we build on the work of Swinger et al. (2019), which showed that word embeddings of names typically reflect the societal biases that are associated with those names, including race, gender, and age biases, as well encoding information about other factors that influence naming practices such as nationality and religion. By using word embeddings of names as a tool for mitigating bias, our method is conceptually simple and empirically powerful. Much like the "proxy fairness" approach of Gupta et al. (2018), it is applicable when protected attributes are not available; however, it additionally eliminates the need to specify which biases are to be mitigated, and allows simultaneous mitigation of multiple biases, including those that relate to group intersections. Moreover, our method only requires access to proxy information (i.e., names) at training time and not at deployment time, which avoids disparate treatment concerns and extends fairness gains to individuals with ambiguous names. For example, a method that explicitly or implicitly infers protected attributes from names at deployment time may fail to correctly infer that an individual named Alex is female and, in turn, fail to mitigate gender bias for her. Methodologically, our work is also similar to that of Zafar et al. (2017), which promotes fairness by requiring that the covariance between a protected attribute and a data point's distance from a classifier's decision boundary is smaller than some constant. However, unlike our method, it requires access to protected attributes, and does not facilitate simultaneous mitigation of multiple biases.

We present our method in Section 2. In section 3, we describe our evaluation, followed by results in Section 4 and conclusions in Section 5.

2 Method

Our method discourages an occupation classifier from learning a correlation between the predicted probability of an individual's occupation and a word embedding of their name. In this section, we present two variations of our method—i.e., two penalties that can be added to an arbitrary loss function and used when training any classifier.

We assume that each data point corresponds to an individual, with a label indicating that individual's occupation. We also assume access to the names of the individuals represented in the training set. The first variation, which we call Cluster Constrained Loss (CluCL), uses k-means to cluster word embeddings of the names in the training set. Then, for each pair of clusters, it minimizes between-cluster disparities in the predicted probabilities of the true labels for the data points that correspond to the names in the clusters. In contrast, the second variation minimizes the covariance between the predicted probability of an individual's occupation and a word embedding of their name. Because this variation minimizes the covariance directly, we call it Covariance Constrained Loss (CoCL). The most salient difference between these variations is that CluCL only minimizes disparities between the latent groups captured by the clusters. For example, if the clusters correspond only to gender, then CluCL is only capable of mitigating gender bias. However, given a sufficiently large number of clusters, CluCL is able to simultaneously mitigate multiple biases, including those that relate to group intersections. For both variations, individual's names are not used as input to the classifier itself; they appear only in the loss function used when training the classifier. The resulting trained classifier can therefore be deployed without access to individuals' names.

2.1 Formulation

We define $x_i = \{x_i^1, \ldots, x_i^M\}$ to be a data point, y_i to be its corresponding (true) label, and n_i^f and n_i^l to be the first and last name of the corresponding individual. The classification task is then to (correctly) predict the label for each data point:

$$p_i = H(x_i) \tag{1}$$

$$\hat{y}_i = \operatorname*{arg\,max}_{1 \leq j \leq |C|} p_i[j], \tag{2}$$

where $H(\cdot)$ is the classifier, C is the set of possible classes, $p_i \in \mathbb{R}^{|C|}$ is the output of the classifier for data point x_i—e.g., $p_i[j]$ is the predicted probability of x_i belonging to class j—and $\hat{y}_i$ is the predicted label for x_i. We define p_i^y to be the predicted probability of y_i—i.e., the true label for x_i.

The conventional way to train such a classifier is to minimize some loss function $\mathcal{L}$, such as the cross-entropy loss function. Our method simply adds an additional penalty to this loss function:

$$\mathcal{L}_{\text{total}} = \mathcal{L} + \lambda \cdot \mathcal{L}_{\text{CL}}, \tag{3}$$

where $\mathcal{L}_{\text{CL}}$ is either $\mathcal{L}_{\text{CluCL}}$ or $\mathcal{L}_{\text{CoCL}}$ (defined in Sections 2.2 and 2.3, respectively), and λ is a hyperparameter that determines the strength of the penalty. This loss function is only used during training, and plays no role in the resulting trained classifier. Moreover, it can be used in any standard setup for training a classifier—e.g., training a deep neural network using mini-batches and the Adam optimization algorithm (Kingma and Ba, 2014).

2.2 Cluster Constrained Loss

This variation represents each first name n_i^f and last name n_i^l as a pair of low-dimensional vectors using a set of pretrained word embeddings E. These are then combined to form a single vector:

$$n_i^e = \frac{1}{2}\left(E[n_i^f] + E[n_i^l]\right). \tag{4}$$

Using k-means (Arthur and Vassilvitskii, 2007), CluCL then clusters the resulting embeddings into k clusters, yielding a cluster assignment k_i for each name (and corresponding data point). Next, for each class $c \in C$, CluCL computes the following average pairwise difference between clusters:

$$l_c = \frac{1}{k(k-1)} \times \sum_{u,v=1}^{k} \left(\frac{1}{N_{c,u}} \sum_{\substack{i:y_i=c,\\ k_i=u}} p_i^y - \frac{1}{N_{c,v}} \sum_{\substack{i:y_i=c,\\ k_i=v}} p_i^y \right)^2, \tag{5}$$

where u and v are clusters and $N_{c,u}$ is the number of data points in cluster u for which $y_i = c$. CluCL considers each class individually because different classes will likely have different numbers of training data points and different disparities. Finally, CluCL computes the average of $l_1, \ldots l_{|C|}$ to yield

$$\mathcal{L}_{\text{CluCL}} = \frac{1}{|C|} \sum_{c \in C} l_c. \tag{6}$$

2.3 Covariance Constrained Loss

This variation minimizes the covariance between the predicted probability of a data point's label and the corresponding individual's name. Like CluCL, CoCL represents each name as a single vector n_i^e and considers each class individually:

$$l_c = \mathbb{E}_{i:y_i=c}\left[\left(p_i^y - \mu_p^c\right) \cdot \left(n_i^e - \mu_n^c\right)\right], \tag{7}$$

where $\mu_p^c = \mathbb{E}_{i:y_i=c}[p_i^y]$ and $\mu_n^c = \mathbb{E}_{i:y_i=c}[n_i^e]$. Finally, CoCL computes the following average:

$$\mathcal{L}_{\text{CoCL}} = \frac{1}{|C|} \sum_{c \in C} \|l_c\|,$$

where $\|\cdot\|$ is the ℓ_2 norm.

3 Evaluation

One of our method's strengths is its ability to simultaneously mitigate multiple biases without access to protected attributes; however, this strength also poses a challenge for evaluation. We are unable to quantify this ability without access to these attributes. To facilitate evaluation, we focus on race and gender biases only because race and gender attributes are more readily available than attributes corresponding to other biases. We further conceptualize both race and gender to be binary ("white/non-white" and "male/female") but note that these conceptualizations are unrealistic, reductive simplifications that fail to capture many aspects of race and gender, and erase anyone who does not fit within their assumptions. We emphasize that we use race and gender attributes only for evaluation—they do not play a role in our method.

3.1 Datasets

We use two datasets to evaluate our method: the adult income dataset from the UCI Machine Learning Repository (Dheeru and Karra Taniskidou, 2017), where the task is to predict whether an individual earns more than \$50k per year (i.e., whether their occupation is "high status"), and a dataset of online biographies (De-Arteaga et al., 2019), where the task is to predict an individual's occupation from the text of their online biography.

Each data point in the *Adult* dataset consists of a set of binary, categorical, and continuous attributes, including race and gender. We preprocess these attributes to more easily allow us to understand the classifier's decisions. Specifically, we normalize continuous attributes to be in the range $[0, 1]$ and we convert categorical attributes into binary indicator variables. Because the data points do not have names associated with them, we generate synthetic first names using the race and gender attributes. First, we use the dataset of Tzioumis (2018) to identify "white" and "non-white" names. For each name, if the proportion of "white" people with that name is higher than 0.5, we deem the name to be "white;" otherwise, we deem it to be "non-white."[1] Next, we use Social Security Administration data about baby names (2018) to identify "male" and "female" names. For each name, if the proportion of boys with that name is higher than 0.5, we deem the name to be "male;" otherwise, we deem it to be "female."[2] We then take the intersection of these two sets of names to yield a single set of names that is partitioned into four non-overlapping categories by (binary) race and gender. Finally, we generate a synthetic first name for each data point by sampling a name from the relevant category.

Each data point in the *Bios* dataset consists of the text of an individual's biography, written in the third person. We represent each biography as a vector of length V, where V is the size of the vocabulary. Each element corresponds to a single word type and is equal to 1 if the biography contains that type (and 0 otherwise). We limit the size of the vocabulary by discarding the 10% most common word types, as well as any word types that occur fewer than twenty times. Unlike the *Adult* dataset, each data point has a name associated with it. And, because biographies are typically written in the third person and because pronouns are gendered in English, we can extract (likely) self-identified gender. We infer race for each data point by sampling from a Bernoulli distribution with probability equal to the average of the probability that an individual with that first name is "white" (from the dataset of Tzioumis (2018), using a threshold of 0.5, as described above) and the probability that an individual with that last name is "white" (from the dataset of Comenetz (2016), also using a threshold of 0.5).[3] Finally, like De-Arteaga et al. (2019), we consider two versions of the *Bios* dataset: one where first names and pronouns are available to the classifier and one where they are "scrubbed."

Throughout our evaluation, we use the fastText word embeddings, pretrained on Common Crawl data (Bojanowski et al., 2016), to represent names.

3.2 Classifier and Loss Function

Our method can be used with any classifier, including deep neural networks such as recurrent neural networks and convolutional neural networks. However, because the focus of this paper is mitigating bias, not maximizing classifier

---

[1] For 90% of the names, the proportion of "white" people with that name is greater than 0.7 or less than 0.3, so there is a clear distinction between "white" and "non-white" names.

[2] For 98% of the names, the proportion of boys with that name is greater than 0.7 or less than 0.3, so there is an even clearer distinction between "male" and "female" names.

[3] We note that, in general, an individual's race or gender should be directly reported by the individual in question; inferring race or gender can be both inaccurate and reductive.

accuracy, we use a single-layer neural network:

$$h_i = W_h \cdot x_i + b_h$$
$$p_i = \text{softmax}(h_i)$$

where $W_h \in \mathbb{R}^{|C| \times M}$ and $b_h \in \mathbb{R}^{|C|}$ are the weights. This structure allows us to examine individual elements of the matrix W_h in order to understand the classifier's decisions for any dataset.

Both the *Adult* dataset and the *Bios* dataset have a strong class imbalance. We therefore use a weighted cross-entropy loss as $\mathcal{L}$, with weights set to the values proposed by King and Zeng (2001).

3.3 Quantifying Bias

To quantify race bias and gender bias, we follow the approach proposed by De-Arteaga et al. (2019) and compute the true positive rate (TPR) race gap and the TPR gender gap—i.e., the differences in the TPRs between races and between genders, respectively—for each occupation. The TPR race gap for occupation c is defined as follows:

$$\text{TPR}_{r,c} = P\left[\hat{Y} = c \,|\, R = r, Y = c\right] \quad (8)$$
$$\text{Gap}_{r,c} = \text{TPR}_{r,c} - \text{TPR}_{\sim r,c}, \quad (9)$$

where r and $\sim r$ are binary races, $\hat{Y}$ and Y are random variables representing the predicted and true occupations for an individual, and R is a random variable representing that individual's race. Similarly, the TPR gender gap for occupation c is

$$\text{TPR}_{g,c} = P\left[\hat{Y} = c \,|\, G = g, Y = c\right] \quad (10)$$
$$\text{Gap}_{g,c} = \text{TPR}_{g,c} - \text{TPR}_{\sim g,c}, \quad (11)$$

where g and $\sim g$ are binary genders and G is a random variable representing an individual's gender.

To obtain a single score that quantifies race bias, thus facilitating comparisons, we calculate the root mean square of the per-occupation TPR race gaps:

$$\text{Gap}_r^{\text{RMS}} = \sqrt{\frac{1}{|C|} \sum_{c \in C} \text{Gap}_{r,c}^2}. \quad (12)$$

We obtain a single score that quantifies gender bias similarly. The motivation for using the root mean square instead of an average is that larger values have a larger effect and we are more interested in mitigating larger biases. Finally, to facilitate worst-case analyses, we calculate the maximum TPR race gap and the maximum TPR gender gap.

We again emphasize that race and gender attributes are used only for evaluating our method.

4 Results

We first demonstrate that word embeddings of names encode information about race and gender. We then present the main results of our evaluation, before examining individual elements of the matrix W_h in order to better understand our method.

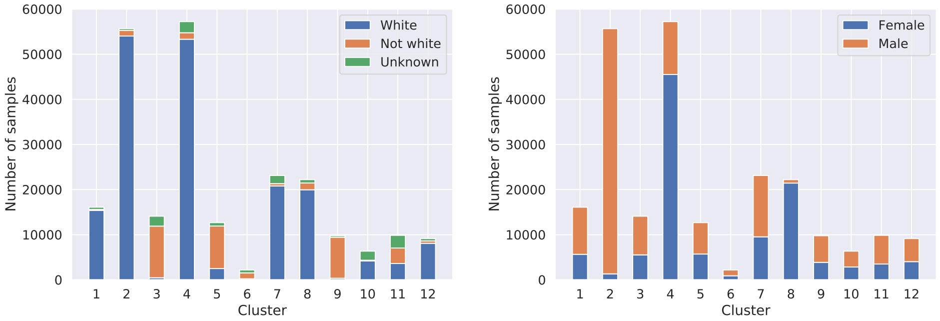
4.1 Word Embeddings of Names as Proxies

We cluster the names associated with the data points in the *Bios* dataset, represented as word embeddings, to verify that such embeddings indeed capture information about race and gender. We perform k-means clustering (using the k-means++ algorithm) with $k = 12$ clusters, and then plot the number of data points in each cluster that correspond to each (inferred) race and gender. Figures 1a and 1b depict these numbers, respectively.

Clusters 1, 2, 4, 7, 8, and 12 contain mostly "white" names, while clusters 3, 5, and 9 contain mostly "non-white names." Similarly, clusters 4 and 8 contain mostly "female" names, while cluster 2 contains mostly "male" names. The other clusters are more balanced by race and gender. Manual inspection of the clusters reveals that cluster 9 contains mostly Asian names, while cluster 8 indeed contains mostly "female" names. The names in cluster 2 are mostly "white" and "male," while the names in cluster 4 are mostly "white" and "female." This suggests that the clusters are capturing at least some intersections. Together these results demonstrate that word embeddings of names do indeed encode at least some information about race and gender, even when first and last names are combined into a single embedding vector. For a longer discussion of the societal biases reflected in word embeddings of names, we recommend the work of Swinger et al. (2019).

4.2 *Adult* Dataset

The results of our evaluation using the *Adult* dataset are shown in Table 1. The task is to predict whether an individual earns more than $50k per year (i.e., whether their occupation is "high status"). Because the dataset has a strong class imbalance, we report the balanced TPR—i.e., we compute the per-class TPR and then average over the classes. We experiment with different values of the hyperparameter λ. When $\lambda = 0$, the method is equivalent to using the conventional weighted cross-entropy loss function. Larger values of λ increase the strength of the penalty, but may lead to



(a) Race.

(b) Gender.

Figure 1: Number of data points (from the *Bios* dataset) in each cluster that correspond to each race and gender.

Method	λ	Balanced TPR	$\mathrm{Gap}_g^{\mathrm{RMS}}$	$\mathrm{Gap}_r^{\mathrm{RMS}}$	$\mathrm{Gap}_g^{\max}$	$\mathrm{Gap}_r^{\max}$
None	0	**0.795**	0.299	0.120	0.303	0.148
CluCL	1	0.788	0.278	0.121	0.297	0.145
CluCL	2	0.793	0.259	0.085	0.282	0.114
CoCL	1	0.794	0.215	0.091	0.251	0.119
CoCL	2	0.790	**0.163**	**0.080**	**0.201**	**0.109**

Table 1: Results for the *Adult* dataset. Balanced TPR (i.e., per-occupation TPR, averaged over occupations), gender bias quantified as $\mathrm{Gap}_g^{\mathrm{RMS}}$, race bias quantified as $\mathrm{Gap}_r^{\mathrm{RMS}}$, maximum TPR gender gap, and maximum TPR race gap for different values of hyperparameter λ. Results are averaged over four runs with different random seeds.

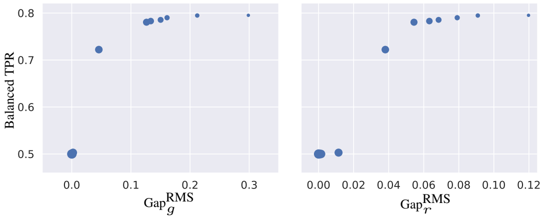


Figure 2: Gender bias quantified as $\mathrm{Gap}_g^{\mathrm{RMS}}$ (left) and race bias quantified as $\mathrm{Gap}_r^{\mathrm{RMS}}$ (right) versus balanced TPR for the CoCL variation of our method with different values of hyperparameter λ (a larger dot means a larger value of λ) for the *Adult* dataset. Results are averaged over four runs with different random seeds.

a less accurate classifier. Using $\lambda = 0$ leads to significant gender bias: the maximum TPR gender gap is 0.303. This means that the TPR is 30% higher for men than for women. We emphasize that this does *not* mean that the classifier is more likely to predict that a man earns more than \$50k per year, but means that the classifier is more likely to *correctly* predict that a man earns more than \$50k per year. Both variations of our method significantly reduce race and gender biases. With CluCL, the root mean square TPR race gap is reduced from 0.12 to 0.085, while the root mean square TPR gender gap is reduced from 0.299 to 0.25. These reductions in bias result in less than one percent decrease in the balanced TPR (79.5% is decreased to 79.3%). With CoCL, the race and gender biases are further reduced: the root mean square TPR race gap is reduced to 0.08, while the root mean square TPR gender gap is reduced to 0.163, with 0.5% decrease in the balanced TPR.

We emphasize that although our proposed method significantly reduces race and gender biases, neither variation can completely eliminate them. In order to understand how different values of hyperparameter λ influence the reduction in race and gender biases, we perform additional experiments using CoCL where we vary λ from 0 to 10. Figure 2 depicts these results. Larger values of λ indeed reduce race and gender biases; however, to achieve a root mean square TPR gender gap of zero means reducing the balanced TPR to 50%, which is unacceptably low. That said, there are a wide range of values of λ that significantly reduce race and gender biases, while maintaining an acceptable balanced TPR. For example, $\lambda = 6$ results in a root mean square TPR race gap of 0.038 and a root mean square TPR gender gap of 0.046, with only a 7.3% decrease in the balanced TPR.

Method	λ	Balanced TPR	$\text{Gap}_g^{\text{RMS}}$	$\text{Gap}_r^{\text{RMS}}$	$\text{Gap}_g^{\max}$	$\text{Gap}_r^{\max}$

CoCL	1	0.785	0.168	0.048	0.507	**0.109**
CoCL	2	0.779	0.169	0.048	0.512	0.116

Table 2: Results for the original *Bios* dataset. Balanced TPR (i.e., per-occupation TPR, averaged over occupations), gender bias quantified as $\text{Gap}_g^{\text{RMS}}$, race bias quantified as $\text{Gap}_r^{\text{RMS}}$, maximum TPR gender gap, and maximum TPR race gap for different values of hyperparameter λ. Results are averaged over four runs with different random seeds.

Method	λ	Balanced TPR	$\text{Gap}_g^{\text{RMS}}$	$\text{Gap}_r^{\text{RMS}}$	$\text{Gap}_g^{\max}$	$\text{Gap}_r^{\max}$
None	0	**0.785**	0.111	0.049	0.385	0.123
CluCL	1	0.782	**0.107**	0.048	**0.383**	0.112
CluCL	2	0.778	0.112	0.046	0.395	**0.107**
CoCL	1	0.780	0.109	0.047	0.388	0.117
CoCL	2	0.775	0.108	**0.046**	0.387	0.109

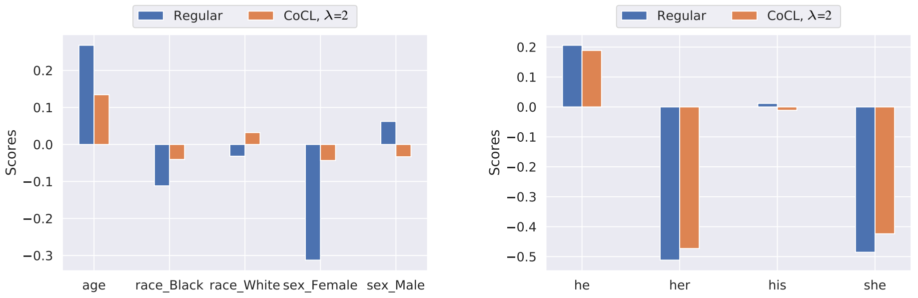
Table 3: Results for the "scrubbed" *Bios* dataset. Balanced TPR (i.e., per-occupation TPR, averaged over occupations), gender bias quantified as $\text{Gap}_g^{\text{RMS}}$, race bias quantified as $\text{Gap}_r^{\text{RMS}}$, maximum TPR gender gap, and maximum TPR race gap for different values of hyperparameter λ. Again, results are averaged over four runs.

4.3 *Bios* Dataset

The results of our evaluation using the original and "scrubbed" (i.e., names and pronouns are "scrubbed") versions of the *Bios* dataset are shown in Tables 2 and 3, respectively. The task is to predict an individual's occupation from the text of their online biography. Because the dataset has a strong class imbalance, we again report the balanced TPR. CluCL and CoCL reduce race and gender biases for both versions of the dataset. For the original version, CluCL reduces the root mean square TPR gender gap from 0.173 to 0.165 and the maximum TPR gender gap by 2.5%. Race bias is also reduced, though to a lesser extent. These reductions reduce the balanced TPR by 0.7%. For the "scrubbed" version, the reductions in race and gender biases are even smaller, likely because most of the information about race and gender has been removed by "scrubbing" names and pronouns. We hypothesize that these smaller reductions in race and gender biases, compared to the *Adult* dataset, are because the *Adult* dataset has fewer attributes and classes than the *Bios* dataset, and contains explicit race and gender information, making the task of reducing biases much simpler. We also note that each biography in the *Bios* dataset is represented as a vector of length V, where V is over 11,000. This means that the corresponding classifier has a very large number of weights, and there is a strong overfitting effect. Because this overfitting effect increases with λ, we suspect it explains why CluCL has a larger root mean square TPR gender gap when $\lambda = 2$ than when $\lambda = 1$. Indeed, the root mean square TPR gender gap for the training set is 0.05 when $\lambda = 2$. Using dropout and ℓ_2 weight regularization lessened this effect, but did not eliminate it entirely.

4.4 Understanding the Method

Our method mitigates bias by making training-time adjustments to the classifier's weights that minimize the correlation between the predicted probability of an individual's occupation and a word embedding of their name. Because of our choice of classifier (a single-layer neural network, as described in Section 3.2), we can examine individual elements of the matrix W_h to understand the effect of our method on the classifier's decisions. Figure 3a depicts the values of several weights for the conventional weighted cross-entropy loss function (i.e., $\lambda = 0$) and for CoCL with $\lambda = 2$ for the *Adult* dataset. When $\lambda = 0$, the attributes "sex_Female" and "sex_Male" have large negative and positive weights, respectively. This means that the classifier is more likely to predict that a man earns more than \$50k per year. With CoCL, these weights are much closer to zero. Similarly, the weights for the race attributes are also closer to zero. We note that the weight for



(a) *Adult* dataset.

(b) *Bios* dataset, occupation "surgeon."

Figure 3: Classifier weight values for several attributes for the conventional weighted cross-entropy loss function (i.e., $\lambda = 0$) and for CoCL with $\lambda = 2$. Results are averaged over four runs with different random seeds.

the attribute "age" is also reduced, suggesting that CoCL may have mitigated some form of age bias.

Figure 3b depicts the values of several weights specific to the occupation "surgeon" for the conventional weighted cross-entropy loss function (i.e., $\lambda = 0$) and for CoCL with $\lambda = 2$ for the original version of the *Bios* dataset. When $\lambda = 0$, the attributes "she" and "her" have large negative weights, while the attribute "he" has a positive weight. This means that the classifier is less likely to predict that a biography that contains the words "she" or "her" belongs to a surgeon. With CoCL, these magnitudes of these weights are reduced, though these reductions are not as significant as the reductions shown for the *Adult* dataset.

5 Conclusion

In this paper, we propose a method for reducing bias in machine learning classifiers without relying on protected attributes. In contrast to previous work, our method eliminates the need to specify which biases are to be mitigated, and allows simultaneous mitigation of multiple biases, including those that relate to group intersections. Our method leverages the societal biases that are encoded in word embeddings of names. Specifically, it discourages an occupation classifier from learning a correlation between the predicted probability of an individual's occupation and a word embedding of their name. We present two variations of our method, and evaluate them using a large-scale dataset of online biographies. We find that both variations simultaneously reduce race and gender biases, with almost no reduction in the classifier's overall true positive rate. Our method is conceptually simple and empirically powerful, and can be used with any classifier, including deep neural networks. Finally, although we focus on English, we expect our method will work well for other languages, but leave this direction for future work.
