Table 2 presents the intrinsic performance of the cipher grounder over all PL-CL pairs considered. The difference between the best and the worst performing PL for each CL ranges from 24.62 percentage points for Swahili to 48.34 points for French, and an average difference of 34.5 points among all languages. The case when PL=CL is also presented in Table 2 as a reference and provides a reliable upper-bound under zero-resource conditions. It is worth noting the difference in accuracy when comparing the best performing PL for each CL with its corresponding PL=CL upper-bound. Among all CLs, the best cipher grounder for French (es-fr) gets the closest to its upper-bound with just 4.81 percentage points of difference, followed by the English grounder (fr-en) with 13.53 points of difference. On the other hand, the best Swahili grounder (ar-sw) is the most distant from its upper-bound with 30.45 points of difference.

Given such wide performance gaps in the CL set, the choice of a suitable PL becomes crucial for performance; therein the cipher model confidence and typological similarity are explored as possible choice criteria. With regards to model confidence, the Pearson correlation between accuracy scores and PPL, expected to be negative, ranges from -0.71 for English to 0.40 for Farsi. Since the PPL values for different PLs are not comparable, we first z-normalize PPL per CL and then concatenate the results for all CLs. The Pearson correlation of the resulting PPL-accuracy values is -0.13. This last result indicates that the most confident model might not be the most accurate, hence this criterion is not suitable for choosing a suitable PL.

With regards to typological similarity, we find that the Pearson correlation between accuracy scores and cosine similarity of typological feature vectors, expected to be positive, ranges from 0.44 for English to -0.14 for Farsi. The total correlation is found to be 0.18. Again, we find that the most typologically similar s might not be the most accurate, hence this criterion is not suitable either.

Hence, it becomes obvious that choosing a single PL is an inefficient strategy that does not leverage the contribution that other PLs could bring. In this situation, the combination of cipher grounders for several PLs represents a sound strategy when no prior linguistic information of a certain CL is available. As shown in Table 2, this model, CIPHER-AVG, obtains accuracy scores of 56.4, 58.6, 37.4, and 37.8 % for en, fr, fa, and sw, respectively. When compared to the best performing PL for each CL (see bold cells in Table 2), it can be noticed that the performance gap ranges from just 1.2 percentage points for Swahili to 13.3 points for French, with an average of 6.1 points among all target languages.

Let us now compare the performance of CIPHER-AVG with that of a vanilla supervised neural model.[11] Table 3 shows precision, recall, and F1 scores for the NOUN tag. Even though CIPHER-AVG achieved mixed results (mid to low accuracy), the model robustly achieves mid-range performance according to F1-score for all CLs. The results are even more optimistic in terms of recall for English and French, and in terms of precision for Farsi and Swahili. This gives us hope that CIPHER-AVG can provide a useful, if noisy, signal to downstream tasks that depend on non-trivial performance over specific POS tags, such as name tagging, as exposed in the next section.

---

[11] We use UDPipe v1.2.0 (Straka and Straková, 2017) to train the models.

CL	Parent Language (PL) en	de	fr	it	es	ja	cs	ru	ar	sw	CIPHER-AVG	PL=CL

sw	53.46	51.82	52.63	98.88	97.50	98.18

Table 3: Comparison of performance over the NOUN tag, as measured by precision (P), recall (R), and F1 scores, between our combined cipher grounder (CIPHER-AVG) and a supervised tagger.

5.2 Extrinsic evaluation

In the name tagging task, our LSTM-CNN baseline obtains 78.76% and 70.76% F1 score for Kinyarwanda and Sinhalese, respectively. When enriching the input representation with CIPHER-AVG tags, the performance goes up to 80.16% and 71.71% respectively. These results suggest that the signal provided by the combined cipher grounder is significant enough for relevant tags such as common, proper nouns and noun modifiers. As an example, consider the sentence `Kwizera Peace Ndaruhutse , wari wambaye nomero 11.` The baseline model fails to recognize `Kwizera Peace Ndaruhutse` as a person name. In contrast, with the PROPN tag assigned by CIPHER-AVG to `Kwizera`, `Peace`, and `Ndaruhutse`, our model is able to identify this name.

Likewise, the utility of CIPHER-AVG tags for dependency parsing under zero-resource scenarios is summarized in Table 4 and Table 5. It is important to point out that, even though the MALOPA setup follows the no-treebank setup of Ammar et al. (2016), parsing scores in the first row of Table 4 differ from those reported by them (Table 8 in Ammar et al. (2016)). Such difference is to be expected since the underlying parser used in our experiments is a graph-based neural parser (Dozat and Manning, 2017) instead of a transition-based one (Dyer et al., 2015).[12] As mentioned earlier, our objective is to analyze the effect of our tagger's signal on parsing performance under no-resource scenarios, instead of pushing the state-of-the-art for the task.

We first analyze the effect of POS tag information at test time for the MALOPA setup in Table 4. First we remove all POS signal except trivial punctuation information (NONE row), and, predictably, the scores drop significantly across all target languages. Then, we use our cipher tags (CIPHER row) and see improvements for all languages in LAS and for all but one language in UAS (de). This demonstrates the value of our cipher approach.

We then take the next logical step and remove the parallel data-grounded embeddings, replacing them with fully unsupervised MUSE embeddings. Table 5 summarizes these results. Let us compare MUSE-NONE setup (no POS signal at train or test time) with MUSE-GOLD (gold POS signal at train and test time). It can be observed that POS signal improves performance greatly for all languages when using MUSE embeddings. However, consider GUO-GOLD and MUSE-NONE. Here we note a mixed result: whilst de, sv, and it do benefit from POS information, the other languages do not, obtaining great improvements from MUSE embed-

---

[12] Due to time constraints, we could not experiment with longer training regimes possibly needed given the high block dropout rates in Dozat and Manning (2017).

dings instead. Finally, consider MUSE-CIPHER (gold POS tags during training, cipher tags during testing). When compared to MUSE-NONE setup, it can be observed that, unfortunately, the heuristic POS tagger is too noisy and gets in MUSE's way.

6 Related Work

Our proposed tagging pipeline can be interpreted as first reducing the vocabulary size to a fixed number of clusters, and then finding a cluster–POS tag mapping table that best explains the data without any path constraint (a cluster ID could be mapped to any POS tag). In this sense, our approach applies EM to simplify the task (e.g. when using Brown clustering (Brown et al., 1992)), followed by another EM run to optimize cipher table parameters.

Under this lens, the methods closest to our approach are those which attempt to reduce or constrain the parameter search space prior to running EM. For instance, Ravi and Knight (2009) explicitly search for the smallest model that explains the data using Integer Programming, and then use EM to set parameter values. In a different approach, Goldberg et al. (2008) obtain competitive performance with a classic HMM model by initializing the emission probability distribution with a mixture of language-specific, linguistically constrained distributions. However, both of these approaches are framed around the task of unsupervised POS *disambiguation* with a full dictionary (Merialdo, 1994). Previous work relaxes the full dictionary constraint by leveraging monolingual lexicons (Haghighi and Klein, 2006; Smith and Eisner, 2005; Merialdo, 1994; Ravi and Knight, 2009), multilingual tagged dictionaries (Li et al., 2012; Fang and Cohn, 2017), and parallel corpora (Duong et al., 2014; Täckström et al., 2013; Das and Petrov, 2011).

In addition, previous work includes sequence models that do not rely on any resource besides raw text during training, namely unsupervised POS *induction* models. These models are based, with few exceptions, on extensions to the standard HMM; most, in the form of appropriate priors over the HMM multinomial parameters (Goldwater and Griffiths, 2007; Johnson, 2007; Ganchev et al., 2009); others, by using logistic distributions instead of multinomial ones (Berg-Kirkpatrick et al., 2010; Stratos et al., 2016). However, these models still need to ground or map hidden states to actual POS tags to evaluate, and they inevitably resort to many-to-one or one-to-one accuracy scoring. Some previous work has been cautious in pointing out this ill-defined setting (Ravi and Knight, 2009; Christodoulopoulos et al., 2010), and we argue its inappropriateness for scenarios in which the test set is extremely small or even when no annotated reference corpus exists.

Therefore, the problem of grounding the sequence of states or cluster IDs to POS tags without using any linguistic resource remains unsolved. We formulate this task as a decipherment problem. Decipherment aims to find a substitution table between alphabets or tokens of an encrypted code and a known language without the need of parallel corpora. The task has been successfully applied in alphabet mapping for lost languages (Snyder et al., 2010), and machine translation at the character (Pourdamghani and Knight, 2017) and token level (Ravi and Knight, 2011; Dou et al., 2015). For the task of POS tag grounding, the sequence of states or cluster IDs is modeled as an encrypted code to be deciphered back to a POS sequence. Furthermore, we tackle the problem from a 'universal' perspective by allowing the cipher learn from POS sequences from a varied pool of languages.

Other recent work has declared a 'radically universal' mantra to language inclusivity. Hermjakob et al. (2018) presents a Romanizer that covers all writing systems known to Unicode. Pan et al. (2017) extends name tagging and linking capability to hundreds of languages by leveraging Wikipedia. Kirov et al. (2016) has semi-automatically built inflectional paradigms for hundreds of languages.

7 Conclusion

We present a POS tag grounding strategy based on decipherment that does not require human-labeled data to map states or clusters to actual POS tags and thus can be used in real-world situations requiring grounded POS tags. The decipherment model considers state or word cluster IDs of a CL as a cipher text to be deciphered back to a POS sequence.

The model operates on top of Brown cluster IDs and requires a POS language model trained on annotated corpora of one or more PLs. Experimental results over a large and linguistically varied set of PLs show that the choice of which PL to decipher

Table 5: Changing to unsupervised MUSE embeddings boosts MALOPA's zero-resource performance significantly (**bold** entries), in many cases doing so even without any POS tag information (*italic* entries), however noisy decipherment-based POS tags are no longer helpful.

POS tags from is crucial for performance. We explore model confidence, as measured by perplexity and typological similarities, as intuitive criteria for PL choice. However, both criteria prove to be not correlated with tagging accuracy scores. Thus, we propose a cipher model combination strategy in order to leverage the word-order patterns in several PLs, at the cost of an accuracy drop ranging from just 1.15 percentage points to 13.33 points.

The resulting combined grounder is completely language agnostic, making it attractive for the analysis of languages new to the academic community. Furthermore, analysis over the tasks of name tagging and dependency parsing demonstrate that the tags induced by the combined grounder provide a non-trivial signal for improvement of the downstream task. We obtain state-of-the-art results for name tagging in Kinyarwanda and Sinhalese, languages for which POS annotated corpora is nearly non-existent.

Abstract

Different languages might have different word orders. In this paper, we investigate cross-lingual transfer and posit that an order-agnostic model will perform better when transferring to distant foreign languages. To test our hypothesis, we train dependency parsers on an English corpus and evaluate their transfer performance on 30 other languages. Specifically, we compare encoders and decoders based on Recurrent Neural Networks (RNNs) and modified self-attentive architectures. The former relies on sequential information while the latter is more flexible at modeling word order. Rigorous experiments and detailed analysis shows that RNN-based architectures transfer well to languages that are close to English, while self-attentive models have better overall cross-lingual transferability and perform especially well on distant languages.

1 Introduction

Cross-lingual transfer, which transfers models across languages, has tremendous practical value. It reduces the requirement of annotated data for a target language and is especially useful when the target language is lack of resources. Recently, this technique has been applied to many NLP tasks such as text categorization (Zhou et al., 2016a), tagging (Kim et al., 2017), dependency parsing (Guo et al., 2015, 2016) and machine translation (Zoph et al., 2016). Despite the preliminary success, transferring across languages is challenging as it requires understanding and handling differences between languages at levels of morphology, syntax, and semantics. It is especially difficult to learn invariant features that can robustly transfer to distant languages.

Prior work on cross-lingual transfer mainly focused on sharing word-level information by leveraging multi-lingual word embeddings (Xiao and Guo, 2014; Guo et al., 2016; Sil et al., 2018). However, words are not independent in sentences; their combinations form larger linguistic units, known as *context*. Encoding context information is vital for many NLP tasks, and a variety of approaches (e.g., convolutional neural networks and recurrent neural networks) have been proposed to encode context as a high-level feature for downstream tasks. In this paper, we study how to transfer generic contextual information across languages.

For cross-language transfer, one of the key challenges is the variation in word order among different languages. For example, the Verb-Object pattern in English can hardly be found in Japanese. This challenge should be taken into consideration in model design. RNN is a prevalent family of models for many NLP tasks and has demonstrated compelling performances (Mikolov et al., 2010; Sutskever et al., 2014; Peters et al., 2018). However, its sequential nature makes it heavily reliant on word order information, which exposes to the risk of encoding language-specific order information that cannot generalize across languages. We characterize this as the "*order-sensitive*" property. Another family of models known as "Transformer" uses self-attention mechanisms to capture context and was shown to be effective in various NLP tasks (Vaswani et al., 2017; Liu et al., 2018; Kitaev and Klein, 2018). With modification in position representations, the self-attention mechanism can be more robust than RNNs to the change of word order. We refer to this as the "*order-free*" property.

In this work, we posit that *order-free* models have better transferability than *order-sensitive* models because they less suffer from overfitting

language-specific word order features. To test our hypothesis, we first quantify language distance in terms of word order typology, and then systematically study the transferability of order-sensitive and order-free neural architectures on cross-lingual dependency parsing.

We use dependency parsing as a test bed primarily because of the availability of unified annotations across a broad spectrum of languages (Nivre et al., 2018). Besides, word order typology is found to influence dependency parsing (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Ammar et al., 2016; Aufrant et al., 2016). Moreover, parsing is a low-level NLP task (Hashimoto et al., 2017) that can benefit many downstream applications (McClosky et al., 2011; Gamallo et al., 2012; Jie et al., 2017).

We conduct evaluations on 31 languages across a broad spectrum of language families, as shown in Table 1. Our empirical results show that *order-free* encoding and decoding models generally perform better than the *order-sensitive* ones for cross-lingual transfer, especially when the source and target languages are distant.

2 Quantifying Language Distance

We first verify that we can measure "language distance" base on word order since it is a significant distinctive feature to differentiate languages (Dryer, 2007). The World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013) provides a great reference for word order typology

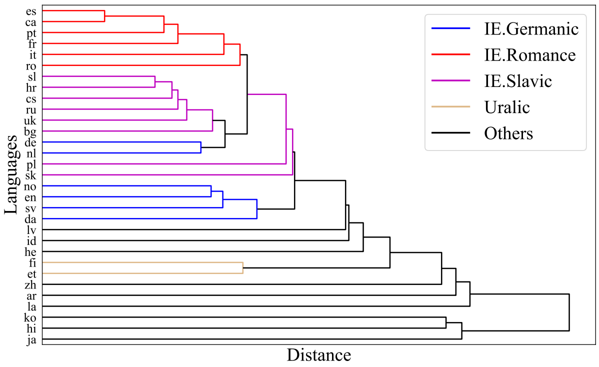

Figure 1: Hierarchical clustering (with the Nearest Point Algorithm) dendrogram of the languages by their word-ordering vectors.

and can be used to construct feature vectors for languages (Littell et al., 2017). But since we already have the universal dependency annotations, we take an empirical way and directly extract word order features using directed dependency relations (Liu, 2010).

We conduct our study using the Universal Dependencies (UD) Treebanks (v2.2) (Nivre et al., 2018). We select 31 languages for evaluation and analysis, with the selection criterion being that the total token number in the treebanks of that language is over 100K. We group these languages by their language families in Table 1. Detailed statistical information of the selected languages and treebanks can be found in Appendix A[1].

We look at finer-grained dependency types than the 37 universal dependency labels[2] in UD v2 by augmenting the dependency labels with the universal part-of-speech (POS) tags of the head and modifier[3] nodes. Specifically, we use triples "(ModifierPOS, HeadPOS, DependencyLabel)" as the augmented dependency types. With this, we can investigate language differences in a fine-grained way by defining directions on these triples (i.e. modifier before head or modifier after head).

We conduct feature selection by filtering out rare types as they can be unstable. We defer the results in 52 selected types and more details to Appendix C. For each dependency type, we collect the statistics of directionality (Liu, 2010; Wang and Eisner, 2017). Since there can be only two directions for an edge, for each dependency type,

---

[2] http://universaldependencies.org/u/dep/index.html

[3] In this paper, we use the term of "modifier", which can also be described as "dependent" or "child" node.

we use the relative frequency of the left-direction (modifier before head) as the directional feature. By concatenating the directional features of all selected triples, we obtain a word-ordering feature vector for each language. We calculate the *word-ordering distance* using these vectors. In this work, we simply use Manhattan distance, which works well as shown in our analysis (Section 4.3).

We perform hierarchical clustering based on the word-ordering vectors for the selected languages, following Östling (2015). As shown in Figure 1, the grouping of the ground truth language families is almost recovered. The two outliers, German (de) and Dutch (nl), are indeed different from English. For instance, German and Dutch adopt a larger portion of Object-Verb order in embedded clauses. The above analysis shows that word order is an important feature to characterize differences between languages. Therefore, it should be taken into consideration in the model design.

3 Models

Our primary goal is to conduct cross-lingual transfer of syntactic dependencies without providing any annotation in the target languages. The overall architecture of models that are studied in this research is described as follows. The first layer is an input embedding layer, for which we simply concatenate word and POS embeddings. The POS embeddings are trained from scratch, while the word embeddings are fixed and initialized with the multilingual embeddings by Smith et al. (2017). These inputs are fed to the encoder to get contextual representations, which is further used by the decoder for predicting parse trees.

For the cross-lingual transfer, we hypothesize that the models capturing less language-specific information of the source language will have better transferability. We focus on the word order information, and explore different encoders and decoders that are considered as *order-sensitive* and *order-free*, respectively.

3.1 Contextual Encoders

Considering the sequential nature of languages, RNN is a natural choice for the encoder. However, modeling sentences word by word in the sequence inevitably encodes word order information, which may be specific to the source language. To alleviate this problem, we adopt the self-attention based encoder (Vaswani et al., 2017) for cross-lingual parsing. It can be less sensitive to word order but not necessarily less potent at capturing contextual information, which makes it suitable for our study.

RNNs Encoder Following prior work (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017), we employ k-layer bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) on top of the input vectors to obtain contextual representations. Since it explicitly depends on word order, we will refer it as an *order-sensitive* encoder.

Self-Attention Encoder The original self-attention encoder (Transformer) takes absolute positional embeddings as inputs, which capture much order information. To mitigate this, we utilize relative position representations (Shaw et al., 2018), with further simple modification to make it order-agnostic: the original relative position representations discriminate left and right contexts by adding signs to distances, while we discard the directional information.

We directly base our descriptions on those in (Shaw et al., 2018). For the relative positional self-attention encoder, each layer calculates multiple attention heads. In each head, the input sequence of vectors $\mathbf{x} = (x_1, \ldots, x_n)$ are transformed into the output sequence of vectors $\mathbf{z} = (z_1, \ldots, z_n)$, based on the self-attention mechanism:

$$z_i = \sum_{j=1}^{n} \alpha_{ij}(x_j W^V + a_{ij}^V)$$

$$\alpha_{ij} = \frac{\exp e_{ij}}{\sum_{k=1}^{n} \exp e_{ik}}$$

$$e_{ij} = \frac{x_i W^Q (x_j W^K + a_{ij}^K)^T}{\sqrt{d_z}}$$

Here, a_{ij}^V and a_{ij}^K are relative positional representations for the two position i and j. Similarly, we clip the distance with a maximum threshold of k (which is empirically set to 10), but we do not discriminate positive and negative values. Instead, since we do not want the model to be aware of directional information, we use the absolute values of the position differences:

$$a_{ij}^K = w_{clip(|j-i|,k)}^K \quad a_{ij}^V = w_{clip(|j-i|,k)}^V$$
$$clip(x, k) = \min(|x|, k)$$

Therefore, the learnable relative postion representations have $k+1$ types rather than $2k+1$: we have $w^K = (w_0^K, \ldots, w_k^K)$, and $w^V = (w_0^V, \ldots, w_k^V)$.

With this, the model knows only what words are surrounding but cannot tell the directions. Since self-attention encoder is less sensitive to word order, we refer to it as an *order-free* encoder.

3.2 Structured Decoders

With the contextual representations from the encoder, the decoder predicts the output tree structures. We also investigate two types of decoders with different sensitivity to ordering information.

Stack-Pointer Decoder Recently, Ma et al. (2018) proposed a top-down transition-based decoder and obtained state-of-the-art results. Thus, we select it as our transition-based decoder. To be noted, in this Stack-Pointer decoder, RNN is utilized to record the decoding trajectory and also can be sensitive to word order. Therefore, we will refer to it as an *order-sensitive* decoder.

Graph-based Decoder Graph-based decoders assume simple factorization and can search globally for the best structure. Recently, with a deep biaffine attentional scorer, Dozat and Manning (2017) obtained state-of-the-art results with simple first-order factorization (Eisner, 1996; McDonald et al., 2005). This method resembles the self-attention encoder and can be regarded as a self-attention output layer. Since it does not depend on ordering information, we refer to it as an *order-free* decoder.

4 Experiments and Analysis

In this section, we compare four architectures for cross-lingual transfer dependency parsing with a different combination of order-free and order-sensitive encoder and decoder. We conduct several detailed analyses showing the pros and cons of both types of models.

4.1 Setup

Settings In our main experiments[4] (those except Section 4.3.5), we take English as the source language and 30 other languages as target languages. We only use the source language for both training and hyper-parameter tuning. During testing, we directly apply the trained model to target languages with the inputs from target languages passed through pretrained multilingual embeddings that are projected into a common space as the source language. The projection is done by the offline transformation method (Smith et al., 2017) with pre-trained $300d$ monolingual embeddings from FastText (Bojanowski et al., 2017). We freeze word embeddings since fine-tuning on them may disturb the multi-lingual alignments. We also adopt gold UPOS tags for the inputs.

For other hyper-parameters, we adopted similar ones as in the Biaffine Graph Parser (Dozat and Manning, 2017) and the Stack-Pointer Parser (Ma et al., 2018). Detailed hyper-parameter settings can be found in Appendix B. Throughout our experiments, we adopted the language-independent UD labels and a sentence length threshold of 140. The evaluation metrics are Unlabeled attachment score (UAS) and labeled attachment score (LAS) with punctuations excluded[5]. We trained our cross-lingual models five times with different initializations and reported average scores.

Systems As described before, we have an *order-free* (Self-Attention) and an *order-sensitive* (BiLSTM-RNN) encoder, as well as an *order-free* (Biaffine Attention Graph-based) and an *order-sensitive* (Stack-Pointer) decoder. The combination gives us four different models, named in the format of "Encoder" plus "Decoder". For clarity, we also mark each model with their encoder-decoder order sensitivity characteristics. For example, "SelfAtt-Graph (OF-OF)" refers to the model with self-attention order-free encoder and graph-based order-free decoder. We benchmark our models with a baseline shift-reduce transition-based parser, which gave previous state-of-the-art results for single-source zero-resource cross-lingual parsing (Guo et al., 2015). Since they used older datasets, we re-trained the model on our datasets with their implementation[6]. We also list the supervised learning results using the "RNN-Graph" model on each language as a reference of the upper-line for cross-lingual parsing.

4.2 Results

The results on the test sets are shown in Table 2. The languages are ordered by their order typology distance to English. In preliminary experiments, we found our lexicalized models performed poorly

---

[4] Our implementation is publicly available at: https://github.com/uclanlp/CrossLingualDepParser

[5] In our evaluations, we exclude tokens whose POS tags are "PUNCT" or "SYM". This setting is different from the one adopted in the CoNLL shared task (Zeman et al., 2018). However, the patterns are similar as shown in Appendix D where we report the punctuation-included test evaluations.

[6] https://github.com/jiangfeng1124/acl15-clnndep. We also evaluated our models on the older dataset and compared with their results, as shown in Appendix F.

Table 2: Results (UAS%/LAS%, excluding punctuation) on the test sets. Languages are sorted by the word-ordering distance to English, as shown in the second column. '*' refers to results of delexicalized models, '†' means that the best transfer model is statistically significantly better (by paired bootstrap test, $p < 0.05$) than all other transfer models. Models are marked with their encoder and decoder order sensitivity, OF denotes order-free and OS denotes order-sensitive.

on Chinese (zh) and Japanese (ja). We found the main reason was that their embeddings were not well aligned to English. Therefore, we use delexicalized models, where only POS tags are used as inputs. The delexicalized results[7] for Chinese and Japanese are listed in the rows marked with "*".

Overall, the "SelfAtt-Graph" model performs the best in over half of the languages and beats the runner-up "RNN-Graph" by around 1.3 in UAS and 1.2 in LAS on average. When compared with "RNN-Stack" and "SelfAtt-Stack", the average difference is larger than 1.5 points. This shows that models capture less word order information generally perform better at cross-lingual parsing. Compared with the baseline, our superior results show the importance of the contextual encoder. Compared with the supervised models, the cross-lingual results are still lower by a large gap, indicating space for improvements.

After taking a closer look, we find an interesting pattern in the results: while the model performances on the source language (English) are similar, RNN-based models perform better on languages that are closer to English (upper rows in the table), whereas for languages that are "distant" from English, the "SelfAtt-Graph" performs much better. Such patterns correspond well with our hypothesis, that is, the design of models considering word order information is crucial in cross-lingual transfer. We conduct more thorough analysis in the next subsection.

---

[7] We found delexicalized models to be better only at zh and ja, for about 5 and 10 points respectively. For other languages, they performed worse for about 2 to 5 points. We also tried models without POS, and found them worse for about 10 points on average. We leave further investigation of input representations to future work.

Model	UAS%	LAS%
SelfAtt-Relative (Ours)	64.57	54.14
SelfAtt-Relative+Dir	63.93	53.62
RNN	63.25	52.94
SelfAtt-Absolute	61.76	51.71
SelfAtt-NoPosi	28.18	21.45

Table 3: Comparisons of different encoders (averaged results over all languages on the original training sets).

4.3 Analysis

We further analyze how different modeling choices influence cross-lingual transfer. Since we have not touched the training sets for languages other than English, in this subsection, we evaluate and analyze the performance of target languages using training splits in UD. Performance of English is evaluated on the test set. We verify that the trends observed in test set are similar to those on the training sets. As mentioned in the previous section, the bilingual embeddings for Chinese and Japanese do not align well with English. Therefore, we report the results with delexicalizing. In the following, we discuss our observations, and detailed results are listed in Appendix E.

4.3.1 Encoder Architecture

We assume models that are less sensitive to word order perform better when transfer to distant languages. To empirically verify this point, we conduct controlled comparisons on various encoders with the same graph-based decoder. Table 3 shows the average performances in all languages.

To compare models with various degrees of sensitivity to word order, we include several variations of self-attention models. The "SelfAtt-NoPosi" is the self-attention model without any positional information. Although it is most insensitive to word order, it performs poorly possibly because of the lack of access to the locality of contexts. The self-attention model with absolute positional embeddings ("SelfAtt-Absolute") also does not perform well. In the case of parsing, relative positional representations may be more useful as indicated by the improvements brought by the directional relative position representations ("SelfAtt-Relative+Dir") (Shaw et al., 2018). Interestingly, the RNN encoder ranks between "SelfAtt-Relative+Dir" and "SelfAtt-Absolute"; all these three encoders explicitly capture word order information in some way. Finally, by discarding the information of directions, our relative position representation ("SelfAtt-Relative") performs the best (significantly better at $p < 0.05$).

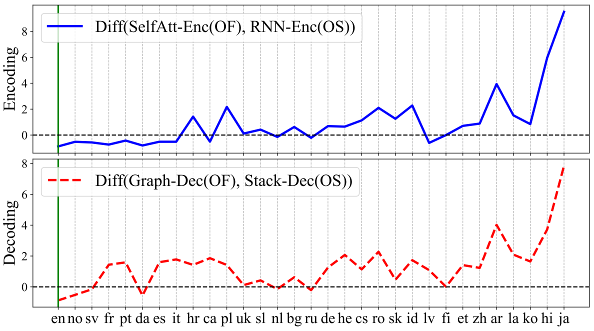

Figure 2: Evaluation score differences between Order-Free (OF) and Order Sensitive (OS) modules. We show results of both encoder (blue solid curve) and decoder (dashed red curve). Languages are sorted by their word-ordering distances to English from left to right. The position of English is marked with a green bar.

One crucial observation we have is that the patterns of breakdown performances for "SelfAtt-Relative+Dir" are similar to those of RNN: on closer languages, the direction-aware model performs better, while on distant languages the non-directional one generally obtains better results. Since the only difference between our proposed "SelfAtt-Relative" model and the "SelfAtt-Relative+Dir" model is the directional encoding, we believe the better performances should credit to its effectiveness in capturing useful context information without depending too much on the language-specific order information.

These results suggest that a model's sensitivity to word order indeed affects its cross-lingual transfer performances. In later sections, we stick to our "SelfAtt-Relative" variation of the self-attentive encoder and focus on the comparisons among the four main models.

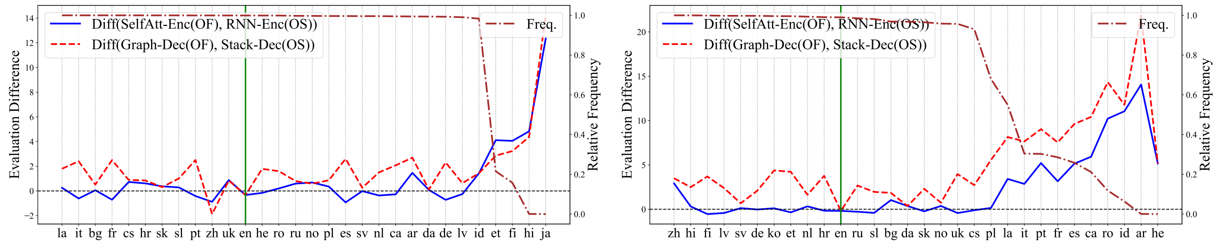
4.3.2 Performance v.s. Language Distance

We posit that order-free models can do better than order-sensitive ones on cross-lingual transfer parsing when the target languages have different word orders to the source language. Now we can analyze this with the word-ordering distance.

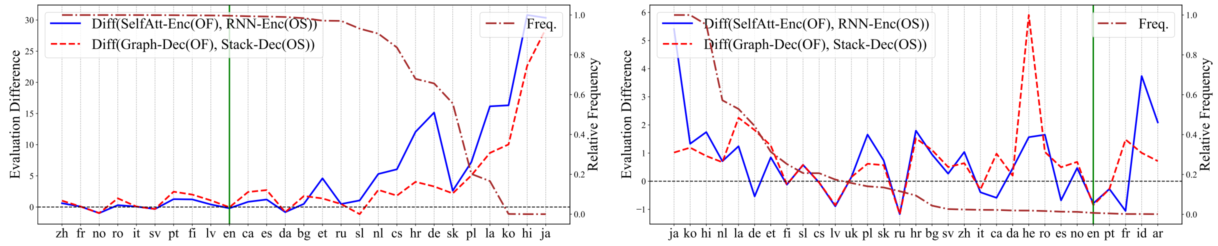
For each target language, we collect two types of distances when comparing it to English: one is the *word-ordering distance* as described in Section 2, the other is the *performance distance*, which is the gap of evaluation scores[8] between the target language and English. The performance distance can represent the general transferability from En-

---

[8] In the rest of this paper, we simply average UAS and LAS for evaluation scores unless otherwise noted.



(a) Adposition & Noun (ADP, NOUN, case)
(b) Adjective & Noun (ADJ, NOUN, amod)



(c) Auxiliary & Verb (AUX, VERB, aux)
(d) Object & Verb (NOUN, VERB, obj)

Figure 3: Analysis on specific dependency types. To save space, we merge the curves of encoders and decoders into one figure. The blue and red curves and left y-axis represent the differences in evaluation scores, the brown curve and right y-axis represents the relative frequency of left-direction (modifier before head) on this type. The languages (x-axis) are sorted by this relative frequency from high to low.

glish to this language. We calculate the correlation of these two distances on all the concerned languages, and the results turn to be quite high: the Pearson and Spearman correlations are *around 0.90 and 0.87* respectively, using the evaluations of any of our four cross-lingual transfer models. This suggests that word order can be an important factor of cross-lingual transferability.

Furthermore, we individually analyze the encoders and decoders of the dependency parsers. Since we have two architectures for each of the modules, when examining one, we take the highest scores obtained by any of the other modules. For example, when comparing RNN and Self-Attention encoders, we take the best evaluation scores of "RNN-Graph" and "RNN-Stack" for RNN and the best of "SelfAtt-Graph" and "SelfAtt-Stack" for Self-Attention. Figure 2 shows the score differences of encoding and decoding architectures against the languages' distances to English. For both the encoding and decoding module, we observe a similar overall pattern: the order-free models, in general, perform better than order-sensitive ones in the languages that are distant from the source language English. On the other hand, for some languages that are closer to English, order-sensitive models perform better, possibly benefiting from being able to capture similar word ordering information. The performance gap between order-free and order-sensitive models are positively correlated with language distance.

4.3.3 Performance Breakdown by Types

Moreover, we compare the results on specific dependency types using concrete examples. For each type, we sort the languages by their relative frequencies of left-direction (modifier before head) and plot the performance differences for encoders and decoders. We highlight the source language English in green. Figure 3 shows four typical example types: Adposition and Noun, Adjective and Noun, Auxiliary and Verb, and Object and Verb. In Figure 3a, we examine the "case" dependency type between adpositions and nouns. The pattern is similar to the overall pattern. For languages that mainly use prepositions as in English, different models perform similarly, while for languages that use postpositions, order-free models get better results. The patterns of adjective modifier (Figure 3b) and auxiliary (Figure 3c) are also similar.

On dependencies between verbs and object nouns, although in general order-free models perform better, the pattern diverges from what we expect. There can be several possible explanations for this. Firstly, the tokens which are noun objects of verbs only take about 3.1% on average over all tokens. Considering just this specific dependency type, the correlation between frequency distances and performance differences is 0.64, which is far

d	English	Average
<-2	14.36	12.93
-2	15.45	11.83
-1	31.55	30.42
1	7.51	14.22
2	9.84	10.49
>2	21.29	20.11

Table 4: Relative frequencies (%) of dependency distances. English differs from the Average at d=1.

less than 0.9 when considering all types. Therefore, although Verb-Object ordering is a typical example, we cannot take it as the whole story of word order. Secondly, Verb-Object dependencies can often be difficult to decide. They sometimes are long-ranged and have complex interactions with other words. Therefore, merely reducing modeling order information can have complicated effects. Moreover, although our relative-position self-attention encoder does not explicitly encode word positions, it may still capture some positional information with relative distances. For example, the words in the middle of a sentence will have different distance patterns from those at the beginning or the end. With this knowledge, the model can still prefer the pattern where a verb is in the middle as in English's Subject-Verb-Object ordering and may find sentences in Subject-Object-Verb languages strange. It will be interesting to explore more ways to weaken or remove this bias.

4.3.4 Analysis on Dependency Distances

We now look into dependency lengths and directions. Here, we combine dependency length and direction into dependency distance d, by using negative signs for dependencies with left-direction (modifier before head) and positive for right-direction (head before modifier). We find a seemingly strange pattern at dependency distances $|d|$=1: for all transfer models, evaluation scores on d=-1 can reach about 80, but on d=1, the scores are only around 40. This may be explained by the relative frequencies of dependency distances as shown in Table 4, where there is a discrepancy between English and the average of other languages at d=1. About 80% of the dependencies with $|d|$=1 in English is the left direction (modifier before head), while overall other languages have more right directions at $|d|$=1. This suggests an interesting future direction of training on more source languages with different dependency distance distributions.

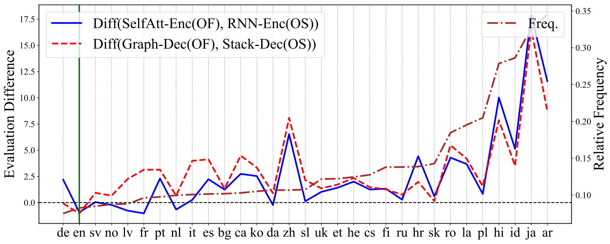


Figure 4: Evaluation differences of models on d=1 dependencies. Annotations are the same as in Figure 3, languages are sorted by percentages (represented by the brown curve and right y-axis) of d=1 dependencies.

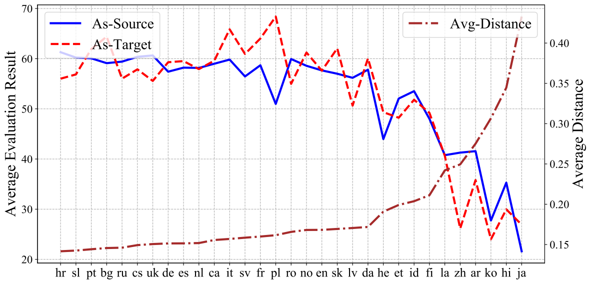

Figure 5: Transfer performance of all source-target language pairs. The blue and red curves show the averages over columns and over rows of the source-target pair performance matrix (see text for details). The brown curve and the right y-axis legend represent the average language distance between one language and all others.

We further compare the four models on the d=1 dependencies and as shown in Figure 4, the familiar pattern appears again. The order-free models perform better at the languages which have more d=1 dependencies. Such finding indicates that our model design of reducing the ability to capture word order information can help on short-ranged dependencies of different directions to the source language. However, the improvements are still limited. One of the most challenging parts of unsupervised cross-lingual parsing is modeling cross-lingually shareable and language-unspecific information. In other words, we want flexible yet powerful models. Our exploration of the order-free self-attentive models is the first step.

4.3.5 Transfer between All Language Pairs

Finally, we investigate the transfer performance of all source-target language pairs.[9] We first generate a performance matrix A, where each entry (i, j) records the transfer performance from a source language i to a target language j. We then report the following two aggregate perfor-

---

[9] Because the size of training corpus for each language is different in UD, to compare among languages, we train a parser on the first 4,000 sentences for each language and evaluate its transfer performance on all other languages.

mance measures on A in Figure 5: 1) *As-source* reports the average over columns of A for each row of the source language and 2) *As-target* reports the average over rows of A for each column of the target language. As a reference, we also plot the average word-order distance between one language to other languages. Results show that both *As-source* (blue line) and *As-target* (red line) highly are anti-correlated (Pearson correlation coefficients are -0.90 and -0.87, respectively) with average language distance (brown line).

5 Related Work

Cross-language transfer learning employing deep neural networks has widely been studied in the areas of natural language processing (Ma and Xia, 2014; Guo et al., 2015; Kim et al., 2017; Kann et al., 2017; Cotterell and Duh, 2017), speech recognition (Xu et al., 2014; Huang et al., 2013), and information retrieval (Vulić and Moens, 2015; Sasaki et al., 2018; Litschko et al., 2018). Learning the language structure (e.g., morphology, syntax) and transferring knowledge from the source language to the target language is the main underneath challenge, and has been thoroughly investigated for a wide variety of NLP applications, including sequence tagging (Yang et al., 2016; Buys and Botha, 2016), name entity recognition (Xie et al., 2018), dependency parsing (Tiedemann, 2015; Agić et al., 2014), entity coreference resolution and linking (Kundu et al., 2018; Sil et al., 2018), sentiment classification (Zhou et al., 2015, 2016b), and question answering (Joty et al., 2017).

Existing work on unsupervised cross-lingual dependency parsing, in general, trains a dependency parser on the source language and then directly run on the target languages. Training of the monolingual parsers are often delexicalized, i.e., removing all lexical features from the source treebank (Zeman and Resnik, 2008; McDonald et al., 2013), and the underlying feature model is selected from a shared part-of-speech (POS) representation utilizing the Universal POS Tagset (Petrov et al., 2012). Another pool of prior work improves the delexicalized approaches by adapting the model to fit the target languages better. Cross-lingual approaches that facilitate the usage of lexical features includes choosing the source language data points suitable for the target language (Søgaard, 2011; Täckström et al., 2013), transferring from multiple sources (McDonald et al., 2011; Guo et al., 2016; Täckström et al., 2013), using cross-lingual word clusters (Täckström et al., 2012) and lexicon mapping (Xiao and Guo, 2014; Guo et al., 2015). In this paper, we consider single-source transfer–train a parser on a single source language, and evaluate it on the target languages to test the transferability of neural architectures.

Multilingual transfer (Ammar et al., 2016; Naseem et al., 2012; Zhang and Barzilay, 2015) is another broad category of techniques applied to parsing where knowledge from many languages having a common linguistic typology is utilized. Recent works (Aufrant et al., 2016; Wang and Eisner, 2018a,b) demonstrated the significance of explicitly extracting and modeling linguistic properties of the target languages to improve cross-lingual dependency parsing. Our work is different in that we focus on the neural architectures and explore their influences on cross-lingual transfer.

6 Conclusion

In this work, we conduct a comprehensive study on how the design of neural architectures affects cross-lingual transfer learning. We examine two notable families of neural architectures (sequential RNN v.s. self-attention) using dependency parsing as the evaluation task. We show that *order-free* models perform better than *order-sensitive* ones when there is a significant difference in the word order typology between the target and source language. In the future, we plan to explore multi-source transfer and incorporating prior linguistic knowledge into the models for better cross-lingual transfer.

A Multi-Task Approach for Disentangling Syntax and Semantics in Sentence Representations

Mingda Chen **Qingming Tang** **Sam Wiseman** **Kevin Gimpel**

Abstract

We propose a generative model for a sentence that uses two latent variables, with one intended to represent the syntax of the sentence and the other to represent its semantics. We show we can achieve better disentanglement between semantic and syntactic representations by training with multiple losses, including losses that exploit aligned paraphrastic sentences and word-order information. We also investigate the effect of moving from bag-of-words to recurrent neural network modules. We evaluate our models as well as several popular pretrained embeddings on standard semantic similarity tasks and novel syntactic similarity tasks. Empirically, we find that the model with the best performing syntactic and semantic representations also gives rise to the most disentangled representations.[1]

1 Introduction

As generative latent variable models, especially of the continuous variety (Kingma and Welling, 2014; Goodfellow et al., 2014), have become increasingly important in natural language processing (Bowman et al., 2016; Gulrajani et al., 2017), there has been increased interest in learning models where the latent representations are disentangled (Hu et al., 2017). Much of the recent NLP work on learning disentangled representations of text has focused on disentangling the representation of attributes such as sentiment from the representation of content, typically in an effort to better control text generation (Shen et al., 2017; Zhao et al., 2017; Fu et al., 2018).

In this work, we instead focus on learning sentence representations that disentangle the syntax and the semantics of a sentence. We are moreover interested in disentangling these representations not for the purpose of controlling generation, but for the purpose of calculating semantic or syntactic similarity between sentences (but not both). To this end, we propose a generative model of a sentence which makes use of both semantic and syntactic latent variables, and we evaluate the induced representations on both standard semantic similarity tasks and on several novel syntactic similarity tasks.

We use a deep generative model consisting of von Mises Fisher (vMF) and Gaussian priors on the semantic and syntactic latent variables (respectively) and a deep bag-of-words decoder that conditions on these latent variables. Following much recent work, we learn this model by optimizing the ELBO with a VAE-like (Kingma and Welling, 2014; Rezende et al., 2014) approach.

Our learned semantic representations are evaluated on the SemEval semantic textual similarity (STS) tasks (Agirre et al., 2012; Cer et al., 2017). Because there has been less work on evaluating syntactic representations of sentences, we propose several new syntactic evaluation tasks, which involve predicting the syntactic analysis of an unseen sentence to be the syntactic analysis of its nearest neighbor (as determined by the latent syntactic representation) in a large set of annotated sentences.

In order to improve the quality and disentanglement of the learned representations, we incorporate simple additional losses in our training, which are designed to force the latent representations to capture different information. In particular, our semantic multi-task losses make use of aligned paraphrase data, whereas our syntactic multi-task loss makes use of word-order information. Additionally, we explore different encoder and decoder architectures for learning better syntactic representations. Experimentally, we find that by training in this way we are able to force the learned represen-

Proceedings of NAACL-HLT 2019, pages 2453–2464
Minneapolis, Minnesota, June 2 - June 7, 2019.

tations to capture different information (as measured by the performance gap between the latent representations on each task). Moreover, we find that we achieve the best performance on all tasks when the learned representations are most disentangled.

2 Related Work

There is a growing amount of work on learning interpretable or disentangled latent representations both in machine learning (Tenenbaum and Freeman, 2000; Reed et al., 2014; Makhzani et al., 2015; Mathieu et al., 2016; Higgins et al., 2016; Chen et al., 2016; Hsu et al., 2017) and in various NLP applications, including sentence sentiment and style transfer (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018; Zhao et al., 2018, *inter alia*), morphological reinflection (Zhou and Neubig, 2017), semantic parsing (Yin et al., 2018), text generation (Wiseman et al., 2018), and sequence labeling (Chen et al., 2018). Another related thread of work is text-based variational autoencoders (Miao et al., 2016; Bowman et al., 2016; Serban et al., 2017; Xu and Durrett, 2018).

In terms of syntax and semantics in particular, there is a rich history of work in analyzing their interplay in sentences (Jurafsky, 1988; van Valin, Jr., 2005). We do not intend to claim that the two can be entirely disentangled in distinct representations. Rather, our goal is to propose modica of knowledge via particular multi-task losses and measure the extent to which this knowledge leads learned representations to favor syntactic or semantic information from a sentence.

There has been prior work with similar goals for representations of words (Mitchell and Steedman, 2015) and bilexical dependencies (Mitchell, 2016), finding that decomposing syntactic and semantic information can lead to improved performance on semantic tasks. We find similar trends in our results, but at the level of sentence representations. A similar idea has been explored for text generation (Iyyer et al., 2018), where adversarial examples are generated by controlling syntax.

Some of our losses use sentential paraphrases, relating them to work in paraphrase modeling (Wieting et al., 2016; Wieting and Gimpel, 2018). Deudon (2018) recently proposed a variational framework for modeling paraphrastic sentences, but our focus here is on learning disentangled representations.

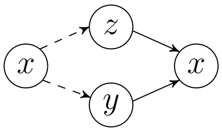

Figure 1: Graphical model of VGVAE. Dashed lines indicate inference model. Solid lines indicate generative model.

As part of our evaluation, we develop novel syntactic similarity tasks for sentence representations learned without any syntactic supervision. These evaluations relate to the broad range of work in unsupervised parsing (Klein and Manning, 2004) and part-of-speech tagging (Christodoulopoulos et al., 2010). However, our evaluations differ from previous evaluations in that we employ k-nearest-neighbor syntactic analyzers using our syntactic representations to choose nearest neighbors.

There is a great deal of work on applying multitask learning to various NLP tasks (Plank et al., 2016; Rei, 2017; Augenstein and Søgaard, 2017; Bollmann et al., 2018, *inter alia*) and, recently, as a way of improving the quality or disentanglement of learned representations (Zhao et al., 2017; Goyal et al., 2017; Du et al., 2018; John et al., 2018).

3 Proposed Approach

Our goal is to extract the disentangled semantic and syntactic information from sentence representations. To achieve this, we introduce the vMF-Gaussian Variational Autoencoder (VGVAE). As shown in Figure 1, VGVAE assumes a sentence is generated by conditioning on two independent variables: semantic variable y and syntactic variable z. In particular, our model gives rise to the following joint likelihood

$$\begin{aligned} p_\theta(x, y, z) &= p_\theta(y) p_\theta(z) p_\theta(x|y, z) \\ &= p_\theta(y) p_\theta(z) \prod_{t=1}^{T} p(x_t \,|\, y, z), \end{aligned}$$

where x_t is the tth word of x, T is the sentence length, and $p(x_t|y, z)$ is given by a softmax over a vocabulary of size V. Further details on the parameterization are given below.

To perform inference, we assume a factored posterior $q_\phi(y, z|x) = q_\phi(y|x) q_\phi(z|x)$, as has been used in prior work (Zhou and Neubig, 2017; Chen et al., 2018). Learning of VGVAE maximizes a lower bound on marginal log-likelihood:

$$
\begin{aligned}
&\log p_\theta(x) \geq \mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} [\log p_\theta(x|z,y) \\
&- \log \frac{q_\phi(z|x)}{p_\theta(z)} - \log \frac{q_\phi(y|x)}{p_\theta(y)}] \\
&= \mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} [\log p_\theta(x|z,y)] - KL(q_\phi(z|x)\|p_\theta(z)) \\
&- KL(q_\phi(y|x)\|p_\theta(y)) \stackrel{\text{def}}{=\!=} \text{ELBO}
\end{aligned} \tag{1}
$$

3.1 Parameterizations

VGVAE uses two distribution families in defining the posterior over latent variables, namely, the von Mises-Fisher (vMF) distribution and the Gaussian distribution.

vMF Distribution. vMF can be regarded as a Gaussian distribution on a hypersphere with two parameters: μ and κ. $\mu \in \mathbb{R}^m$ is a normalized vector (i.e. $\|\mu\|_2 = 1$) defining the mean direction. $\kappa \in \mathbb{R}_{\geq 0}$ is often referred to as a concentration parameter analogous to the variance in a Gaussian distribution. vMF has been used for modeling similarity between two sentences (Guu et al., 2018), which is particularly suited to our purpose here, since we will evaluate our semantic representations in the context of modeling paraphrases (See Sections 4.1 and 4.2 for more details). Therefore, we assume $q_\phi(y|x)$ follows vMF$(\mu_\alpha(x), \kappa_\alpha(x))$ and the prior $p_\theta(y)$ follows the uniform distribution vMF$(\cdot, 0)$.

With this choice of prior and posterior distribution, the $KL(q_\phi(y|x)\|p_\theta(y))$ appearing in the ELBO can be computed in closed-form:

$$
\begin{aligned}
&\kappa_\alpha \frac{\mathcal{I}_{m/2}(\kappa_\alpha)}{\mathcal{I}_{m/2-1}(\kappa_\alpha)} + (m/2-1)\log\kappa_\alpha - \\
&(m/2)\log(2\pi) - \log\mathcal{I}_{m/2-1}(\kappa_\alpha) + \\
&\frac{m}{2}\log\pi + \log 2 - \log\Gamma(\frac{m}{2}),
\end{aligned} \tag{2}
$$

where $\mathcal{I}_v$ is the modified Bessel function of the first kind at order v and $\Gamma(\cdot)$ is the Gamma function. We follow Davidson et al. (2018) and use an acceptance-rejection scheme to sample from vMF.

Gaussian Distribution.[2] We assume $q_\phi(z|x)$ follows a Gaussian distribution $\mathcal{N}(\mu_\beta(x), \text{diag}(\sigma_\beta(x)))$ and that the prior $p_\theta(z)$ is $\mathcal{N}(0, I_d)$, where I_d is an $d \times d$ identity matrix. Since we only consider a diagonal covariance matrix, the KL divergence term $KL(q_\phi(z|x)\|p_\theta(z))$ can also be computed efficiently:

$$
\frac{1}{2}(-\sum_i \log\sigma_{\beta i} + \sum_i \sigma_{\beta i} + \sum_i \mu_{\beta i}^2 - d) \tag{3}
$$

Inference and Generative Models. The inference models $q_\phi(y|x)$ and $q_\phi(z|x)$ are two independent word averaging encoders with additional linear feedforward neural networks for producing $\mu(x)$ and $\sigma(x)$ (or $\kappa(x)$). The generative model $p_\theta(x|y,z)$ is a feedforward neural network g_θ with the output being a bag of words. In particular, the expected output log-probability (the first term in Eq. 1) is computed as follows:

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} [\log p_\theta(x|y,z)] = \\
&\mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} \left[\sum_{t=1}^{T} \log \frac{\exp g_\theta([y;z])_{x_t}}{\sum_{j=1}^{V} \exp g_\theta([y;z])_j}\right]
\end{aligned}
$$

Where V is the vocabulary size, $[;]$ indicates concatenation, T is the sentence length and x_t is the index of the t'th word's word type.

Recurrent Neural Networks. To facilitate better learning of syntax, we also consider replacing both the generative and inference models with RNN-based sequence models, rather than bag-of-words models. In this setting, the generative model $p_\theta(x|y,z)$ is a unidirectional long-short term memory network (LSTM; Hochreiter and Schmidhuber, 1997) and a linear feedforward neural network for predicting the word tokens (shown in Figure 2). The expected output log-probability is computed as follows:

$$
\begin{aligned}
&\mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} [\log p_\theta(x|y,z)] = \\
&\mathop{\mathbb{E}}_{\substack{y\sim q_\phi(y|x)\\ z\sim q_\phi(z|x)}} \left[\sum_{t=1}^{T} \log p_\theta(x_t|y,z,x_{1:t-1})\right]
\end{aligned}
$$

Where V is the vocabulary size, T is the sentence length and x_t is the index of the t'th word's word type.

The inference model $q_\phi(y|x)$ is still a word averaging encoder, but $q_\phi(z|x)$ is parameterized by

---

[2] In preliminary experiments, we observed that using two distribution families can lead to better performance. This is presumably because the Gaussian distribution complements the norm information lost in the vMF distribution.

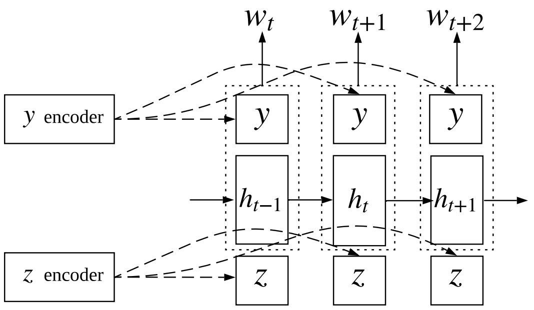

Figure 2: Diagram showing LSTM decoder that uses the semantic variable y and the syntactic variable z.

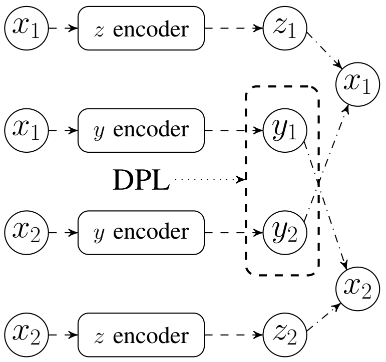

Figure 3: Diagram showing the training process when using the discriminative paraphrase loss (DPL; dotted lines) and paraphrase reconstruction loss (PRL; dash-dotted lines). The pair (x_1, x_2) is a sentential paraphrase pair, the y's are the semantic variables corresponding to each x, and the z's are syntactic variables.

a bidirectional LSTM, where we concatenate the forward and backward hidden states and then take the average. The output of the LSTM is then used as input to a feedforward network with one hidden layer for producing $\mu(x)$ and $\sigma(x)$ (or $\kappa(x)$).

In the following sections, we will introduce several losses that will be added into the training of our base model, which empirically shows the ability of further disentangling the functionality between the semantic variable y and the syntactic variable z.

4 Multi-Task Training

We attempt to improve the quality and disentanglement of our semantic and syntactic representations by introducing additional losses, which encourage y to capture semantic information and z to capture syntactic information. We elaborate on these losses below.

4.1 Paraphrase Reconstruction Loss

Our first loss is a paraphrase reconstruction loss (PRL). The key assumption underlying the PRL is that for a paraphrase pair x_1, x_2, the semantic information is equivalent between the two sentences and only the syntactic information varies. To impose such constraints, PRL is defined as

$$\begin{aligned}&\underset{\substack{y_2 \sim q_\phi(y|x_2)\\ z_1 \sim q_\phi(z|x_1)}}{\mathbb{E}}[-\log p_\theta(x_1|y_2, z_1)]+\\ &\underset{\substack{y_1 \sim q_\phi(y|x_1)\\ z_2 \sim q_\phi(z|x_2)}}{\mathbb{E}}[-\log p_\theta(x_2|y_1, z_2)]\end{aligned} \tag{4}$$

That is, we swap the semantic variables, keep the syntactic variables, and attempt to reconstruct the sentences (shown in Figure 3). While instead of using a multi-task objective we could directly model paraphrases x_1 and x_2 as being generated by the same y (which naturally suggests a product-of-experts style posterior, as in Wu and Goodman (2018)), we found that for the purposes of our downstream tasks training with the multi-task loss gave superior results.

4.2 Discriminative Paraphrase Loss

Our second loss is a discriminative paraphrase loss (DPL). The DPL explicitly encourages the similarity of paraphrases x_1, x_2 to be scored higher than the dissimilar sentences n_1, n_2 (i.e., negative samples; see Sec. 5 for more details) by a given margin δ. As shown in Figure 3, the similarity function in this loss only uses the semantic variables in the sentences. The loss is defined as

$$\begin{aligned}&\max(0, \delta - d(x_1, x_2) + d(x_1, n_1))+\\ &\max(0, \delta - d(x_1, x_2) + d(x_2, n_2))\end{aligned} \tag{5}$$

The similarity function we choose is the cosine similarity between the mean directions of the semantic variables from the two sentences:

$$d(x_1, x_2) = \text{cosine}(\mu_\alpha(x_1), \mu_\alpha(x_2)) \tag{6}$$

4.3 Word Position Loss

It has been observed in previous work that word order typically contributes little to the modelling of semantic similarity (Wieting et al., 2016). We interpret this as evidence that word position information is more relevant to syntax than semantics, at least as evaluated by STS tasks. To guide the syntactic variable to represent word order, we introduce a word position loss (WPL). Although our word averaging encoders only have access to the bag of words of the input, using this loss can be viewed as a denoising autoencoder where we have maximal input noise (i.e., an orderless representation of the input) and the encoders need to learn to reconstruct the ordering. For both word averaging encoders and LSTM encoders, WPL is parameterized by a three-layer feedforward neural network $f(\cdot)$ with input from the concatenation of the samples of the syntactic variable z and the embedding vector e_i at input position i; we then attempt to predict a one-hot vector representing the position i. More specifically, we define

$$\mathrm{WPL} \overset{\mathrm{def}}{=\!=} \mathop{\mathbb{E}}_{z\sim q_\phi(z|x)} \left[-\sum_i \log \mathrm{softmax}(f([e_i; z]))_i \right]$$

where $\mathrm{softmax}(\cdot)_i$ indicates the probability at position i.

5 Training

KL Weight. Following previous work on VAEs (Higgins et al., 2016; Alemi et al., 2016), we attach a weight to the KL divergence and tune it based on development set performance.

Negative Samples. When applying DPL, we select negative samples based on maximizing cosine similarity to sentences from a subset of the data. In particular, we accumulate k mini-batches during training, yielding a "mega-batch" $\mathcal{S}$ (Wieting and Gimpel, 2018). Then the negative samples are selected based on the following criterion:

$$n_1 = \mathop{\mathrm{argmax}}_{n\in\mathcal{S}\wedge n\neq x_2} \mathrm{cosine}(\mu_\alpha(x_1), \mu_\alpha(n))$$

where x_1, x_2 forms the paraphrase pair and the mega-batch size is fixed to $k = 20$ for all of our experiments. Since all of our models are trained from scratch, we observed some instabilities with DPL during the initial stages of training. We suspect that this is because the negative samples at these initial stages are of low quality. To overcome this issue, DPL is included starting at the second epoch of training so that the models can have a warm start.

6 Experiments

6.1 Setup

We subsampled half a million paraphrase pairs from ParaNMT-50M (Wieting and Gimpel, 2018) as our training set. We use SemEval semantic textual similarity (STS) task 2017 (Cer et al., 2017) as a development set. For semantic similarity evaluation, we use the STS tasks from 2012 to 2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016) and the STS benchmark test set (Cer et al., 2017). For evaluating syntactic similarity, we propose several evaluations. One uses the gold parse trees from the Penn Treebank (Marcus et al., 1993), and the others are based on automatically tagging and parsing five million paraphrases from ParaNMT-50M; we describe these tasks in detail below.

For hyperparameters, the dimensions of the latent variables are 50. The dimensions of word embeddings are 50. We use cosine similarity as similarity metric for all of our experiments. We tune the weights for PRL and reconstruction loss from 0.1 to 1 in increments of 0.1 based on the development set performance. We use one sample from each latent variable during training. When evaluating VGVAE based models on STS tasks, we use the mean direction of the semantic variable y, while for syntactic similarity tasks, we use the mean vector of the syntactic variable z.

6.2 Baselines

Our baselines are a simple word averaging (WORDAVG) model and bidirectional LSTM averaging (BLSTMAVG) model, both of which have been shown to be very competitive for modeling semantic similarity when trained on paraphrases (Wieting and Gimpel, 2018). Specifically, WORDAVG takes the average over the word embeddings in the input sequence to obtain the sentence representation. BLSTMAVG uses the averaged hidden states of a bidirectional LSTM as the sentence representation, where forward and backward hidden states are concatenated. These models use 50 dimensional word embeddings and 50 dimensional LSTM hidden vectors per direction. These baselines are trained with DPL only. Additionally, we scramble the input sentence for BLSTMAVG since it has been reported beneficial for its performance in semantic similarity tasks (Wieting and Gimpel, 2017).

We also benchmark several pretrained embeddings on both semantic similarity and syntactic similarity datasets, including GloVe (Pennington et al., 2014),[3] SkipThought (Kiros et al., 2015),[4]

InferSent (Conneau et al., 2017),[5] ELMo (Peters et al., 2018),[6] and BERT (Devlin et al., 2018).[7] For GloVe, we average word embeddings to form sentence embeddings. For ELMo, we average the hidden states from three layers and then average the hidden states across time steps. For BERT, we use the averaged hidden states from the last attention block.

7 Results and Analysis

7.1 Semantic Similarity

As shown in Table 1, the semantic and syntactic variables of our base VGVAE model show similar performance on the STS test sets. As we begin adding multi-task losses, however, the performance of these two variables gradually diverges, indicating that different information is being captured in the two variables. More interestingly, note that when *any* of the three losses is added to the base VGVAE model (even the WPL loss which makes no use of paraphrases), the performance of the semantic variable increases and the performance of the syntactic variable decreases; this suggests that each loss is useful in encouraging the latent variables to learn complementary information.

Indeed, the trend of additional losses both increasing semantic performance and decreasing syntactic performance holds even as we use more than two losses, except for the single case of VGVAE + PRL + DPL, where the syntactic performance increases slightly. Finally, we see that when the bag-of-words VGVAE model is used with all of the multi-task losses ("ALL"), we observe a large gap between the performance of the semantic and syntactic latent variables, as well as strong performance on the STS tasks that outperforms all baselines.

Using LSTM modules further strengthens the disentanglement between the two variables and leads to even better semantic performance. While using an LSTM encoder and a bag-of-words decoder is difficult to justify from a generative modeling perspective, we include results with this configuration to separate out the contributions of the LSTM encoder and decoder.

7.2 Syntactic Similarity

So far, we have only confirmed empirically that the syntactic variable has learned to *not* capture semantic information. To investigate what the syntactic variable has captured, we propose several syntactic similarity tasks.

In particular, we consider using the syntactic latent variable in calculating nearest neighbors for a 1-nearest-neighbor syntactic parser or part-of-speech tagger. We use our latent variables to define the similarity function in these settings and evaluate the quality of the output parses and tag sequences using several metrics.

Our first evaluation involves constituency parsing, and we use the standard training and test splits from the Penn Treebank. We predict a parse tree for each sentence in the test set by finding its nearest neighbor in the training set based on the cosine similarity of the mean vectors for the syntactic variables. The parse tree of the nearest neighbor will then be treated as our prediction for the test sentence. Since the train and test sentences may differ in length, standard parse evaluation metrics are not applicable, so we use tree edit distance (Zhang and Shasha, 1989)[8] to compute the distance between two parse tree without consider-

Numbers are bolded if they are worst in the "semantic variable" column or best in the "syntactic variable" column. "ALL" indicates all the multi-task losses are used.

ing word tokens.

To better understand the difficulty of this task, we introduce two baselines. The first randomly selects a training sentence. We calculate its performance by running it ten times and then reporting the average. We also report the upper bound performance given the training set. Since computing tree edit distance is time consuming, we subsample 100 test instances and compute the minimum tree edit distance for each sampled instance. Thus, this number can be seen as the approximated upper bound performance for this task given the training set.

To use a more standard metric for these syntactic similarity tasks, we must be able to retrieve training examples with the same number of words as the sentence we are trying to parse. We accordingly parse and tag the five million paraphrase subset of the ParaNMT training data using Stanford CoreNLP (Manning et al., 2014). To form a test set, we group sentences in terms of sentence length and subsample 300 sentences for each sentence length. After removing the paraphrases of the sentences in the test set, we use the rest of the training set as candidate sentences for nearest neighbor search, and we restrict nearest neighbors to have the same sentence length as the sentence we are attempting to parse or tag, which allows us to use standard metrics like labeled F_1 score and tagging accuracy for evaluation.

7.2.1 Results

As shown in Table 2, the syntactic variables and semantic variables demonstrate similar trends across these three syntactic tasks. Interestingly, both DPL and PRL help to improve the performance of the syntactic variables, even though these two losses are only imposed on the semantic variables. We saw an analogous pattern in Table 1, which again suggests that by pushing the semantic variables to learn information shared by paraphrastic sentences, we also encourage the syntactic variables to capture complementary syntactic information. We also find that adding WPL brings the largest improvement to the syntactic variable, and keeps the syntactic information carried by the semantic variables at a relatively low level. Finally, when adding all three losses, the syntactic variable shows the strongest performance across the three tasks.

In addition, we observe that the use of the LSTM encoder improves syntactic performance by a large margin and the LSTM decoder improves further, which suggests that the use of the LSTM decoder contributes to the amount of syntactic information represented in the syntactic variable.

Among pretrained representations, SkipThought shows the strongest performance overall and ELMo has the second best performance in the last two columns. While InferSent performs worst in the first column, it gives reasonable performance for the other two. BERT performs

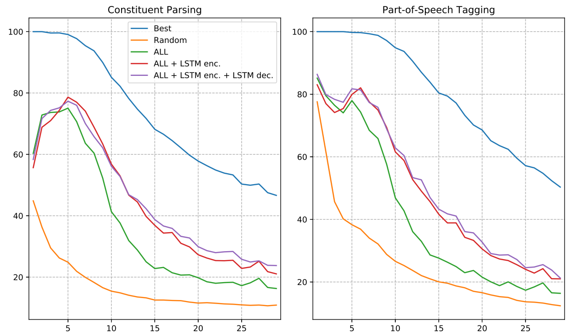

Figure 4: Constituency parsing F_1 scores and part-of-speech tagging accuracies by sentence length, for 1-nearest neighbor parsers based on semantic and syntactic variables, as well as a random baseline and an oracle nearest neighbor parser ("Best").

relatively well in the first column but worse in the other two.

To investigate the performance gap between the bag-of-words VGVAE and VGVAE with LSTM modules, in Figure 4 we plot the performance of our models and baselines as the length of the target sentence increases. We see that performance in all settings degrades as the sentences get longer. This may be due to the fact that the data is much sparser as sentence length increases (leaving fewer candidate nearest neighbors for prediction). We also see that above 4 words or so the performance gap between the bag-of-words VGVAE and VGVAE with LSTM modules becomes more and more obvious. This may be because the bag-of-words encoder has a harder time capturing syntactic information as sentence length increases. In addition, there is a slight improvement from using an LSTM decoder when the sentence length increases beyond 12 or so, which suggests that a bag-of-words decoder may struggle to capture certain parts of the syntactic information in the sentence, even when using an LSTM encoder.

7.3 Qualitative Analysis

To qualitatively evaluate our latent variables, we find (via cosine similarity) nearest neighbor sentences to test set examples in terms of both the semantic and syntactic representations. We also find nearest neighbors of words (which we view as single-word sentences). We discuss the results of this analysis below.

7.3.1 Lexical Analysis

Table 3 shows word nearest neighbors for both syntactic and semantic representations. We see that the most similar words found by the syntactic variable share the same part-of-speech tags with the query words. For example, "starting" is close to "getting" and "taking," even though these words are not semantically similar. Words retrieved according to the semantic variable, however, are more similar semantically, e.g., "begin" and "starts". As another example, "times" is similar to words that are either related to descriptions of frequency (e.g., "twice" and "often") or related to numbers (e.g., "thousand", "seven").

7.3.2 Sentential Analysis

As shown in Table 4, sentences that are similar in terms of their semantic variables tend to have similar semantics. However, sentences that are similar in terms of their syntactic variables are mostly semantically unrelated but have similar surface forms. For example, "you 're gon na save her life ." has the same meaning as "you will save her ." while having a similar syntactic structure to "you 're gon na give a speech ." (despite having very different meanings). As another example, although the semantic variable does not find a good match for "i have much more colours at home .", which can be attributed to the limited size of candidate sentences, the nearest syntactic neighbor ("you have a beautiful view from here .") has a very similar syntactic structure to the query sentence.

8 Discussion

In this paper we explored simple methods to disentangle syntax and semantics in latent representations of sentences. One goal was to measure the impact of simple decisions on the disentanglement of both the semantic and syntactic variables, even when restricting ourselves to simplified bag-of-words encoders. Due to the constrained nature of these bag-of-words models, we found that it was important to use different word embedding spaces for the semantic and syntactic encoders. In preliminary experiments, we experimented with the use of the same word embedding space but distinct feed-forward layers in the two latent variable encoders. However, this setting proved extremely difficult to achieve a disentanglement between syntax and semantics. Hence an important component of disentanglement with these bag-of-words encoders is the use of different word embedding spaces.

starting	*syntactic:* getting heading sitting chasing taking require trying sharing bothering pushing paying *semantic:* begin start stopping forward rising wake initial starts goes started again getting beginning
area	*syntactic:* engines certificate guests bottle responsibility lesson pieces suit bags vessel applications *semantic:* sector location zone fields rooms field places yard warehouse seats coordinates territory
considered	*syntactic:* stable limited odd scary classified concerned awful purple impressive embarrassing jealous *semantic:* thought assumed regard reasons wished understood purposes seemed expect guessed meant
jokes	*syntactic:* gentlemen photos finding baby missile dna parent shop murder science recognition sheriff *semantic:* funny humor prize stars cookie paradise dessert worthy smile happiness thrilled ideal kidding
times	*syntactic:* princess officer wounds plan gang ships feelings user liar elements coincidence degrees pattern *semantic:* twice later thousand pages seven every once often decade forgotten series four eight day time

Table 3: Examples of the most similar words to particular query words using syntactic variable (first row) or semantic variable (second row).

Query Sentence	Semantically Similar	Syntactically Similar
i have much more colours at home .	even if there was food , would n't it be at least 300 years old ?	you have a beautiful view from here .
victor had never known darkness like it .	he had never experienced such darkness as this .	you seem like a really nice kid .
this is , uh , too serious .	but this is too serious .	it is , however , illegal discrimination .
you 're gon na save her life .	you will save her .	you 're gon na give a speech .
we 've got to get a move on .	come on , we got ta move .	you 'll have to get in there .
and that was usually the highlight of my day .	i really enjoyed it when i did it .	and yet that was not the strangest aspect of the painting .
we do need to collect our taxes somehow .	we have to earn the money we need .	now i have to do my job .
this is just such a surprise .	oh . this is a surprise .	this is just a little gain .
okay . aw , that 's so romantic .	it 's so romantic !	oh . well , that 's not good .
we 're gon na have to do something about this .	we 'll have to do something about that .	we 're gon na have to do something about yours .

Table 4: Examples of most similar sentences to particular query sentences in terms of the semantic variable or the syntactic variable.

We also conducted experiments using LSTM encoders and decoders as recurrent neural networks are a natural way to capture syntactic information in a sentence. We found this approach to give us additional benefits for both disentangling semantics and syntax and achieving better results overall. Nonetheless, we find it encouraging that even when using bag-of-words encoders, our multi-task losses are able to achieve a separation as measured by our semantic and syntactic similarity tasks.

9 Conclusion

We proposed a generative model and several losses for disentangling syntax and semantics in sentence representations. We also proposed syntactic similarity tasks for measuring the amount of disentanglement between semantic and syntactic representations. We characterized the effects of the losses as well as the use of LSTM modules on both semantic tasks and syntactic tasks. Our models achieve the best performance across both sets of similarity tasks when the latent representations are most disentangled.

Abstract

Unsupervised document representation learning is an important task providing pre-trained features for NLP applications. Unlike most previous work which learn the embedding based on self-prediction of the surface of text, we explicitly exploit the inter-document information and directly model the relations of documents in embedding space with a discriminative network and a novel objective. Extensive experiments on both small and large public datasets show the competitiveness of the proposed method. In evaluations on standard document classification, our model has errors that are relatively 5 to 13% lower than state-of-the-art unsupervised embedding models. The reduction in error is even more pronounced in scarce label setting.

1 Introduction

Rapid advance in deep methods for natural language processing has contributed to a growing need for vector representation of documents as input features. Applications for such vector representations include machine translation (Sutskever et al., 2014), text classification (Dai and Le, 2015), image captioning (Mao et al., 2015), multi-lingual document matching (Pham et al., 2015), question answering (Rajpurkar et al., 2016), and more. This work studies *unsupervised* training for encoders that can efficiently encode long paragraph of text into compact vectors to be used as pre-trained features. Existing solutions are mostly based on the assumption that a good document embedding can be learned through modeling the **intra**-document information by predicting the occurrence of terms inside the document itself. We argue that such an assumption might not be sufficient to obtain meaningful a document embedding as they do not consider **inter**-document relationships.

Traditional document representation models such as Bag-of-words (BoW) and TF-IDF show competitive performance in some tasks (Wang and Manning, 2012). However, these models treat words as flat tokens which may neglect other useful information such as word order and semantic distance. This in turn can limit the models effectiveness on more complex tasks that require deeper level of understanding. Further, BoW models suffer from high dimensionality and sparsity. This is likely to prevent them from being used as input features for downstream NLP tasks.

Continuous vector representations for documents are being developed. A successful thread of work is based on the distributional hypothesis, and use contextual information for context-word predictions. Similar to Word2Vec (Mikolov et al., 2013), PV (Le and Mikolov, 2014) is optimized by predicting the next words given their contexts in a document, but it is conditioned on a unique document vector. Word2Vec-based methods for computing document embeddings achieve state-of-the-art performance on document embedding. Such methods rely on one strong underlying assumption: it is necessary to train the document embedding to optimize the prediction of the target words in the document. In other words, the objective requires the model to learn to predict the target words in surface text. We argue that there are several concerns with such a self-prediction assumption.

The strategy of predicting target words therefore only exploits in-document information, and do not explicitly model the inter-document distances. We believe an ideal embedding space should also infer the relations among training documents. For example, if all documents in the corpus are about *machine learning*, then the con-

---

[*] Equally contribution.

Proceedings of NAACL-HLT 2019, pages 2465–2474
Minneapolis, Minnesota, June 2 - June 7, 2019.

cept of *machine learning* becomes less critical in the embedding. However, if the corpus contains documents from different areas of computer science, then the concept of *machine learning* should be encoded in any document relevant to it. We therefore claim that *the embedding of a document should not only depend on the document itself but also the other documents in the corpus*, even though previous work seldom makes this consideration.

In addition, accurate predictions at the lexicon or word level do not necessarily reflect that the "true semantics" have been learned. For example, in IMDB dataset review No.10007:

$$\text{"}...the\,father\,did\,such\,a\,good\,job.\text{"}$$

Obviously, *good* can be replaced with synonyms like *nice* without significantly altering the meaning of the sentence. However, since the synonyms are treated as independent tokens in PV and Doc2VecC, the lexicon *good* must be predicted exactly. Moreover, to accurately predict the final word *job*, the embedding probably only needs to know that *did a good job* is a very common phrase, without having to understand the true meaning of *job*. This example shows that in order to accurately predict a local lexicon, the embedding might opt to encode the syntactic relationship instead of true semantics. Enforcing document embeddings to make predictions at the word level could be too strong of an objective. More specifically, we argue that the true semantics should not only depend on a small context, but also the relations with other training documents at document level.

To address the above concerns we propose a novel model for learning document embedding unsupervisedly. In contrast with previous work (PV and Doc2Vec), we model documents according to two aspects.

First, we abandon the concept of context word prediction when training an embedding model. Instead we propose a self-supervision learning framework to model inter-document information. Conceptually, we use the embedding to determine whether a sentence belongs to a document. Our encoder is equipped with a discriminator to classify whether a sentence embedding is derived from a document given that document's embedding. This explicitly enforces documents to be spread reasonably in the embedding space without any labels so that they can be discriminated. To the best of our knowledge, this is the first deep embedding work to explicitly model the inter-document relationship.

Second, in our approach the predictions are inferred at the sentence level. This avoids the effect of only predicting the surface meaning in word level (e.g. good vs. nice). Unlike previous work, our model is explicitly optimized to represent documents as combinations of sequence embedding beyond words seen in training.

Below we summarize the key contributions:

- We present a deep and general framework and a novel objective for learning document representation unsupervisedly. Our models are end-to-end, easy to implement, and flexible to extend.
- We perform experiments through sentiment analysis and topic classification to show that our model, referred to as *self-discriminative document embedding (SDDE)*, is competitive to the state-of-the-art solutions based on traditional context-prediction objectives.
- Our extensive experiments quantitatively and qualitatively show that SDDE learns more effective features that capture more document-level information. To the best of our knowledge, SDDE is the first deep network to model inter-instance information at document level.
- We further propose to evaluate unsupervised document embedding models in weakly-supervised classification. That is, lots of unlabeled documents with only few labels attached to some of them, which is a realistic scenario that unsupervised embedding could be particularly useful.

2 Related Work

Here we give an overview of other related methods on learning unsupervised text representations. Besides BoW and TF-IDF, Latent Dirichlet Allocation models (Deerwester et al., 1990; Blei et al., 2003) leverage the orthogonality of high-dimensional BoW features by clustering a probabilistic BoW for latent topics.

Several models extend from Word2Vec (Mikolov et al., 2013), using context-word predictions for training document embedding end-to-end. PV (Le and Mikolov, 2014) keeps a document embedding matrix in memory and is jointly trained. The required training parameters are linear to the number of documents and thus prohibit PV from being trained on a large corpus. Moreover, expensive inference for new documents is required during testing. To address the above concerns, Doc2VecC (Chen, 2017) combines PV and a denoising autoencoder (DEA) (Chen et al., 2012) with BoW vectors as global document information instead. The final document embedding are then produced by simply averaging the jointly trained word embedding.

Another thread of work uses two-stage pipelines to construct sentence/document embedding from pre-trained word embedding. Arora et al. (2017) propose post-processing weighting strategies on top of word embedding to build sentence representations. WME (Wu et al., 2018) propose a random feature kernel method based on distance between pairs of words, which also shows inter-document information helps. However, the cost scales with the size of training samples such that it is hard to be applied on large-scale dataset.

There have been more embedding work on sentences compared to documents. These approaches mostly learn the sentence embedding by modeling the sentence-level (Kiros et al., 2015; Tang et al., 2017b,a; Logeswaran and Lee, 2018) or word-level (Pagliardini et al., 2018; Kenter et al., 2016; Arora et al., 2018) distribution hypothesis (Harris, 1954; Polajnar et al., 2015) in a large ordered corpus. We note that the main difference between learning embedding for sentences and documents is that documents are not ordered in a corpus. Some other work model sentences with RNN autoencoders (Hill et al., 2016a; Gan et al., 2017). Documents often refer to long-length text containing multiple sentences, which might be hard to model with RNNs (Pascanu et al., 2013; Jing et al., 2017) and time-consuming on large corpus.

3 Model and Design Rationale

To facilitate downstream tasks, a document embedding is required to compress useful features into a compact representation. It is not an easy task to learn discriminable features unsupervisedly since validation information is not accessible for training. We first introduce some notations:

- $\mathcal{V}$: the training corpus vocabulary of size $|\mathcal{V}|$;
- $\mathcal{X} = \{X_1, \cdots, X_n\}$: a training corpus of document size $n = |\mathcal{X}|$, in which each document X_i is a set of sentences $\mathcal{S}_i$;
- $\mathcal{S}_i = \{\mathbf{s}_i^1, \cdots, \mathbf{s}_i^{|x_i|}\}$: a document divided into a set of sentences, of set size $|\mathcal{S}_i|$, in which each sentence $\mathbf{s}_i^j \in \mathcal{R}^{|\mathcal{V}| \times T_j}$ contains a sequence of variable length T_j of word one-hot vectors $\mathbf{w}_j^1, \cdots, \mathbf{w}_j^{T_j}$, each in $\mathcal{R}^{|\mathcal{V}| \times 1}$. $\mathcal{S}$ is the set of total sentences $\bigcup\limits_{i=1}^{n} \mathcal{S}_i$ in the training corpus, of size $m = |\mathcal{S}|$;
- h_w: the size of the word embedding and $\mathbf{U} \in \mathcal{R}^{h_w \times |\mathcal{V}|}$: the word embedding projection matrix. We use $\mathbf{u}_w$ to denote the column in $\mathbf{U}$ for word $\mathbf{w}$
- h_s: the size of the sentence embedding and $\mathbf{e_s} \in \mathcal{R}^{h_s}$: the embedding of sentence $\mathbf{s}$.
- $\mathbf{d}_i \in \mathcal{R}^{h_s}$: document X_i's embedding.

Our goal is to learn a function $F : \mathcal{X} \rightarrow \mathcal{R}^{h_s \times n}$ that maps document X_i to $\mathbf{d}_i$ unsupervisedly.

Next, we formulate how SDDE represents a document, then introduce our self-discriminative learning procedure we use to train it.

3.1 Document Representation

We consider a document as **mean of sentences**, i.e., breaking a document into several subsequences. We demonstrate several benefits of the design in SDDE. First, decomposing long documents into shorter but reasonable semantic unit (e.g., sentences) makes encoding easier and faster since they can be processed in parallel. Similar concepts of modeling documents hierarchically have shown benefits in some supervised tasks such as text classification (Yang et al., 2016). It also makes the model insensitive to document length, which is important because length varies greatly in real documents (see Table 1).

In training, we further propose to represent a document *during training* using the average of only a subset of its sentences. This special **sentence-level dropout** is beneficial for training by creating up to $\binom{|X_i|}{q}$ combinations for each document, where q is the number of sentences to keep. This enforces the local sentence representations to capture global information of a document by representing it with a subset of sentences in it. The word embedding is used as globally shared building blocks for sentence embedding.

For a document $X_i = \{\mathbf{s}_i^j\}$, or $\mathcal{S}_i$, the embedding is derived from averaging the respective representations of subsequences. Noted as:

$$\mathbf{d}_i = \frac{1}{q} \sum_{\substack{j=1,\\ \mathbf{s}\sim P_{\mathcal{S}_i}(\mathbf{s})}}^{q} \mathbf{e}_{\mathbf{s}}^{j}, \tag{1}$$

where

$$\mathbf{e}_{\mathbf{s}} = E(\mathbf{s}), \tag{2}$$

where a sentence encoder E is introduced to produce sentence embedding for $\mathbf{s}_i^j$. In practice, sentences can be obtained by simply segmenting documents with punctuation. In testing, the document embedding is obtained by averaging all the sentences in which:

$$\mathbf{d} = \frac{1}{|\mathcal{S}_i|} \sum_{\forall \mathbf{s} \in \mathcal{S}_i} \mathbf{e}_{\mathbf{s}}. \tag{3}$$

We note that averaging subsequences differs from averaging of words in two aspects. First, each sentence is encoded individually before being averaged, allowing incorporation of word order into design rationale at least in a reasonable range. Second, subsequences may have different lengths that reveal syntactic information. To illustrate, BoW/mean-of-word models suffer from ambiguously modeling two different documents which are similar in word distributions but differ in some aspects of interest. Mean-of-sentence model avoids such concern by modeling documents at the sentence level. It could be expected that it is much less likely to find two documents with similar sentence distribution than similar word distribution. Mean-of-sentences formulation can be smoothly reduced to mean-of-word models (by treating each word as a sentence) or pure sequence models (by treating each document as a very long sentence).

3.2 Self-Discriminative Learning

Unlike PV or Doc2VecC which emphasize modeling distributional information within individual documents, we model relations across documents. The basic idea is that we hope to learn an embedding for each sentence in the document as well as a discriminator that determines whether a sentence belongs to a document. Self-discriminative learning uses a discriminator network D to determine whether a sentence belongs to a document. The aim is to learn a suitable embedding and a good discriminator to determine if a sentence belongs to a document. The overall procedure is summarized in Algorithm 1.

Algorithm 1 Self-Discriminative Learning for Unsupervised Document Embedding

```
Input: Documents $\mathcal{X} = \{X_i\}_1^n$, $p$, $k$, $h_w$, $h_s$.
Output: Function $F : \mathcal{X} \to \mathcal{R}^{h_s}$ that maps text of a document to an embedding $\mathbf{d} \in \mathcal{R}^{h_s}$.
Compute $\mathcal{S} = \bigcup_{i=1}^{n} \mathcal{S}_i$ from set $\mathcal{S}_i$ of each $X_i$.
Create and initialize $D$, $\mathbf{U}$.
Create and initialize $E$ as in Eq. 5 or Eq. 6.
while not converge do:
  for $i = 1, \dots, n$ do
    Sample $\mathbf{s}$ from $\mathcal{S}_i$.
    Get $\mathbf{e}_{\mathbf{s}}^p \leftarrow E(\mathbf{s})$ as a positive sample.
    Sample $\mathbf{s}_i^1, \dots, \mathbf{s}_i^q$ from $\mathcal{S}_i \setminus \{\mathbf{s}\}$.
    for $j = 1, \dots, q$ do
      Get $\mathbf{e}_{\mathbf{s}}^j \leftarrow E(\mathbf{s}_i^j)$
    end for
    Get $\mathbf{d}_i$ with Eq. 1 given $\{\mathbf{e}_{\mathbf{s}}^j\}_{j=1}^q$.
    for $\ell = 1, \dots, k$ do
      Sample $\mathbf{s}'_\ell$ from $\mathcal{S} \setminus \mathcal{S}_i$.
      Get $\mathbf{e}_{\mathbf{s}'}^\ell \leftarrow E(\mathbf{s}'_\ell)$ as a negative sample.
    end for
    Compute Eq. 4 given $\mathbf{d}_i$, $\mathbf{e}_{\mathbf{s}}^p$, $\{\mathbf{e}_{\mathbf{s}'}^\ell\}_{\ell=1}^k$.
    Backprop and update for $E$, $D$, $\mathbf{U}$.
  end for
end while
Return $F(E, \mathbf{U})$,
```

We propose an objective that explicitly optimizes SDDE towards representing a document with mean of (encoded) sentences. To optimize the discriminator D, we formulate it as a binary classifier that takes pairs of document embedding $\mathbf{d}$ of a document X_i and a sentence embedding $\mathbf{e}_{\mathbf{s}}$, $(\mathbf{d}, \mathbf{e}_{\mathbf{s}})$, as inputs. The discriminator is asked to discriminate using $\mathbf{d}$ whether the sentence $\mathbf{s}$ belongs to the document X_i or the other documents $X' \in \mathcal{X} \setminus \{X_i\}$. The loss then becomes:

$$log(1 - D(\mathbf{d}, \mathbf{e}_{\mathbf{s}}^p)) + \sum_{\ell=1}^{k} \mathop{\mathbb{E}}_{\substack{\mathbf{s}'\sim P_{\mathcal{S}},\\ \mathbf{s}'\notin \mathcal{S}_i}} \left[log(D(\mathbf{d}, \mathbf{e}_{\mathbf{s}'}^{\ell})) \right], \tag{4}$$

for each document with one positive sample $\mathbf{e}_{\mathbf{s}}^p$ and k negative samples of sentences $\mathbf{e}_{\mathbf{s}'}$, where $\mathbf{s}'$ are not in the sentence set $\mathcal{S}_i$ of X_i, as $\mathbf{s}' \notin \mathcal{S}_i$. Note that $\mathbf{e}_{\mathbf{s}}^p$ is not used for $\mathbf{d}$ otherwise it would be trivial to be solved by the discriminator.

The spirits of self-discriminative learning can be understood as unsupervisedly mimicking supervised inference without knowledge of any label information by treating sentences from other documents as fake/negative samples. One main concern that it is possible to find similar sentences in two different documents. Our discriminator particularly addresses this issue by optimizing for the most discriminative sentences rather than similar ones that might not be critical to shape the embedding. To minimize the loss, the encoder would tend to preserve the most essential feature to facilitate the discriminator to push away any two documents, which should encourage the embedding points spread even more widely across the space. This in turn should result in more ease in downstream tasks: for example in learning a decision hyperplane in a classification task.

3.3 Sentence Encoder

Next, we narrow down to sentence encoder E. Given a sequence of word one-hot vectors as a sentence $\mathbf{s} = [\mathbf{w}^1, \ldots, \mathbf{w}^T]$, we project them into an embedding layer $\mathbf{U}$ to retrieve their corresponding word embedding. Note that the word embedding are trained jointly.

Our first method uses:

$$E(\mathbf{s}) = \phi(ReLU(G(\mathbf{U}\mathbf{s}^t))), \tag{5}$$

where G is a single-layer RNN encoder using GRU cells to process the word embedding sequences and ϕ is a linear transform for dimension h_s of sentence embedding.

Our second method, we use a schema of mean-of-word for advantage of fast generation, we average the word embedding $\mathbf{w}$ within a sentence $\mathbf{s}$ along time axis as AVG encoder:

$$E(\mathbf{s}) = \phi(ReLU(\frac{1}{|\mathbf{s}|}\sum_{i=1}^{|\mathbf{s}|}\mathbf{U}\mathbf{w}_i^t)), \tag{6}$$

Let us stress that the role of encoder E is to extract local feature from every sentence, and the overall objective encourages SDDE to represent documents as mean of sentence embedding.

3.4 Discriminator

An undesired pitfall comes from a learned weak encoder with a powerful discriminator causing the embedding produced by the encoder useless for downstream tasks. To avoid such a pitfall, we adopt lightweight network structures for discriminators. For the IMDB datasets, we find inner product $(\mathbf{d}\mathbf{V})^t E(\mathbf{s})$ with a learnable matrix $\mathbf{V}$ sufficient. For the other datasets in Table 1, two fully-connected layers with ReLU activations in latent are used.

Dataset	#Class	#Train / #Test	Doc Length	Sent Length
IMDB	2	75k / 25k	124.6±8,856.7	11.6±105.5
Yelp P.	2	560k / 38k	70.0±4,117.8	8.2±48.7
AG's News	4	120k / 7.6k	27.2±66.1	11.8±66.7
DBPedia	14	560k / 70k	32.8±231.3	9.7±68.6

Table 1: Statistics of the datasets. Length of document and sentence in words (mean±variance), which could be high for real-world scenarios such as online reviews.

Dataset	k	p	h_w	h_s
IMDB	1	3	100	100
Yelp P.	1	3	300	500
AG's News	3	1	100	100
DBPedia	4	2	300	500

Table 2: Hyperparameters used in experiments. The document embedding trained with the same hyperparameters are used for all the evaluations without task-specific tuning.

3.5 Sampling Sentences

We relate our method to the Negative Sampling (Mikolov et al., 2013) technique which is a simplified objective of softmax approximation (Mikolov et al., 2013; Mnih and Teh, 2012; Zoph et al., 2016). Negative sampling has been used as an efficient and effective technique in learning word embedding. We reformulate it to train document embedding by sampling in sentence level, which is easy to implement and efficient to train just like Word2Vec (Mikolov et al., 2013).

In practice, when training with mini-batches the documents for negative samples are from the same mini-batch, which requires small extra computation efforts.

SDDE requires a similar number of parameters as Doc2VecC does, but much less than PV. In addition, the sentence encoder is flexible and can incorporate other techniques of text processing such as attention methods.

4 Experiments

4.1 Setup

Public datasets on sentiment analysis and topic classification across diverse domains including online reviews, news, and Wiki pages are used including IMDB dataset (Maas et al., 2011) and the others from Zhang et al. (2015). Table 1 provides a summary. Only the training splits are used in training embedding with subsampled training split for cross-validations.

We preprocess the datasets by normalizing the text to lower class and replacing words appearing less than 10 times with a *UNK* token. Out-of-vocabulary words in testing set are also replaced. All our baseline models use the same input data. To define the sentences for experiment, we utilize the sentence tokenizer from NLTK. For the documents containing only one sentence we simply divide it into multiple subsequences for sampling. We use RMSProp method for optimization. Dropout 50% of input to the discriminator. Weights are random-uniformly initialized between [-1, 1].

The other hyperparameters are summarized in Table 2. All the models use the same embedding size for fair comparison. The trained document embedding are used for all the evaluations without specific tuning.

4.2 Evaluation

Generally, it is not easy to evaluate an unsupervised embedding model. In Section 4.3 and 4.4, we evaluate the performance on standard document classification following the common practice used by previous work (Chen, 2017; Wu et al., 2018; Arora et al., 2017): a classification task with a linear SVM (Fan et al., 2008) trained on the labels in each dataset. Next, we study unsupervised document embedding on two novel aspects. In Section 4.5, we study a weakly-supervised classification setting that fits the realistic scenario of using unsupervised embedding with only a few labels. In Section 4.6, we provide a metric to evaluate the effectiveness of modeling inter-document information.

4.3 Sentiment Analysis with IMDB Dataset

We first compare our models with the others state-of-the-art competitors. RNN-LM (Mikolov et al., 2010) and Skip-thought (Kiros et al., 2015) are RNN-based. SIF (Arora et al., 2017), W2V-AVG (Mikolov et al., 2013), and WME (Wu et al., 2018) are two-stage approach that post-processing on word embedding. We collect the results reported on the widely-used benchmark sentiment classification dataset IMDB. For PV, we use Gensim implementation (Řehůřek and Sojka, 2010); versions of both Distributed Memory (DM) and Distributed Bag of Words (DBoW) are reported. For different encoders in SDDE, AVG is for averaging word embedding and RNN is for the RNN encoder.

Model	Error%
Skip-thought* (Kiros et al., 2015)	17.4
SIF (GloVe) (Arora et al., 2017)	15.0
RNN-LM* (Mikolov et al., 2010)	13.6
W2V-AVG* (Mikolov et al., 2013)	12.7
DEA* (Chen et al., 2012)	12.5
PV-DM	20.0
PV-DBoW	12.0
WME (Wu et al., 2018)	11.5
Doc2VecC* (Chen, 2017)	11.7
SDDE-AVG	**10.6**
SDDE-RNN	**10.2**

Table 3: Sentiment Classification on IMDB Benchmark. *Results are collected from Chen (2017).

Pred	SDDE-RNN		Doc2VecC	
	True	False	True	False
#Sent	14.8	14.7	14.5	14.8

Table 4: Mean of #sentence per document in IMDB dataset, in groups of classification correctness.

Self-Discriminative Learning is Effective From the experiment result in Table 3, we can see that our self-discriminative learning is effective and superior on the document embedding models for both AVG and RNN versions. SDDE-RNN achieves best accuracy on IMDB dataset 1.5% margin against Doc2VecC.

Study the Property of SDDE Unlike previous work modeling documents on the word or short context level, SDDE operates on the sentence level. We study the false and true predictions output by SVM upon SDDE in comparison with Doc2VecC. Table 5 show some examples that have the largest difference. We observed SDDE can better capture contradicting or contrasting opinions. We observe some wrong predictions (Row 3) are due to the ambivalent reviews. SDDE is insensitive to the number of sentences; we found the effect of the number of sentences per document was trivial as shown in Table 4.

4.4 Large-Scale Document Classification on More Dataset

Next, we borrow some public large-scale dataset in Table 1 to further validate the effectiveness of SDDE compared to the other models. For Doc2vecC and SIF, we use the code from the au-

---

https://www.nltk.org/

Label: 1 SDDE: 0.89 Doc2VecC: 0.27	i don t even like watching those late night talk shows , but i found this one really interesting . i imagine it s probably close to the truth — it feels like an honest account , if that means anything . kinda feel for the people somewhat when you watch it . a nice movie for a saturday night .
Label: 0 SDDE: 0.12 Doc2VecC: 0.75	i m a boorman fan but this is arguably his least successful film . comedy has never been his strong suit , and here his attempts at screwball farce are clumsily done . still , it s almost worth seeing for boorman s eye for talent : this is one of uma thurman s first starring roles , and as always she is ravishing to watch . on a sad side note boorman wrote the script with his daughter , <UNK> who died a couple years ago .
Label: 0 SDDE: 0.77 Doc2VecC: 0.10	michael dudikoff stars as joe armstrong a martial artist who fights ninjas who are stealing weapons from the u s army , in this entertaining yet admittedly brainless martial arts actioner , which is hampered by too many long pauses without action , but helped by some high energy action <UNK> as well as steve james performance .

Table 5: IMDB Examples with scores 0 to 1 for negative to positive assigned by SVM.

Model	Yelp P.	AG	DBP.
PV-DM	17.6	39.6	21.6
PV-DBoW	12.1	16.8	10.4

Doc2VecC	7.4	10.4	2.0
SDDE-RNN	8.7	12.7	8.6
SDDE-AVG	**6.7**	**9.8**	**1.8**

Table 6: Testing error rate (%) with standard classification on public datasets. Bold text indicates passing hypothesis test with p-value < 0.05 with different random initialization.

Model	IMDB	Yelp P.	AG	DBP.
Doc2VecC	12.5	11.5	13.9	3.6
PV-DBoW	13.7	18.6	13.9	13.1
SDDE	**11.7**	**10.0**	**10.0**	**2.9**

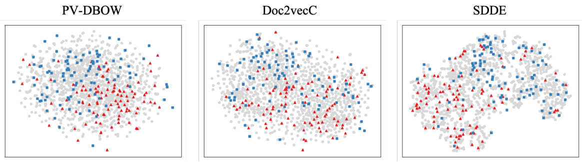
Table 7: Testing error (%) in weakly-supervised setting. Only 1k labeled data per class were used. 4.5).

thors. We use SIF to generate document embedding with Word2Vec trained on each dataset as its inputs.

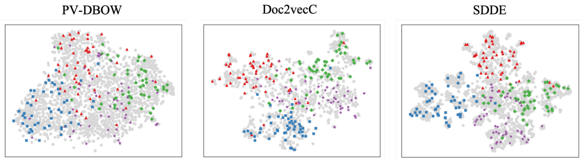
Results are shown in Table 6. SDDE-AVG performs slightly better across different dataset. We hypothesis SDDE gets larger improvement on IMDB dataset since SDDE can handle longer documents better by exploiting sentence embeddings. On the other hand, the RNN version of SDDE performs significantly worse than the word-averaging version. We may remind the reader that state-of-the-art unsupervised document embedding models are not RNN-based. The effects of word order are still unclear. Wieting and Gimpel (2017) provides a study of sentence embedding. We hypothesize that it may be difficult for an RNN encoder to learn to incorporate multi-domain information in datasets with many classes (e.g., DBpedia) unsupervisedly. This would be our future work.

4.5 Classification with Few Labeled Data

Next, we consider a more real-world weakly-supervised learning scenario: classification on the datasets we have used in previous experiments, but this time only when very few labels are available.



(a) IMDB



(b) AG's news

Figure 1: t-SNE embedding Visualizations of weakly-supervised learning experiments in Section 4.5. Colored points are labeled training data in the experiments and gray points are the unlabeled testing documents.

We hypothesize that SDDE is particularly useful for classification with few labels since the self-discriminative learning has exploited the possible features to map the text onto the embedding space properly during the representation learning phase. The embedding is expected to be more discriminable to facilitate finding the classification decision hyperplanes with fewer labeled data.

We randomly sample equal number of instances from each class to train a SVM and verify with the whole testing set. PV-DBoW, Doc2VecC, and SDDE-AVG are examined in this experiment. We use the same pre-trained document embedding as in the previous experiments. We repeat the whole procedure 30 times and report the means and tune the penalty parameter C to find the best value for each model. Results in Figure 2 and Table 7 show SDDEs outperform PV and Doc2VecC. We visualize the training points with t-SNE. As shown in Figure 1, SDDE seems to be able to spread the embedded data more widely, which eventually leads to better usage of scarce data for classification.

Table 8: Distances of Intra & Inter-class cosine similarity. A for IntraCos and E for InterCos, note that they cannot be compared across different models. Instead, distance A-E defined in Equation 7 is reported to study a method's effectiveness of modeling inter-document features. The higher the number the better.

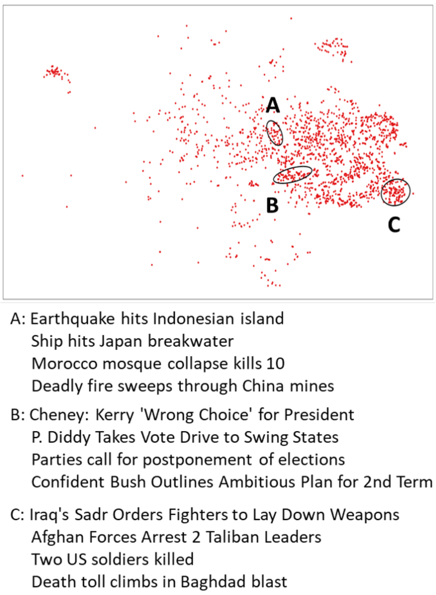
4.6 Distance of Intra&Inter-Class Pairwise Cosine Similarity

Definition We examine our assumption of the ability of SDDE to model inter-document feature. Similar to (Hill et al., 2016b), we consider pairwise cosine similarity between documents with topic labels, this allows us to quantitatively evaluate unsupervised document embedding at inter-document level. Our assumption is that: if pairwise similarity between documents is calculated based on different kinds of embedding, the better embedding results should comply with the properties of both high similarities between those documents within the same underlying class, denoted as $IntraCos(d, d')$ and low similarities between document pairs from different classes, or $InterCos(d, \tilde{d})$. The mean distance:

$$mean(IntraCos) - mean(InterCos), \quad (7)$$

is considered as our metric to avoid simply maximizing IntraCos or minimizing InterCos.

SDDE Provides High Separation Table 8 shows the evaluation. The distances (Eq. 7) for the baseline models are small, which support our assumption that these methods are not able to model inter-document features properly. On the other hand, distances for SDDE are significantly larger. With the classification experiments, we believe SDDE better preserves meaningful inter-document features. Figure 3 shows some meaningful clusters in SDDE in the World class as cohesive sub-classes.



A: Earthquake hits Indonesian island
Ship hits Japan breakwater
Morocco mosque collapse kills 10
Deadly fire sweeps through China mines

B: Cheney: Kerry 'Wrong Choice' for President
P. Diddy Takes Vote Drive to Swing States
Parties call for postponement of elections
Confident Bush Outlines Ambitious Plan for 2nd Term

C: Iraq's Sadr Orders Fighters to Lay Down Weapons
Afghan Forces Arrest 2 Taliban Leaders
Two US soldiers killed
Death toll climbs in Baghdad blast

Figure 3: SDDE-AVG t-SNE visualization of class "World" in AG News dataset testing set. Titles of documents are shown. Meaningful clusters such as (A) disaster, (B) election, and (C) war.

5 Conclusion

Compared to mainstream unsupervised document embedding models (trained to perform predictions on the lexicon level) SDDE embeddings capture information at the inter-document level, as they are trained to maximize the distance between a sentence and a corresponding document. We hope the underlying idea of SDDE offers the document-embedding community a new investigation direction. Self-discriminative learning shows potential for real-world scarcely-labeled scenarios, and our future work will focus on joint training of representations for semi-supervised learning.

Abstract

In this paper, we present an adaptive convolution for text classification to give stronger flexibility to convolutional neural networks (CNNs). Unlike traditional convolutions that use the same set of filters regardless of different inputs, the adaptive convolution employs adaptively generated convolutional filters that are conditioned on inputs. We achieve this by attaching filter-generating networks, which are carefully designed to generate input-specific filters, to convolution blocks in existing CNNs. We show the efficacy of our approach in existing CNNs based on our performance evaluation. Our evaluation indicates that adaptive convolutions improve all the baselines, without any exception, as much as up to 2.6 percentage point in seven benchmark text classification datasets.

1 Introduction

Text classification assigns topics to texts by understanding the semantics of the texts. It is one of the fundamental tasks in natural language processing (NLP) which has a broad range of applications, including web search (Broder et al., 2007), contextual advertising (Lee et al., 2013), and user profiling (Kazai et al., 2016). Traditional approaches to text classification use sparse representations of text, such as bag-of-words (Lodhi et al., 2002). To date, neural network-based text embedding techniques, particularly convolutional neural networks (CNNs) (Kim, 2014; Zhang et al., 2015; Wang et al., 2018b) have shown remarkable results in text classification.

One of the driving forces of CNNs is a convolution operation. It screens local information which appear in inputs (either input texts or outputs from the previous convolution block) by convolving a set of filters with inputs. In the context of text classification, this operation is analogous to questions and answers. Convolutional filters are like questions asking for the intensity of particular patterns in receptive fields. Outputs of convolution operations are the answers from the inputs to the questions. CNNs derive the right class with stacked convolution blocks[1]. On this point, CNNs can be likened to players of the *twenty questions* who guess the answers by iteratively asking questions and receiving information.

However, differences exist between humans and traditional CNNs in the manner in which they play this game. Humans adaptively ask questions by fully utilizing information they have obtained. If players have narrowed the answer down to the name of a person, they would not want to ask questions such as, “Does that have four legs?”. Rather, they would prefer questions related to the target’s profession or origin that are practical for inferring the answer. In contrast, typical CNNs use the same set of filters in any circumstances (Kim, 2014; Johnson and Zhang, 2017; Wang et al., 2018b). This may hamper CNNs from leveraging the information they have as intermediate hidden representations of inputs processed in consecutive convolution operations, and focusing their capacity on disentangling uncertainty.

Motivated by this, we propose an adaptive convolution to give stronger flexibility to networks and allow networks to simulate human capabilities of utilizing the information they have. The adaptive convolution performs convolution operations with filters (questions) dynamically generated conditioned on inputs (outputs from the previous convolution block). We achieve this by attaching filter-generating networks, carefully

---

[1] Pooling can be interleaved with convolution. However, this does not affect the nature of a convolution block.

Proceedings of NAACL-HLT 2019, pages 2475–2485
Minneapolis, Minnesota, June 2 - June 7, 2019.

designed modular networks for generating filters, to convolutional blocks in CNNs. Each attached filter-generating network produces filters from the input and pass the filters to its convolution block. Generated filters are reflections of the information contained in the inputs and allow the networks to focus on extracting informative features. We further propose a hashing technique to substantially compress the size of the filter-generating networks, and prevent a considerable increase in the number of parameters when applying the adaptive convolution.

Our adaptive convolution can easily be applied to existing CNNs, because of the modularity of the filter-generating networks. We demonstrate that significant gains can be realized by applying adaptive convolutions to baseline CNNs (Kim, 2014; Johnson and Zhang, 2017; Wang et al., 2018b), based on a performance evaluation. Our adaptive convolutions improve performance of all the baseline CNNs as much as up to 2.6 percentage point, without any exception, in seven text classification benchmark datasets.

To summarize, our technical contributions are three fold:

- We propose an adaptive convolution which can give stronger flexibility to existing CNNs.
- We design a hashing technique to apply the adaptive convolution without a considerable increase in the number of required parameters.
- We show the effectiveness of our approach based on an evaluation on seven text classification benchmark datasets.

The remainder of this paper is organized as follows. Section 2 discusses related works and Section 3 describes the proposed methodology. We present our evaluation in Section 4 and conclude the paper in Section 5.

2 Related Works

2.1 CNN-based Text Classification

Ever since single layer CNNs were successfully applied to text classification with pre-trained word embeddings (Kim, 2014), many researches have sought effective utilization of CNNs in text classification. Kalchbrenner et al. (2014) introduced a dynamic k-max pooling to handle variable length sequences. Zhang et al. (2015) classified texts wholly based on the characters in the texts. Lai et al. (2015) and Xiao et al. (2016) incorporated recurrent neural networks (RNNs) into CNNs. Conneau et al. (2017) and Johnson et al. (2017) investigated deepening CNNs. Wang et al. (2018b) used dense connections to reuse features from upstream layers at downstream layers. Interests of these researches were concentrated to network architectures, pooling operations or input structures, accepting the nature of the convolution operation. Our work is different from them in that we focus on the convolution operation.

2.2 Parameter Generation

Generating parameters in neural networks have been examined in various researches. Noh et al. (2016) used embedded questions to adaptively create parameters for a fully connected layer in visual question answering. Bertinetto et al. (2016) predicted parameters of a predictor network from an exemplar in a one-shot learning framework. Van den Oord et al. (2016) generated feature-wise biases from descriptive labels or tags that were directly added to layer outputs for conditional image generation. Liu et al. (2017) introduced a specifically designed meta network to produce weights for compositional matrices in tree structured neural networks.

Several researches have adopted parameter generation for conditional normalization (CN). In these studies, parameters in the normalization layer were substituted with learned functions of conditioning information, the outputs from which were then used as normalizing parameters. Different types of CN include conditional instance normalization (Dumoulin et al., 2017) for style transfer, dynamic layer normalization (Kim et al., 2017) for speech recognition and conditional batch normalization (De Vries et al., 2017) for visual question answering. Perez et al. (Perez et al., 2018) relaxed CN by modulating inputs with affine transformation without normalization.

Studies that are most similar to our own involve generating convolutional filters in the field of computer vision. Klein et al. (2015) proposed a dynamic convolution layer for weather prediction. They generated filters for subsequent frames with the previous image. De Brabandere et al. (2016) expanded the dynamic convolution layer by allowing position-specific filters. Niklaus et al (2017) estimated convolutional filters with images in receptive patches to interpolate their corresponding output pixels. Kang et al. (2017) produced convolutional filters with side information such as camera perspective for crowd counting. These approaches can be generalized by the hypernetworks (Ha et al., 2017) in which all weights for the main networks are generated with original inputs. Although this idea can be directly applied for text processing (Shen et al., 2018a), our approach is different from theirs in that we generate filters with outputs from previous convolution blocks, to fully utilize intermediate information obtained from networks as they process inputs.

3 Proposed Methodology

This section introduces our adaptive convolution. Instead of convolving the same set of filters with inputs, an adaptive convolution uses dynamically generated filters conditioned on the outputs from the previous convolution block. In Section 3.1, we explain how the filters are generated in the filter-generating network. In Section 3.2, we show how the adaptive convolution operates with the generated filters, and how it can be applied to existing CNNs.

3.1 Filter-Generating Network

Figure 1 schematically shows the overall architecture of our filter-generating network. The filter-generating network takes an input to a convolution block $I = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_m]$. m is the length which can be the number of words in each text or reduced number of it as a result of a pooling operation. Entry $\mathbf{x}_i \in \mathbb{R}^d$ is a d-dimensional vector in the i^{th} position in the input. d is equal to the number of filters of the previous convolution block, except for the first convolution block which uses word embedding dimension. It outputs a set of k convolutional filters $\mathcal{F} = [\boldsymbol{f}_1, \boldsymbol{f}_2, \cdots, \boldsymbol{f}_k]$. Each filter $\boldsymbol{f}_i \in \mathbb{R}^{h \cdot d}$ consists of a filter size h by d weights.

The filter-generating network generates filters in two phases: context vector generation and filter generation. During context vector generation, the variable size input I is encapsulated into a fixed size g-dimensional context vector $\boldsymbol{c} \in \mathbb{R}^g$. During filter generation, the filter-generating network adaptively produces filters from the context vector.

Context Vector Generation We generate a context vector by leveraging the sequential information inherent in inputs. An input to each convolution block is an intermediate hidden representation of a text. Clearly, text has a sequential nature. This property is preserved when text is processed in typical CNNs because they do not shuffle position information between convolution blocks. Operations in CNNs produce an entry for each position from the corresponding position of the filters. As words within a text are dependent on each other, entries within an input are related.

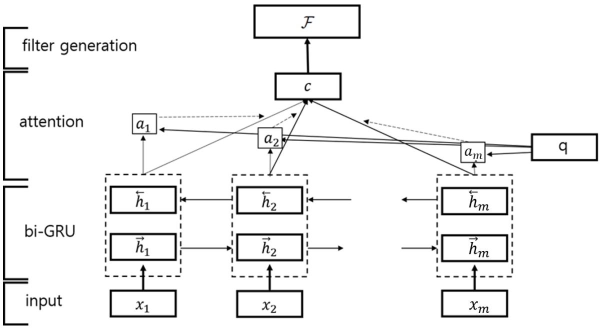

Figure 1: Graphical illustration of filter-generating network. It generates context vector by self-attending hidden states of bidirectional GRU. Convolutional filters are generated from context vector.

To gain some dependencies between entries in a sequence, we use the Gated Recurrent Unit (GRU) (Cho et al., 2014). We found from our preliminary experiments that GRU shows comparable performance to the Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) with fewer parameters and lower computational cost. We obtain a hidden state $\boldsymbol{h}_t \in \mathbb{R}^g$ for entry $\mathbf{x}_t$ by concatenating two hidden states of bidirectional GRU at time step t :

$$\begin{aligned} \overrightarrow{\boldsymbol{h}_t} &= \overrightarrow{GRU}(\mathbf{x}_t, \overrightarrow{\boldsymbol{h}_{t-1}}), \\ \overleftarrow{\boldsymbol{h}_t} &= \overleftarrow{GRU}(\mathbf{x}_t, \overleftarrow{\boldsymbol{h}_{t+1}}), \\ \boldsymbol{h}_t &= [\overrightarrow{\boldsymbol{h}_t}; \overleftarrow{\boldsymbol{h}_t}] \end{aligned} \tag{1}$$

We then have m number of hidden states $H = [\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_m]$. We encapsulate H into a fixed size context vector $\boldsymbol{c}$ by the weighted sum of hidden states :

$$\boldsymbol{c} = \sum_{j=1}^{m} a_j \boldsymbol{h}_j \tag{2}$$

where a_j is a scalar weight of each hidden state h_j

calculated as follows:

$$a_j = \frac{\exp(\boldsymbol{q}^\top \boldsymbol{h}_j)}{\sum_{k=1}^{m} \exp(\boldsymbol{q}^\top \boldsymbol{h}_k)} \tag{3}$$

where $\boldsymbol{q}$ is a trainable query vector. This is a special case of self-attention (Lin et al., 2017) with a hop size of one and without a hidden state projection. The context vector $\boldsymbol{c}$ is an effective summarization of the input, and convolutional filters can be readily generated from the fixed size context vector.

Filter Generation : Once we obtain the context vector $\boldsymbol{c}$ by attending hidden states of the bidirectional GRU, we generate convolutional filters $\mathcal{F}$ by a function of $\boldsymbol{c}$.

$$\mathcal{F} = f(\boldsymbol{c}) \tag{4}$$

Although any kinds of function can be applied, we are interested in adding filter-generating networks to existing CNNs. In order for existing CNNs to be trained in an end-to-end fashion even after filter-generating networks are added to them, a differentiable architecture is preferred so that gradients can be backpropagated. We use a fully-connected layer for its simplicity. With this layer, convolutional filters can be generated in two different approaches: *full generation* and *hashed generation*. For clarity, we explain how each filter $\boldsymbol{f}_i$ is generated. All filters in $\mathcal{F}$ are produced in the same manner.

Full Generation: The most straightforward way to generate a convolutional filter is to use an output of a fully-connected layer directly as a convolutional filter. The layer takes the context vector $\boldsymbol{c}$ and yields filter $\boldsymbol{f}_i$ as follows:

$$\boldsymbol{f}_i = \boldsymbol{W}_i \boldsymbol{c} \tag{5}$$

where $\boldsymbol{W}_i \in \mathbb{R}^{(h \cdot d) \times g}$ is the weight matrix for generating i^{th} filters.

Hashed Generation: Full generation requires numerous parameters because the size of the matrix $\boldsymbol{W}_i$ increases quadratically between the size of the context vector and the convolutional filter. This may cause a memory issue in very deep CNNs. To address this issue, we employ a hashing trick. The hashing trick allows the filter to be generated with only a fraction of the required number of parameters for full generation.

Our hashing trick is motivated by the recently proposed hash embeddings (Svenstrup et al., 2017), which constructs word embeddings with the weighted sum of n *component vectors* from a shared pool. Based on this idea, we generate each $\boldsymbol{f}_i$ by a linear combination of *component filters* from a shared pool. The shared pool $\boldsymbol{E} \in \mathbb{R}^{b \times (h \cdot d)}$ contains b component filters. We select n component filters for $\boldsymbol{f}_i$ from the shared pool using predefined hash functions. The filter $\boldsymbol{f}_i$ is generated by the linear combination as follows:

$$\boldsymbol{f}_i = \sum_{j=1}^{n} p_{i,j} \mathcal{H}_j(\hat{\boldsymbol{f}}_i) \tag{6}$$

where $p_{i,j}$ is the *importance parameter* which determines the weight for the linear combination, and $\mathcal{H}_j$ is a function that outputs a component filter from an ID of the filter, which is denoted as $\hat{\boldsymbol{f}}_i$. $\mathcal{H}_j$ is implemented by $\mathcal{H}_j = \boldsymbol{E}_{D_j(\hat{\boldsymbol{f}}_i)}$, where D_j is a hash function. More specifically, D_j takes $\hat{\boldsymbol{f}}_i$, and outputs a bucket index in $\{1, \cdots, b\}$. The component filter is extracted by taking a row of the bucket index in $\boldsymbol{E}$. To obtain input-specific filters, we control p_i^k as follows:

$$p_{i,j} = \boldsymbol{w_{i,j}}^\top \boldsymbol{c} \tag{7}$$

where $\boldsymbol{w}_{i,j} \in \mathbb{R}^g$ is a vector for generating $p_{i,j}$ from the context vector.

Because we require n numbers of $p_{i,j}$, $n \cdot g$ parameters are needed to generate each filter. The number of the importance parameters n can be chosen to be quite small (we typically use five), and it can provide a huge reduction in the number of parameters compared to the full generation, which uses $h \cdot d \cdot g$ parameters. The additional parameters for the hashed generation come from the shared pool E. Yet, their portion is relatively small, because E is shared across the filters and the size of the shared pool b can be moderate (we typically use 20).

3.2 Adaptive Convolution

We achieve the adaptive convolution by adding a filter-generating network to each convolution block. The filter-generating network yields filters from its input (output from the previous convolution block). The adaptive convolution involves the input-specifically generated filters, which are applied to inputs to produce new outputs. More formally, a feature $o_{i,j}$ corresponding to the filter $\boldsymbol{f}_i$ and j^{th} position

of window in inputs is computed as follows:

$$o_{i,j} = \phi(\boldsymbol{f}_i^\top \mathbf{x}_{j:j+h-1}) \tag{8}$$

where $\mathbf{x}_{j:j+h-1}$ denotes the concatenation of inputs $[\mathbf{x}_j, \mathbf{x}_{j+1}, \cdots, \mathbf{x}_{j+h-1}]$, and ϕ is an activation function such as ReLU (Nair and Hinton, 2010). A position feature $\boldsymbol{o}_j$ is produced by concatenating features from all filters $\boldsymbol{f}_1, \boldsymbol{f}_2, \cdots, \boldsymbol{f}_k$, which are applied to the j^{th} position of a window. The output of an adaptive convolution is a sequence of position features $\boldsymbol{O} = [\boldsymbol{o}_1, \boldsymbol{o}_2, \cdots, \boldsymbol{o}_{m-h+1}]$. This output becomes the input to the next convolution block, after operations predefined in the network structure (such as a pooling) are applied. This procedure is repeated for all convolution blocks in the network. Algorithm 1 details our approach. Models adopted with our adaptive convolution can be trained in a typical backpropagation, as all components in adaptive convolution are differentiable.

4 Experiments

4.1 Experimental Settings

Datasets and Data Preprocessing We employ seven datasets covering seven different classification tasks compiled by Zhang et al. (2015). Statistics are summarized in Table 1. 'AG','DBPedia' and 'Yahoo' are news, ontology, and topic classification datasets, respectively. The others are sentiment classification datasets, where '.p'(polarity) in the dataset name indicates that labels are binary and '.f' (full) means that the labels refer to the number of stars.

We tokenize each text using Stanford's CoreNLP (Manning et al., 2014) after converting all uppercase letters to lowercase letters. In building a vocabulary, we retain words that appear more than five times in a corpus. We replace remaining words with the special 'UNK' tokens.

Baselines We select three baseline CNNs to which we apply our adaptive convolution. First one is *CNN* (Kim, 2014), the basic form of CNNs consists of a single convolution block. The others are recently proposed *DPCNN* (Johnson and Zhang, 2017) and *DenseCNN* (Wang et al., 2018b) which employ multiple convolution blocks. We reproduce these three models and apply adaptive convolutions to assess the efficacy of our methodology. All of them are word-level CNNs. We do not apply adaptive convolutions to character-level CNNs (Zhang et al., 2015; Conneau et al., 2017) because of their relatively poor performance compared to word-level CNNs (Johnson and Zhang, 2016). We also compare the performance of our methodology with *ACNN* (Shen et al., 2018a). Similar to our approach, *ACNN* employs dynamically generated filters for convolutions. Different from our approach, however, it generates filters with original inputs from a single subnetwork. Note that *ACNN* is a specifically designed network architecture, so its filter generation approach can not readily be applied to other existing CNNs. Models other than CNNs, such as RNNs (Yang et al., 2016; Lin et al., 2017; Wang et al., 2017) and word embedding-based models (Joulin et al., 2017; Shen et al., 2018b; Wang et al., 2018a) are also included as baseline models. We do not include

the models where transfer learning is applied, such as ULMFiT (Howard and Ruder, 2018) to compare the capacity of models by themselves, not the effectiveness of transfer.

Training Details We implement all of the models with PyTorch (Paszke et al., 2017) framework. For all the models and datasets, we use 300 dimensional GloVe (Pennington et al., 2014) vectors trained on 840 billion words for word embedding initialization and initialize out-of-vocabulary words with Gaussian distribution with the standard deviation of 0.6. We do not use the *text region embedding* (Johnson and Zhang, 2017), for fair comparisons with other comparative models. We optimize parameters using Adam (Kingma and Ba, 2015) with initial learning rate of 0.01 and batch size of 128. Gradients are clipped at 5.0 by norm. We use ReLU activation after convolution operations.

Model-specific configurations are as follows:

- *CNN*: We use the total of 300 filters, with 100 filters each having window size of 3,4 and 5.
- *DPCNN*: We use 100 filters with a size of 3, for each convolution operation. We set the depth to 11 for all the datasets except for the 'AG' dataset in which depth is set to 9.
- *DenseCNN*: We use 75 filters with a size of 3 for each convolution block. Input texts are padded or truncated to a fixed length. We set the fixed length to 300, except for the 'AG' in which 100 is used. For 'AG' dataset, we use six convolution blocks and seven for all the other datasets.

These configurations are set on the validation set held out by 10% from the training data. If not specified, the same configurations are used in all the datasets. Once we fit model settings, we apply our adaptive convolution to those settings. We use 600 for the context vector size (i.e. 300 for GRU hidden states). In the hashed generation, we use 20 for the hash (shared) pool size and five for the number of importance parameters.

4.2 Main Results

Table 2 shows the evaluation results on the datasets. In the table, *CharCNN* and *VDCNN* are character level CNNs. *FastText*, *SWEM* and *LEAM* are word embedding-based models. *HAN*, *KnnLSTM* and *Self-Attention* are RNN variants. '*AC*' in the model names indicate that adaptive convolution is applied in the model. Both 'full generation' and 'hashed generation' are filter-generating methods.

As shown in the table, adaptive convolutions improve all baseline CNNs in all datasets, with no exception. The performance improvements are relatively small for datasets in which known performances are already nearly 100%. In DBPedia dataset, performance improves by as much as 0.15 percentage point (%p) over the baselines. However, for datasets with a potential for considerable performance improvement, such as Yelp.f and Yahoo datasets, adaptive convolutions produce significant results. The performance improvements are up to 2.6%p for Yelp.f dataset.

Without adaptive convolutions, RNNs show better performance than CNNs on most datasets. However, when adaptive convolutions are applied, our baselines perform better than RNN variants on every dataset. Also our approaches perform better than word embedding-based models except for LEAM model on Yahoo dataset. Furthermore, our adaptive convolutions beat *ACNN* on all the datasets. This suggests that generating filters block by block with outputs from the previous convolution block is much more efficient than generating filters with original inputs in a single subnetwork.

Adaptive convolutions are found to be effective both in the full and hashed generation. The performance differences between the hashed generation and the full generation are within 0.3%p except for a few cases (AG and Yahoo datasets in *DenseCNN*). However, the hashed generation is much more efficient than the full generation in terms of the parameter size. Overall, the total number of parameters for models with the hashed generation is less than 3% that of the full generation (Table 3).

4.3 Analysis

Analysis on model settings To further demonstrate the effectiveness of our adaptive convolutions, we compare the performance with varying filter sizes and depths. We select *CNN* and *AC CNN* with filter sizes ranging from 2 to 150 to check the performance with different filter sizes. To analyze the effect of depths, we choose

DPCNN and *DenseCNN*, and their counterparts to which adaptive convolutions are applied. We evaluate the performance with depths ranging from 2 to 13.

The results are illustrated in Figure 2. Note that validation accuracies are lower than test accuracies because only 90% of the training set is used to save remaining 10% for the validation set. As can be seen in the figure, models adopted with our adaptive convolutions show stable performance. In case of filter sizes, *CNN* drastically drops performance when the filter size gets smaller. Its performance with the filter size of two is 8.4%p lower than that of the filter size of 100. However, the performance of *AC CNN* with the filter size of two declines by 0.6%p from the model with the filter size of 100, which is only 10 percent of the performance loss of *CNN*.

This tendency is also found in the analysis on depths. Performance of *DPCNN* and *DenseCNN* with depths of two or three are 0.6%p lower than that of the baselines with the best performing depths. Contrarily, models with adaptive convolutions perform only 0.12%p lower with depths of two or three than models with the best performing depths.

These results demonstrate that adaptive convolutions effectively generate filters for capturing important information that need to be disambiguated given current inputs. Only few filters and shallow depths are enough for the adaptive convolution to extract such information. This suggests that the required effort to tune hyperparameters can be mitigated by applying adaptive convolutions.

Additional noteworthy fact is that increasing filter sizes and depths beyond a certain level does not lead to performance improvements in all the baseline CNNs. In case of *CNN*, no change in performance is observed when the filter size exceeds 100. In case of *DenseCNN*, increasing depths more than seven rather results in a performance drop and increasing depths of *DPCNN* exceeding eleven has no effect on the performance. This implies that performance gain is caused by the effectiveness of the proposed adaptive convolution, instead of the increased number of parameters (Table. 3).

Analysis on hashed generation We investigate the effect of the hashed generation settings on the performance with different importance parameters and hash (shared) pool sizes. The number of importance parameters is ranging from 2 to 9 and the hash (shared) pool size is in the range from 10 to 100. The results are shown in Figure 3. As illustrated, increasing the sizes of hash pool and importance parameters beyond certain threshold does not guarantee performance gain. The number of importance parameter is optimal at five. Higher value of it has no effect on performance and in some cases, negatively affect performance. In case of the hash pool size, 20 is enough for containing candidate filters.

	AC CNN	*AC DPCNN*	*AC DenseCNN*
with GRU	75.86	75.87	75.72
w/o GRU	74.76	75.37	75.36

Table 4: Validation accuracies on Yahoo dataset for the hashed generation-based models with different context generation settings.

This observation supports the previous finding (Denil et al., 2013) that many redundant parameters exist in deep neural networks. Our results reveal that the networks can be parameterized with a set of candidate weights, and their size can be sufficiently small to significantly reduce the number of required parameters in the network with little performance loss.

Effect of GRU We perform an ablation test to validate the usage of GRUs in generating the context vector. Table 4 shows the results of the ablation test. In all models, utilizing GRUs in generating the context vector significantly improves performance as much as up to 1.1%p. This clearly indicates the existence of dependencies between entries in each layer. These can be effectively captured and incorporated into the context vector with GRUs and attention-based context vector generation scheme.

Filter visualization To better understand generated filters by adaptive convolutions with different inputs, we visualize filters with *t*-SNE (Maaten and Hinton, 2008). We compare filters trained with the baseline *CNN* as well as filters generated by *AC CNN* from different input texts. The corresponding results are shown in Figure 4. As clearly seen, filters from *CNN* are dispersed in the projected space. By contrast, filters generated by *AC CNN* with a positively and a negatively labeled sample are concentrated on the upper right

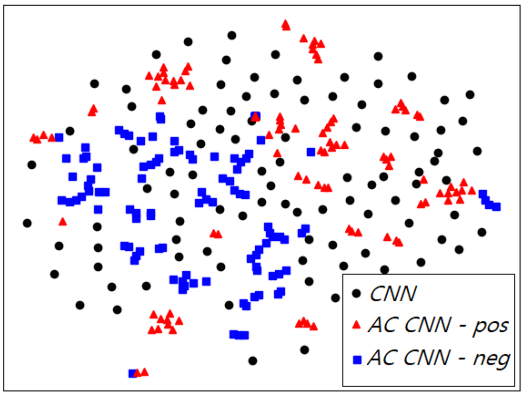

Figure 4: Filters visualized with *t*-SNE. Filters generated by *AC CNN* and trained in *CNN* on Yelp.p dataset are visualized. Negatively and positively labeled samples are used to generate filters from *AC CNN*.

and the lower left part of the space, respectively. This demonstrates that the generated filters in adaptive convolutions are focused to disambiguate uncertainty in given information. Filters trained in *CNN* are not specified to given inputs, but are generally tuned to solve given tasks.

5 Conclusion

In this paper, we have introduced the adaptive convolution to endow flexibility to convolution operations. Further, we have proposed the hashing technique which can drastically reduce the number of parameters for adaptive convolutions. We have validated our approach based on the performance evaluation with seven datasets, and investigated the effectiveness of adaptive convolutions through analysis. We believe that our methodology is applicable to other NLP tasks with text pairs, such as textual entailment, question answering. We plan to apply the proposed approach to those tasks in the future.

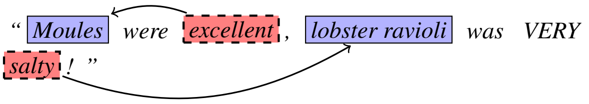
Abstract

Aspect-based sentiment analysis involves the recognition of so called opinion target expressions (OTEs). To automatically extract OTEs, supervised learning algorithms are usually employed which are trained on manually annotated corpora. The creation of these corpora is labor-intensive and sufficiently large datasets are therefore usually only available for a very narrow selection of languages and domains. In this work, we address the lack of available annotated data for specific languages by proposing a zero-shot cross-lingual approach for the extraction of opinion target expressions. We leverage multilingual word embeddings that share a common vector space across various languages and incorporate these into a convolutional neural network architecture for OTE extraction. Our experiments with 5 languages give promising results: We can successfully train a model on annotated data of a source language and perform accurate prediction on a target language without ever using any annotated samples in that target language. Depending on the source and target language pairs, we reach performances in a zero-shot regime of up to 77% of a model trained on target language data. Furthermore, we can increase this performance up to 87% of a baseline model trained on target language data by performing cross-lingual learning from multiple source languages.

1 Introduction

In recent years, there has been an increasing interest in developing sentiment analysis models that predict sentiment at a more fine-grained level than at the level of a complete document. A paradigm coined as Aspect-based Sentiment Analysis (ABSA) addresses this need by defining the sentiment expressed in a text relative to an opinion target (also called *aspect*). Consider the following example from a restaurant review:



In this example, there are two sentiment statements, one positive and one negative. The positive one is indicated by the word “*excellent*” and is expressed towards the opinion target “*Moules*”. The second, negative sentiment, is indicated by the word “*salty*” and is expressed towards the “*lobster ravioli*”.

A key task within this fine-grained sentiment analysis consists of identifying so called *opinion target expressions* (OTE). To automatically extract OTEs, supervised learning algorithms are usually employed which are trained on manually annotated corpora. In this paper, we are concerned with how to transfer classifiers trained on one domain to another domain. In particular, we focus on the transfer of models across languages to alleviate the need for multilingual training data. We propose a model that is capable of accurate zero-shot cross-lingual OTE extraction, thus reducing the reliance on annotated data for every language. Similar to Upadhyay et al. (2018), our model leverages multilingual word embeddings (Smith et al., 2017; Lample et al., 2018) that share a common vector space across various languages. The shared space allows us to transfer a model trained on source language data to predict OTEs in a target language for which no (i.e. zero-shot setting) or only small amounts of data are available, thus allowing to apply our model to under-resourced languages.

Our main contributions can be summarized as follows:

- We present the first approach for zero-shot cross-lingual opinion target extraction and achieve up to 87% of the performance of a monolingual baseline.
- We investigate the benefit of using multi-

Proceedings of NAACL-HLT 2019, pages 2486–2495
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

ple source languages for cross-lingual learning and show that we can improve by 6 to 8 points in F_1-Score compared to a model trained on a single source language.

- We investigate the benefit of augmenting the zero-shot approach with additional data points from the target language. We observe that we can save hundreds of annotated data points by employing a cross-lingual approach.
- We compare two methods for obtaining cross-lingual word embeddings on the task.

2 Approach

A common approach for extracting opinion target expressions is to phrase the task as a sequence tagging problem using the well-known IOB scheme (Tjong Kim Sang and Veenstra, 1999) to represent OTEs as a sequence of tags. According to this scheme, each word in our text is marked with one of three tags, namely **I**, **O** or **B** that indicate if the word is at the **B**eginning[1], **I**nside or **O**utside of a target expression. An example of such an encoding can be seen below:

The	*wine*	*list*	*is*	*also*	*really*	*nice*	*.*
O	**I**	**I**	O	O	O	O	O

By rephrasing the task in this way, we can address it using established sequence tagging models. In this work, we use a multi-layer convolutional neural network (CNN) as our sequence tagging model. The model receives a sequence of words as input features and predicts an output sequence of IOB tags. In order to keep our model simple and our results clear, we restrict our input representation to a sequence of word embeddings. While additional features such as Part-of-Speech (POS) tags are known to perform well in the domain of OTE extraction (Toh and Su, 2016; Kumar et al., 2016; Jebbara and Cimiano, 2016), they would require a separately trained model for POS-tag prediction which can not be assumed to be available for every language. We refrain from using more complex architectures such as memory networks as our goal is mainly to investigate the possibility of performing zero-shot cross-lingual transfer learning for OTE prediction. Being the first approach proposing this, we leave the question of how to increase performance of the approach by using more complex architectures to future work.

In the following, we describe our monolingual CNN model for OTE extraction which we use as our baseline model. Afterwards, we show how we adapt this model for a cross-lingual and even zero-shot regime.

2.1 Monolingual Model

Our monolingual baseline model consists of a word embedding layer, a stack of convolution layers, a standard feed-forward layer followed by a final output layer. Formally, the word sequence $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_n)$ is passed to the word embedding layer that maps each word $\mathbf{w}_i$ to its embedding vector $\mathbf{x}_i$ using an embedding matrix $\mathbf{W}$. The sequence of word embedding vectors $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$ is processed by a stack of L convolutional layers[2], each with a kernel width of l^{conv}, d^{conv} filter maps and RELU activation function f (Nair and Hinton, 2010). The final output of these convolution layers is a sequence of abstract representations $\mathbf{h}^L = (\mathbf{h}_1^L, \ldots, \mathbf{h}_n^L)$ that incorporate the immediate context of each word by means of the learned convolution operations. The hidden states $\mathbf{h}_i^L$ of the last convolution layer are processed by a regular feed-forward layer to further increase the model's capacity and the resulting sequence is passed to the output layer.

In a last step, each hidden state is projected to a probability distribution over all possible output tags $q_i = (q_i^B, q_i^I, q_i^O)$ using a standard feed-forward layer with weights $\mathbf{W}^{tag}$, bias $\mathbf{b}^{tag}$ and a softmax activation function.

Since the prediction of each tag can be interpreted as a classification, the network is trained to minimize the categorical cross-entropy between expected tag distribution p_i and predicted tag distribution q_i of each word i:

$$H(p_i, q_i) = -\sum_{t \in \mathcal{T}} p_i^t \log(q_i^t),$$

where $\mathcal{T} = \{I, O, B\}$ is the set of IOB tags, $p_i^t \in \{0, 1\}$ is the expected probability of tag t and $q_i^t \in [0, 1]$ the predicted probability. Figure 1 depicts the sequence labeling architecture.

---

[1] Note that the **B** token is only used to indicate the boundary of two consecutive phrases.

[2] The input sequences are padded with zeros to allow the application of the convolution operations to the edge words.

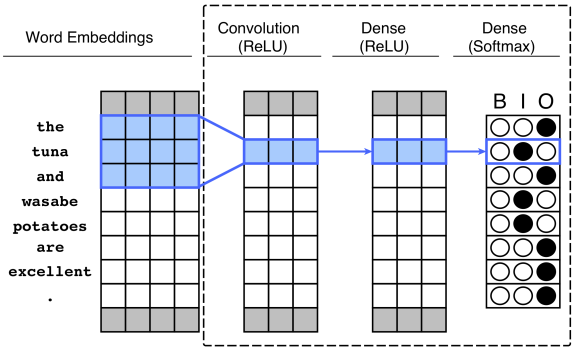


Figure 1: Model for sequence tagging using convolution operations. For simplicity, we only show a single convolution operation. The gray boxes depict padding vectors. The layers inside the dashed box are shared across multiple languages.

2.2 Cross-Lingual Model

Our cross-lingual model works purely with cross-lingual embeddings that have been trained on monolingual datasets and in a second step have been aligned across languages. In fact, the embeddings are pre-computed in an offline fashion and are not adapted while training the convolutional network on data from a specific language. As the inputs to the convolutional network are only the cross-lingual embeddings, the network can be applied to any language for which the embeddings have been aligned.

Since the word embeddings for source and target language share a common vector space, the shared parts of the target language model are able to process data samples from the completely unseen target language and perform accurate prediction i.e. enabling zero-shot cross-lingual extraction of opinion target expressions.

We rely on two approaches to compute embeddings that are aligned across languages. Both methods rely on fastText (Bojanowski et al., 2017) to compute monolingual embeddings trained on Wikipedia articles. The first method is the one proposed by Smith et al. (2017), which computes a singular value decomposition (SVD) on a dictionary of translated word pairs to obtain an optimal, orthogonal projection matrix from one space into the other. We refer to this method as `SVD-aligned`. We use these embeddings[3] in our experiments in Sections 3.3, 3.4 and 3.6.

The second method proposed by Lample et al. (2018) performs the alignment of embeddings across languages in an unsupervised fashion, without requiring translation pairs.

The approach uses adversarial training to initialize the cross-lingual mapping and a synthetically generated bilingual dictionary to fine-tune it with the Procrustes algorithm (Schönemann, 1966). We refer to the multilingual embeddings[4] from Lample et al. (2018) as `ADV-aligned`. These are used in Section 3.5.

3 Evaluation

In this section, we investigate the proposed zero-shot cross-lingual approach and evaluate it on the widely used dataset of Task 5 of the SemEval 2016 workshop. With our evaluation, we answer the following research questions:

RQ1: To what degree is the model capable of performing OTE extraction for unseen languages?

RQ2: Is there a benefit in training on more than one source language?

RQ3: What improvements can be expected when a small amount of samples for the target language are available?

RQ4: How big is the impact of the used alignment method on the OTE extraction performance?

Before we answer these questions, we give a brief overview over the used datasets and resources.

3.1 Datasets

As part of Task 5 of the SemEval 2016 workshop (Pontiki et al., 2016), a collection of datasets for aspect-based sentiment analysis on various languages and domains was published. Due to its relatively large number of samples and high coverage of languages and domains, the datasets are commonly used to evaluate ABSA approaches. To answer our research questions, we make use of a selection of the available datasets. We evaluate our cross-lingual approach on the available datasets for the restaurant domain for the 5 languages Dutch (`nl`), English (`en`), Russian (`ru`), Spanish (`es`) and Turkish (`tr`)[5]. Table 1 gives a brief overview of the used datasets.

Table 1: Statistics of the SemEval 2016 ABSA dataset for the restaurant domain.

3.2 Experimental Settings

In all our experiments, we report F_1-scores for the extracted opinion target expressions computed on exact matches of the character spans as in the original SemEval task (Pontiki et al., 2016).

As described in Section 2.2, our model relies on pretrained multilingual embeddings. For both `SVD-aligned` and `ADV-aligned`, we use the embeddings as provided by the original authors. However, we restrict our vocabulary to the most frequent 50,000 words per language[6] to reduce memory consumption.

For all experiments, we fix our model architecture to 5 convolution layers with each having a kernel size of 3, a dimensionality of 300 units and a ReLU activation function (Nair and Hinton, 2010). The penultimate feed-forward layer has 300 dimensions and a ReLU activation, as well. We apply dropout (Srivastava et al., 2014) on the word embedding layer with a rate of 0.3 and between all other layers with 0.5. The word embeddings and the penultimate layer are L1-regularized (Ng, 2004).

The network's parameters are optimized using the stochastic optimization technique *Adam* (Kingma and Ba, 2015). We optimize the number of training epochs for each model using early stopping (Caruana et al., 2000) but do not tune other hyperparameters of our models. We always pick 20% of our available training data for the validation process. For the zero-shot scenario, this entails that we optimize the number of epochs on the source language and not on the target language to simulate true zero-shot learning.

3.3 Zero-Shot Transfer Learning

In this section, we present our evaluation for zero-shot learning. We first examine a setting with a single source language. Then, we evaluate the effect of cross-lingual learning from multiple source languages.

Single Source Language This part of our evaluation addresses our first research question:

RQ1: To what degree is the model capable of performing OTE extraction for unseen languages?

To answer this question, we perform a set of experiments in the zero-shot setting. We train a model on the training portion of a source language and evaluate the model performance on all possible target languages. Figure 2 shows the obtained scores. The reported results are averaged over 10 runs with different random seeds. The main diagonal represents results of models both trained and tested on target language data. We considered these our monolingual baselines.

In general, the proposed approach achieves relatively high scores for some language pairs, although with large performance differences depending on the exact source and target language pairs. Looking at the absolute scores, the best performing cross-lingual language pair is `en`→`es` with an F_1-score of 0.5. This is followed by `en`→`nl` at 0.46. The lowest is `es`→`tr` with an F_1-score of 0.14. When considering the results relative to their respective monolingual baselines, the highest relative performance is achieved by `en`→`nl` at 77% of a `nl`→`nl` model, followed by `en`→`es` and `ru`→`nl`, which both reach an F-Measure of about 74%. The weakest performing language pair is still `es`→`tr` at 29% relative performance. In general, the Turkish language seems to benefit the least from the cross-lingual transfer learning, while Russian is on average the best source language in terms of relative performance achievement for the target languages.

Overall, the presented results show that it is in fact possible for most considered languages to train a model for OTE extraction without ever using any annotated data in that target language.

Multiple Source Languages In the next experiment, we want to address our second research question:

---

[6] As appearing in the respective embedding files.

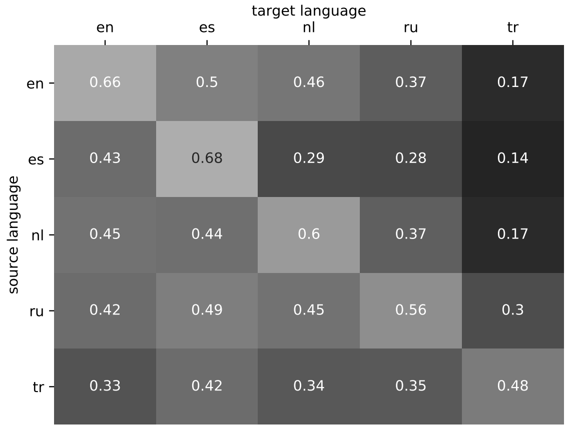

Figure 2: Zero-shot F_1-scores for cross-lingual learning from a single source to a target language.

target	en	es	nl	ru	tr
best→target	0.45	0.50	0.46	0.37	0.30
all others→target	0.52	0.58	0.53	0.43	0.27
target→target	0.66	0.68	0.60	0.56	0.48

Table 2: Zero-shot results for cross-lingual learning from multiple source languages to a target language. The row `best→target` represents the best performing cross-lingual model from Figure 2 for each target language. `all others→target` are the results for training on all languages except for the target language. `target→target` shows the monolingual scores that act as a baseline.

RQ2: Is there a benefit in training on more than one source language?

As we explained in Section 2.2, our approach allows us to train and test on any number of source and target languages, provided that we have aligned word embeddings for each considered language.

In order to answer our second research question, we train a model on the available training data for all but one language and perform prediction on the test data for the left-out language. The results for these experiments are summarized in Table 2. We can see that all languages with the exception of Turkish seem to profit from a cross-lingual transfer setting with multiple source languages. The absolute improvements are in the range of 6 to 8 points in F_1-Score while the performance on Turkish samples drops by 3 points.

We can summarize that we can obtain substantial improvements for most languages when training on a combination of multiple source languages. In fact, for `en`, `es`, `nl` and `ru`, the results of our cross-lingual models trained on all other languages reach between 78% to 87% relative performance of a model trained with target language data.

3.4 Cross-Lingual Transfer Learning with Additional Target Language Data

While our goal is to reduce the effort of annotating huge amounts of data in a target language to which the model is to be transferred, it might still be reasonable to provide a few annotated samples for a target language. Our next research question addresses this issue:

RQ3: What improvements can be expected when a small amount of samples for the target language are available?

We answer this question by training our models jointly on a source language dataset as well as a small amount of target language samples and compare this to a baseline model that only uses target language samples. By gradually increasing the available target samples, we can directly observe their benefit on the test performance. Figure 3 shows a visualization for the source language `en` and the target languages `es`, `nl`, `ru`, and `tr`.

We can immediately see that a monolingual model requires at least 100 target samples to produce meaningful results as opposed to a cross-lingual model that performs well with source language samples alone. Training on increasing amounts of target samples improves the model performances monotonically for each target language and the model leveraging the bilingual data consistently outperforms the monolingual baseline model. The benefits of the source language data are especially pronounced when very few target samples are available, i.e. less than 200. As an example, a model trained on bilingual data using all available English samples and 200 Dutch samples is competitive to a monolingual model trained on 1000 Dutch samples (0.55 vs. 0.56).

As one would expect, the results in Table 2 and Figure 3 suggest that training the model on more data samples leads to a better performance. Since our model can leverage the data from all languages simultaneously, we can exhaust our resources and train an instance of our model that has access to all training data samples from all languages, including the target training data. This is reflected by the dashed line in Figure 3. We see, however, that the model cannot leverage the other source languages

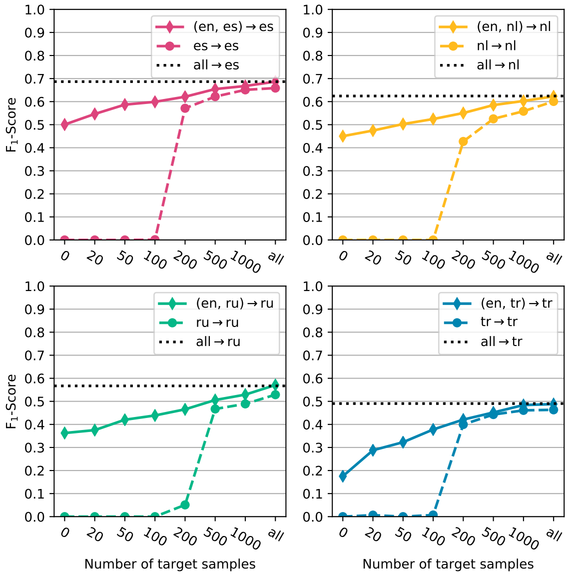

Figure 3: Cross-lingual results for increasing numbers of training samples from the target language.

	en	es	nl	ru	tr
en	0.74	-0.82	-4.6	-2.4	2.3
es	3.5	-0.41	4.7	1.9	4.9
nl	1.2	0.097	-0.87	-4.6	2.9
ru	2	-1.8	-3.7	-0.44	0.17
tr	3.5	-3.3	-6.2	-2.9	-1.1

Figure 4: Zero-shot results comparing the multilingual embeddings `ADV-aligned` to `SVD-aligned`. A positive value means higher absolute F_1 score for `ADV-aligned` and vice versa. For readability, score differences are scaled by a factor of 100.

beyond what it achieves with the combination of the full target and English language data alone.

3.5 Comparison of Alignment Methods

The previous experiments show that we can achieve good performance in a cross-lingual setting for OTE extraction using the multilingual word embeddings proposed by Smith et al. (2017). Now we address our final research question:

RQ4: How big is the impact of the used alignment method on the OTE extraction performance?

With our final research question, we compare our previous results to an alternative method of aligning word embeddings in multiple languages. We repeat our experiments in Section 3.3 using the embeddings of Lample et al. (2018) which we refer to as `ADV-aligned`.

To enable a direct comparison to the zero-shot results in Section 3.3, we report absolute differences in F_1-Score to the scores obtained with `SVD-aligned` for all source and target language combinations.

As can be seen in Figure 4, the two methods do perform well overall, albeit different for specific language pairs. In a monolingual setting (i.e. main diagonal), `ADV-aligned` performs slightly worse than `SVD-aligned` with the exception of `en`→`en`. Using `ADV-aligned`, Spanish appears to be a more effective source language than using `SVD-aligned` as the average performance is about 2.9 points higher. It can also be observed that the cross-lingual transfer learning works better for English as a target language using `ADV-aligned` since the average performance is about 2.2 points higher than for `SVD-aligned`. The opposite is true for Dutch as a target language, which shows a reduction in performance by 2.1 points on average. Overall, for 13 of the 25 language pairs, the embeddings based on `SVD-aligned` perform better than embeddings aligned with `ADV-aligned`.

3.6 Comparison to State-of-the-Art

In this last part of our evaluation, we want to put our work into perspective of prior systems for opinion target extraction on the SemEval 2016 restaurant datasets. We report results for our multilingual model that is trained on the combined training data of all languages and evaluated on the corresponding test datasets. We compare our model to the respective state-of-the-art for each language in Table 3.

We can see that the competition is strongest for English where we fall behind recent monolingual systems. This corresponds to rank 7 of 19 of the original SemEval competition. Regarding the other languages, we see that we are close to the best Spanish and Dutch systems and even clearly outperform systems for Russian and Turkish by at least 7 points in F_1-score. With that, we present the first approach on this task to achieve such competitive performances for a variety of languages

System	`en`	`es`	`nl`	`ru`	`tr`
Toh and Su (2016)	0.723	–	–	–	–
Àlvarez-López et al. (2016)	0.666	0.685	–	–	–
Kumar et al. (2016)	0.685	**0.697**	**0.644**	–	–
Pontiki et al. (2016)*	0.441	0.520	0.506	0.493	0.419
Li and Lam (2017)	**0.734**	–	–	–	–
`all→target` (Ours)	0.660	0.687	0.624	**0.567**	**0.490**

Table 3: Overview of the current state-of-the-art for opinion target extraction for 5 languages. Our model is trained on the combined training data of all languages and evaluated on the respective test datasets. The row marked with * is the baseline provided by the workshop organizers. To our knowledge, no better model is published for Russian and Turkish.

with a single, multilingual model.

3.7 Discussion and Future Work

The presented experiments shed light on the performance of our proposed approach under various circumstances. In the following, we want to discuss its limitations and consider explanations for performance differences of different language pairs.

Model Limitations The core of our proposed sequence labeling approach consists of aligned word embeddings and shared CNN layers. Due to the limited context of a CNN layer, the model can only base its decisions for each word on the local information around that word. In many cases, this information is sufficient since most opinion target expressions are adjective-noun phrases[7] which are well enough identified by the local context for most considered languages.

As future work, it is worth to investigate in how far our findings translate to more complex model architectures that have been proposed for OTE extraction, such as memory networks or attention-based models.

Language Characteristics Due to the inherent variability of natural languages and of the used datasets, it is difficult to identify the exact reasons for the observed performance differences between language pairs. However, we suspect that language features such as word order, inflection, or agglutination affect the *compatibility* of languages. As an example, Turkish is considered a highly agglutinative language, that is, complex words are composed by attaching several suffixes to a word stem. This sets it apart from the other 4 languages. This language feature might present a difficulty in our approach since the appending of suffixes is not optimally reflected in the tokenization process and the used word embeddings. An approach that performs alignment of languages on subword units might alleviate this problem and lead to performance gains for language pairs with similar inflection rules.

Syntactic regularities such as word order might also play a role in our transfer learning approach. It is reasonable to assume that the CNN layers of our approach pick up patterns in the word order of a source language that are indicative of an opinion target expression, e.g. *"the [NOUN] is good"*. When applying such a model to a target language with drastically different word order regularities, these patterns might not appear as such in the target language.

For the considered languages, we see following characteristics: Where English and Spanish are generally considered to follow a Subject-Verb-Object (SVO) order, Dutch largely exhibits a combination of SOV and SVO cases. Turkish and Russian are overall flexible in their word order and allow a variety of syntactic structures. In the case of Turkish, its morphological and syntactic features seem to explain some of the relatively low results. However, with the small sample of languages and the many potential influencing factors at play, we are aware that it is not possible to draw any strong conclusions. Further research has to be conducted in this direction to answer open questions.

4 Related Work

Our work brings together the domains of opinion target extraction on the one side and cross lingual learning on the other side. In this section, we give a brief overview of both domains and point out parallels to previous work.

Opinion Target Extraction San Vicente et al. (2015) present a system that addresses opinion target extraction as a sequence labeling problem based on a perceptron algorithm with token, word shape and clustering-based features.

Toh and Wang (2014) propose a Conditional Random Field (CRF) as a sequence labeling model that includes a variety of features such as Part-of-Speech (POS) tags and dependency tree features, word clusters and features derived from the WordNet taxonomy. The model is later improved us-

---

[7] 90% of OTEs in the English dataset consist of zero or more adjectives followed by at least one noun.

ing neural network output probabilities (Toh and Su, 2016) and achieved the best results on the SemEval 2016 dataset for English restaurant reviews.

Jakob and Gurevych (2010) follow a very similar approach that addresses opinion target extraction as a sequence labeling problem using CRFs. Their approach includes features derived from words, Part-of-Speech tags and dependency paths, and performs well in a single and cross-domain setting.

Kumar et al. (2016) present a CRF-based model that makes use of a variety of morphological and linguistic features and is one of the few systems that submitted results for more than one language for the SemEval 2016 ABSA challenge. The strong reliance on high-level NLP features, such as dependency trees, named-entity information and WordNet features restricts its wide applicability to resource-poor languages.

Among neural network models Poria et al. (2016) and Jebbara and Cimiano (2016) use deep convolutional neural network (CNN) with Part-of-Speech (POS) tag features. Poria et al. (2016) also extend their base model using linguistic rules.

Wang et al. (2017) use coupled multi-layer attentions to extract opinion expressions and opinion targets jointly. This approach, however, relies on additional annotations for opinion expressions alongside annotations for the opinion targets.

Li and Lam (2017) propose two LSTMs with memory interaction to detect aspect and opinion terms. In order to generate opinion expression annotations for the SemEval dataset, a sentiment lexicon is used in combination with high precision dependency rules.

For a more comprehensive overview of ABSA and OTE extraction approaches we refer to Pontiki et al. (2016).

Cross-Lingual and Zero-Shot Learning for Sequence Labelling With the CLOpinionMiner, Zhou et al. (2015) present a method for cross-lingual opinion target extraction that relies on machine translation. The approach derives an annotated dataset for a target language by translating the annotated source language data. Part-of-Speech tags and dependency path-features are projected into the translated data using the word alignment information of the translation algorithm. The approach is evaluated for English to Chinese reviews. A drawback of the presented method is that it requires access to a strong machine translation algorithm for source to target language that also provides word alignment information. Additionally, it builds upon NLP resources that are not available for many potential target languages.

Addressing the task of zero-shot spoken language understanding (SLU), Upadhyay et al. (2018) follow a similar approach as our work. They use the aligned embeddings from Smith et al. (2017) in combination with a bidirectional RNN and target zero-shot SLU for Hindi and Turkish.

Overall, our work differs from the related work by presenting a simple model for the zero-shot extraction of opinion target expressions. By using no annotated target data or elaborate NLP resources, such as Part-of-Speech taggers or dependency parsers, our approach is easily applicable to many resource-poor languages.

5 Conclusion

In this work, we presented a method for cross-lingual and zero-shot extraction of opinion target expressions which we evaluated on 5 languages. Our approach uses multilingual word embeddings that are aligned into a single vector space to allow for cross-lingual transfer of models.

Using English as a source language in a zero-shot setting, our approach was able to reach an F_1-score of 0.50 for Spanish and 0.46 for Dutch. This corresponds to relative performances of 74% and 77% compared to a baseline system trained on target language data. By using multiple source languages, we increased the zero-shot performance to F_1-scores of 0.58 and 0.53, respectively, which correspond to 85% and 87% in relative terms. We investigated the benefit of augmenting the zero-shot approach with additional data points from the target language. Here, we observed that we can save several hundreds of annotated data points by employing a cross-lingual approach. Among the 5 considered languages, Turkish seemed to benefit the least from cross-lingual learning in all experiments. The reason for this might be that Turkish is the only agglutinative language in the dataset. Further, we compared two approaches for aligning multilingual word embeddings in a single vector space and found their results to vary for individual language pairs but to be comparable overall. Lastly, we compared our multilingual model with the state-of-the-art for all languages and saw that we achieve competitive performances for some languages and even present the best system for Russian and Turkish.

Abstract

Cross-domain sentiment classification aims to predict sentiment polarity on a target domain utilizing a classifier learned from a source domain. Most existing adversarial learning methods focus on aligning the global marginal distribution by fooling a domain discriminator, without taking category-specific decision boundaries into consideration, which can lead to the mismatch of category-level features. In this work, we propose an adversarial category alignment network (ACAN), which attempts to enhance category consistency between the source domain and the target domain. Specifically, we increase the discrepancy of two polarity classifiers to provide diverse views, locating ambiguous features near the decision boundaries. Then the generator learns to create better features away from the category boundaries by minimizing this discrepancy. Experimental results on benchmark datasets show that the proposed method can achieve state-of-the-art performance and produce more discriminative features.

1 Introduction

Sentiment classification aims to automatically identify the sentiment polarity (i.e., positive or negative) of the textual data. It has attracted a surge of attention due to its widespread applications, ranging from movie reviews to product recommendations. Recently, deep learning-based methods have been proposed to learn good representations and achieved remarkable success. However, the performances of these works are highly dependent on manually annotated training data while annotation process is time-consuming and expensive. Thus, cross-domain sentiment classification, which aims to transfer knowledge learned on labeled data from related domains (called source domain) to a new domain (called target domain), becomes a promising direction.

One key challenge of cross-domain sentiment classification is that the expression of emotional tendency usually varies across domains. For instance, considering reviews about two sorts of products: **Kitchen** and **Electronics**. One set of reviews would contain opinion words such as “delicious” or “tasty”, and the other “rubbery” or “blurry”, to name but a few. Due to the small intersection of two domain words, it remains a significant challenge to bridge the two domains divergence effectively.

Researchers have developed many algorithms for cross-domain sentiment classification in the past. Traditional pivot-based works (Blitzer et al., 2007; Yu and Jiang, 2016) attempt to infer the correlation between pivot words, i.e., the domain-shared sentiment words, and non-pivot words, i.e., the domain-specific sentiment words by utilizing multiple pivot prediction tasks. However, these methods share a major limitation that manual selection of pivots is required before adaptation. Recently, several approaches (Sun et al., 2016; Zellinger et al., 2017) focus on learning domain invariant features whose distribution is similar in source and target domain. They attempt to minimize the discrepancy between domain-specific latent feature representations. Following this idea, most existing adversarial learning methods (Ganin et al., 2016; Li et al., 2017) reduce feature difference by fooling a domain discriminator. Despite the promising results, these adversarial methods suffer from inherent algorithmic weakness. Even if the generator perfectly fools the discriminator, it merely aligns the marginal distribution of the two domains and ignores the category-specific decision boundaries. As shown in Figure 1 (left), the generator may generate ambiguous or even mismatched features near the decision boundary, thus

[†] Corresponding author

Proceedings of NAACL-HLT 2019, pages 2496–2508
Minneapolis, Minnesota, June 2 - June 7, 2019.

hindering the performance of adaptation.

To address the aforementioned limitations, we propose an adversarial category alignment network (ACAN) which enforces the category-level alignment under a prior condition of global marginal alignment. Based on the cluster assumption in (Chapelle et al., 2009), the optimal predictor is constant on high density regions. Thus, we can utilize two classifiers to provide diverse views to detect points near the decision boundaries and train the generator to create more discriminative features into high-density region. Specifically, we first maximize the discrepancy of the outputs of two classifiers to locate the inconsistent polarity prediction points. Then the generator is trained to avoid these points in the feature space by minimizing the discrepancy. In such an adversarial manner, the ambiguous points are kept away from the decision boundaries and correctly distinguished, as shown in Figure 1 (right).

We evaluate our method on the Amazon reviews benchmark dataset which contains data collected from four domains. ACAN is able to achieve the state-of-the-art results. We also provide analyses to demonstrate that our approach can generate more discriminative features than the approaches only aligning global marginal distribution (Zhuang et al., 2015).

2 Related Work

Sentiment Classification: Deep learning based models have achieved great success on sentiment classification (Zhang et al., 2011). These models usually contain one embedding layer which maps each word to a dense vector, and different network architectures then process combined word vectors to generate a representation for classification. According to diverse network architectures, four categories are divided including Convolutional Neural Networks (CNNs) (Kalchbrenner et al., 2014; Kim, 2014), Recurrent Neural Networks (RNNs) (Yang et al., 2016; Zhou et al., 2016b), Recursive Neural Networks (RecNNs) (Socher et al., 2013) and other neural networks (Iyyer et al., 2015).

Domain Adaption: The fundamental challenge to solve the domain adaptation lies here is that data from the source domain and target domain have different distributions. To alleviate this difference, there are many pivot-based methods (Blitzer et al., 2007; He et al., 2011; Gouws et al., 2012; Yu and Jiang, 2016; Ziser and Reichart, 2018) which try to align domain-specific opinion (non-pivot) words through domain-shared opinion (pivot) words as the expression of emotional tendency usually varies across domains, which is a major reason of the domain difference. However, selecting pivot words for these methods first is very tedious, and the pivot words they find may not be accurate. Apart from pivot-based methods, denoising auto-encoders (Glorot et al., 2011; Chen et al., 2012; Yang and Eisenstein, 2014) have been extensively explored to learn transferable features during domain adaption by reconstructing noise input. Despite their promising results, they are based on discrete representation. Recently, some adversarial learning methods (Ganin et al., 2016; Li et al., 2017, 2018) propose to reduce this difference by minimizing the distance between feature distributions. But these methods solely focus on aligning the global marginal distribution by fooling a domain discriminator, which can lead to the mismatch of category-level features. To solve this issue, we propose to further align the category-level distribution by taking the decision boundary into consideration. Some recent works with class-level alignment have been explored in computer vision applications (Saito et al., 2017, 2018).

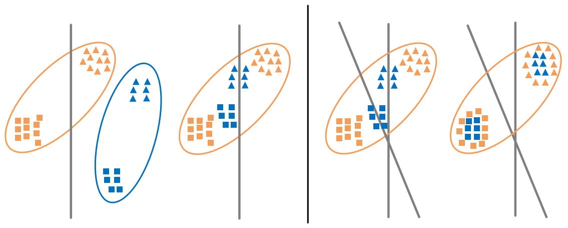

Figure 1: **Left:** marginal distribution alignment by minimizing the distance between two domains can generate ambiguous feature near the decision boundary. **Right:** two different classifiers locate ambiguous features by considering decision boundary to make category-level alignment.

Semi-supervised learning: Considering the target samples as unlabeled data, our work is somehow related to semi-supervised learning (SSL). SSL has several critical assumptions, such as cluster assumption that the optimal predictor is constant or smooth on connected high density regions (Chapelle et al., 2009), and manifolds assumption that support set data lies on low-dimensional manifolds (Chapelle et al., 2009; Luo et al., 2017). Our work takes these assumptions to develop the approach.

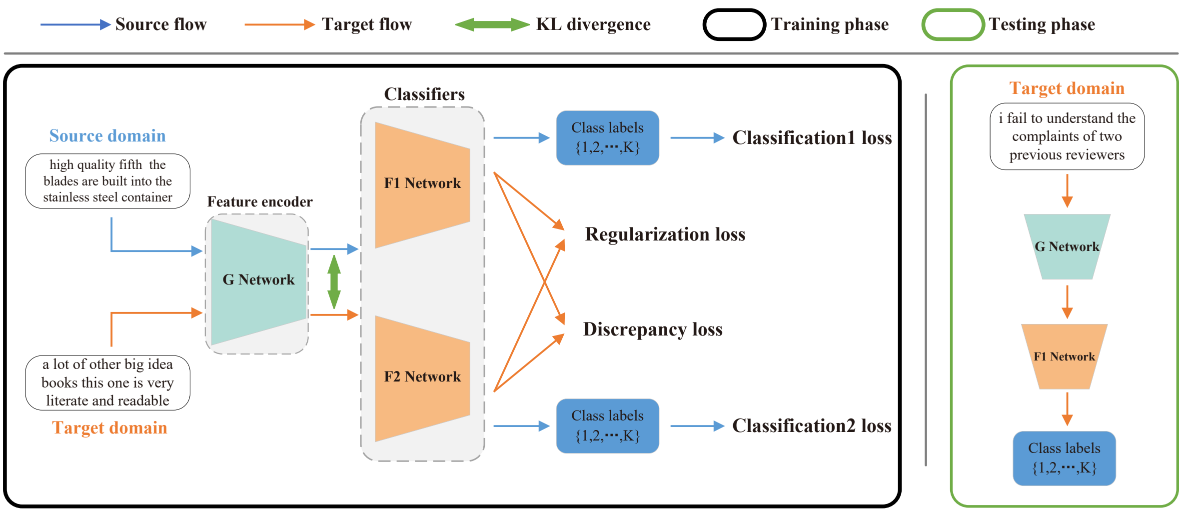

Figure 2: The overview of the proposed adversarial category alignment network in training and test phase.

3 Method

3.1 Problem Definition and Overall Framework

We are given two domains D_s and D_t, denoting the source domain and the target domain respectively. $D_s = \left\{x_i^{(s)}, y_i^{(s)}\right\}_{i=1}^{n_s}$ are n_s labeled source domain examples, where $x_i^{(s)}$ means a sentence and $y_i^{(s)}$ is the corresponding polarity label. $D_t = \left\{x_i^{(t)}\right\}_{i=1}^{n_t}$ are n_t unlabeled target domain examples. In our proposed method, we denote G as a feature encoder that extracts features from the input sentence. Then two classifiers F_1 and F_2 map these features to soft probabilistic outputs $p_1(y|x)$ and $p_2(y|x)$ respectively.

The goal is to train a model to classify the target examples correctly with the aid of source labeled data and target unlabeled data. To achieve this, we first train G, F_1 and F_2 to obtain global marginal alignment. This step reduces the distance between two domains but generates ambiguous target features near the decision boundary. Thus, F_1 and F_2 are adjusted to detect them by maximizing prediction discrepancy. After that, G is trained to generate better features avoiding appearing near the decision boundary. The method also regularizes G by taking the target data samples into consideration. In this way, we can achieve the category alignment. The proposed Adversarial Category Alignment Network (ACAN) is illustrated in Figure 2. The detailed training progress is described in Appendix D.

3.2 Marginal Distribution Alignment

To solve the domain adaption problem, we first consider minimize the classification error on the source labeled data for two classifiers:

$$\begin{aligned} L_{\text{cls}} = &-\frac{1}{n_s}\sum_{i=1}^{n_s}\sum_{j=1}^{K} y_i^{(s)}(j)\log \widetilde{y}_{1i}^{(s)}(j) \\ &-\frac{1}{n_s}\sum_{i=1}^{n_s}\sum_{j=1}^{K} y_i^{(s)}(j)\log \widetilde{y}_{2i}^{(s)}(j) \\ \widetilde{y}_{1i} =& F_1(G(x_i^{(s)})) \quad \widetilde{y}_{2i} = F_2(G(x_i^{(s)})) \end{aligned} \tag{1}$$

where K denotes the number of different polarities. In addition, similar to (Zhuang et al., 2015), our method tries to explicitly minimize the distance between the embedding features from both the source and the target domains. We adopt the Kullback−Leibler (KL) to estimate the distribution divergence:

$$\begin{aligned} L_{\text{kl}} &= \sum_{i=1}^{n} g_s(i)\log\frac{g_s(i)}{g_t(i)} + \sum_{i=1}^{n} g_t(i)\log\frac{g_t(i)}{g_s(i)} \\ g'_s &= \frac{1}{n_s}\sum\nolimits_{i=1}^{n_s} G(x_i^{(s)}), \quad g_s = \frac{g'_s}{||g'_s||_1} \\ g'_t &= \frac{1}{n_t}\sum\nolimits_{i=1}^{n_t} G(x_i^{(t)}), \quad g_t = \frac{g'_t}{||g'_t||_1} \end{aligned} \tag{2}$$

where $g_s, g_t \in \mathcal{R}^D$, $||\cdot||_1$ denotes L1 normalization. In this way, the latent network representations of two domains are encouraged to be similar. In other words, the marginal distribution is forced to be aligned.

3.3 Category-level Alignment

Diverse Views: Considering the marginal distribution alignment, there could be some ambiguous features near the decision boundary, which are easy to be incorrectly categorized into a specific class. If we alter the boundary of classifier F_1 and F_2, the samples closer to the decision boundary would have larger change. To explore these samples, we use F_1 and F_2 to provide diverse guidance. We define a discrepancy between probabilistic outputs of the two classifiers $p_1(y|x)$ and $p_2(y|x)$. The formula is:

$$L_{\text{dis}} = E_{x \sim D_t}[d(p_1(y|x), p_2(y|x))] \tag{3}$$

where $d(p_1(y|x), p_2(y|x))$ defines the average absolute difference for K classes, which is:

$$d(p_1(y|x), p_2(y|x)) = \frac{1}{K} \sum_{i=1}^{K} |p_{1_i}(y|x) - p_{2_i}(y|x)| \tag{4}$$

Specifically, we first fix the generator G and train the classifiers F_1,F_2 to detect points near the decision boundary by maximizing their discrepancy. The objective is as follows:

$$\max_{F1,F2} E_{x \sim D_t}[\frac{1}{K} \sum_{i=1}^{K} |p_{1_i}(y|x) - p_{2_i}(y|x)|] \tag{5}$$

Then, this discrepancy is minimized by optimizing G in order to keep these points away from the decision boundary and categorized into correct classes. The objective is as follows:

$$\min_{G} E_{x \sim D_t}[\frac{1}{K} \sum_{i=1}^{K} |p_{1_i}(y|x) - p_{2_i}(y|x)|] \tag{6}$$

This adversarial step is repeated in the whole training process so that we can continuously locate non-discriminative points and classify them correctly, forcing the model to achieve category-level alignment on two domains.

3.4 Training Steps

The whole training procedure can be divided into three steps. In the first step, we consider both minimizing the classification error and marginal distribution discrepancy to achieve global marginal alignment. The loss function of this step can be written as:

$$L_1 = L_{\text{cls}} + \lambda_1 L_{\text{kl}} \tag{7}$$

In the second step, we consider increasing the difference of two classifiers F_1 and F_2 for the fixed G, thus the ambiguous features can be located by the diverse views. The loss function is defined as below:

$$L_2 = L_{\text{cls}} - \lambda_2 L_{\text{dis}} \tag{8}$$

L_{cls} is used here to ensure the stability of the training process. λ_2 is a hyper-parameter controlling the range of classifiers. In the third step, the difference of two classifiers should be reduced for the fixed F_1 and F_2:

$$L_3 = L_{\text{cls}} + \lambda_3 L_{\text{dis}} \tag{9}$$

L_{cls} and λ_3 used here are similar to the second step. We repeat this step n times to balance the generator and two classifiers. After each step, the corresponding part of the network parameters will be updated. Algorithm 1 describes the overall training procedure.

Algorithm 1 Training procedure of ACAN

    end for
  end for
```

3.5 Generator Regularizer

To further enhance the feature generator, we introduce to regularize G with the information of unlabeled target data. Generally, the mapping of $G(\cdot)$ can been seen a low-dimensional feature of the input. According to the manifolds assumption (Chapelle et al., 2009), this feature space is expected to be low-dimensional manifold and linearly separable. Inspired by (Luo et al., 2017), we consider the connections between data points to regularize $G(\cdot)$ in the feature space. Specifically, the regularizer is formulated as follows:

$$R(G) = \sum_{x \in D_t} l_G(x_i, x_j) \tag{10}$$

here l_G is to approximate the semantic similarity of two feature embeddings. Possible options include triplet loss (Wang et al., 2016), Laplacian eigenmaps (Belkin and Niyogi, 2003) etc. After exploring many tricks, we find below is optimal which is also used by (Luo et al., 2017):

$$l_G = \begin{cases} d_{i,j}^2 & s_{ij} = 1 \\ \max(0, m - d_{i,j})^2 & s_{ij} = 0 \end{cases} \tag{11}$$

where $d_{i,j}$ is L2 distance between data points, m is a predefined distance, and s_{ij} indicates whether x_i and x_j belong to the same class or not. Eq. 10 serves as a regularization that encourages the output of $R(G)$ to be distinguishable among classes. It is applied on target data and integrated in the framework in the third training step, weighted by λ_4. During the training, the underlying label of x_i is estimated by taking the maximum posterior probability of the two classifiers.

3.6 Theoretical Analysis

In this subsection, we provide a theoretical analysis of our method, which is inspired by the theory of domain adaptation in (Ben-David et al., 2010).

For each domain, there is a labeling function on inputs X, defined as $f : X \to [0, 1]$. Thus, the source domain is denoted as $\langle D_s, f_s \rangle$ and the target domain as $\langle D_t, f_t \rangle$. We define a hypothesis function h: $X \to [0, 1]$ and a disagreement function:

$$\epsilon(h_1, h_2) = E[|h_1(x) - h_2(x)|] \tag{12}$$

Then the expected error on the source samples $\epsilon_s(h, f)$ of h is defined as:

$$\epsilon_s(h) = \epsilon_s(h, f_s) = E_{x \sim D_s}[|h(x) - f_s(x)|] \tag{13}$$

Also for the target domain, we have

$$\epsilon_t(h) = \epsilon_s(h, f_t) = E_{x \sim D_t}[|h(x) - f_t(x)|] \tag{14}$$

As is introduced in (Ben-David et al., 2010), the probabilistic bound of the error of hypothesis h on the target domain $\epsilon_t(h)$ is defined as:

$$\forall h \in \mathcal{H}, \epsilon_t(h) \leq \epsilon_s(h) + \tfrac{1}{2} d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t) + \lambda \tag{15}$$

where the expected error $\epsilon_t(h)$ is bounded by three terms: (1) the expected error on the source examples $\epsilon_s(h)$; (2) the divergence between the distributions D_s and D_t; (3) the combined error of the ideal joint hypothesis λ.

First, the training algorithm is easy to minimize $\epsilon_s(h)$ with source label information. Second, λ is expected to be negligibly small and can be usually disregarded. Therefore, the second term $d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t)$ is important quantitatively in computing the target error.

Regarding $d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t)$, we have

$$\begin{aligned} d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t) &= 2 \sup_{h, h' \in \mathcal{H}} |\epsilon_s(h, h') - \epsilon_t(h, h')| \\ &= 2 \sup_{h, h' \in \mathcal{H}} |E_{x \sim D_s}[|h(x) - h'(x)|] - E_{x \sim D_t}[|h(x) - h'(x)|]| \end{aligned} \tag{16}$$

where h and h' are two sets of hypotheses in $\mathcal{H}$. As we have sufficient labeled source examples to train, h and h' can have consistent and correct predictions on the source domain data. Thus, $d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t)$ is approximately calculated as $E_{x \sim D_t}[|h(x) - h'(x)|]$. In our model, the hypothesis h can be decomposed into the feature extractor G and the classifier F using the notation $\circ$. Thus $d_{\mathcal{H}\Delta\mathcal{H}}(D_s, D_t)$ can be formulated as:

$$\sup_{F1, F2} E_{x \sim D_t}[|F_1 \circ G(x) - F_2 \circ G(x)|] \tag{17}$$

For fixed G, sup can be replaced by max. Therefore, F_1 and F_2 are trained to maximize the discrepancy of their outputs and we expect G to minimize this discrepancy. So we obtain

$$\min_{G} \max_{F1, F2} E_{x \sim D_t}[|F_1 \circ G(x) - F_2 \circ G(x)|] \tag{18}$$

The maximization of F_1 and F_2 is to provide diverse views, to find ambiguous points near the decision boundary, and the minimization of G is to keep these points away from the decision boundary. To optimize Eq. 18, we assist the model to capture the whole feature space on the target domain better and achieve lower errors.

4 Experiments

4.1 Data and Experimental Setting

We evaluate the proposed ACAN on the **Amazon reviews** benchmark datasets collected by Blitzer (2007). It contains reviews from four different domains: Books (B), DVDs (D), Electronics (E), Kitchen appliances (K). There are 1000

Source → Target	Previous Work Models					ACAN Models			
	SVM	AuxNN	DANN	PBLM	DAS	Baseline	ACAN-KL	ACAN-KM	ACAN

Average	73.66	79.85	80.29	80.40	81.96	79.55	80.48	81.78	**82.15**

Table 1: Accuracy of adaptation on Amazon benchmark. All results are the averaged performance of each neural model by a 5-fold cross-validation protocol.

positive and 1000 negative reviews for each domain, as well as a few thousand unlabeled examples, of which the positive and negative reviews are balanced. Following the convention of previous works (Zhou et al., 2016a; Ziser and Reichart, 2018; He et al., 2018), we construct 12 cross-domain sentiment classification tasks. In our transferring task, we employ a 5-fold cross-validation protocol, that is, in each fold, 1600 balanced samples are randomly selected from the labeled data for training and the rest 400 for validation. The results we report are the averaged performance of each model across these five folds.

4.2 Training Details and Hyper-parameters

In our implementation, the feature encoder G consists of three parts including a 300-dimensional word embedding layer using GloVe (Pennington et al., 2014), a one-layer CNN with ReLU activation function adopted in (Yu and Jiang, 2016; He et al., 2018) and a max-over-time pooling through which final sentence representation is obtained. Specifically, the convolution filter and the window size of this one-layer CNN are 300 and 3 separately. Similarly, the classifier F_1 and F_2 can be decomposed into one dropout layer and one fully connected output layer. For the fully connected layer, we constrain the l2-norm of the weight vector, setting its max norm to 3. For the implementation of generator regularizer, we apply doubly stochastic sampling approximation due to the computational complexity.

The margin m is set to 1 in this procedure. During training period, $\lambda_1, \lambda_2, \lambda_3, \lambda_4$, and n are set to 5.0, 0.1, 0.1, 1.5, 2. Similar to (He et al., 2018), we parametrize λ_4 as a dynamic weight $\exp[-5(1-\frac{t}{max-epochs})^2]\lambda_4$. This is to minimize the effort of the regularizer as the predictor is not good at the beginning of training. We train 30 epochs for all our experiments with batch-size 50 and dropout rate 0.5. RMSProp (Tieleman and Hinton, 2012) optimizer with learning rate set to 0.0001 is used for all experiments.

4.3 Methods for Comparison

We consider the following approaches for comparisons (The URLs of previous methods code and data we use are in Appendix A):

SVM (Fan et al., 2008): This is a non-domain-adaptation method, which trains a linear SVM on the raw bag-of-words representation of the labeled source domain.

AuxNN (Yu and Jiang, 2016): This method uses two auxiliary tasks to learn sentence embeddings that works well across two domains. For fair comparison, we replace the neural model in this work with our CNN encoder.

DANN (Ganin et al., 2016): This method exploits a domain classifier to minimize the discrepancy between two domains via adversarial training manner. we replace its encoder with our CNN-based encoder.

PBLM (Ziser and Reichart, 2018): This is a representation learning model that exploits the structure of the input text. Specifically, we choose CNN as the task classifier.

DAS (He et al., 2018): This method employs two regularizations: entropy minimization and self-ensemble bootstrapping to refine the classifier while minimizing the domain divergence.

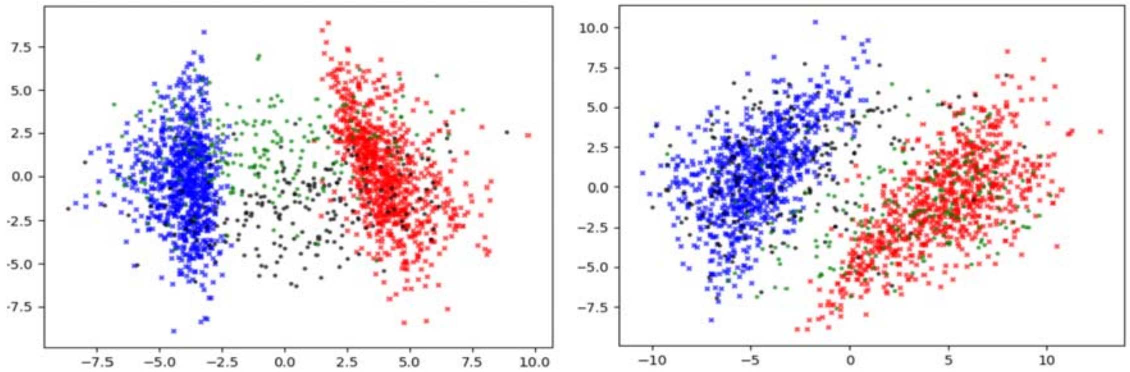

Figure 3: Visualization by applying principal component analysis to the representation of source training data and target testing data produced by ACAN-KL (left) and ACAN (right) for K→E task. The red, blue, green, and black points denote the source positive, source negative, target positive, and target negative examples correspondingly.

Baseline: Our baseline model is a non-adaptive CNN similar to (Kim, 2014), trained without using any target domain information, which is a variant of our model by setting $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ to zeros.
ACAN-KL: ACAN-KL is a variant of our model which minimizes the distance between the features of two domains by minimizing the KL divergence. (set $\lambda_2 = \lambda_3 = \lambda_4 = 0$)
ACAN-KM: ACAN-KM introduces the adversarial category mapping based on ACAN-KL without the regularizer. (set $\lambda_4 = 0$).
ACAN: It is our full model.

4.4 Results

Table 1 shows the classification accuracy of different methods on the Amazon reviews, and we can see that the proposed **ACAN** outperforms all other methods generally. It is obvious to see that **SVM** performs not well in domain transferring task, beaten by **Baseline**. We can notice that exploring the structure of the input text (**AuxNN** and **PBLM**) brings some improvements over **Baseline**. However, these two pivot-based methods present relatively lower ability than **DAS**, which jointly minimizes global feature divergence and refines classifier. Compared to **DAS**, our proposed **ACAN** can improve 0.19% on the average accuracy. This can be explained by that we deal with the relationship between target features distribution and classifier more precisely. Finally, we conduct experiments on the variants of the **ACAN**. It is clear that the performances of **Baseline**, **ACAN-KL**, **ACAN-KM** and **ACAN** present a growing trend in most cases. Compared with **ACAN-KL**, **ACAN** achieves large gain from 80.48% to 82.15%, showing the effectiveness of category-level alignment.

4.5 Case Study

To better understand the results of different models, we conduct experiments on task B → E. For each sentiment polarity, we first extract the most related CNN filters according to the learned weights of the output layer in classifier F_1. Since all listed models use a window size of 3, the outputs of CNN with the highest activation values correspond to the most useful trigrams.

As shown in Table 2, we identify the top trigrams from 10 most related CNN filters on the target domain. It is obvious that **Baseline** and **ACAN-KL** are more likely to capture the domain-independent words, such as “pointless”, “disappointing” and “great”. Thus, the performance of these two models drops much when applied to the target domain. Besides, **DAS** can capture more words of the target domain, but it is limited to nouns with less representativeness, such as ”receiver”, ”product” and etc. Compared to them, **ACAN** is able to extract the domain-specific words like “flawlessly” and “rechargeable”. These results are consistent with the accuracy of each model’s predictions. We also conduct experiments on the tasks **B** → **K** and **K** → **D**. Due to the space limitations, the results are presented in Appendix B.

4.6 Visualization of features

For more intuitive understanding of the differences between the global marginal alignment and category alignment, we further perform a visualization of the feature representations of the **ACAN-KL** and **ACAN** model for the training data in the source domain and the testing data in the target domain for the K→E task. As can be seen in Figure 3, global marginal alignment causes ambiguous

Method	Negative Sentiment	Positive Sentiment

features locating between two clusters while category alignment effectively projects these points into clusters, thus leading a more robust classification result. We also conduct experiments on the tasks **B** → **E** and **B** → **K**. Due to the space limitations, the results are presented in Appendix C.

4.7 Model Analysis

In this part, we provide analysis to our proposed **ACAN** variants. In Figure 4, we show the comparison between **Baseline** and **ACAN** under a setting that some labeled target data are randomly selected and mixed with training data. Here, we present results on two transferring tasks while a similar tendency can be observed in other pairs. With an increase in the number of randomly selected labeled target data, the difference between the two models gradually decreases and **ACAN** also progressively obtains better results. These trends indicate that our **ACAN** is more effective with no or little-labeled target data and can further benefit from more labeled target data. In Figure 5, we can easily observe that **ACAN** continuously shows better results during the whole training process among four settings. After some epochs, **ACAN-KL** starts presenting lower testing accuracy than **Baseline**. One possible reason is that those categories which are initially well aligned between the source and target may be incorrectly mapped because of ignoring category-level feature distribution. This observation can prove our motivation in some degree.

5 Conclusion

In this paper, we propose a novel approach, which utilizes diverse view classifiers to achieve category-level alignment for sentiment analysis. Unlike previous works, we take the decision boundary into consideration, thus classifying the target samples correctly into the corresponding category. Experiments show the proposed ACAN significantly outperforms state-of-the-art methods on the Amazon benchmark. In future we would like to adapt our method to other domain adaptation tasks and consider more effective alternatives for the generator regularizer.

B Trigram Full Results

In the paper, Table 2 shows the top trigrams chosen from 10 most related CNN filters learned on the task **B** → **E** by the DAS the and variants of the ACAN. For a more comprehensive presentation, we also conduct experiments on the task **B** → **K** and **K** → **D**, and the results are listed in Table 3 and Table 4 respectively. It is obvious that the proposed **ACAN** is better to capture domain-specific words, compared to its variants and DAS.

C Visualization full results

In this paper, Figure 3 visualizes the feature representations of the **ACAN-KL** and **ACAN** model for the training data in the source domain and the testing data in the target domain for the K→E task. For a more comprehensive presentation, we also conduct experiments on the task **B** → **E** and **B** → **K**, and the results are listed in Figure 7 and Figure 8 respectively. It is obvious that global marginal alignment causes ambiguous features locating between two clusters while category alignment effectively projects these points into clusters.

D Detailed Illustration of Training Phase

The overview of the propose ACAN is shown in Figure 2. For a better understanding, we present the changes of decision boundaries and data distribution during the network training process, shown in Figure 6. First, we train F_1 and F_2 to locate the points near the decision boundary by maximizing their discrepancy. Then, we train G to minimize the discrepancy to achieve category-level alignment. At the same time, the generator G is regularized with data from target domain.

Abstract

Opinion target extraction and opinion words extraction are two fundamental subtasks in Aspect Based Sentiment Analysis (ABSA). Recently, many methods have made progress on these two tasks. However, few works aim at extracting opinion targets and opinion words as pairs. In this paper, we propose a novel sequence labeling subtask for ABSA named TOWE (Target-oriented Opinion Words Extraction), which aims at extracting the corresponding opinion words for a given opinion target. A target-fused sequence labeling neural network model is designed to perform this task. The opinion target information is well encoded into context by an Inward-Outward LSTM. Then left and right contexts of the opinion target and the global context are combined to find the corresponding opinion words. We build four datasets for TOWE based on several popular ABSA benchmarks from laptop and restaurant reviews. The experimental results show that our proposed model outperforms the other compared methods significantly. We believe that our work may not only be helpful for downstream sentiment analysis task, but can also be used for pair-wise opinion summarization.

1 Introduction

Sentiment analysis, also known as opinion mining (Pang and Lee, 2007; Liu, 2012), has drawn increasing attention of researchers and industries in recent years. It can provide valuable information from user-generated reviews. However, sentiment analysis at sentence level or document level sometimes cannot provide more detailed information, thus a finer-grained task, Aspect-Based Sentiment Analysis (ABSA) (Pontiki et al., 2014), is proposed to identify the opinions of a specific target or aspect in reviews. ABSA consists of multiple subtasks including aspect category detection, opinion target extraction, aspect level sentiment classification etc. Opinion target extraction (OTE) and opinion words extraction (OWE) are two such fundamental subtasks. Opinion targets, sometimes called aspect terms, are the words or phrases in the sentence representing features or entities towards which users show attitude. Opinion words (or opinion terms) refer to those terms used to express attitude explicitly. For example, in the sentence "*The menu is limited but almost all of the dishes are excellent.*", the words "*menu*" and "*dishes*" are two opinion targets, and the words "*limited*" and "*excellent*" are opinion words. More examples can be found in the upper part of Figure 1.

Review:
"My friends and I were on vacation in NY and was referred to Chance by a friend. I found the food to be outstanding, particularly the salmon dish I had. I also ordered the Change Mojito, which was out of this world. My friends settled for rice dishes, but we came back the following day to try the dim sum, which was not outstanding, but good. We ate out in the back patio, which is worth it as it's cool and the music is hear well there. Overall, excellent restaurant!"

The list of extracted targets and opinion words as pairs:

- food : [outstanding]
- salmon dish : [outstanding]
- Change Mojito : [out of this world]
- dim sum : [not outstanding, good]
- back patio : [worth, cool]
- music : [hear well]
- restaurant : [excellent]

Figure 1: The upper part is a restaurant review and the lower part shows the pairs of extracted opinion targets (in red) and opinion words (in blue).

Recently, a great number of works based on neural networks have been done on these two subtasks (Liu et al., 2015; Poria et al., 2016; Xu et al., 2018). Furthermore, some works also integrate the two subtasks into a multi-task learning architecture to extract them jointly, which achieves great progress on both subtasks (Wang et al., 2016, 2017;

---

[*] Corresponding author.

Proceedings of NAACL-HLT 2019, pages 2509–2518
Minneapolis, Minnesota, June 2 - June 7, 2019.

Li and Lam, 2017). However, the extracted opinion targets and opinion words are not in pairs and the correspondence is not extracted. For instance, in the example sentence, ⟨*menu:limited*⟩ and ⟨*dishes:excellent*⟩ are two opinion pairs. Obviously, extracting them as pairs is significant for ABSA. Additionally, in Figure 1, the list of pairs extracted from the example review can be considered to be an extractive pair-wise opinion summarization.

Considering the significance of the pairs in reviews and promising results of targets extraction in previous works, in this paper, we propose a new subtask for ABSA named **TOWE** (Target-oriented Opinion Words Extraction). Given a review and a target in the review, the objective of TOWE is to extract the corresponding opinion words describing or evaluating the target from the review. Then, TOWE can form pairs of the given target and its corresponding opinion words.

Motivated by the success of neural networks in natural language processing, we design a powerful sequence labeling neural network model to perform TOWE. The task TOWE aims to extract the target-oriented opinion terms. In the same review, for different targets, the model needs to output different results. Therefore, a core challenge is the learning of target-specific context representations. We design a neural encoder to incorporate target information and generate the target-fused context. To be specific, we propose an Inward-Outward LSTM to pass target information to the left context and the right context of the target respectively. Then we combine the left, right and global context to encode the sentence and make sequence labeling. It is essential and reasonable to formulate TOWE as a sequence labeling task because some opinion terms include several words and one opinion target may correspond to multiple opinion terms. We try two different decoding strategies in the experiment.

Our main contributions are summarized as follows:

- We propose a sequence labeling subtask for ABSA: TOWE (Target-oriented Opinion Words Extraction), which can offer assistance and interpretability for downstream tasks in ABSA.

- We design a novel sequence labeling neural network model to perform TOWE. It can generate target-specific context representations for different targets in the same review.

- We build four datasets from different domains serving as a benchmark for future works. We conduct extensive experiments on these datasets, and the results show that our model could significantly exceed a variety of baselines.

We release the datasets and our source code at `https://github.com/NJUNLP/TOWE`

2 Related works

A lot of works have been carried out for Opinion Targets Extraction. Traditional methods can be categorized into unsupervised/semi-supervised methods (Hu and Liu, 2004; Zhuang et al., 2006; Qiu et al., 2011) and supervised methods (Jakob and Gurevych, 2010; Shu et al., 2017). Recently, deep learning methods have also made progress in this task. Liu et al. (2015) apply a recurrent neural network with pre-trained word emebddings to solve this task. Yin et al. (2016) exploit a CRF with dependency-paths enhanced word embeddings for aspect term extraction. Poria et al. (2016) use a deep convolutional neural network (CNN) and Xu et al. (2018) propose a CNN model with double embeddings.

Some works extract the targets and opinion words jointly as a co-extraction strategy. Qiu et al. (2011) propose double propagation to expand opinion targets and opinion words lists in a bootstrapping way. Liu et al.(2013) extract the targets and opinion words jointly with modeling the relation from a statistical word alignment model. This co-extraction strategy can also be adopted in neural networks with multi-task learning (Wang et al., 2016, 2017; Li and Lam, 2017). However, in all these works, the extracted targets and opinion words are separated.

In the literature, only a few works discussed opinion pairs. Hu and Liu (2004) use the distance information and recognize the nearest adjective of target as the opinion words. Zhuang et al. (2006) utilize lexicons and human-built word lists to extract the targets and opinion words in the corpus, and then identify valid feature-opinion pairs with syntactic rule templates based on dependency parsing trees. However, these two methods heavily depend on the external resources such as parsers or lexicons and the performance of these approaches relies on the quality of parsing result. By contrast, our model is a purely data-driven supervised learning method and does not need any external linguistic knowledge, lexicons or handcrafted templates. Moreover, in these two methods, the process of detecting opinion words and the process of discovering correspondence is separated into two tasks, which suffers from error propagation. Our model for TOWE aims at detecting the corresponding opinion words in one step with sequence labeling.

3 Our Methods

3.1 Task Formulation

Given a sentence $s = \{w_1, w_2, \dots, w_i, \dots, w_n\}$ consisting of n words, and a opinion target t in the sentence, the task is to make sequence labelling on the sentence to extract the target-oriented opinion words. We use the BIO tagging scheme (Ramshaw and Marcus, 1995) on this task. For each word w_i in the sentence s, it should be tagged as $y_i \in \{B, I, O\}$ (B: Beginning, I: Inside, O: Others).

For example, for different opinion targets, the sentence "*Waiters are very friendly and the pasta is out of this world .*" is tagged in w_i/y_i style as follows:

1. *Waiters/O are/O very/O* [*friendly/B*] *and/O the/O pasta/O is/O out/O of/O this/O world/O ./O* (Given opinion target: ***waiter***, extract ***"friendly"*** as corresponding opinion word).

2. *Waiters/O are/O very/O friendly/O and/O the/O pasta/O is/O* [*out/B of/I this/I world/I*] *./O* (Given Opinion target: ***pasta***, extract ***"out of this world"*** as corresponding opinion words).

3.2 Framework

Figure 2 shows the framework of our methods, which follows an encoder-decoder architecture. We propose a target-fused encoder to incorporate the target information into context and learn target-specific context representations, then pass them to the decoder for sequence labeling. In the target-fused encoder, we first use an Inward-Outward LSTM to model the left context and right context of the target, then combine them with the global context. In the decoder, we can adopt two different decoding strategies. We present the details of each component in the following sections.

3.3 Target-Fused Encoder

We first generate the input vectors for each word by using a embedding lookup table $\mathbb{L} \in \mathbb{R}^{d \times |V|}$, where d is the embedding dimension and $|V|$ is the vocabulary size. The embedding lookup table will map $s = \{w_1, w_2, \dots, w_t, \dots, w_n\}$ to a sequence of vectors $\{\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_i, \dots, \mathbf{e}_n\}$ as words representations where $\mathbf{e}_i \in \mathbb{R}^d$.

Typically, neural sequence labeling models use recurrent neural networks, such as LSTM (Hochreiter and Schmidhuber, 1997) or BiLSTM, to model the sentence. However, merely using BiLSTM to model the whole sentence is totally target-independent. For the different target terms in the same sentence, BiLSTM outputs equal representation and cannot generate target-specific results.

As mentioned before, the core challenge of TOWE is the learning of target-specific context representations. It is evident that different targets have different positions in the sentence and thus different contexts. So, we first split the sentence into three segments: left context $\{w_1, w_2, \cdots, w_l\}$, target term $\{w_{l+1}, \cdots, w_{r-1}\}$ and right context $\{w_r, \cdots, w_n\}$ and left and right contexts are target-specific.We use a left LSTM to model the left context plus target and a right LSTM to model the target plus right context respectively. In this way the target-specific contexts could generate target-specific context representations. However, the direction of the two LSTMs is a crucial problem.

3.3.1 Inward-LSTM

We can use a simple strategy called Inward-LSTM, which follows the design of TD-LSTM (Tang et al., 2016). As Figure 2 shows, Inward-LSTM runs the two LSTMs from the two ends of the sentence to the middle target respectively. It runs the left LSTM from the first word to opinion target as a forward-LSTM and a right LSTM from the last word to the opinion target as a backward-LSTM, so we call it as Inward. This is a process of passing the context to target. We obtain left context representations $\mathbf{H}^{\mathrm{L}}$ and right context representations $\mathbf{H}^{\mathrm{R}}$ as follows:

$$\mathbf{h}_i^{\mathrm{L}} = \overrightarrow{\mathrm{LSTM}}(\mathbf{h}_{i-1}^{\mathrm{L}}, \mathbf{e}_i), \forall i \in [1, \cdots, r-1]\,, \quad (1)$$

$$\mathbf{h}_i^{\mathrm{R}} = \overleftarrow{\mathrm{LSTM}}(\mathbf{h}_{i+1}^{\mathrm{R}}, \mathbf{e}_i), \forall i \in [l+1, \cdots, n]\,. \quad (2)$$

It is obvious that the words of opinion target $\{w_{l+1}, \cdots, w_{r-1}\}$ are represented twice in the left LSTM and right LSTM. We simply average the two representations for the same word to get the representation of target words:

$$\mathbf{h}_i^{\mathrm{LR}} = \frac{(\mathbf{h}_i^{\mathrm{L}} + \mathbf{h}_i^{\mathrm{R}})}{2}, \forall i \in [l+1, \cdots, r-1]\,. \quad (3)$$

Then the context representation is: $\mathbf{H}^{\mathrm{I}} = \{\mathbf{h}_1^{\mathrm{L}}, \cdots, \mathbf{h}_l^{\mathrm{L}}, \mathbf{h}_{l+1}^{\mathrm{LR}}, \cdots, \mathbf{h}_{r-1}^{\mathrm{LR}}, \mathbf{h}_r^{\mathrm{R}}, \cdots, \mathbf{h}_n^{\mathrm{R}}\}$.

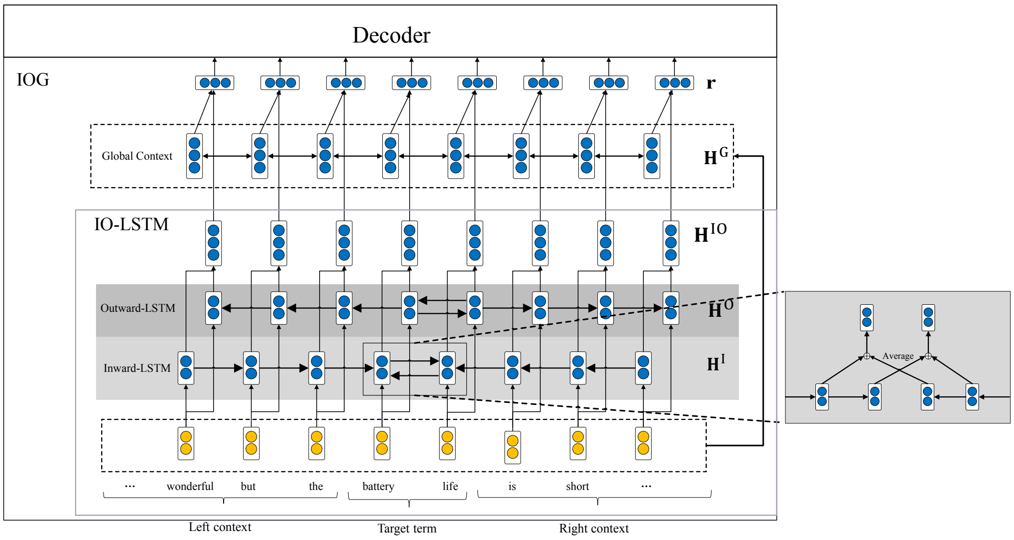

Figure 2: The framework of our method. The subfigure on the right side is an illustration for averaging the hidden states of the Opinion Target.

3.3.2 Outward-LSTM

Although passing contexts to the target in Inward-LSTM is a good strategy for encoding whole sentence representation, only using this strategy is not enough for TOWE because the target information is not passed to the left and right context. For example, in the sentence *"I found the food to be outstanding."*, the opinion target is *"food"*, the Inward-LSTM will first model *"outstanding"* and then model *"food"*. The representation of *"outstanding"* does not contain the information of *"food"*.

To solve this problem, we design a novel strategy specifically for TOWE, i.e., Outward-LSTM. The idea of the Outward-LSTM is to pass the target to the context, which we believe is a better choice. As Figure 2 shows, the Outward-LSTM starts two LSTMs from the target in the middle and run towards the both ends of the sentence, which means the left LSTM is a backward LSTM and the right LSTM is a forward LSTM. We average the duplicate target hidden states and get the target-fused context representations $\mathbf{H}^{\mathrm{O}} = \{\mathbf{h}_1^{\mathrm{L}}, \cdots, \mathbf{h}_l^{\mathrm{L}}, \mathbf{h}_{l+1}^{\mathrm{LR}}, \cdots, \mathbf{h}_{r-1}^{\mathrm{LR}}, \mathbf{h}_r^{\mathrm{R}}, \cdots, \mathbf{h}_n^{\mathrm{R}}\}$:

$$\mathbf{h}_i^{\mathrm{L}} = \overleftarrow{\mathrm{LSTM}}(\mathbf{h}_{i+1}^{\mathrm{L}}, \mathbf{e}_i), \forall i \in [1, \cdots, r-1], \tag{4}$$

$$\mathbf{h}_i^{\mathrm{R}} = \overrightarrow{\mathrm{LSTM}}(\mathbf{h}_{i-1}^{\mathrm{R}}, \mathbf{e}_i), \forall i \in [l+1, \cdots, n], \tag{5}$$

$$\mathbf{h}_i^{\mathrm{LR}} = \frac{(\mathbf{h}_i^{\mathrm{L}} + \mathbf{h}_i^{\mathrm{R}})}{2}, \forall i \in [l+1, \cdots, r-1]. \tag{6}$$

This concise and reasonable strategy can solve the problems remaining in the Inward-LSTM. As we start the LSTM from the target, the target's information is fused into each word in the sentence. Also, the Outward-LSTM ensures that for different targets each word has different representations. Take the sentence *"Its camera is wonderful but the battery life is short !"* as an example. For target *"camera"* or *"battery life"*, the target-fused representations for *"short"* are different and can generate target-specific results.

3.3.3 IO-LSTM

We can combine the both strategy and adopt an Inward-Outward LSTM (IO-LSTM). IO-LSTM concatenates the outputs of Outward-LSTM and Inward-LSTM. The output of Outward-LSTM is crucial for incorporating target information into context, while the Inwards-LSTM is included so they can complement each other and act as a Target-specific Bidirectional LSTM. The target-fused context representations are denoted as $\mathbf{H}^{\mathrm{IO}}$:

$$\mathbf{h}_i^{\mathrm{IO}} = \left[\mathbf{h}_i^{\mathrm{I}}; \mathbf{h}_i^{\mathrm{O}}\right]. \tag{7}$$

3.3.4 IOG: IO-LSTM + Global context

To extract the target-oriented opinion words, only considering the context of each side in isolation is not enough. The left context and right context in the IO-LSTM are separated, and the left LSTM and right LSTM only share the opinion target. It is important to understand the global meaning of the whole sentence while detecting the opinion words on the left and right context. So we introduce the global context to further improve the IO-LSTM. We use a BiLSTM to model the whole sentence embeddings $\mathbf{e} = \{\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_i, \ldots, \mathbf{e}_n\}$ and obtain global contextualized representation $\mathbf{H}^{\mathrm{G}}$ as follows:

$$\mathbf{h}_i^{\mathrm{G}} = \left[\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i\right], \tag{8}$$

$$\overrightarrow{\mathbf{h}}_i = \mathrm{LSTM}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i), \tag{9}$$

$$\overleftarrow{\mathbf{h}}_i = \mathrm{LSTM}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{e}_i). \tag{10}$$

Then we combine left-right contexts from IO-LSTM and global context, as shown in Figure 2. This enables us to obtain the final target-specific contextualized representation $\mathbf{r}$ for each word:

$$\mathbf{r}_i = \left[\mathbf{h}_i^{\mathrm{IO}}; \mathbf{h}_i^{\mathrm{G}}\right]. \tag{11}$$

The final representation $\mathbf{r}$ is fused with both target information and global context information, which can be passed to the decoder for sequence labeling.

3.4 Decoder and Training

Given a sequential representation $\mathbf{r}$, we can use $\mathbf{r}$ to compute $p(\mathbf{y}|\mathbf{r})$ where $\mathbf{y} = \{y_1, \cdots, y_n\}$ are BIO-label sequence for the sentence and $y_i \in \{\mathrm{B}, \mathrm{I}, \mathrm{O}\}$. Two different decoding policies can be adopted.

3.4.1 Greedy decoding

The first is greedy decoding, formulated as a three-class classification problem at each position independently. We use softmax to compute the probability:

$$p(y_i|\mathbf{r}_i) = \mathrm{softmax}\left(\mathbf{W}_s\mathbf{r}_i + \mathbf{b}_s\right). \tag{12}$$

Greedy decoding just simply selects the tag with highest point-wise probability. It does not consider the dependencies between tags but runs faster. We use the negative log likelihood (NLL) as the loss for one sentence:

$$L(s) = -\sum_{i=1}^{n}\sum_{k=1}^{3}\mathbb{I}(y_i = k)\log p(y_i = k|w_i). \tag{13}$$

3.4.2 CRF

The second decoding method is to use Conditional Random Field (CRF) (Lafferty et al., 2001). CRF considers the correlations between tags in neighborhoods and score the whole sequence of tags. Specifically, we use a linear-chain CRF and score the tag sequence as conditional probability:

$$p(\mathbf{y}|\mathbf{r}) = \frac{\exp(s(\mathbf{r}, \mathbf{y}))}{\sum_{\mathbf{y}' \in Y}\exp(s(\mathbf{r}, \mathbf{y}'))}, \tag{14}$$

where Y is the set of all possible tag sequences and $s(\mathbf{r}, \mathbf{y})) = \sum_i^n \left(\mathbf{A}_{y_{i-1}, y_i} + \mathbf{P}_{i, y_i}\right)$ is the score function. $\mathbf{A}_{y_{i-1}, y_i}$ measures the transition score from y_{i-1} to y_i and $\mathbf{P}_i = \mathbf{W}_s\mathbf{r}_i + \mathbf{b}_s$. So we use negative log likehood as the loss of the sentence:

$$L(s) = -\log p(\mathbf{y}|\mathbf{r}). \tag{15}$$

When given a new sentence for decoding, we will output the tag sequence that maximizes the conditional probability with Viterbi algorithm.

Finally, we minimize the loss for training:

$$J(\theta) = \sum_{s}^{|D|} L(s). \tag{16}$$

4 Experiments

4.1 Datasets

We build the datasets based on the SemEval challenge 2014 Task4, SemEval Challenge 2015 task 12 and SemEval Challenge 2016 task 5 (Pontiki et al., 2014, 2015, 2016). The SemEval challenge provides several datasets from restaurant and laptop domain. These datasets are very popular benchmarks for many ABSA subtasks, including Aspect category detection, Opinion Target Extraction, Opinion Words Extraction and Target-Dependent Sentiment Analysis (TDSA).

In the original datasets of SemEval challenge, the opinion targets (aspect terms) are annotated, but the opinion words and the correspondence with targets are not provided. So we annotate the corresponding opinion words for the annotated targets. Every sentence is annotated by two people, and the conflicts will be checked. Each instance of the datasets consists of a sentence, the position of the target and the positions of the corresponding opinion words. Note that we only keep the sentences that contain pairs of target and opinion words. The sentences without targets or with implicit opinion expressions are not included.

Finally, we generate four datasets: **14res** and **14lap** from SemEval 2014, **15res** from SemEval 2015 and **16res** from SemEval 2016. **14res**, **15res**, and **16res** contain reviews from restaurant domain. The sentences in **14lap** come from laptop domain. The statistics of the four datasets is shown in Table 1.

4.2 Settings

In our experiments, we initialize word embedding vectors with 300-dimension GloVe vectors which

Dataset		#sentences	#targets
14res	Training	1627	2643
	Testing	500	865
14lap	Training	1158	1634
	Testing	343	482
15res	Training	754	1076
	Testing	325	436
16res	Training	1079	1512
	Testing	329	457

Table 1: Statistics of datasets. The number of targets is identical to the number of pairs and instances

are pre-trained on unlabeled data of 840 billion tokens (Pennington et al., 2014). The word embeddings are fixed and not fine-tuned during the training stage. The dimension of hidden states in all the LSTM cell is set as 200. Adam (Kingma and Ba, 2015) is chosen as the optimization method with the default setting in the original paper. We randomly split 20% of the train set as dev set for tunning the hyperparameters and early stopping. Then we test the models on testing sets and the average result of five runs is reported.

4.3 Evaluation Metrics

Precision, recall and F1 score are used as the metrics to measure the performance of models. An extracted opinion words span is regarded as a correct prediction when the starting and ending offset of the predicted span are both identical to those of a golden opinion words span. We compute Precision, Recall and F1 with the span as the unit.

4.4 Compared Methods

Since we are the first to study this sequence labeling task, there is no available sequence labeling model in the literature to be compared. Although there are a number of complicated models in TDSA, the task is different. Those TDSA models focus on sentence-level representations for sentiment classification, while for TOWE the representation on token-level representations is more crucial. Simply transferring the TDSA models for TOWE is not suitable.

Except for two rule-based methods, we can only design and implement the baselines for TOWE ourselves. Our final model is the IOG encoder with a greedy decoding strategy. We compare it with the following baselines:

- **Distance-rule**: Hu and Liu(2004) use the distance and POS tags to determine the opinion words. Following this idea, we first use the nltk toolkit to make part-of-speech tagging on each word and select the nearest adjective from the target as the corresponding opinion word.
- **Dependecy-rule**: We adopt the strategies proposed in (Zhuang et al., 2006) which uses dependency-tree based templates to identify opinion pairs. The POS tag of opinion targets and opinion words and the dependency path between them in the training set are recorded as rule templates.[1] The high-frequency dependency templates are used for detecting the related opinion words in the testing set.
- **LSTM/BiLSTM**: This method is an LSTM/BiLSTM network built on top of word embeddings proposed by (Liu et al., 2015). We pass the whole sentence into the LSTM/BiLSTM and each hidden state is fed to a softmax layer for three-class classification, which works as sentence-level opinion words extraction.
- **Pipeline**: This method combines BiLSTM and Distance-rule method in a pipelined way. We first train a sentence-level opinion words extraction model with BiLSTM and extract all the opinion words in the test sentences; then we select the closest extracted opinion words of the target as the result.
- **Target-Concatenated BiLSTM (TC-BiLSTM)**: This method incorporates the target information into sentence by concatenation. A target vector is obtained by the average pooling of target word embeddings. The word representation at each position is the concatenation of word embedding and target vector, which is then fed into a BiLSTM for sequence labeling.

4.5 Results and Discussion

The main results can be found in Table 2. Note that all the neural models in Table 2 adopt greedy decoding. The performance of Distance-rule method is not satisfactory and the worst among all the methods; its recall score is especially low. IOG obtains an F1 score with a greater-than 30% improvement over the Distance-rule method. Dependency-rule method obtains a general improvement than Distance-rule, but it was still lower than the below sequence-labeling based methods. This reveals the

Table 3: Comparisions for different model design in terms of Precsion, Recall and F1-score.

lack of robustness in rule-based approaches. The error propagation from syntactic parsers is also a reason for poor performance.

The Pipeline model performs much better than rule-based methods, obtaining an especially high precision, showing that machine-learning methods can obtain better opinion words extraction. However, pipeline model is still not ideal, and the F1-score is approximately 10% lower than our proposed model in several datasets. This reflects that the distance information is not sufficient for detecting target-oriented opinion words while IOG could better handle long distance dependency problem. Also, this strategy cannot solve the cases where one target corresponds to more than one opinion term. It also suffers from error propagation.

LSTM and BiLSTM are both target-independent leading to low precision, and their performance is even worse than pipeline method. IOG outperforms BiLSTM by about 15% averagely, which indicates the target information should be included.

TC-BiLSTM includes the target information by concatenation and obtains better general performance than LSTM and BiLSTM. However, TC-BiLSTM is still over 10% lower than IOG and is slightly inferior to Pipeline, showing that the concatenation is not a good way to incorporate the target information for TOWE. We believe that the problem is that the concatenated target may interfere with the other targets in the same sentence.

IOG achieves the best performance on all datasets from different domains compared to both the rule-based methods and neural models. We can conclude that IOG can learn target-specific representations more effectively and can better capture the correspondence between targets and opinion words.

4.6 Model Analysis

To compare the different design of our model and provide more compared models, we also report the results of the variants of our models in Table 3.

- **Inward-LSTM**: $\mathbf{H}^{\mathrm{I}}$ computed from (1), (2), (3) are fed to the greedy decoder for sequence labeling.
- **Outward-LSTM**: $\mathbf{H}^{\mathrm{O}}$ computed from (4), (5), (6) are fed for greedy decoding
- **IO-LSTM**: Combining Inwards-LSTM and Outwards-LSTM, $\mathbf{H}^{\mathrm{IO}}$ is obtained by concatenation of $\mathbf{H}^{\mathrm{I}}$ and $\mathbf{H}^{\mathrm{O}}$ in (7), which is then used for greedy decoding.
- **IOG+CRF**: Passing the representations $\mathbf{r}$ in IOG to a CRF decoder.

The performance of Inward-LSTM is inferior, similar to the target-independent BiLSTM. This demonstrates that only passing the context to target is similar to not considering the target information owing to the problems we discussed before.

The F1-score of Outward-LSTM exceeds that of the Inward-LSTM by more than 10%. This shows

Sentence	Distance-rule	Dependency rule	Pipeline	BiLSTM	TC-BiLSTM	IOG
The bread is top notch as well .	*top*✗	NULL✗	*top notch*✓	*top notch*✓	NULL✗	*top notch*✓
BEST spicy tuna roll, great asian salad .	*asian*✗	*“great”, ”asian”*✗	*great*✓	*asian*✗	*“BEST”, ”great”*✗	*great*✓
I love the drinks , esp lychee martini , and the food is also VERY good .	*lyche*✗	*love*✓	*love*✓	*“love”,“good”*✗	*“love”,“good”*✗	*love*✓
Food was decent , but not great .	*decent* ✗	*“decent”, “great”* ✗	*decent* ✗	*“decent”, “not great”* ✓	*decent* ✗	*“decent”, “not great”* ✓
The food was excellent - authentic Italian cuisine made absolutely fresh .	*excellent*✓	*NULL*✗	*excellent*✓	*excellent*✓	*“excellent”, “fresh”*✗	*excellent*✓
The food was excellent - authentic Italian cuisine made absolutely fresh .	*Italian*✗	*“authentic”, “Italian ”*✗	*authentic*✗	*excellent*✗	*“authentic”, “excellent ”, “fresh”*✗	*“authentic”, “fresh”*✓

Table 4: Examples for the extracted result, the target terms are in red and the golden corresponding opinion words are in blue.

that passing target into context is a better choice and learning the target-specific word representations is crucial. In fact, Outward-LSTM has already outperformed all the previous baselines, which indicates that this is a really good design for TOWE. IO-LSTM which combine the Inward and Outward is slightly better than Outward-LSTM, showing that Inward-LSTM can still provide supplementary information for Outward-LSTM. Through combining global context with IO-LSTM as IOG model, we roughly obtain a further 1% improvement.

We also test our model with a linear Conditional-Random-Field as the decoder. CRF considers the label dependencies. It can be observed that IOG with CRF obtains a slight improvement.

4.7 Case Study

To demonstrate the effectiveness of our model, we pick some examples in the test dataset in **14res** and show the extracted results of different models.

In the first sentence, since the Distance-rule cannot extract phrases, the extraction it makes is incorrect. In addition, merely selecting the nearest adjective using the Distance-rule approach does not enable coverage in all cases, as shown in the second and third sentence (e.g., the *“asian”* and *“lyche”*). Dependency-rule in some cases fails to extract any word owing to the error of parser and no template to match. Pipeline method has the problem that it cannot handle the cases that one target corresponds to multiple opinion terms (e.g., *“not great”* is not extracted in the fourth sentence). The drawback of BiLSTM is that it does not include target information, so it extracts both *“love”* and *“good”* in the third sentence while only *“love”* is the corresponding opinion word for *“drinks”*. Although TC-BiLSTM is a target-specific model, it tends to extract irrelevant opinion words because of the interference from concatenation. In the last two rows of Table 4, we show the same sentence with two different targets and only IOG does not make mistakes for both targets. IOG outputs the correct results for all the sentences in the table.

5 Conclusion and Future Works

In this paper, we propose a novel subtask for aspect-based sentiment analysis: Target-oriented Opinion Words Extraction (TOWE) which aims at extracting the corresponding opinion words for a given opinion target. We design a novel neural model IOG to solve this task. IOG can effectively encode target information into left and right context respectively. Then we combine the left and right context of the opinion target and global context for extracting the corresponding opinion word in the decoder. We contribute four datasets based on several benchmarks. The experimental results demonstrate that our model achieves the best performance across all the datasets from different domains.

In future works, TOWE could be utilized to further improve the performance on downstream sentiment analysis tasks with building a more interpretable model, such as enhanced-feature or multi-task learning. In addition, an end-to-end opinion extractive summary method without given golden targets is also a future work.

Abstractive Summarization of *Reddit* Posts with Multi-level Memory Networks

Byeongchang Kim **Hyunwoo Kim** **Gunhee Kim**

Abstract

We address the problem of abstractive summarization in two directions: proposing a novel dataset and a new model. First, we collect *Reddit TIFU* dataset, consisting of 120K posts from the online discussion forum Reddit. We use such informal crowd-generated posts as text source, in contrast with existing datasets that mostly use formal documents as source such as news articles. Thus, our dataset could less suffer from some biases that key sentences usually locate at the beginning of the text and favorable summary candidates are already inside the text in similar forms. Second, we propose a novel abstractive summarization model named *multi-level memory networks* (MMN), equipped with multi-level memory to store the information of text from different levels of abstraction. With quantitative evaluation and user studies via Amazon Mechanical Turk, we show the *Reddit TIFU* dataset is highly abstractive and the MMN outperforms the state-of-the-art summarization models. The code and dataset are available at `http://vision.snu.ac.kr/projects/reddit-tifu`.

1 Introduction

Abstractive summarization methods have been under intensive study, yet they often suffer from inferior performance compared to extractive methods (Allahyari et al., 2017; Nallapati et al., 2017; See et al., 2017). Admittedly, by task definition, abstractive summarization is more challenging than extractive summarization. However, we argue that such inferior performance is partly due to some biases of existing summarization datasets. The source text of most datasets (Over et al., 2007; Hermann et al., 2015; Cohan et al., 2018; Grusky et al., 2018; Narayan et al., 2018a) originates from formal documents such as news articles, which have some structural patterns of which extractive methods better take advantage.

In formal documents, there could be a strong tendency that key sentences locate at the beginning of the text and favorable summary candidates are already inside the text in similar forms. Hence, summarization methods could generate good summaries by simply memorizing keywords or phrases from particular locations of the text. Moreover, if abstractive methods are trained on these datasets, they may not show much abstraction (See et al., 2017), because they are implicitly forced to learn structural patterns (Kedzie et al., 2018). Grusky et al. (2018) and Narayan et al. (2018a) recently report similar extractive bias in existing datasets. They alleviate this bias by collecting articles from diverse news publications or regarding intro sentences as gold summary.

Different from previous approaches, we propose to alleviate such bias issue by changing the source of summarization dataset. We exploit user-generated posts from the online discussion forum `Reddit`, especially `TIFU` subreddit, which are more casual and conversational than news articles. We observe that the source text in `Reddit` does not follow strict formatting and disallows models to simply rely on locational biases for summarization. Moreover, the passages rarely contain sentences that are nearly identical to the gold summary. Our new large-scale dataset for abstractive summarization named as *Reddit TIFU* contains 122,933 pairs of an online post as source text and its corresponding long or short summary sentence. These posts are written by many different users, but each pair of post and summary is created by the same user.

Another key contribution of this work is to propose a novel memory network model named *multi-level memory networks* (MMN). Our model is equipped with multi-level memory networks, storing the information of source text from different

Proceedings of NAACL-HLT 2019, pages 2519–2531
Minneapolis, Minnesota, June 2 - June 7, 2019.

levels of abstraction (*i.e.* word-level, sentence-level, paragraph-level and document-level). This design is motivated by that abstractive summarization is highly challenging and requires not only to understand the whole document, but also to find salient words, phrases and sentences. Our model can sequentially read such multiple levels of information to generate a good summary sentence.

Most abstractive summarization methods (See et al., 2017; Li et al., 2017; Zhou et al., 2017; Liu et al., 2018; Cohan et al., 2018; Paulus et al., 2018) employ sequence-to-sequence (seq2seq) models (Sutskever et al., 2014) where an RNN encoder embeds an input document and another RNN decodes a summary sentence. Our MMN has two major advantages over seq2seq-based models. First, RNNs accumulate information in a few fixed-length memories at every step regardless of the length of an input sequence, and thus may fail to utilize far-distant information due to vanishing gradient. It is more critical in summarization tasks, since input text is usually very long (>300 words). On the other hand, our convolutional memory explicitly captures long-term information. Second, RNNs cannot build representations of different ranges, since hidden states are sequentially connected over the whole sequence. This still holds even with hierarchical RNNs that can learn multiple levels of representation. In contrast, our model exploits a set of convolution operations with different receptive fields; hence, it can build representations of not only multiple levels but also multiple ranges (*e.g.* sentences, paragraphs, and the whole document).

Our experimental results show that the proposed MMN model improves abstractive summarization performance on both our new Reddit TIFU and existing Newsroom-Abs (Grusky et al., 2018) and XSum (Narayan et al., 2018a) datasets. It outperforms several state-of-the-art abstractive models with seq2seq architecture such as (See et al., 2017; Zhou et al., 2017; Li et al., 2017). We evaluate with quantitative language metrics (*e.g.* perplexity and ROUGE (Lin, 2004)) and user studies via Amazon Mechanical Turk (AMT).

The contributions of this work are as follows.

1. We newly collect a large-scale abstractive summarization dataset named *Reddit TIFU*. As far as we know, our work is the first to use non-formal text for abstractive summarization.
2. We propose a novel model named *multi-level memory networks* (MMN). To the best of our knowledge, our model is the first attempt to leverage memory networks for the abstractive summarization. We discuss the unique updates of the MMN over existing memory networks in Section 2.
3. With quantitative evaluation and user studies via AMT, we show that our model outperforms state-of-the-art abstractive summarization methods on both Reddit TIFU, Newsroom abstractive subset and XSum dataset.

2 Related Work

Our work can be uniquely positioned in the context of the following three topics.

Neural Abstractive Summarization. Many deep neural network models have been proposed for abstractive summarization. One of the most dominant architectures is to employ RNN-based seq2seq models with attention mechanism such as (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2016; Cohan et al., 2018; Hsu et al., 2018; Gehrmann et al., 2018).In addition, recent advances in deep network research have been promptly adopted for improving abstractive summarization. Some notable examples include the use of variational autoencoders (VAEs) (Miao and Blunsom, 2016; Li et al., 2017), graph-based attention (Tan et al., 2017), pointer-generator models (See et al., 2017), self-attention networks (Liu et al., 2018), reinforcement learning (Paulus et al., 2018; Pasunuru and Bansal, 2018), contextual agent attention (Celikyilmaz et al., 2018) and integration with extractive models (Hsu et al., 2018; Gehrmann et al., 2018).

Compared to existing neural methods of abstractive summarization, our approach is novel to replace an RNN-based encoder with explicit multi-level convolutional memory. While RNN-based encoders always consider the whole sequence to represent each hidden state, our multi-level memory network exploits convolutions to control the extent of representation in multiple levels of sentences, paragraphs, and the whole text.

Summarization Datasets. Most existing summarization datasets use formal documents as source text. News articles are exploited the most, including in DUC (Over et al., 2007), Gigaword (Napoles et al., 2012), CNN/DailyMail (Nallapati et al., 2016; Hermann et al., 2015), News-

[Short Summary] (16 words)

TIFU by forgetting my chemistry textbook and all of my notes in a city five hours away

[Long Summary] (29 words)

TL;DR I forgot my chemistry textbook and binder full of notes in Windsor, which is five hour drive away and I am now screwed for the rest of the semester.

[Source Text] (282 words)

(…) So the past three days I was at a sporting event in Windsor. I live pretty far from Windsor, around a 5 hour drive. (…)
A five hour drive later, I finally got back home. I was ready to start catching up on some homework when I realized I left my binder (which has all of my assignments, homework etc.) in it, and my chemistry textbook back in Windsor.
I also have a math and chem test next week which I am now so completely screwed for. (…)

Figure 1: An example post of the `TIFU` subreddit.

room (Grusky et al., 2018) and XSum (Narayan et al., 2018a) datasets. Cohan et al. (2018) introduce datasets of academic papers from arXiv and PubMed. Hu et al. (2015) propose the LCSTS dataset as a collection of Chinese microblog's short text each paired with a summary. However, it selects only formal text posted by verified organizations such as news agencies or government institutions. Compared to previous summarization datasets, our dataset is novel in that it consists of posts from the online forum Reddit.

Rotten Tomatoes and Idebate dataset (Wang and Ling, 2016) use online text as source, but they are relatively small in scale: 3.7K posts of RottenTomatoes compared to 80K posts of TIFU-short as shown in Table 1. Moreover, Rotten Tomatoes use multiple movie reviews written by different users as single source text, and one-sentence consensus made by another professional editor as summary. Thus, each pair of this dataset could be less coherent than that of our TIFU, which is written by the same user. The Idebate dataset is collected from short arguments of debates on controversial topics, and thus the text is rather formal. On the other hand, our dataset contains the posts of interesting stories happened in daily life, and thus the text is more unstructured and informal.

Neural Memory Networks. Many memory network models have been proposed to improve memorization capability of neural networks (Kaiser et al., 2017; Na et al., 2017; Yoo et al., 2019). Weston et al. (2014) propose one of early memory networks for language question answering (QA); since then, many memory networks have been proposed for QA tasks (Sukhbaatar et al., 2015; Kumar et al., 2016; Miller et al., 2016). Park et al. (2017) propose a convolutional read memory network for personalized image captioning. One of the closest works to ours may be Singh et al. (2017), which use a memory network for text summarization. However, they only deal with extractive summarization by storing embeddings of individual sentences into memory.

Dataset	# posts	# words/post	# words/summ
`RottenTomatoes`	3,731	2124.7 (1747)	22.2 (22)
`Idebate`	2,259	178.3 (160)	11.4 (10)
`TIFU-short`	79,949	342.4 (269)	9.33 (8)
`TIFU-long`	42,984	432.6 (351)	23.0 (21)

Table 1: Statistics of the Reddit TIFU dataset compared to existing opinion summarization corpora, *RottenTomatoes* and *Idebate* (Wang and Ling, 2016). We show average and median (in parentheses) values.

Compared to previous memory networks, our MMN has four novel features: (i) building a multi-level memory network that better abstracts multi-level representation of a long document, (ii) employing a dilated convolutional memory write mechanism to correlate adjacent memory cells, (iii) proposing normalized gated tanh units to avoid covariate shift within the network, and (iv) generating an output sequence without RNNs.

3 Reddit TIFU Dataset

We introduce the Reddit TIFU dataset whose key statistics are outlined in Table 1. We collect data from Reddit, which is a discussion forum platform with a large number of subreddits on diverse topics and interests. Specifically, we crawl all the posts from 2013-Jan to 2018-Mar in the `TIFU` subreddit, where every post should strictly follow the posting rules, otherwise they are removed. Thanks to the following rules[1], the posts in this subreddit can be an excellent corpus for abstractive summarization: *Rule 3: Posts and titles without context will be removed. Your title must make an attempt to encapsulate the nature of your f***up. Rule 11: All posts must end with a TL;DR summary that is descriptive of your f***up and its consequences.* Thus, we regard the body text as source, the title as short summary, and the TL;DR summary as long summary. As a result, we make two sets of datasets: *TIFU-short* and *TIFU-long*. Figure 1 shows an example post of the `TIFU` subreddit.

Table 2: Comparison of F1 ROUGE scores between different datasets (row) and methods (column). `PG` is a state-of-the-art abstractive summarization method, and `Lead` and `Ext-Oracle` are extractive ones. `PG/Lead` and `PG/Oracle` are the ROUGE-L ratios of `PG` with `Lead` and `Ext-Oracle`, respectively. We report the numbers for each dataset (row) from the corresponding cited papers.

3.1 Preprocessing

We build a vocabulary dictionary $\mathcal{V}$ by choosing the most frequent V(=15K) words in the dataset. We exclude any urls, unicodes and special characters. We lowercase words, and normalize digits to 0. Subreddit names and user ids are replaced with @subreddit and @userid token, respectively. We use `markdown`[2] package to strip markdown format, and `spacy`[3] to tokenize words. Common prefixes of summary sentences (*e.g.* tifu by, tifu-, tl;dr, etc) are trimmed. We do not take OOV words into consideration, since our vocabulary with size 15K covers about 98% of word frequencies in our dataset. We set the maximum length of a document as 500. We exclude the gold summaries whose lengths are more than 20 and 50 for *TIFU-short* and *TIFU-long*, respectively. They amount to about 0.6K posts in both datasets (*i.e.* less than 1% and 3%). We use these maximum lengths, based on previous datasets (*e.g.* 8, 31, 56 words on average per summary in Gigaword, DUC, and CNN/DailyMail datasets, respectively). We randomly split the dataset into 95% for training, 5% for test.

3.2 Abstractive Properties of Reddit TIFU

We discuss some abstractive characteristics found in Reddit TIFU dataset, compared to existing summarization datasets based on news articles.

Weak Lead Bias. Formal documents including news articles tend to be structured to emphasize key information at the beginning of the text. On the other hand, key information in informal online text data are more spread across the text. Figure 2 plots the density histogram of the relative locations of bigrams of gold summary in the source text. In the CNN/DailyMail and Newsroom, the bigrams are highly concentrated on the front parts of documents. Contrarily, our Reddit TIFU dataset shows rather uniform distribution across the text.

This characteristic can be also seen from the ROUGE score comparison in Table 2. The `Lead` baseline simply creates a summary by selecting the first few sentences or words in the document. Thus, a high score of the Lead baseline implicates a strong lead bias. The `Lead` scores are the lowest in our TIFU dataset, in which it is more difficult for models to simply take advantage of locational bias for the summary.

Strong Abstractness. Besides the locational bias, news articles tend to contain wrap-up sentences that cover the whole article, and they often have resemblance to its gold summary. Its existence can be measured by the score of the `Ext-Oracle` baseline, which creates a summary by selecting the sentences with the highest average score of F1 ROUGE-1/2/L. Thus, it can be viewed as an upper bound for extractive models (Narayan et al., 2018a,b; Nallapati et al., 2017).

(a) Multi-level Memory (b) Sequence Decoder

Figure 3: Illustration of the proposed *multi-level memory network* (MMN) model.

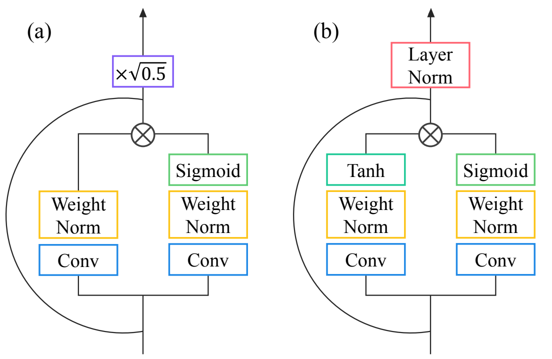

Figure 4: Comparison between (a) the gated linear unit (Gehring et al., 2017) and (b) the proposed normalized gated tanh unit.

In Table 2, the ROUGE scores of the `Ext-Oracle` are the lowest in our TIFU dataset. It means that the sentences that are similar to gold summary scarcely exist inside the source text in our dataset. This property forces the model to be trained to focus on comprehending the entire text instead of simply finding wrap-up sentences.

Finally, `PG/Lead` and `PG/Oracle` in Table 2 are the ROUGE-L ratios of `PG` with `Lead` and `Ext-Oracle`, respectively. These metrics can quantify the dataset according to the degree of difficulty for extractive methods and the suitability for abstractive methods, respectively. High scores of the TIFU dataset in both metrics show that it is potentially an excellent benchmark for evaluation of abstractive summarization systems.

4 Multi-level Memory Networks (MMN)

Figure 3 shows the proposed *multi-level memory network* (MMN) model. The MMN memorizes the source text with a proper representation in the memory and generates a summary sentence one word at a time by extracting relevant information from memory cells in response to previously generated words. The input of the model is a source text $\{x_i\} = x_1, ..., x_N$, and the output is a sequence of summary words $\{y_t\} = y_1, ..., y_T$, each of which is a symbol from the dictionary $\mathcal{V}$.

4.1 Text Embedding

Online posts include lots of morphologically similar words, which should be closely embedded. Thus, we use the `fastText` (Bojanowski et al., 2016) trained on the Common Crawl corpus, to initialize the word embedding matrix $\mathbf{W}_{emb}$. We use the same embedding matrix $\mathbf{W}_{emb}$ for both source text and output sentences. That is, we represent a source text $\{x_i\}_{i=1}^N$ in a distributional space as $\{\mathbf{d}_i^0\}_{i=1}^N$ by $\mathbf{d}_i^0 = \mathbf{W}_{emb}\mathbf{x}_i$ where $\mathbf{x}_i$ is a one-hot vector for i-th word in the source text. Likewise, output words $\{y_t\}_{t=1}^T$ is embedded as $\{\mathbf{o}_t^0\}_{t=1}^T$, and $\mathbf{d}_i^0$ and $\mathbf{o}_t^0 \in \mathbb{R}^{300}$.

4.2 Construction of Multi-level Memory

As shown in Figure 3(a), the multi-level memory network takes the source text embedding $\{\mathbf{d}_i^0\}_{i=1}^N$ as an input, and generates S number of memory tensors $\{\mathbf{M}_s^{a/c}\}_{s=1}^S$ as output, where superscript a and c denote input and output memory representation, respectively. The multi-level memory network is motivated by that when human understand a document, she does not remember it as a single whole document but ties together several levels of abstraction (*e.g.* word-level, sentence-level, paragraph-level and document-level). That is, we generate S sets of memory tensors, each of which associates each cell with different number of neighboring word embeddings based on the level of abstraction. To build memory slots of such multi-level memory, we exploit a multi-layer CNN as the write network, where each layer is chosen based on the size of its receptive field.

However, one issue of convolution is that large receptive fields require many layers or large filter sizes. For example, stacking 6 layers with a filter size of 3 results in a receptive field size of 13, *i.e.* each output depends on 13 input words. In order to grow the receptive field without increasing the computational cost, we exploit the *dilated* convolution (Yu and Koltun, 2016; Oord et al., 2016a) for the write network.

Memory Writing with Dilated Convolution. In dilated convolution, the filter is applied over an area larger than its length by skipping input values with a certain gap. Formally, for a 1-D n-length input $\mathbf{x} \in \mathbb{R}^{n\times 300}$ and a filter $\mathbf{w} : \{1, ..., k\} \to \mathbb{R}^{300}$, the dilated convolution operation $\mathcal{F}$ on s elements of a sequence is defined as

$$\mathcal{F}(\mathbf{x}, s) = \sum_{i=1}^{k} \mathbf{w}(i) * \mathbf{x}_{s+d\cdot(i-\lfloor k/2 \rfloor)} + \mathbf{b}, \quad (1)$$

where d is the dilation rate, k is the filter size, $s - d \cdot (i - \lfloor k/2 \rfloor)$ accounts for the direction of dilation and $\mathbf{w} \in \mathbb{R}^{k\times 300\times 300}$ and $\mathbf{b} \in \mathbb{R}^{300}$ are the parameters of the filter. With $d = 1$, the dilated convolution reduces to a regular convolution. Using a larger dilation enables a single output at the top level to represent a wider range of input, thus effectively expanding the receptive field.

To the embedding of a source text $\{\mathbf{d}_i^0\}_{i=1}^N$, we recursively apply a series of dilated convolutions $F(\mathbf{d}^0) \in \mathbb{R}^{N\times 300}$. We denote the output of the l-th convolution layer as $\{\mathbf{d}_i^l\}_{i=1}^N$.

Normalized Gated Tanh Units. Each convolution is followed by our new activation of *normalized gated tanh unit* (NGTU), which is illustrated in Figure 4(b):

$$\text{GTU}(\mathbf{d}^l) = \tanh(\mathcal{F}_f^l(\mathbf{d}^l)) \circ \sigma(\mathcal{F}_g^l(\mathbf{d}^l)), \quad (2)$$

$$\mathbf{d}^{l+1} = \text{LayerNorm}(\mathbf{d}^l + \text{GTU}(\mathbf{d}^l)), \quad (3)$$

where σ is a sigmoid, $\circ$ is the element-wise multiplication and F_f^l and F_g^l denote the filter and gate for l-th layer dilated convolution, respectively.

The NGTU is an extension of the existing gated tanh units (GTU) (Oord et al., 2016a,b) by applying weight normalization (Salimans and Kingma, 2016) and layer normalization (Ba et al., 2016). This mixed normalization improves earlier work of Gehring et al. (2017), where only weight normalization is applied to the GLU. As in Figure 4(a), it tries to preserve the variance of activations throughout the whole network by scaling the output of residual blocks by $\sqrt{0.5}$. However, we observe that this heuristic does not always preserve the variance and does not empirically work well in our dataset. Contrarily, the proposed NGTU not only guarantees preservation of activation variances but also significantly improves the performance.

Multi-level Memory. Instead of using only the last layer output of CNNs, we exploit the outputs of multiple layers of CNNs to construct S sets of memories. For example, memory constructed from the 4-th layer, whose receptive field is 31, may have sentence-level embeddings, while memory from the 8-th layer, whose receptive field is 511, may have document-level embeddings. We obtain each s-th level memory $\mathbf{M}_s^{a/c}$ by resembling key-value memory networks (Miller et al., 2016):

$$\mathbf{M}_s^a = \mathbf{d}^{\mathbf{m}(s)}, \ \mathbf{M}_s^c = \mathbf{d}^{\mathbf{m}(s)} + \mathbf{d}^0. \quad (4)$$

Recall that $\mathbf{M}_s^a$ and $\mathbf{M}_s^c \in \mathbb{R}^{N\times 300}$ are input and output memory matrix, respectively. $\mathbf{m}(s)$ indicates an index of convolutional layer used for the s-th level memory. For example, if we set $S = 3$ and $\mathbf{m} = \{3, 6, 9\}$, we make three-level memories, each of which uses the output of the 3-rd, 6-th, and 9-th convolution layer, respectively. To output memory representation $\mathbf{M}_s^c$, we add the document embedding $\mathbf{d}^0$ as a skip connection.

4.3 State-Based Sequence Generation

We discuss how to predict the next word y_{t+1} at time step t based on the memory state and previously generated words $y_{1:t}$. Figure 3(b) visualizes the overall procedure of decoding.

We first apply max-pooling to the output of the last layer of the encoder network to build a whole document embedding $\mathbf{d}^{whole} \in \mathbb{R}^{300}$:

$$\mathbf{d}^{whole} = \text{maxpool}([\mathbf{d}_1^L; ...; \mathbf{d}_N^L]). \quad (5)$$

The decoder is designed based on WaveNet (Oord et al., 2016a) that uses a series of causal dilated convolutions, denoted by $\hat{\mathcal{F}}(\mathbf{o}^l_{1:t}) \in \mathbb{R}^{t\times 300}$. We globally condition $\mathbf{d}^{whole}$ to obtain embeddings of previously generated words $\mathbf{o}^l_{1:t}$ as:

$$\mathbf{h}^l_{f/g} = \hat{\mathcal{F}}^l_{f/g}(\mathbf{o}^l_{1:t} + \mathbf{W}^l_{f/g}\mathbf{d}^{whole}), \quad (6)$$

$$\mathbf{h}^l_a = \tanh(\mathbf{h}^l_f) \circ \sigma(\mathbf{h}^l_g), \quad (7)$$

$$\mathbf{o}^{l+1}_{1:t} = \text{LayerNorm}(\mathbf{o}^l_{1:t} + \mathbf{h}^l_a), \quad (8)$$

where $\mathbf{h}^l_{f/g}$ are the filter and gate hidden state respectively, and learnable parameters are $\mathbf{W}^l_f$ and $\mathbf{W}^l_g \in \mathbb{R}^{300\times 300}$. We initialize $\mathbf{o}^0_t = \mathbf{W}_{emb}\mathbf{y}_t$. We set the level of the decoder network to $L = 3$ for TIFU-short and $L = 5$ for TIFU-long.

Next, we generate S number of query vectors $\{\mathbf{q}^s_t\}^S_{s=1}$ at time t to our memory network as

$$\mathbf{q}^s_t = \tanh(\mathbf{W}^s_q\mathbf{o}^L_t + \mathbf{b}^s_q), \quad (9)$$

where $\mathbf{W}^s_q \in \mathbb{R}^{300\times 300}$ and $\mathbf{b}^s_q \in \mathbb{R}^{300}$.

Each of these query vectors $\{\mathbf{q}^s_t\}^S_{s=1}$ is fed into the attention function of each level of memory. As in (Vaswani et al., 2017), the attention function is

$$\mathbf{M}^s_{o_t} = \text{softmax}(\frac{\mathbf{q}^s_t(\mathbf{M}^a_s)^T}{\sqrt{d^{emb}}})\mathbf{M}^c_s, \quad (10)$$

where we set $d^{emb} = 300$ for the embedding dimension and $\mathbf{M}^s_{o_t} \in \mathbb{R}^{300}$.

Next, we obtain the output word probability:

$$\mathbf{s}_t = \text{softmax}(\mathbf{W}_o[\mathbf{M}^1_{o_t}; ...; \mathbf{M}^S_{o_t}; \mathbf{o}^L_t]), \quad (11)$$

where $\mathbf{W}_o \in \mathbb{R}^{(300\times(S+1))\times V}$. Finally, we select the word with the highest probability $y_{t+1} = \text{argmax}_{\mathbf{s}\in\mathcal{V}}(\mathbf{s}_t)$. Unless y_{t+1} is an EOS token, we repeat generating the next word by feeding y_{t+1} into the output convolution layer of Eq.(8).

4.4 Training

We use the softmax cross-entropy loss from estimated y_t to its target $y_{GT,t}$. However, it forces the model to predict extremes (zero or one) to distinguish among the ground truth and alternatives. The label smoothing alleviates this issue by acting as a regularizer that makes the model less confident in its prediction. We smooth the target distribution with a uniform prior distribution u (Pereyra et al., 2017; Edunov et al., 2017; Vaswani et al., 2017). Thus, the loss over the training set $\mathcal{D}$ is

$$\mathcal{L} = -\sum \log p_\theta(\mathbf{y}|\mathbf{x}) - D_{KL}(u||p_\theta(\mathbf{y}|\mathbf{x})).$$

We implement label smoothing by modifying the ground truth distribution for word $y_{GT,t}$ to be $p(y_{GT,t}) = 1 - \epsilon$ and $p(y') = \epsilon/\mathcal{V}$ for $y' \neq y_{GT,t}$ where ϵ is a smoothing parameter set to 0.1. Further details can be found in the Appendix.

5 Experiments

5.1 Experimental Setting

Evaluation Metrics. We evaluate the summarization performance with two language metrics: perplexity and standard F1 ROUGE scores (Lin, 2004). We remind that lower perplexity and higher ROUGE scores indicate better performance.

Datasets. In addition to Reddit TIFU, we also evaluate on two existing datasets: abstractive subset of `Newsroom` (Grusky et al., 2018) and `XSum` (Narayan et al., 2018a). These are suitable benchmarks for evaluation of our model in two aspects. First, they are specialized for abstractive summarization, which meets well the goal of this work. Second, they have larger vocabulary size (40K, 50K) than Reddit TIFU (15K), and thus we can evaluate the learning capability of our model.

Baselines. We compare with three abstractive summarization methods, one basic seq2seq model, two heuristic extractive methods and variants of our model. We choose `PG` (See et al., 2017), `SEASS` (Zhou et al., 2017), `DRGD` (Li et al., 2017) as the state-of-the-art methods of abstractive summarization. We test the attention based seq2seq model denoted as `s2s-att` (Chopra et al., 2016). As heuristic extractive methods, the `Lead-1` uses the first sentence in the text as summary, and the `Ext-Oracle` takes the sentence with the highest average score of F1 ROUGE-1/2/L with the gold summary in the text. Thus, `Ext-Oracle` can be viewed as an upper-bound for extractive methods.

We also test variants of our method `MMN-*`. To validate the contribution of each component, we exclude one of key components from our model as follows: (i) `-NoDilated` with conventional convolutions instead, (ii) `-NoMulti` with no multi-level memory (iii) `-NoNGTU` with existing gated linear units (Gehring et al., 2017). That is, `-NoDilated` quantifies the improvement by the dilated convolution, `-NoMulti` assesses the effect of multi-level memory, and `-NoNGTU` validates the normalized gated tanh unit.

Please refer to the Appendix for implementation details of our method.

TIFU-short				
Methods	PPL	R-1	R-2	R-L
`Lead-1`	n/a	3.4	0.0	3.3
`Ext-Oracle`	n/a	8.0	0.0	7.7
`s2s-att` (Chopra et al., 2016)	46.2	18.3	6.4	17.8
`PG` (See et al., 2017)	40.9	18.3	6.5	17.9

`DRGD`	**46.7**	17.3	15.0	**61.0**	23.0	16.0
Gold	27.0	**58.0**	15.0	22.3	**73.7**	4.0

Table 5: AMT results on the TIFU-short/long between our `MMN` and four baselines and gold summary. We show percentages of responses that turkers vote for our approach over baselines.

5.2 Quantitative Results

Table 3 compares the summarization performance of different methods on the TIFU-short/long dataset. Our model outperforms the state-of-the-art abstractive methods in both ROUGE and perplexity scores. `PG` utilizes a pointer network to copy words from the source text, but it may not be a good strategy in our dataset, which is more abstractive as discussed in Table 2. `SEASS` shows strong performance in DUC and Gigaword dataset, in which the source text is a single long sentence and the gold summary is its shorter version. Yet, it may not be sufficient to summarize much longer articles of our dataset, even with its second-level representation. `DRGD` is based on the variational autoencoder with latent variables to capture the structural patterns of gold summaries. This idea can be useful for the similarly structured formal documents but may not go well with diverse online text in the TIFU dataset.

These state-of-the-art abstractive methods are not as good as our model, but still perform better than extractive methods. Although the `Ext-Oracle` heuristic is an upper-bound for extractive methods, it is not successful in our highly abstractive dataset; it is not effective to simply retrieve existing sentences from the source text. Moreover, the performance gaps between abstractive and extractive methods are much larger in our dataset than in other datasets (See et al., 2017; Paulus et al., 2018; Cohan et al., 2018), which means too that our dataset is highly abstractive.

Table 4 compares the performance of our MMN on Newsroom-Abs and XSum dataset. We report the numbers from the original papers. Our model outperforms not only the RNN-based abstractive methods but also the convolutional-based methods in all ROUGE scores. Especially, even trained on single end-to-end training procedure, our model outperforms `T-ConvS2S`, which necessitates two training stages of LDA and `ConvS2S`. These results assure that even on formal documents with large vocabulary sizes, our multi-level memory is effective for abstractive datasets.

5.3 Qualitative Results

We perform two types of qualitative evaluation to complement the limitation of automatic language metrics as summarization evaluation.

User Preferences. We perform Amazon Mechanical Turk (AMT) tests to observe general users' preferences between the summarization of different algorithms. We randomly sample 100 test examples. At test, we show a source text and two summaries generated by our method and one baseline in a random order. We ask turkers to choose the more relevant one for the source text. We obtain answers from three different turkers for each test example. We compare with four abstractive baselines (`s2s-att`, `PG`, `SEASS` and `DRGD`)

[Source Text]

(…) I decided to go over to my friends house to a small party at 1 in the morning. I knew my parents would say no so I snuck out of the house. (…) I had been talking to my mom about how sad even hearing the theme song made me. Also she had seen me watching a bunch of sad anime theme songs and tearing up a little so she must have thought I was depressed. When I got home today my mom was practically in tears. (…)

[Short Summary]

(GT) sneaking out of my friends house last night
(Ours) sneaking out of my friends house
(PG) not watching my friends
(SEASS) accidentally spoiling my mom song
(s2s-att) sneaking out of town
(DRGD) watching a movie

[Source Text]

(…) Saturday was on my way to a party and this dog was walking in the road. (…) Since it was a holiday I couldn't get her scanned for a chip but she was obviously neglected. Missing fur from flea infestation, (…) Yesterday I was able to go get her scanned for a chip. No chip. So I get ready to take her home and deflea her. (…) Anyway a third party today starts accusing me of stealing (…) and talking about pressing charges. (…)

[Long Summary]

(GT) Saved a dog. Had to give dog back to possible abusers. Being accused of stealing the fucking dog. No good deed goes unpunished.
(Ours) tried to help a dog got a bit and got accused of stealing
(PG) _EOS
(SEASS) called a dog a _UNK might get charged with _UNK
(s2s-att) got accused of being a dog by stealing a _UNK bit the dog and accused of stealing dog to the police
(DRGD) i was a _UNK dog and I wasn't playing attention and got arrested for being a _UNK _UNK

Figure 5: Examples of abstractive summary generated by our model and baselines. In each set, we too show the source text and gold summary.

and the gold summary (Gold).

Table 5 summarizes the results of AMT tests, which validate that human annotators significantly prefer our results to those of baselines. As expected, the gold summary is voted the most.

Summary Examples. Figure 5 shows selected examples of abstractive summarization. Baselines often generate the summary by mostly focusing on some keywords in the text, while our model produces the summary considering both keywords and the whole context thanks to multi-level memory. We present more examples in the Appendix.

6 Conclusions

We introduced a new dataset *Reddit TIFU* for abstractive summarization on informal online text. We also proposed a novel summarization model named *multi-level memory networks* (MMN). Experiments showed that the Reddit TIFU dataset is uniquely abstractive and the MMN model is highly effective. There are several promising future directions. First, ROUGE metrics are limited to correctly capture paraphrased summaries, for which a new automatic metric of abstractive summarization may be required. Second, we can explore the data in other online forums such as Quora, Stackoverflow and other subreddits.

TIFU-long	27.4	76.7	92.5	97.0

Table 7: Comparison of novel N-gram ratios between Reddit TIFU and other summarization datasets.

A Implementation Details

All the parameters are initialized with the Xavier method (Glorot and Bengio, 2010). We apply the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.999$ and $\epsilon = 1e - 8$. We apply weight normalization (Salimans and Kingma, 2016) to all layers. We set learning rate to 0.001 and clip gradient at 0.3. At every 4 epochs, we divide learning rate by 10 until it reaches 0.0001. We train our models up to 12 epochs for TIFU-short and 60 epochs for TIFU-long.

Table 6 summarizes the setting of hyperparameters for our model in all experiments on TIFU-short/long dataset, Newsroom abstractive subset and XSum.

B Novel N-gram Ratios

Table 7 compares the ratios of novel N-grams in the reference summary between datasets. Following (See et al., 2017; Narayan et al., 2018a), we compute this ratio as follows; we first count the number of N-grams in the reference summary that do not appear in the source text and divide it with the total number of N-grams. The higher the ratio is, the less the identical N-grams are in the source text. The CNN/DailyMail, New York Times, Newsroom datasets all, for example, exhibit low novel 1-gram ratios as 10.3%, 11.0%, 15.6 % respectively. This means that about 90% of the words in reference summary already exist inside the source text. It is due to that the summaries from formal documents (*e.g.* news and academic papers) tend to have same expressions with the source documents. Therefore, these datasets may be more suitable for extractive summarization than abstractive one; on the other hand, our dataset is more abstractive.

We also compare the novel N-gram ratio for XSum and three subsets of Newsroom;

(i) Newsroom-Ext, a subset favorable for extractive methods, (ii) Newsroom-Mix, a subset favorable for mixed methods, and (iii) Newsroom-Abs, a subset favorable for abstrac-

[Source Text]
(…) This weekend I went out and bought myself a motorcycle! I've been planning on buying one this summer and I finally went out and did it. (…) I geared up and went on my way for my first ride. (…) I went all the way back to my house and alas, no phone. So I spent the next 4 hours walking the route to my girlfriends house looking along the side of the road for my phone. These are all back roads to my girlfriends house so I had to really get in the undergrowth to look for my phone. It got dark and I headed home feeling dejected. The next morning my friend came over with my phone! The only damage was a few scuffs to my otterbox. I couldn't believe he found it, and as it turns out it fell off my bike and tumbled onto the side of his driveway. I chalked this up as a win and considered myself lucky. Until yesterday. I woke up with poison ivy all over my body. And when I say all over my body, I mean ALL OVER my body. I have some on my arms, legs, face, and most importantly all over my dick. And the worst spot of them all is on my dick. I have never been so uncomfortable in my life. I must have had some of the oil on my hands and scratched an itch down there. Needless to say I haven't been on my new motorcycle since I've had this and I've been doing as little moving as possible at my job and at home. F***.

[Short Summary]
(Gold) taking a ride on my new motorcycle
(Ours) buying my new motorcycle
(s2s-att) trying to be a good samaritan
(PG) not wearing my cargo helmet
(SEASS) going for a ride
(DRGD) getting my phone stuck

[Source Text]
(…) Later that night, the rest of the family proceeded to play cards and become quite intoxicated. Me, being the little shit that I was, and probably still am, took this opportunity to raid the liquor cooler, and made off with a bottle of wine. I, along with a few other of my underage cousins, ran off to consume our loot. Now, in most situations, this really wouldn't be a that big deal, however, getting drunk at 18 wasn't where my f*** up occurred. (…) John tells her it'll be okay, that he will smooth talk it over with them, and that she should bring them a bottle of their favorite wine. Well John and Jane are having dinner outside to meet the parents, and when Jane goes to retrieve her gift of wine to John's parents, she discovers the wine is gone. Jane then begins to panic, and starts tearing up the surrounding area looking for it. John's parents have no idea what she's freaking out about, or why John would bring crazy to the family reunion. (…) Jane now slips into complete hysteria, and runs inside to lock herself in the bathroom. (…) The day after, John convinces his parents to try again, and all goes very well, especially since last night's thief is still recovering from his first wine hangover. (…)

[Short Summary]
(Gold) stealing a bottle of wine
(Ours) getting drunk and stealing a wine bottle
(s2s-att) getting drunk and making a family cry
(PG) ruining my future dinner vacation
(SEASS) accidentally stealing alcohol from my cousin’s parent′s party
(DRGD) smoking a cigarette

[Source Text]
(…) We use an internal messaging application software at work which has been great for communicating with other teammates. A lot of us have started using it to complain about things we are not happy about at work. (…) This leads me to today where just as i am about to go home my manager calls me in to a private meeting looking really upset. Then they mentioned the program name and that they had received an email, and suddenly I realized I had fucked up one of the quirks of this program is that when someone is offline it emails them the message. A recently ex co-worker is still active on the chat for quick questions for the next 2 weeks. They came online so we started having a conversation, then another co-worker walked up to me for a chat who has been having a rough week and complained about our boss. When they finished their rant, I then messaged my ex co-worker that my boss wasn't popular with the staff at the moment as that was the second minor complaint I had heard that week. They had gone offline, so an email was sent to their old work email. Past employees emails get sent to the boss, in case important emails are sent to them. So after the meeting I still have my job. I had an awkward conversation with my boss (…)

[Long Summary]
(Gold) message program at work emailed a private message between a past co worker and myself to my boss saying how people where not happy with them
(Ours) sent a message to my boss and now i ’m in a meeting with my boss
(s2s-att) i lied about my boss to get my job and now i ’m in a job with a new job
(PG) i got a program that sacked from work and i got sent to a metting by my boss

[Source Text]
(…) My girlfriend and I have just started to "get a bit more uncomfortable with each other". (…) My curfew for the night had been midnight, however we both got a bit carried away in the beautiful setting (…) I had over extended my curfew by around an hour. This prompted my mother to call me angrily and groggily claiming that she was mad at me. I defended myself by saying that we both fell asleep listening to the docile tones of Steve Harvey on "Family Feud". (…) I sent my girlfriend a text that said something along the lines of "X acts of affection. Comments questions, or complaints?" However upon hitting the send button I noticed that it was heading in the direction of my birth giver. I panicked and luckily managed to put it into airplane mode! (…) I quickly googled "How to prevent texts from sending" and it said to simply delete the text while it was on airplane mode. I did so, and proceeded to turn airplane mode off, however the "always correct Internet" was wrong and I hear my mom receive the text in the next room over. I quickly went into her room to try and crack her phone's code in order to diffuse the bomb (…) I then asked my mother for her phone so that I could "call mine". She reluctantly agreed and I hurriedly rushed to my room. (…)

[Long Summary]
(Gold) did some funky stuff with my date
(Ours) accidentally sent an inappropriate text to a girl and then accidentally sent it to my mother′s phone and now i’m trouble
(PG) tifu by answering an airplane call and accidentally adding my mothers phone and her phone to find out she was sleeping on me
(SEASS) I accidentally sent a text to my mom that I was sending her a text from the _UNK bomb

Figure 6: Examples of abstractive summary generated by our model and baselines. In each set, we too show the source text and reference summary.

tive methods. We summarize two interesting observations as follows. First, as expected, the more favorable for abstractive methods is, the higher novel n-gram ratio is. Second, novel n-gram ratios of `Newsroom-Abs` and `XSum` are higher than those of our dataset, even though their data sources are news publications. Thus, we argue that novel n-gram ratios are pretty good but not a sufficient measure to find extractive bias in the summarization dataset.

C More Examples

Figure 6 illustrates selected examples of summary generation. In each set, we show a source text, a reference summary and generated summaries by our method and baselines. In the examples, while baselines generate summary by mostly focusing on some keywords, our model produces summary considering both keywords and the whole context thanks to the multi-level memory.

Automatic learner summary assessment for reading comprehension

Abstract

Automating the assessment of learner summaries provides a useful tool for assessing learner reading comprehension. We present a summarization task for evaluating non-native reading comprehension and propose three novel approaches to automatically assess the learner summaries. We evaluate our models on two datasets we created and show that our models outperform traditional approaches that rely on exact word match on this task. Our best model produces quality assessments close to professional examiners.

1 Introduction

Summarization is a well-established method of measuring reading proficiency in traditional English as a second or other language (ESOL) assessment. It is considered an effective approach to test both cognitive and contextual dimensions of reading (Weir et al., 2013). However, due to the high time and cost demands of manual summary assessment, modern English exams usually replace the summarization task with multiple choice or short answer questions that are easier to score (Alderson, 2005). Automating the assessment of learner summarization skills provides an efficient evaluation method for the quality of the learner summary and can lead to effective educational applications to enhance reading comprehension tasks.

In this paper, we present a summarization task for evaluating non-native reading comprehension and propose three novel machine learning approaches to assessing learner summaries. First, we extract features to measure the content similarity between the reading passage and the summary. Secondly, we calculate a similarity matrix based on sentence-to-sentence similarity between the reading passage and the summary, and apply a Convolutional Neural Network (CNN) model to assess the summary quality using the similarity matrix. Thirdly, we build an end-to-end summarization assessment model using the Long Short Term Memory (LSTM) model. Finally, we combine the three approaches in a single system using a simple parallel ensemble modeling technique. We compiled two datasets to evaluate our models, and we release this data with the paper. We show that our models outperform traditional approaches that rely on exact word match on the task and that our best model produces quality assessments close to professional examiners.

2 Related Work

Most of the previous studies on summary assessment are aimed at evaluating automated summarization systems (Lin, 2004; Lin and Hovy, 2003; Nenkova et al., 2007). In contrast to this line of work, our goal is to assess human-written summaries rather than machine-generated ones.

Within the educational domain, several applications have been developed to help students with their writing summarization skills. Summary Street (Wade-Stein and Kintsch, 2004) is an educational software designed for children to develop summarization skills. It asks students to write a summary to a reading passage, and scores the summary by using Latent Semantic Analysis (LSA) to construct semantic representations of the text. This system uses the cosine similarity score based on LSA as the sole indicator of content similarity. OpenEssayist (Whitelock et al., 2013) is an interactive system that provides students with the automated feedback about their summative essays. The system extracts the key words, phrases and sentences from the essays and helps the students to investigate their distribution in text and the po-

Minneapolis, Minnesota, June 2 - June 7, 2019.

tential implications for the clarity of the narrative.

The work that is most similar to ours is the automatic scoring of a summarization task by Madnani et al. (2013), who designed a task to measure the reading comprehension skills of American students. In their experiments, students were asked to write a four-sentence summary for each of the two three-paragraph reading passages, with the first sentence summarizing the whole passage and the following three sentences summarizing each paragraph. To build an automated system to score the summaries, they randomly select a student summary with the highest score as the reference, and use 8 feature types to train a logistic regression classifier to predict the summary score. They train a separate classifier for each of the two passages, and obtain accuracy scores of 65% and 52% respectively, outperforming the most-frequent-score baselines of 51% and 32%. Most of the features used in Madnani et al. (2013) are based on verbatim overlap. Although such metrics prove to be effective in various tasks, they cannot capture the content similarity when paraphrasing or a higher level of abstraction are used in the summary.

Few studies have addressed summarization assessment at a higher level. More recently, Ruseti et al. (2018) have used Recurrent Neural Networks (RNNs) to automatically score summaries. In their model, a concatenated representation of the summary and the text built from two separate RNNs as well as a complexity score of the text are fed to a fully connected layer to predict a real number between $[0, 1]$. This number is then mapped to 3 discrete classes representing the quality of the summary using linear regression. Their best model achieves 55.24% in accuracy on a dataset of 636 summaries collected using Mechanical Turk.

In this paper, we address several limitations of previous work. We build a system that uses verbatim features as well as features capturing higher level of abstraction. First, we aim to build a generic system that can evaluate the quality of a summary without having to train a separate model for each text. Second, whereas Madnani et al. (2013) use a student summary with the highest score as the reference to evaluate the candidate summary, our goal is to build a fully-automated system that does not require selecting a pre-defined reference. Third, we aim to explore features and structures capable of better modeling semantic similarity beyond verbatim overlap.

3 Data

This section outlines the summarization task used in our experiments. First, learners, regardless of their proficiency level, were asked to read three reading passages extracted from the Cambridge English Exams dataset of Xia et al. (2016) at the lower (B1), upper intermediate (B2), and advanced (C1) levels of the Common European Framework of Reference for Languages (CEFR). Then they were asked to write a summary of 50, 100, and 120 words for each of the three tasks.[1]

3.1 Pilot study with simulated learner data

Before launching the experiments with the actual language learners and in order to develop the automated summary evaluation system, we first ran a pilot study and collected "simulated learner" summaries from 50 members of our university. Since most participants of this study would speak English at an advanced (C1-C2) level, we asked them to write a "good summary" and a "bad summary" for each reading passage, mimicking a learner. The participants were asked to produce grammatically correct sentences and to write a "bad" summary in a way that a learner who does not fully understand the original passage might produce. In total, 300 summaries were collected (with 150 good summaries and 150 bad ones). The simulated learner data was then used to train binary classification systems to assess whether a summary captures the passage content properly or not.

3.2 Real learner data

Learner levels	Count
B1	40
B2	40
C1-C2	57
Total	137

Table 1: The distribution of the learner proficiency levels in the real learner data

Next, we collected summaries from second language learners at B1, B2 and C1-C2 levels of proficiency.[2] In total, 411 summaries from 137 learners were collected. The distribution of the learner proficiency levels is shown in Table 1.

---

[1] The word limits on the summarization tasks are set to keep a relatively constant compression ratio between the summary and the length of the original passage.

[2] The proficiency levels of learners were self-identified.

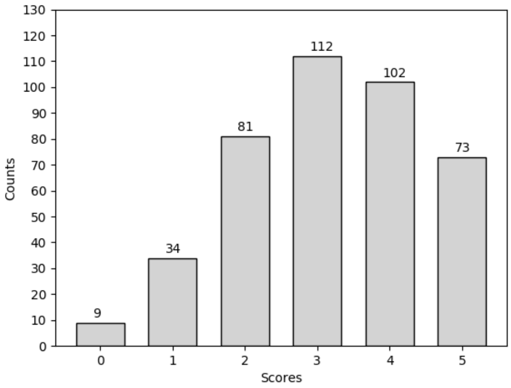

Figure 1: A histogram illustrating the score distribution in the real learner data

The summaries were then scored by three professional ESOL annotators using a 6-point scale defined as follows:

Band 5: *The summary demonstrates excellent understanding of the original passage: Content covers all the main points of the passage. All content included is accurate, with no irrelevant details or repetitions. Target reader is fully informed.*

Band 4: *Performance shares features of Bands 3 and 5.*

Band 3: *The summary demonstrates acceptable understanding of the passage: Most of the main points are included. Most of the content is relevant and paraphrased, with some irrelevant details, repetitions or inaccuracy of content. Target reader is on the whole informed.*

Band 2: *Performance shares features of Bands 1 and 3.*

Band 1: *The summary demonstrates very little understanding of the passage: Most of the content is of limited relevance, with repetitions or verbatim borrowing from the original text. In some paraphrased parts of the text, inaccuracy of content or omissions of main points are evident. Target reader is minimally informed.*

Band 0: *No understanding of the passage is demonstrated. The content is totally irrelevant to the original passage. Target reader is not informed.*

Figure 1 shows the distribution of the scores for the learner summaries. The pairwise correlation between annotators ranges between 0.690 and 0.794. To derive the final score for each summary, we take the average of the scores by the three annotators. This results in a set of real-valued average scores on the scale of $[0, 5]$ and allows us to treat this task as a regression problem and make use of the continuity of the assessment scale. The goal of the experiments on this data is then to train a regression model to predict a score that correlates well with the annotators' judgments.

4 Methods

In this section, we introduce three different approaches to the automated evaluation of the learner summaries.

4.1 Measures for summary assessment

First of all, we extract a number of features to describe the similarity of the summary and the reading text and apply a machine learning model to predict the summary quality.

The summarization task for reading comprehension examines the content relevance and the ability to convey the main ideas of the text in the summary. To automatically assess the learner summary, we compare the candidate summary against a reference to assess the quality of its content.

We experiment with two types of references to evaluate the candidate summary: firstly, we compare the candidate summary against the *original passage* directly, and secondly, we extract key sentences from the original text with an automated extractive summarizer and compare the candidate summary to the set of key sentences. Ideally, an extractive summarizer extracts a subset of sentences from the passage that are highly representative of the original text. Although the extracted key sentences are not necessarily coherent among themselves, they provide a representation of the main ideas of the text. Comparing the candidate summary against the key sentences allows us to examine the content relevance and the coverage of the main ideas in the candidate summary. We compare two popular summarizers in selecting the key sentences for reference: *TextRank* (Mihalcea and Tarau, 2004) and *MEAD* (Radev et al., 2004). We also compare the extractive summarizers against the baseline of using a *random selection* of sentences as the reference.

After obtaining the reference, we derive four types of linguistic features to evaluate the quality of the learner summary: (1) verbatim features, (2) semantic similarity features, (3) features based on distributed vector representations of the summary, and (4) features that describe discourse and other textual characteristics of the summary.

4.1.1 Verbatim features

Verbatim similarity is the most straightforward measure that indicates content similarity. Verbatim features measure the lexical overlap of the text units between the candidate summary and the reference. We use the following metrics to measure verbatim similarity: **ROUGE** (Lin, 2004), **BLEU** (Papineni et al., 2002), and **METEOR** (Denkowski and Lavie, 2011). The three metrics are commonly used to assess automated summarization systems. ROUGE and BLEU are based on exact word match of N-grams, and METEOR extends the exact word match with stem, synonym, and paraphrase matches extracted from the WordNet (Miller, 1995) and a background dictionary, which allows for more flexible expressions.

4.1.2 Semantic similarity features

Although verbatim overlap metrics prove to be effective in various tasks, they fail to capture the content similarity when paraphrasing and higher levels of abstraction are used in the summary. To compensate for this, word embeddings and sentence embeddings are used to model semantic similarity at the word and the sentence level. We measure the semantic similarity between words and sentences in the texts and combine the scores into a measure of document-level semantic similarity.

1. **Word similarity**: **Word2vec** (Mikolov et al., 2013) is a model for learning distributed vector representations of words from a large corpus of text. We use embeddings pre-trained on Wikipedia to compute word-to-word cosine similarity between the candidate summary and the reference. We experiment with three scoring functions to construct the text-level semantic similarity measures from the word-to-word scores:

   (1) *average word similarity* on every word pair in the candidate summary and the reference;

   (2) *a greedy method* (Mihalcea et al., 2006) that finds the best-matching word with maximum similarity scores and computes the average over the greedily selected pairs;

   (3) *optimal matching* (Rus and Lintean, 2012) that finds the optimal alignment of word pairs and then takes the average over the alignment.

2. **Sentence similarity**: **Skip-thought** (Kiros et al., 2015) is a model for learning distributed representations of sentences. It uses an RNN-encoder to compose the sentence vector, and a decoder conditioned on the resulting vector that tries to predict the previous and the next sentences in the context. We use the model pre-trained on the BookCorpus (Zhu et al., 2015) to generate our sentence vectors. Additionally, we experiment with composing the sentence vectors using word embedding summation and taking the average (**average word embeddings**). We use the same functions for word-level similarity to compute the text semantic similarity from the sentence vectors.

4.1.3 Distributed vector representations of the summary

In addition to the word and sentence similarities, we investigate methods to model the content similarity between the candidate summary and the reference directly at the document level.

Specifically, we use the following five approaches to construct vector representations of learner summaries:

TF-IDF is a common method to construct document representations in information retrieval. TF-IDF weighted document vectors are frequently used for measuring query-document similarity.

Doc2Vec (Le and Mikolov, 2014) is a neural network model for learning distributed representation of documents. We use the "distributed memory of paragraph vectors (PV-DM)" variant of the model to construct our vector representation of the summary. The PV-DM model maps the document to a vector space and uses a combination of the document vector and the vectors of surrounding words to predict a target word.

Latent Semantic Analysis (LSA) (Landauer, 2006) applies singular value decomposition (SVD) on the term-document matrix to obtain vector space representation of documents.

Latent Dirichelet Allocation (LDA) (Blei et al., 2003) represents the documents as mixtures of topics. It can be used to measure the content similarity and topical relevance of documents.

We also make use of the **average word embeddings** to encode the summary.

We use the Simple English Wikipedia corpus[3] as our background resource to learn the document representations. The Simple English Wikipedia data is used to train the models because its documents are rendered simple for English learners. Therefore, the lexical usage and syntactic structure in Simple English Wikipedia are more similar to the summaries written by learners. We take

---

[3] `https://simple.wikipedia.org`

the cosine similarity between the candidate and the reference vectors to evaluate their similarity.

4.1.4 Discourse and other textual features

Apart from the content-based measures of the summary, the textual quality of the summary is also important for its overall quality estimation. For instance, good summaries tend to be more coherent and logically consistent. We extract **lexical chain**-based discourse measures to assess the coherence of the text. Lexical chains model the semantic relations among entities throughout the text. We implement the lexical chaining algorithm developed by Galley and McKeown (2003) and extract 7 lexical chain-based features.[4]

We also measure the following superficial textual features:

Length: Number of words in the summary.

Compression ratio: The ratio of the number of words in the summary to the number of words in the reading passage.

Type-token ratio: The ratio of the number of unique words to the total number of words in the summary.

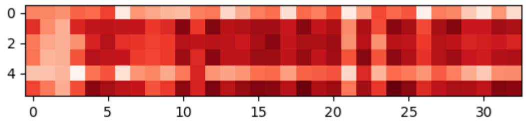
Text readability: The reading difficulty (the CEFR level) of the passage to be summarized.

After the features are extracted, we train a Support Vector Machine (SVM) (Cortes and Vapnik, 1995) model for the classification task (Section 3.1) and a Kernel Ridge Regression (KRR) (Saunders et al., 1998) model for the regression task (Section 3.2).

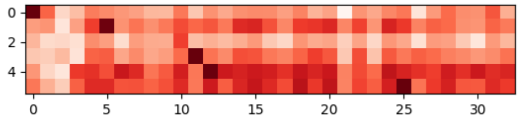
4.2 Assessing summary using similarity matrix

Secondly, we construct a sentence similarity matrix between the candidate summary and the original reading passage and apply a Convolutional Neural Network (CNN) model on the similarity matrix to predict the quality of the summary.

Lemaire et al. (2005) proposed a computational cognitive model for assessing extractive summarization. In their experiments, they presented 278 American school students with two reading passages and asked them to underline three to five sentences that they considered the most important in the texts. The underlined sentences were compared against the set of all the sentences from the original passage. They observed that the important sentences selected by the students are highly connected to the rest of the sentences in the text, where the connection is defined by the semantic similarity of the sentences.



(a) The similarity matrix of a good Summary A



(b) The similarity matrix of a bad Summary B

Figure 2: Similarity matrices of two summaries for the same reading passage from the simulated learner data. Summary A is a good summary and Summary B is a bad summary. The rows of the matrix represent sentences in the summary and the columns of the matrix represent sentences in the reading passage.

Based on their observations, we hypothesize that sentences in a good summary should have a well-distributed connection with as many sentences as possible in the original text, because a good summary is supposed to cover all the important information in the text. In contrast, sentences in a bad summary may fail to form a well-distributed connection with sentences in the original text. For example, if a bad summary only captures a few of the main points in the original text, then the sentences in such a summary would be connected only to the sentences where these points are mentioned in the original text, lacking the connections to the rest of the text. If a bad summary is generally irrelevant to the original text, sentences in such a summary would be minimally connected to most of the sentences in the original text. Beside these extreme cases on summary quality scale, summaries of intermediate quality may display patterns of connection to the original passage that share the characteristics of the good summary and the bad summary to various degrees.

Following this idea, we construct a sentence similarity matrix between the candidate summary and the original text. Each element of the matrix is a cosine similarity score between the vector representations of a sentence from the summary and a

---

[4] Features include: number of lexical chains per document, number of lexical chains normalized by text length, average/maximum lexical chain length, average/maximum lexical chain span, and the number of long chains.

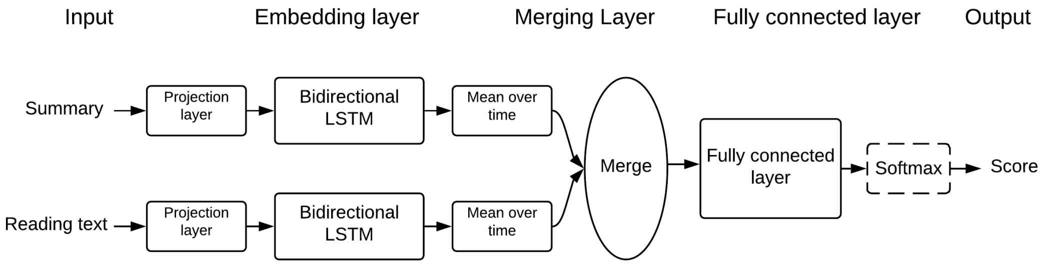


Figure 3: The merged LSTM model

sentence from the original text. We use the two sentence similarity models described in Section 4.1.2, skip-thought and average word embeddings, to build the sentence vectors.

According to our hypothesis, the quality of the summary corresponds to different patterns in the similarity matrix. The similarity matrix can be viewed as a heat map "image" from which we can learn patterns to detect the quality of the summary. Figure 2 demonstrates the similarity matrices of two summaries for the same reading passage from the simulated learner data. The shade of the coloured map indicates the degree of similarity between two sentences: the darker the shade is, the more similar the sentences are. In this example, Summary A is an example of a good summary, and Summary B is an example of a bad summary. We can see that sentences in Summary A are similar to a number of sentences in the original text, resulting in a well-distributed heat map. By contrast, sentences in Summary B are similar to five particular sentences in the text and are less similar to other sentences, which is reflected by the isolated dark patches in the image. On the whole, Summary A has higher similarity scores than Summary B, which makes its heat map darker. These two examples illustrate how different patterns may be observed in the heat map of the summaries of different quality.

To learn these patterns automatically, we apply a CNN model on the similarity matrix to predict the quality of the summary. However, it should be noted that CNNs usually work best when a large amount of training data is available, whereas the summary data we have collected represents a relatively small dataset. We compare the results of the CNN model against the feature extraction approach to investigate how well the model can learn from the limited amount of data.

4.3 Assessing summary using LSTM-based models

Thirdly, we experiment with several LSTM-based neural network models for assessing the summary quality. The LSTM-based models are used to learn representations of the summary and estimate its quality automatically, without having to manually extract features from it.

Recurrent neural networks with LSTM units (Hochreiter and Schmidhuber, 1997) have shown impressive results on various NLP tasks (Wang and Jiang, 2016; Rocktäschel et al., 2015). In essence, they are capable of embedding long text sequences into a vector representation which can later be decoded for use in various applications.

4.3.1 Merged LSTM model

Inspired by the recent advances with LSTMs in NLP tasks, we propose a merged LSTM model (see Figure 3) for assessing learner summaries. The merged LSTM model encodes the summary and the reading text separately with two bidirectional LSTMs, and merges the embedded summary and embedded reading text representations into a joint representation to predict the summary score. We explore four functions to merge the encoded vectors, including *concatenation*, *addition*, *dot product* and *linear combination*.

4.3.2 Attention-based LSTM model

As the merged LSTM model encodes the summary and reading text separately, it needs to propagate dependencies over long sequences to compare the summary and the text. The joint representation obtained in the merged LSTM model cannot fully capture the connection between the summary and the text. In this section, we propose an attention-based LSTM model which makes use of an attention mechanism to better model the relation between the summary and the reading text.

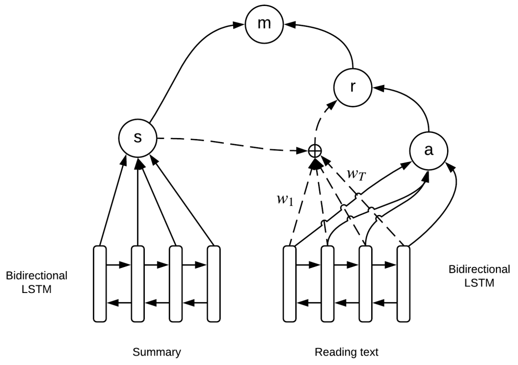

Figure 4: Attention mechanism architecture in the attention-based LSTM model for summary assessment

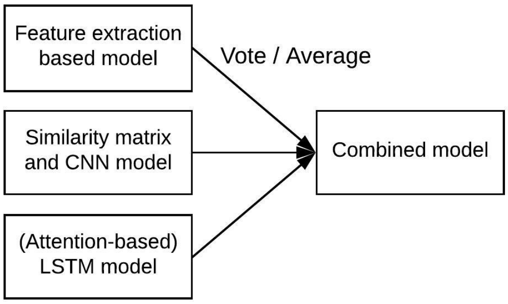

Figure 5: Combining three approaches using ensemble modelling

The attention mechanism was first introduced by Bahdanau et al. (2014) for machine translation. In general, the attention model learns a soft alignment between the input and the output in the encoder-decoder framework. The attention mechanism allows the model to learn what to attend to in the input states and mitigates the long-dependency bottleneck of the LSTM.

In the attention-based model for summary assessment, the original text and the summary are still encoded using two separate LSTMs. However, the text representation is formed by a weighted sum of the hidden states of the text encoder, where the weights can be interpreted as the degree to which the summary attends to a particular token in the text. The summary representation and the text representation are combined with a nonlinear function into a joint representation and then fed into the fully connected layer to predict the summary quality. Figure 4 is an illustration of the attention mechanism between the embedded summary and the embedded input text.

Mathematically, suppose s is the encoded summary vector and $a(t)$ is the hidden state of the LSTM for the text at each token t. Then the final representation r of the encoded text is a weighted sum of $a(t)$:

$$r = a \cdot w = \sum_{t=1}^{T} a(t)w(t)$$

The weight for each token $w(t)$ is computed by:

$$w(t) = \frac{exp(\alpha(t))}{\sum_{t=1}^{T} exp(\alpha(t))}$$

where

$$\alpha(t) = W_{a\alpha} \cdot a(t) + W_{s\alpha} \cdot s$$

is an alignment model.

The joint representation m of the summary and the text is a combination of the summary vector s and the weighted input text vector r.

$$m = tanh(W_{sm} * s + W_{rm} * r + b)$$

where W_{sm}, W_{rm} and b are the parameters of a linear combination function.

4.4 Ensemble modelling

Ensemble modelling combines several machine learning techniques into one model in order to improve the stability and accuracy of the prediction. We explore combining the three different models (see Figure 5) into a single model by taking the majority vote from the binary classification models and taking the average value of the predicted scores from the regression models. We compare the performance of the combined models against the individual models to investigate if and to what extent ensemble modelling is useful for assessing the summaries.

5 Experiments and Results

5.1 Experimental set-up

We evaluate our models on the real learner data and on the simulated learner data, for consistency, using 5-fold cross validation. In each fold, 60% of the data is used as the training set, 20% as the development set, and 20% as the test set.[5]

We compare our models against five baselines: *most frequent baseline*, *random baseline*, *ROUGE*

---

[5] We choose the best model based on the development set, retrain the selected model on the combination of the training and the development data, and evaluate the model on the test set.

Models	Variants			Accuracy
Baseline	Baseline type		most-frequent	50.0%
			random	50.0%
			ROUGE	59.3%
			BLEU	51.7%
			ROUGE + BLEU	59.6%

			addition	68.1%
			multiplication	69.1%
			linear combination	70.4%
	Attention LSTM			**71.1%**
Combined model	SVM+CNN+LSTM			**75.3%***

Table 2: Model performance on the simulated learner data. We use the bold font to indicate the best model for each method. The asterisk sign indicates the best performance across all models.

baseline,[6] *BLEU baseline*, and *ROUGE + BLEU baseline*.

We use accuracy to evaluate the models on the simulated learner data, and on the real learner data, we report scores of two evaluation metrics: Pearson correlation coefficient (PCC) and Root Mean Square Error (RMSE), which are commonly used for evaluating regression models.

5.2 Results

Table 2 shows the results of the baseline and the four types of models on the simulated learner data, and Table 3 reports the results of the models on the real learner data.

On the simulated learner data, the best variants from all three methods outperform the baselines. The improvement is statistically significant ($p<0.05$) using t-test for all three methods. We combine the best variants from the three approaches into a single system by taking the majority vote from the models. The resulting system achieves the best accuracy of 75.3% in predicting the binary type of the summary on the simulated learner data.

On the real learner data, we found that the feature extraction-based model outperforms the CNN model and LSTM-based models, which also significantly outperform the baselines. The results suggest that the neural network-based models are not as effective as the traditional feature extraction-based method for the regression task, at least when the training data is limited in size.

However, although the CNN and LSTM models are not the best-performing models individually, a combination of the three methods (KRR, CNN and LSTM) still improves the performance. We believe that this is because the three independent models capture different aspects of the summary quality that are complementary to each other. In addition, the combined model is more robust to outliers. For example, when two models agree on an instance while the third model does not, the combined model will select the majority vote or the average score of the model estimations, hence achieving a better performance in estimating the summary quality. Overall, the best model performance is close to human performance.

We also observe that when assessing the summaries with extracted features, using the original document as the reference works better than using other types of reference. This might be because the extractive summarizers only select sentences that are highly related to others, where the relation

is typically judged by the word overlap, therefore missing the bits of text where topical words occur less often.

6 Conclusion

In this paper, we introduce a summarization task for testing reading comprehension of learners and present several automated systems to assess the quality of the learner summary. We collected summaries from members of our university and from the real learners to evaluate our systems. We propose and compare three approaches to assess the summaries, including the feature extraction-based model, the CNN-based model using similarity matrix, and the LSTM-based model. The best system, built using a combination of three models, yields an accuracy of 75.3% on the simulated learner data, and $PCC = 0.665$, $RMSE = 0.97$ on the real learner data. Although not directly comparable to other studies, we note that these results are higher than those reported in previous work.

Our systems are generalizable and address the limitations of the previous research in this area as: (1) they are capable of evaluating the quality of a summary without the need of being trained on each input text separately, (2) they do not require a pre-defined reference, and (3) they are capable of capturing content similarity beyond verbatim overlap, taking into account paraphrasing and higher levels of abstraction.

We believe that although the application presented in this paper focuses on assessing learner summaries, these techniques may also be useful for benchmarking automated summarization systems. Evaluation of these techniques for benchmarking automated summarization systems is one direction for our future research.

We make the summary data available at `https://www.cl.cam.ac.uk/~ek358/learner-summaries.html`.

Acknowledgments

This paper reports on research supported by Cambridge Assessment, University of Cambridge. We also thank Cambridge Assessment for their assistance in the collection of the real learner data. We are grateful to the anonymous reviewers for their valuable feedback.

Abstract

Neural sequence-to-sequence models have been successfully applied to text compression. However, these models were trained on huge automatically induced parallel corpora, which are only available for a few domains and tasks. In this paper, we propose a novel interactive setup to neural text compression that enables transferring a model to new domains and compression tasks with minimal human supervision. This is achieved by employing active learning, which intelligently samples from a large pool of unlabeled data. Using this setup, we can successfully adapt a model trained on small data of 40k samples for a headline generation task to a general text compression dataset at an acceptable compression quality with just 500 sampled instances annotated by a human.

1 Introduction

Text compression is the task of condensing one or multiple sentences into a shorter text of a given length preserving the most important information. In natural language generation applications, such as summarization, text compression is a major step to condense the extracted important content of the source documents. But text compression can also be applied in a wide range of related applications, including the generation of headlines (Filippova et al., 2015), captions (Wubben et al., 2016), subtitles (Vandegehinste and Pan, 2004; Luotolahti and Ginter, 2015), and the compression of text for small screens (Corston-Oliver, 2001).

Neural *sequence-to-sequence* (Seq2Seq) models have shown remarkable success in many areas of natural language processing and specifically in natural language generation tasks, including text compression (Rush et al., 2015; Filippova et al., 2015; Yu et al., 2018; Kamigaito et al., 2018). Despite their success, Seq2Seq models have a major drawback, as they require huge parallel corpora with pairs of source and compressed text to be able to learn the parameters for the model. So far, the size of the training data has been proportional to the increase in the model's performance (Koehn et al., 2003; Suresh, 2010), which is a major hurdle if only limited annotation capacities are available to manually produce a corpus. That is why existing research employs large-scale automatically extracted compression pairs, such as the first sentence and the presumably shorter headline of a news article. However, such easy-to-extract source data is only available for a few tasks, domains, and genres and the corresponding models do not generalize well from the task of headline generation to other text compression tasks.

In this paper, we propose an *interactive setup* to neural text compression, which learns to compress based on user feedback acquired during training time. For the first time, we apply *active learning* (AL) methods to neural text compression, which greatly reduces the amount of the required training data and thus yields a much more data-efficient training and annotation workflow. In our experiments, we find that this approach enables the successful transfer of a model trained on headline generation data to a general text compression task with a minimum of parallel training instances.

The objective of AL is to efficiently select unlabeled instances that a user should annotate to advance the training. A key component of AL is the choice of the *sampling strategy*, which curates the samples in order to maximize the model's performance with a minimum amount of user interaction. Many AL sampling strategies have proven effective for human-supervised natural language processing tasks other than compression (Hahn et al., 2012; Peris and Casacuberta, 2018; Liu et al., 2018).

In our work, we exploit the application of uncertainty-based sampling using attention disper-

Proceedings of NAACL-HLT 2019, pages 2543–2554
Minneapolis, Minnesota, June 2 - June 7, 2019.

sion and structural similarity for choosing samples to be annotated for our interactive Seq2Seq text compression model. We employ the AL strategies for (a) learning a model with a minimum data, and (b) adapting a pretrained model with few user inputs to a new domain.

In the remaining paper, we first discuss related work and introduce the state-of-the-art Seq2Seq architecture for the neural text compression task. Then, we propose our novel interactive compression approach and demonstrate how batch mode AL can be integrated with neural Seq2Seq models for text compression. In section 4, we introduce our experimental setup, and in section 5, we evaluate our AL strategies and show that our approach successfully enables (a) learning the Seq2Seq model with a minimum of data, (b) transfer of a pretrained headline generation model to a new compression task and dataset with minimal user interaction. To encourage further research and enable reproducing our results, we publish our code as open-source software.[1]

2 Related Work

In this section, we discuss related work to our research concerning: (1) neural text compression models, (2) existing text compression corpora and (3) active learning for neural models.

Neural text compression. Neural text compression models can be broadly classified into two categories: (a) deletion-based extractive models and (b) abstractive models. The goal of the deletion-based models is to delete unimportant words from a source text to generate a shorter version of the text. In contrast, abstractive models generate a shorter text by inserting, reordering, reformulating, or deleting words of the source text.

Previously, deletion-based extractive methods explored various modeling approaches, including the noisy-channel model (Knight and Marcu, 2002; Turner and Charniak, 2005), integer linear programming (Clarke and Lapata, 2007), variational autoencoders (Miao and Blunsom, 2016), and Seq2Seq models (Filippova et al., 2015). Similarly, recent abstractive models have seen tree-to-tree transduction models (Cohn and Lapata, 2013) and variations of Seq2Seq models, such as attention (Rush et al., 2015), attentive long short-term memory (LSTM) models (Wubben et al., 2016) and operation networks where the Seq2Seq model decoder is replaced with a deletion decoder and a copy-generate decoder (Yu et al., 2018).

Filippova et al. (2015) show that Seq2Seq models without any linguistic features have the ability to delete unimportant information. Kamigaito et al. (2018) incorporate higher-order dependency features into a Seq2Seq model and report promising results. Rush et al. (2015) propose an attention-based Seq2Seq model for generating headlines. Chopra et al. (2016) further improve this task with recurrent neural networks. Although Seq2Seq models show state-of-the-art results on different compression datasets, there is yet no work which investigates whether large training corpora are needed to train neural compression models and if there are efficient ways to train and adapt them to other datasets with few annotations.

Text compression corpora. Early publicly available text compression datasets are manually curated but small (Cohn and Lapata, 2008; Clarke and Lapata, 2006, 2008). These datasets are typically used by unsupervised approaches as they are 200 times smaller in size compared to the annotated data used for training state-of-the-art supervised approaches. Filippova and Altun (2013) introduce an extractive compression dataset of 250k headline and first sentence compression pairs based on Google News, which they use for training a supervised compression method. Similarly, Rush et al. (2015) create another large abstractive dataset of 4 million headline and first sentence compression pairs from news articles extracted from the Annotated Gigaword corpus (Napoles et al., 2012). Although these datasets are large, they predominantly address headline generation for news.

Creating such large corpora manually for a new task or domain is hard. Toutanova et al. (2016) pioneered the manual creation of a multi-reference compression dataset MSR-OANC with 6k sentence–short paragraph pairs from business letters, newswire, journals, and technical documents sampled from the Open American National Corpus[2]. They provide five crowd-sourced rewrites for a fixed compression ratio and also acquire quality judgments. This dataset covers multiple genres compared to the large automatically collected compression datasets, and Toutanova et al. (2016) show that neural Seq2Seq

models trained on headline generation datasets fail to achieve state-of-the-art results as compared to an ILP-based unsupervised method. In our work, we go beyond that and investigate strategies to easily adapt pretrained models to such small datasets employing minimal user input.

Active learning for neural models. AL has been successfully applied to various natural language processing tasks, including corpus annotation (Hahn et al., 2012; Yan et al., 2011), domain adaptation (Chan and Ng, 2007), personalized summarization (P. V. S. and Meyer, 2017), machine translation (Haffari and Sarkar, 2009), language generation (Mairesse et al., 2010), and many more. Only recently, it has been applied to neural models: Wang et al. (2017a) propose an AL approach for a black box semantic role labelling (SRL) model where the AL framework is an add-on to the neural SRL models. Peris and Casacuberta (2018) use AL in neural machine translation. They propose quality estimation sampling, coverage sampling, and attention distraction sampling strategies to query data for interactive machine translation. Liu et al. (2018) additionally propose an AL simulation trained on a high-resource language pair to transfer their model to low-resource language pairs. In another line of research, Sener and Savarese (2018) discuss a core-set AL approach as a batch sampling method for neural image classification based on convolutional neural networks. Although AL techniques have been widely used in natural language processing, to our knowledge, there is yet no work on the use of AL for neural text compression. We fill this gap by putting the human in the loop to learn effectively from a minimal amount of interactive feedback and for the first time, we explore this data-efficient AL-based approach to adapt a model to a new compression dataset.

3 Approach

To address this research problem, we first describe the neural Seq2Seq text compression models we use. Then, we introduce our active learning strategies to select the training samples interactively for in-domain training as well as for domain adaptation, and we describe a novel interactive neural text compression setup. Figure 1 illustrates the main components of our system.

3.1 Neural Seq2Seq Text Compression

In this work, we employ state-of-the-art Seq2Seq models with attention (Seq2Seq-gen) (Rush et al., 2015) and pointer-generated networks with coverage (Pointer-gen) (See et al., 2017) as our base models, which we use for our AL-based interactive text compression setup.

Both Seq2Seq models are built upon the encoder-decoder framework by Sutskever et al. (2014). The encoder encodes the input sequence $\mathrm{x} = (x_1, x_2.., x_n)$ represented by an embedding matrix into a continuous space using a bidirectional LSTM network and outputs a sequence of hidden states. The decoder is a conditional bidirectional LSTM network with attention distribution (Luong et al., 2015)

$$a_i^j = \frac{\exp(e_i^j)}{\sum_{k=1}^{n} \exp(e_k^j)} \quad (1)$$

where e_i^j is computed at each generation step j with the encoder states h_i^{enc} and the decoder states h_j^{dec}:

$$e_i^j = q \cdot \tanh(W_h^{\text{enc}} h_i^{\text{enc}} + W_h^{\text{dec}} h_j^{\text{dec}} + b_{\text{att}}) \quad (2)$$

where q , W_h^{enc}, W_h^{dec} and b_{att} are learnable parameters. The attention distribution a_i^j is used to compute the weighted sum of the encoder hidden states, also known as the context vector

$$c_j^* = \sum_i^n a_i^j h_i^{\text{enc}} \tag{3}$$

To obtain the vocabulary distribution P_j^{vocab} at generation step j, we concatenate the fixed context vector with the decoder state h_j^{dec} and pass it through two linear layers:

$$P_j^{\text{vocab}} = \text{softmax}(W_v(W_v'[h_j^{\text{dec}}; c_j^*] + b_v') + b_v) \tag{4}$$

where W_v, W_v', b_v and b_v' are learnable parameters. P_j^{vocab} is a probability distribution over all words in the vocabulary V. Based on the vocabulary distribution, the model generates the target sequence $\text{y} = y_1, y_2, \ldots, y_m$, $m \leq n$ with

$$y_j = \text{argmax}_w P_j^{\text{vocab}}(w),\ w \in V \tag{5}$$

for each generation step j.

Finally during training, we define the loss function for generation step j as the negative log likelihood of the target word y_j and the overall loss function for the target word sequence as $\mathcal{L}$:

$$\mathcal{L} = \frac{1}{m} \sum_{j=0}^{m} - \log P_j^{\text{vocab}}(y_j) \tag{6}$$

Another state-of-the-art approach we use for our experiments is the pointer-generator networks (Pointer-gen) proposed by See et al. (2017). This model uses a pointer-generator network that determines a probability function to generate the words from the vocabulary V or copy the words from the source text by sampling from the attention distribution a_i^j as shown in Eq. 8. The model achieves this by calculating an additional generation probability p_{gen} for generation step j, which is calculated from the context vector c_j^*, the decoder state h_j^{dec}, and the current input to the decoder x_j':

$$p_{\text{gen}} = \sigma(W_c^T c_j^* + W_{h^{\text{dec}}}^T h_j^{\text{dec}} + W_{x'}^T x_j' + b_{\text{gen}}) \tag{7}$$

$$P_j(w) = p_{\text{gen}} P_j^{\text{vocab}}(w) + (1 - p_{\text{gen}}) \sum_{i=0}^{n} a_i^j \tag{8}$$

where vectors W_c, $W_{h^{\text{dec}}}$, $W_{x'}$, b_{gen} are learnable parameters, n is the number of words in the source text and σ is the sigmoid function.

The model also uses an extra feature of coverage to keep track of words generated by the model to discourage repetition. In the coverage model, a coverage vector is calculated which is the sum of the attention distribution across all the previous decoding steps and it is passed on as an extra input to the attention mechanism:

$$c_i^j = \sum_{k=0}^{j-1} a_i^k \tag{9}$$

$$e_i^j = q \cdot \tanh(W_h^{\text{enc}} h_i^{\text{enc}} + W_h^{\text{dec}} h_j^{\text{dec}} + W_c c_i^j + b_{\text{att}}) \tag{10}$$

where W_c is an additional learnable parameter.

3.2 Active Learning

Toutanova et al. (2016) show that Seq2Seq models, which perform well on large news headline generation datasets, fail to achieve good performance on their MSR-OANC multi-genre compression dataset. A major issue with training Seq2Seq models is the lack of domain-specific data and the expensive process to create parallel compression pairs. It is therefore indispensable to minimize the cost of data annotation. Thus, AL comes into play whose key element is to find a strategy for selecting samples the user should annotate which yield a more efficient training process. For text compression, we suggest AL strategies to maximize the model's coverage and the diversity of the samples. To this end, we build upon work in uncertainty sampling by (Peris and Casacuberta, 2018; Wang et al., 2017b) and propose a new strategy to predict the sample diversity at a structural level.

Coverage constraint sampling (Coverage-AL). An important factor on which text compression models are evaluated is the coverage (Marsi et al., 2010). Coverage can be defined as the text compression models being able to learn the deletion or generation rules from the training samples and apply them on an input source text. Wu et al. (2016) first proposed the idea of using attention weights to calculate coverage penalty for active learning based machine translation systems. The attention weights were further extended by Peris and Casacuberta (2018) to estimate an attention dispersion based uncertainty score for a sentence. The idea of attention dispersion is that if the neural Seq2Seq compression model is uncertain then the attention weights will be dispersed across the source text while generating the target words. The samples with higher dispersion will have their attention weights uniformly distributed across the source sentences. Thus, the goal is to find the samples with high uncertainty based on attention dispersion. As we want to define to the extent to which the attention distribution differs from a normal distribution we propose to use a skewness score. The skewness score calculates the attention dispersion while decoding a target word y_j.

$$\text{skewness}(y_j) = \frac{\frac{1}{n}\sum_{i=1}^{n}(a_i^j - \frac{1}{n})^3}{(\frac{1}{n}\sum_{i=1}^{n}(a_i^j - \frac{1}{n})^2)^{3/2}} \quad (11)$$

a_i^j is the attention weight assigned by the attention layer to the i-th source word when decoding the j-th target word and $\frac{1}{n}$ is the mean of the attention weights of the target word y_j.

The skewness for a normal distribution is zero, and since we are interested in the skewness of samples with heavy tails, we take the negative of the skewness averaged across all target words to obtain the uncertainty coverage score C_{score}.

$$C_{\text{score}}(\mathrm{x}, \mathrm{y}) = \frac{\sum_{j=1}^{m} -\text{skewness}(y_j)}{m} \quad (12)$$

where m is the number of target words.

Diversity constraint sampling (Diversity-AL). Diversity sampling methods have been used in information retrieval (Xu et al., 2007) and image classification (Wang et al., 2017b). The core idea is that samples that are highly similar to each other typically yield little new information and thus low performance. Similarly, to increase the diversity of the samples in neural text compression, we propose a novel scoring metric to measure the diversity of multiple source texts at a structural level. Our intuition is that integrating part-of-speech, dependency and named entity information is useful for text compression, e.g., to learn which named entities are important and how to compress a wide range of phrase types and syntactically complex sentences. Thus, we consider part of speech tags, dependency trees, and named entity embeddings and calculate the structural similarity of the source text with regard to the target text. We use a multi-task convolutional neural network similar to Søgaard and Goldberg (2016) trained on OntoNotes and Common Crawl to learn the structural embeddings consisting of tag, dependency and named entity embeddings. The diversity score D_{score} is calculated using the cosine distance between the average of the structural embeddings of the words in the source sentence and the average of the structural embeddings of the words in the target compression as in Eq. 13:

$$D_{\text{score}}(\mathrm{x}, \mathrm{y}) = \frac{\mathrm{E}_{\text{struc}}(\mathrm{x}) \cdot \mathrm{E}_{\text{struc}}(\mathrm{y})}{||\mathrm{E}_{\text{struc}}(\mathrm{x})|| \cdot ||\mathrm{E}_{\text{struc}}(\mathrm{y})||} \quad (13)$$

where $\mathrm{E}_{\text{struc}}(\cdot)$ is the average structural embedding of a text.

These AL sampling strategies are applied interactively while training to make better use of the data by selecting the most uncertain instances. Additionally, both strategies can be applied for domain adaptation by actively querying user annotations for a domain-specific dataset in an interactive text compression setup, which we describe next.

3.3 Interactive Text Compression

In this subsection, we introduce our interactive text compression setup. Our goal is to select the batch of samples for training efficiently with minimal samples and to become able to transfer the models to new datasets for different domains and genres with few labeled data.

We consider an initial collection of parallel instances $D = \{(\mathrm{x}_i, \mathrm{y}_i) \mid 1 \leq i \leq N\}$ consisting of pairs of input text x_i and their corresponding compression y_i. Additionally, we consider unlabeled instances $D' = \{\mathrm{x}_i \mid i > N\}$, for which we only know the uncompressed source texts. Our goal is to sample sets of unlabeled instances $S_t \subset D'$ which should be annotated by a user in each time step t. The interactive compression model can only see the labeled pairs from the initial dataset D in the beginning, but then incrementally learns from the user annotations.

Algorithm 1 provides an overview of our interactive compression setup. The inputs are the labeled compression pairs D and the unlabeled source texts D'. D is used to initially train the neural text compression model M. In line 5, we start the interactive feedback loop iterating over $t = 0, \ldots, T$. We first sample a set of unlabeled source texts S_t (line 6) by using our AL strategies introduced in section 3.2 and then loop over each of the unlabeled samples to be annotated or supervised by the human in line 10. As the user feedback in the current time step of sample S_t, we obtain the compressions Y_t of the sampled source texts S_t from the user and use them for online training of the model M. After T iterations or if there are no samples left for querying (i.e., $S_t = \emptyset$), we stop the iteration and return the updated Seq2Seq model M.

Algorithm 1 Interactive Text Compression

```
 1: procedure INTERACTIVECOMPRESSION()
 2:     input: Text Compression Pairs $D$,
 3:            Unlabeled Text $D'$
 4:     $M \leftarrow$ learnSeq2Seq($D$)
 5:     for $t = 0, ..., T$ do
 6:         $S_t \leftarrow$ getSample($D'$)
 7:         if $S_t = \emptyset$ then
 8:             return $M$
 9:         else
10:             $Y_t \leftarrow$ queryUser($S_t$)
11:             $M \leftarrow$ update($M, S_t, Y_t$)
12:             $D' \leftarrow D' - S_t$
13:         end if
14:     end for
15: end procedure
```

4 Experimental Setup

4.1 Data

For our experiments, we use the large Google News text compression corpus[3] by Filippova and Altun (2013), which contains 250k automatically extracted the deletion-based compressions from aligned headlines and first sentences of news articles. Recent studies on text compression have extensively used this dataset (e.g., Zhao et al., 2018; Kamigaito et al., 2018). We carry out in-domain active learning experiments on the Google News compression corpus.

To evaluate our interactive setup, we adapt the trained models to the MSR-OANC text compression corpus by Toutanova et al. (2016), which contains 6k crowdsourced multi-genre compressions from the Open American National Corpus. This corpus is well-suited to evaluate our interactive setup, since it is sourced from mixture of newswire, letters, journals, and non-fiction genres, in contrast to the Google News corpus covering only newswire.

Dataset	# Train	# Dev	# Test
Google News	195,000	5,000	10,000
MSR-OANC	5,000	448	785

Table 1: Statistics of the compression datasets

For evaluating the compressions against the reference compressions, we use a Python wrapper[4] of the ROUGE metric (Lin, 2004) with the parameters suggested by Owczarzak et al. (2012) yielding high correlation with human judgments (i.e., with stemming and without stopword removal).[5]

4.2 Preprocessing and Parameters

To preprocess the datasets, we perform tokenization. We obtain the structural embeddings for a sentence using spaCy[6] embeddings learned using a multi-task convolutional neural network.

To evaluate and assess the effectiveness of our active learning-based sampling approaches, we set up our interactive text compression approach for the two state-of-the-art Seq2Seq models consisting of a generative model (Seq2Seq-gen) and a generate-and-copy model (Pointer-gen) as described in Section 3.1. For the neural Seq2Seq text compression experiments, we set the beam size and batch size to 10 and 30 respectively. We use the Adam optimizer (Kingma and Ba, 2015) for the gradient-based optimization. Finally, the parameters for the neural network parameters like weights and biases are randomly initialized.

In order to asses the effectiveness of AL for neural text compression we extend the OpenNMT[7] implementations with our interactive framework following Algorithm 1. The sampling strategy selects instances to be annotated interactively by the user in batches. Next, the neural text compression model is incrementally updated with the selected samples.

Due to the presence of a human in the loop, it typically demands real user feedback, but the cost of collecting sufficient data for various settings of our models is prohibitive. Thus in our experiments, the users were simulated by using the com-

pression pairs from our corpus as the sentences annotated by the user.

5 Results and Analysis

Our experiments address two main research questions for in-domain training and domain adaptation of neural text compression:

- Which active learning strategies are useful in text compression to select training samples such that higher performance can be achieved with a minimum of labeled instances?
- Which instances are to be annotated interactively by the user such that the model adapts quickly to a new dataset?

In-domain Active Learning. For in-domain active learning experiments, we choose the Google News text compression training corpus and sample for corpus sizes between 10% and 100% in ten percent point steps. As a baseline, we use a random sampling strategy to test the state-of-the-art Seq2Seq neural text compression models. Figure 2 suggests that our coverage-based sampling (Coverage-AL) and diversity-based sampling (Diversity-AL) strategies outperform the random sampling strategy throughout all training sizes. A key observation is that our sampling strategies are behind the upper bound by just 0.5% ROUGE-2 when only 20% of the training data is used. Table 2 illustrates the results of our sampling strategies when 20% of the data is used for training. All the results are in comparison to the upper bound (UB) receiving 100% of the training data.

Coverage-AL performs better than the Diversity-AL for both the Seq2Seq-gen and Pointer-gen models. However, they are still not effective in the Seq2Seq-gen model where random sampling performs on par with the active learning sampling approaches. We believe this is due to the Seq2Seq-gen model's inability to copy from the source text in the sampled set as a consequence of active learning in the batch setting. Whereas for Pointer-gen model, we observed that both Coverage-AL and Diversity-AL strategies of adding new samples for training had a greater impact when the model has not adapted. We attribute the effectiveness of the Coverage-AL strategy over Diversity-AL to the exploitation of the model uncertainty, as the Diversity-AL only uses the similarity based on the samples, but misses to integrate the model uncertainty.

Table 3 presents an example sentence compression pair from the Google News dataset and the generated compressions of both neural Seq2Seq models when using one of the three sampling strategies. The example shows that detailed descriptions like the names of the ships “JING GANGSHA” and “HENG SHUI” are dropped by all models. In particular, the Seq2Seq-gen model has the problem of generating words not present in the original text (e.g.,

Seq2Seq-gen	30.05	10.42	26.87	33.51	13.60	30.26	**35.10**	**15.00**	**32.78**	34.85	14.92	32.41
Pointer-gen	35.24	16.57	32.56	38.19	21.87	37.94	**39.59**	**24.87**	**37.02**	39.42	24.70	36.86

Table 4: ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL) achieved by the state-of-the-art models using our sampling strategies when interactively retrained using 10% of the MSR-OANC training set. The results are in comparison to the models trained on in-domain training set (MSR-OANC ID). Bold marks best AL strategy.

“toddlers”, “Scottsbluff”). In contrast, the Pointer-gen model’s ability to copy from the original text restrains the model from generating irrelevant words. Although Diverysity-AL based models recognized the phrasal constructs crucial for the sentence meaning, Coverage-AL generated the closest compression to the reference.

Active learning for domain adaptation. To test our interactive Seq2Seq model using active learning strategies for the domain adaptation scenario, we train the model on the Google News compression corpus and test it on the multi-genre MSR-OANC compression dataset. Additionally, for domain adaptation, the neural Seq2Seq model is updated incrementally using our interactive compression Algorithm 1. The sampling strategies select the instances to be interactively annotated by the user. As the cost of interactive experimentation with real users, we use simulated feedback from the labeled sentence compressions from the MSR-OANC training data. The two sampling strategies used for in-domain active learning are used for interactive compression with the state-of-the-art Seq2Seq models. Table 4 illustrates the results of the interactive text compression model when applied to the MSR-OANC text compression dataset. One interesting observation is the fact that our sampling strategies at 10% of the training data ($\approx$ 500 samples) perform better than models trained on in-domain training data (MSR-OANC ID) with 5k training instances by +8.3% and +8.2% ROUGE-2.

Figure 3 shows the results for the various sample sizes of the 5k training instances. The results show a similar trend as the active learning for the interactive data-selection scenario. The Coverage-AL and Diversity-AL strategies do not show significant differences from each other. However, the two active learning strategies achieve on average +2.5% ROUGE-2 better results than the random sampling. The results demonstrate that the use of relevant training samples is useful for transferring the models to new domains and genres.

Table 5 shows an example from the MSR-OANC compression dataset. The example illustrates similar compression properties as seen in the in-domain settings. In particular, the two models learned to drop appositions, optional modifiers, detailed clauses, etc. Additionally, we also observed that the difficult cases where those where there is little to be removed, but due to higher compression ratios during the training, the models removed more than required. This confirms the

cause for lower ROUGE scores compared to the Google News corpus.

6 Conclusion

We propose a novel neural text compression approach using a neural Seq2Seq method with an interactive setup that aims at (a) learning an in-domain model with a minimum of data and (b) adapting a pretrained model with few user inputs to a new domain or genre. In this paper, we investigate two uncertainty-based active learning strategies with (a) a coverage constraint using attention dispersion and (b) a diversity constraint using structural similarity to make better use of the user in the loop for preparing training data pairs. The active learning based data selection methodology samples the data such that the most uncertain samples are available for training first. Experimental results show that the selected samples achieve comparable performance to the state-of-the-art systems, but trained on 80% less in-domain training data. Active learning with an interactive text compression model helps in transferring models trained on a large parallel corpus for a headline generation task to a general compression dataset with just 500 sampled instances. Additionally, the same in-domain active learning based data selection shows a notable performance improvement in an online interactive domain adaptation setup. Our experiments demonstrate that instead of more training data, relevant training data is essential for training Seq2Seq models in both in-domain training as well as domain adaptation.

In future work, we plan to explore several lines of work. First, we intend to investigate further applications of our interactive setup, e.g., in movie subtitle compression or television closed captions where there is no sufficient training data to build neural models. On a more general level, the interactive setup and the active learning strategies presented can also be used for other natural language processing tasks, such as question answering, to transfer a model to a new domain or genre.

Abstract

We propose a novel conditioned text generation model. It draws inspiration from traditional template-based text generation techniques, where the source provides the content (i.e., *what to say*), and the template influences *how to say it*. Building on the successful encoder-decoder paradigm, it first encodes the content representation from the given input text; to produce the output, it retrieves exemplar text from the training data as “soft templates,” which are then used to construct an exemplar-specific decoder. We evaluate the proposed model on abstractive text summarization and data-to-text generation. Empirical results show that this model achieves strong performance and outperforms comparable baselines.

1 Introduction

Conditioned text generation is the essence of many natural language processing (NLP) tasks, e.g., text summarization (Mani, 1999), machine translation (Koehn, 2009), and data-to-text generation (Kukich, 1983; McKeown, 1992; Reiter and Dale, 1997). In its common neural sequence-to-sequence formulation (Sutskever et al., 2014; Cho et al., 2014), an encoder-decoder architecture is used. The decoder generates the text autoregressively, token-by-token, conditioning on the feature representations encoded from the source, typically with attention (Bahdanau et al., 2015) and copy mechanisms (Gu et al., 2016; See et al., 2017). This paradigm is capable of generating fluent abstractive text, but in an uncontrolled and sometimes unreliable way, often producing degenerate outputs and favoring generic utterances (Vinyals and Le, 2015; Li et al., 2016).

The encoder-decoder approach differs considerably from earlier template-based methods (Becker, 2002; Foster and White, 2004; Reiter et al., 2005; Gatt and Reiter, 2009, *inter alia*), where the source content is filled into the slots of a handcrafted template. These solutions offer higher generation precision compared to neural approaches (Wiseman et al., 2017), but tend to lack the naturalness of neural systems, and are less scalable to open domain settings, where the number of required templates can be prohibitively large.

To sidestep the scalability problems with handcrafted templates, it has been proposed to use similar training samples as **exemplars**, to guide the decoding process (Gu et al., 2018; Guu et al., 2018; Weston et al., 2018; Pandey et al., 2018; Cao et al., 2018a, *inter alia*).[1] In general, existing methods accomplish this by (a) using traditional information retrieval (IR) techniques for exemplar extraction (e.g., TF-IDF), and then (b) concatenating the exemplar to the source as additional inputs, allowing the decoder to attend over and copy from both.

We propose a different strategy for using exemplars. For motivation, Figure 1 shows a source-target pair together with its exemplar from the Gigaword dataset (Graff et al., 2003). The target is a summary of the source sentence, and the exemplar is retrieved from the training set (§3.2).[2] There is word overlap between the exemplar and the desired output, which would be easily captured by an attention/copy mechanism (e.g. *Norway* and *aid*). Despite this, ideally, the model should also exploit the structural and stylistic aspects to produce an output with a similar sentence structure, even if the words are different.

Indeed, in traditional templates, the source

∗ Work done during internship at Google.

[1] The term **exemplar** indicates a training instance used to help generation. We aim to distinguish from “templates,” since here no explicit slot-filling procedure is involved.

[2] We use the *training target* as the exemplar, whose source is most similar to the current input. §3.2 describes the details.

Proceedings of NAACL-HLT 2019, pages 2555–2565

Source: Norway said Friday it would give Zimbabwe 40 million kroner (7.02 million dollars, 4.86 million euros) in aid to help the country deal with a lack of food and clean drinking water and a cholera outbreak.
Exemplar: Norway boosts earthquake aid to Pakistan.
Target: Norway grants aid of 4.86 million euros to Zimbabwe.

Figure 1: A source-target pair from Gigaword training set, along with its exemplar.

is supposed to determine "what to say," while the templates aim to address "how to say it," reminiscent of the classical content selection and surface realization pipeline (Reiter and Dale, 1997). For instance, an ideal template for this example might look as follows:

`_____ grants aid of _____ to _____`

In the neural formulation, the "how to say it" aspect is primarily controlled by the decoder.

Inspired by the above intuition, we propose **exemplar-based adaptive decoding**, where a customized decoder is constructed for each exemplar. This is achieved by letting the exemplars to directly influence decoder parameters through a reparameterization step (§3.1). The adaptive decoder can be used as a drop-in replacement in the encoder-decoder architecture. It offers the potential to better incorporate the exemplars' structural and stylistic aspects into decoding, without excessive increase in the amount of parameters or computational overhead.

We empirically evaluate our approach on abstractive text summarization and data-to-text generation (§4), on which most of the recent efforts on exemplar-guided text generation have been studied. On three benchmark datasets, our approach outperforms comparable baselines, and achieves performance competitive with the state of the art. The proposed method can be applicable in many other conditioned text generation tasks. Our implementation is available at `https://homes.cs.washington.edu/~hapeng`.

2 Background

This section lays out the necessary background and notations for further technical discussion. We begin with conditioned text generation and the encoder-decoder framework (Sutskever et al., 2014; Cho et al., 2014). In the interest of the notation clarity, §3 will use an Elman network (Elman, 1990) as a running example for the decoder, which is briefly reviewed in §3. The proposed technique generalizes to other neural network architectures (§3.3).

Conditioned text generation and the encoder-decoder architecture. Our discussion centers around conditioned text generation, i.e., the model aims to output the target $\mathbf{y} = y_1 y_2 \dots y_T$ given the source input $\mathbf{x} = x_1 x_2 \dots x_S$, both of which are sequences of tokens. Each token x_i, y_i takes one value from a vocabulary $\mathcal{V}$. $\mathbf{x}$ and $\mathbf{y}$ could vary depending on the tasks, e.g., they will respectively be articles and summaries for text summarization; and for data-to-text generation, $\mathbf{x}$ would be structured data, which can sometimes be linearized (Lebret et al., 2016; Wiseman et al., 2018, *inter alia*), and $\mathbf{y}$ is the output text. We aim to learn a (parameterized) conditional distribution of the target text $\mathbf{y}$ given the source $\mathbf{x}$,

$$p(\mathbf{y} \mid \mathbf{x}) = \prod_{t=1}^{T} p(y_t \mid \mathbf{y}_{<t}, \mathbf{x}), \tag{1}$$

where $\mathbf{y}_{<t} = y_1 \dots y_{t-1}$ is the prefix of $\mathbf{y}$ up to the $(t-1)^{\text{th}}$ token (inclusive).

The probability of each target token is usually estimated with a $\operatorname{softmax}$ function:

$$p(y_t \mid \mathbf{y}_{<t}, \mathbf{x}) = \frac{\exp \mathbf{h}_{t-1}^{\top} \mathbf{w}_{y_t}}{\sum_y \exp \mathbf{h}_{t-1}^{\top} \mathbf{w}_y}. \tag{2}$$

$\mathbf{w}_y$ denotes a learned vector for token $y \in \mathcal{V}$. $\mathbf{h}_{t-1}$ depends on $\mathbf{y}_{<t}$ and $\mathbf{x}$, and is computed by a function which we will describe soon.

A typical implementation choice for computing $\mathbf{h}_t$ is the encoder-decoder architecture (Sutskever et al., 2014). More specifically, an **encoder** $\mathbf{g}_{\boldsymbol{\theta}}$ first gathers the feature representations from the source $\mathbf{x}$; then a **decoder** $\mathbf{f}_{\boldsymbol{\phi}}$ is used to compute the $\mathbf{h}_t$ feature vectors:

$$\mathbf{h}_t = \mathbf{f}_{\boldsymbol{\phi}}\Big(y_t, \mathbf{h}_{t-1}, \mathbf{g}_{\boldsymbol{\theta}}(\mathbf{x})\Big). \tag{3}$$

$\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ are, respectively, the collections of parameters for the encoder and the decoder, both of which can be implemented as recurrent neural networks (RNNs) such as LSTMs (Hochreiter and Schmidhuber, 1997) or GRUs (Cho et al., 2014), or the transformer (Vaswani et al., 2017). In Sutskever et al. (2014), the dependence of $\mathbf{f}_{\boldsymbol{\phi}}$ on $\mathbf{g}_{\boldsymbol{\theta}}$ is made by using the last hidden state of the encoder as the initial state of the decoder. Such dependence can be further supplemented with attention (Bahdanau et al., 2015) and copy mechanisms (Gu et al., 2016; See et al., 2017), as we will do in this work.

§3 introduces how we use exemplars to inform decoding, by dynamically constructing the decoder's parameters $\boldsymbol{\phi}$. For the notation clarity, we will use the Elman network as a running example, reviewed below.

Elman networks. Given input sequence $\mathbf{x}$, an Elman network (Elman, 1990) computes the hidden state at time step t from the previous one and the current input token by

$$\mathbf{h}_t = \tanh\big(\mathbf{P}\mathbf{h}_{t-1} + \mathbf{Q}\mathbf{v}_t\big), \tag{4}$$

where $\mathbf{P}$ and $\mathbf{Q}$ are learned $d \times d$ parameter matrices (with d being the hidden dimension), and $\mathbf{v}_t$ is the embedding vector for token x_t. We omit the bias term for clarity.

3 Method

This section introduces the proposed method in detail. Our aim is to use exemplars to inform the decoding procedure (i.e., *how to say it*). To accomplish this, we reparameterize the decoder's parameters with weighted linear sums, where the coefficients are determined by an exemplar. The decoder is **adaptive**, in the sense that its parameters vary according to the exemplars. The adaptive decoder can be used as a drop-in replacement in the encoder-decoder architecture. Before going into details, let us first overview the high-level generation procedure of our model. Given source text $\mathbf{x}$, the model generates an output as follows:

1. Run a standard encoder to gather the content representations $\mathbf{g}_{\boldsymbol{\theta}}(\mathbf{x})$ from the source.
2. Retrieve its exemplar $\mathbf{z}_{\mathbf{x}}$, and compute exemplar-specific coefficients (§3.2).
3. Construct the adaptive decoder parameters $\boldsymbol{\phi}$ (§3.1), using the coefficients computed at step 2. Then the output is generated by applying the adaptive decoder followed by a $\operatorname{softmax}$, just as in any other encoder-decoder architecture.

Aiming for a smoother transition, we will first describe step 3 in §3.1, and then go back to discuss step 2 in §3.2. For clarity, we shall assume that the decoder is implemented as an Elman network (Elman, 1990; Equation 4). The proposed technique generalizes to other neural network architectures, as we will discuss later in §3.3.

3.1 Reparameterizing the RNN Decoder

At its core, the exemplar-specific adaptive decoder involves a reparameterization step, which we now describe. We focus on the parameters of the Elman network decoder, i.e., $\mathbf{P}$ and $\mathbf{Q}$ in Equation 4.

Parameter construction with linear sums. We aim to reparameterize the pair of matrices $(\mathbf{P}, \mathbf{Q})$, in a way that they are influenced by the exemplars.

Let us first consider an extreme case, where one assigns a different pair of parameter matrices to each exemplar, *without* any sharing. This leads to an unreasonably large amount of parameters, which are difficult to estimate reliably.[3]

We instead construct $\mathbf{P}$ and $\mathbf{Q}$ from a set of predefined parameters matrices. Take $\mathbf{P}$ for example, it is computed as the weighted sum of $\mathbf{P}_i$ matrices:

$$\mathbf{P} = \sum_{i=1}^{r} \lambda_i \mathbf{P}_i, \tag{5}$$

where $\mathbf{P}_i \in \mathbb{R}^{d\times d}$, with d being the size of the hidden states. r is a hyperparameter, determining the number of $\mathbf{P}_i$ matrices to use.[4] The summation is weighted by the coefficients λ_i, which are computed from the exemplar $\mathbf{z}_{\mathbf{x}}$. For clarity, the dependence of both $\mathbf{P}$ and λ_i on $\mathbf{z}_{\mathbf{x}}$ is suppressed when the context is clear.

Equation 5 constructs the decoder's parameter matrix $\mathbf{P}$ using a linear combination of $\{\mathbf{P}_i\}_{i=1}^{r}$. The exemplar informs this procedure through the coefficients λ_i's, the detailed computation of which is deferred to §3.2. The other matrix $\mathbf{Q}$ can be similarly constructed by $\mathbf{Q} = \sum_i \lambda_i \mathbf{Q}_i$.

Rank-1 constraints. In the above formulation, the number of parameters is still r times more than a standard Elman network, which can lead to overfitting with a limited amount of training data. Besides, it would be more interesting to compare the adaptive decoder to a standard RNN under a comparable parameter budget. Therefore we want to further limit the amount of parameters. This can be achieved by forcing the ranks of $\mathbf{P}_i$ and $\mathbf{Q}_i$ to be 1, since it then takes $2d$ parameters to form each of them, instead of d^2. More formally, we upper-

---

[3] The amount of parameters grows linearly with the number of possible exemplars, which, as we will soon discuss in §3.2, can be as large as the training set.

[4] Instead of choosing r empirically, we set it equal to d in the experiments. Please see the end of §3.1 for a related discussion.

bound their ranks by construction:

$$\mathbf{P}_i = \mathbf{u}_i^{(p)} \otimes \mathbf{v}_i^{(p)}. \tag{6}$$

$\mathbf{a} \otimes \mathbf{b} = \mathbf{a}\mathbf{b}^\top$ denotes the outer product of two vectors; $\mathbf{u}_i^{(p)}$ and $\mathbf{v}_i^{(p)}$ are learned d-dimensional vectors. Each $\mathbf{Q}_i$ can be similarly constructed by a separate set of vectors $\mathbf{Q}_i = \mathbf{u}_i^{(q)} \otimes \mathbf{v}_i^{(q)}$.

Let $\mathbf{U}_p, \mathbf{V}_p \in \mathbb{R}^{d \times r}$ denote the stack of $\mathbf{u}_i^{(p)}$, $\mathbf{v}_i^{(p)}$ vectors, i.e.,

$$\mathbf{U}_p = \left[\mathbf{u}_1^{(p)}, \dots, \mathbf{u}_r^{(p)}\right], \tag{7a}$$

$$\mathbf{V}_p = \left[\mathbf{v}_1^{(p)}, \dots, \mathbf{v}_r^{(p)}\right]. \tag{7b}$$

Equations 5 and 6 can be compactly written as

$$\mathbf{P} = \mathbf{U}_p \, \mathbf{\Lambda} \, \mathbf{V}_p^\top. \tag{8}$$

where $\mathbf{\Lambda}$ is the diagonal matrix built from the r-dimensional coefficient vector $\boldsymbol{\lambda} = [\lambda_1, \dots, \lambda_r]^\top$:

$$\mathbf{\Lambda} = \operatorname{diag}(\boldsymbol{\lambda}) = \begin{bmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_r \end{bmatrix}. \tag{9}$$

The construction of $\mathbf{Q}$ is similar, but with a different set of parameters matrices $\mathbf{U}_q$ and $\mathbf{V}_q$:[5]

$$\mathbf{Q} = \mathbf{U}_q \, \mathbf{\Lambda} \, \mathbf{V}_q^\top. \tag{10}$$

Note that, despite their similarities to SVD at a first glance, Equations 8 and 10 are not performing matrix factorization. Rather, we are learning $\{\mathbf{U}_p, \mathbf{V}_p, \mathbf{U}_q, \mathbf{V}_q\}$ directly; $\mathbf{P}$, $\mathbf{Q}$, $\{\mathbf{P}_i\}$, and $\{\mathbf{Q}_i\}$ are never explicitly instantiated (Peng et al., 2017, 2018c).

To summarize, we reparameterize $\mathbf{P}$ and $\mathbf{Q}$ as interpolations of rank-1 matrices. By the fact that $\operatorname{rank}(\mathbf{A} + \mathbf{B}) \leq \operatorname{rank}(\mathbf{A}) + \operatorname{rank}(\mathbf{B})$, the ranks of $\mathbf{P}$ and $\mathbf{Q}$ are upper-bounded by r. As pointed out by Krueger and Memisevic (2017), the parameter matrices of a trained RNN tend to have full rank. Therefore, in the experiments, we set r equal to the hidden size d, aiming to allow the adaptive decoder to use full-rank matrices in the recurrent computation. Yet, if one holds *a priori* beliefs that the matrices should have lower ranks, using $r < d$ could be desirable. When $r = d$, an adaptive RNN constructed by the above approach has $4d^2$ parameters, which is comparable to the $2d^2$ parameters in a standard Elman network.[6]

3.2 Incorporating Exemplars

We now discuss the computation of coefficients $\boldsymbol{\lambda}$, through which the exemplars inform the decoder construction (Equations 8 and 10). Before detailing the neural network architecture, we begin by describing the exemplar retrieval procedure.

Retrieving exemplars $\mathbf{z}_\mathbf{x}$. Intuitively, similar source texts should hold similar targets. Therefore, given source input $\mathbf{x}$, we use the *training target* as its exemplar $\mathbf{z}_\mathbf{x}$, whose source is most similar to $\mathbf{x}$.[7] To compute the similarities between source texts, we use bag-of-words (BOW) features and cosine similarity. We extract the top-1 exemplar for each instance. This step is part of the preprocessing, and we do *not* change the exemplars as the training proceeds.

There are, of course, many other strategies to get the exemplars, e.g., using handcrafted or heuristically created hard templates (Reiter et al., 2005; Becker, 2002; Foster and White, 2004, *inter alia*), randomly sampling *multiple* training instances (Guu et al., 2018), or learning a neural reranker (Cao et al., 2018a). Using more sophistically extracted exemplars is definitelly interesting to explore, which we defer to future work.

Computing coefficients. Next we describe the computation of $\boldsymbol{\lambda}$, the r-dimensional coefficient vector, which is used to construct the adaptive decoder (Equations 8 and 10).

Intuitively, the rank-1 matrices ($\mathbf{P}_i$'s and $\mathbf{Q}_i$'s in Equation 6 and thereafter) can be seen as capturing different aspects of the generated text. And $\boldsymbol{\lambda}$ determines how much each of them contributes to the adaptive decoder construction. A natural choice to calculate $\boldsymbol{\lambda}$ is to use the similarities between the exemplar and each of the aspects.

To accomplish this, we run a RNN encoder over $\mathbf{z}_\mathbf{x}$, and use the last hidden state as its vector representation $\mathbf{a}$.[8] We further associate each $(\mathbf{P}_i, \mathbf{Q}_i)$ pair with a learned vector $\mathbf{c}_i$; and then λ_i is computed as the similarity between $\mathbf{a}$ and $\mathbf{c}_i$, using an inner product $\lambda_i = \mathbf{a}^\top \mathbf{c}_i$. More compactly,

$$\boldsymbol{\lambda} = \mathbf{C}\mathbf{a}, \tag{11}$$

with $\mathbf{C} = [\mathbf{c}_1, \dots, \mathbf{c}_r]^\top$.

---

[5] The bias term in the Elman network $\mathbf{b}$ can be constructed as $\mathbf{b} = \mathbf{B}\boldsymbol{\lambda}$, with $\mathbf{B}$ being a learned $d \times r$ matrix.

[6] This does not include the bias term, which contributes additional d^2 parameters to the former, and d to the latter.

[7] The source of an exemplar is only used in the retrieval and never fed into the encoder-decoder model. For a training instance, we additionally disallow using its own target as the exemplar.

[8] For clarity, the dependence of $\mathbf{a}$ on the exemplar $\mathbf{z}_\mathbf{x}$ is suppressed, just as $\boldsymbol{\lambda}$.

Algorithm 1 Adaptive decoder construction.

```
procedure $(\mathbf{x})$
    Retrieve the exemplar $\mathbf{z}_\mathbf{x}$                ▷ §3.2
    Compute $\mathbf{z}_\mathbf{x}$'s representation $\mathbf{a}$      ▷ §3.2
    Compute coefficients $\boldsymbol{\lambda}$                 ▷ Eq.11
    Construct the decoder $\mathbf{f}_\phi$             ▷ Eqs.8, 10
end procedure
```

Closing this section, Algorithm 1 summarizes the procedure to construct an adaptive decoder.

3.3 Discussion.

Although we've based our discussion on Elman networks so far, it is straightforward to apply this method to its gated variants (Hochreiter and Schmidhuber, 1997; Cho et al., 2014, *inter alia*), and other quasi-/non-recurrent neural architectures (Bradbury et al., 2017; Vaswani et al., 2017; Peng et al., 2018a, *inter alia*). Throughout the experiments, we will be using an adaptive LSTM decoder (§4). As a drop-in replacement in the encoder-decoder architecture, it introduces a reasonable amount of additional parameters and computational overhead, especially when one uses a small encoder for the exemplar (i.e., the sizes of the $\mathbf{c}_i$ vectors in Equation 11 are small). It can benefit from the highly-optimized GPU implementations, e.g., CuDNN, since it uses the same recurrent computation as a standard nonadaptive RNN.

In addition to the neural networks, the adaptive decoder requires access to the full training set due to the retrieval step. In this sense it is *semi-parametric*.[9] The idea to dynamically construct the parameters is inspired by Hypernetworks (Ha et al., 2017) and earlier works therein. It proves successful in tasks such as classification (Jia et al., 2016; Liu et al., 2017) and machine translation (Platanios et al., 2018). Many recent template-based generation models include the exemplars as *content* in addition to the source, and allow the decoder to attend over and copy from both (Gu et al., 2018; Guu et al., 2018; Weston et al., 2018; Pandey et al., 2018; Cao et al., 2018a, *inter alia*). We compare to this approach in the experiments, and show that our model offers favorable performance, and that they can potentially be combined to achieve further improvements.

4 Experiments

This section empirically evaluates the proposed model on two sets of text generation tasks: abstractive summarization (§4.2) and data-to-text generation (§4.3). Before heading into the experimental details, we first describe the architectures of the compared models in §4.1.

4.1 Compared Models

In addition to previous works, we compare to the following baselines, aiming to control for confounding factors due to detailed implementation choices.

- SEQ2SEQ. The encoder-decoder architecture enhanced with attention and copy mechanisms. The encoder is implemented with a bi-directional LSTM (BiLSTM; Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997; Graves, 2012), and the decoder a uni-directional one. We tie the input embeddings of both the encoder and the decoder, as well as the $\mathrm{softmax}$ weights (Press and Wolf, 2017). We use beam search during evaluation, with length penalty (Wu et al., 2016).
- ATTEXP. It is based on SEQ2SEQ. It encodes, attends over, and copies from the exemplars, in addition to the source inputs.

Our model using the adaptive decoder (ADADEC) closely builds upon SEQ2SEQ. It uses a dynamically constructed LSTM decoder, and *does not* use attention or copy mechanisms over the encoded exemplars. The extracted exemplars are the same as those used by ATTEXP. To ensure fair comparisons, we use comparable training procedures and regularization techniques for the above models. The readers are referred to the appendix for further details such as hyperparameters.

---

[9] Nothing prohibits adaptively constructing other components of the model, e.g., the encoder $\mathbf{g}_\theta$. Yet, our motivation is to use exemplars to inform *how to say it*, which is primarily determined by the decoder (in contrast, the encoder relates more to selecting the content).

4.2 Text Summarization

Datasets. We empirically evaluate our model on two benchmark text summarization datasets:

- Annotated Gigaword corpus (Gigaword; Graff et al., 2003; Napoles et al., 2012). Gigaword contains news articles sourced from various news services over the last two decades. To produce the dataset, we follow the split and preprocessing by Rush et al. (2015), and pair the first sentences and the headlines in the news articles. It results in a 3.8M/190K/1,951 train/dev./test split. The average lengths of the source and target texts are 31.4 and 8.2, respectively.
- New York Times Annotated Corpus (NYT; Sandaus, 2008). It contains news articles published between 1996 and 2007 by New York Times. We use the split and preprocessing by Durrett et al. (2016).[10] Following their effort, we evaluate on a smaller portion of the test set, where the gold summaries are longer than 50 tokens. We further randomly sample 9,000 instances from the training data for validation, resulting in a 91,834/9,000/3,452 train/dev./test split. Compared to Gigaword, the inputs and targets in NYT are much longer (averaging 939.0 and 48.6, respectively).

Table 1 summarizes some statistics of the datasets. We note that some recent works use a different split of the NYT corpus (Paulus et al., 2018; Gehrmann et al., 2018), and thus are not comparable to the models in Table 3. We decide to use the one by Durrett et al. (2016) because their preprocessing script is publicly available.

For both datasets, we apply byte-paired encoding (BPE; Sennrich et al., 2016), which proves to improve the generation of proper nouns (Fan et al., 2018).

Empirical results. Table 2 compares the models on Gigaword test set in ROUGE F_1 (Lin, 2004).[11]

Model	RG-1	RG-2	RG-L
Open-NMT	35.0	16.6	32.4
†Cao et al., 2018a (BASIC)	36.0	17.1	33.2
†Cao et al., 2018a (FULL)	37.0	**19.0**	34.5
⋆Cao et al. (2018b)	**37.3**	17.6	34.2
This work (SEQ2SEQ)	35.8	17.5	33.5
†This work (ATTEXP)	36.0	17.7	33.1
†This work (ADADEC)	**37.3**	18.5	**34.7**

Table 2: Text summarization performance in ROUGE F_1 scores (dubbed as RG-X) on Gigaword test set (§4.2). † denotes the models using retrieved exemplars, while ⋆ uses handcrafted features. Bold font indicates best performance. Open-NMT numbers are taken from Cao et al. (2018a).

By using adaptive decoders, our model (ADADEC) improves over SEQ2SEQ by more than 1.1 ROUGE scores. Cao et al. (2018b) and the FULL model by Cao et al. (2018a) hold the best published results. The former uses extensive handcrafted features and relies on external information extraction and syntactic parsing systems; while the latter uses additional encoding, attention and copy mechanisms over the exemplars extracted using a novel neural reranker. ADADEC achieves better or comparable performance to the state-of-the-art models, *without* using any handcrafted features or reranking techniques. The BASIC model by Cao et al. (2018a) ablates the reranking component from their FULL model, and uses the top exemplar retrieved by the IR system. Therefore it is a more comparable baseline to ours. ADADEC outperforms it by more than 1.3 ROUGE scores. Surprisingly, we do not observe interesting improvements by ATTEXP over the sequence-to-sequence baseline. We believe that our model can benefit from better extracted exemplars by, e.g., applying a reranking system. Such exploration is deferred to future work.

The NYT experimental results are summarized in Table 3. We follow previous works and report limited-length ROUGE *recall* values.[12] Durrett et al. (2016) is an extractive model, and Paulus et al. (2018) an abstractive approach based on reinforcement learning. Our ADADEC model outperforms both. We observe similar trends when comparing ADADEC to the SEQ2SEQ and ATTEXP baselines, with the exception that ATTEXP *does* improve over SEQ2SEQ.

4.3 Data-to-text Generation

Data-to-text generation aims to generate textual descriptions of structured data, which can be

---

[10] `https://github.com/gregdurrett/berkeley-doc-summarizer`.

[11] Version 1.5.5 of the official script.

[12] Following Durrett et al. (2016) and Paulus et al. (2018), we truncate the predictions to the lengths of the gold summaries, and evaluate ROUGE recall, instead of F_1 on full-length predictions.

Model	**ROUGE-1**	**ROUGE-2**
Durrett et al. (2016)	42.2	24.9
Paulus et al. (2018)	42.9	26.0
This work (SEQ2SEQ)	41.9	25.1
†This work (ATTEXP)	42.5	25.7
†This work (ADADEC)	**43.2**	**26.4**

Table 3: NYT text summarization test performance in ROUGE *recall* values. This is a smaller portion of the original test data, after filtering out instances with summaries shorter than 50 tokens (§4.2; Durrett et al., 2016). † denotes the models using retrieved exemplars, and bold font indicates best performance.

seen as a table consisting of a collection of records (Liang et al., 2009). For a given entity, each record is an *(attribute, value)* tuple. Figure 2 shows an example for entity *Jacques-Louis David*. The table specifies the entity's properties with tuples *(born, 30 August 1748)*, *(nationality, French)*, and so forth. The table is paired with a description, which the model is supposed to generate using the table as input. We refer the readers to Lebret et al. (2016) for more details about the task.

Dataset and implementation details. We use the Wikibio dataset (Lebret et al., 2016). It is automatically constructed by pairing the tables and the opening sentences of biography articles from English Wikipedia. We follow the split and preprocessing provided along with the dataset, with around 583K/73K/73K train/dev./test instances. Following Lebret et al. (2016), we linearize the tables, such that we can conveniently train the sequence-to-sequence style models described in §4.1. Table 1 summarizes some statistics of the dataset.

In contrast to the text summarization experiment (§4.2), we do *not* apply BPE here. Further, the word embeddings are initialized with `GloVe` (Pennington et al., 2014; fixed during training), and *not* tied with the softmax weights. In addition to the models introduced in §4.1, we additionally compare to ADADEC+ATTEXP, aiming to study whether the adaptive decoder can further benefit from attention and copy mechanisms over the exemplars.

Jacques-Louis David

Born	30 August 1748 Paris, Kingdom of France
Died	29 December 1825 (aged 77) Brussels, United Netherlands
Nationality	French
Alma mater	Collège des Quatre-Nations, University of Paris
Known for	Painting, Drawing
Notable work	*Oath of the Horatii* (1784), *The Death of Marat* (1793)
Movement	Neoclassicism
Awards	Prix de Rome Commander of the Legion of Honour

Jacques-Louis David (30 August 1748 – 29 December 1825) was a French painter in the Neoclassical style.

Figure 2: A training instance from the Wikibio dataset. It consists of a collections of records for Jacques-Louis David (top), and a piece of textual description (bottom).

Empirical results. Following Liu et al. (2018) we report ROUGE-4 and BLEU scores (Papineni et al., 2002).[13] Table 4 summarizes the data-to-text generation results on the Wikibio test set. Overall, we observe similar trends to those in the summarization experiment (§4.2): by attending over and copying from the exemplars, ATTEXP improves upon the SEQ2SEQ baseline by around 0.6 absolute scores. Also utilizing exemplar information, our ADADEC model outperforms SEQ2SEQ by a larger margin: 1.3 for ROUGE-4 and 1.1 for BLEU. We further study whether we can get further improvements by combining both. ADADEC+ATTEXP achieves around 0.5 absolute improvements over ADADEC, less than those by ATTEXP over SEQ2SEQ. This provides evidence that, to some extend, the ways ATTEXP and ADADEC incorporate exemplar information might be complementary. Wiseman et al. (2018) is a template-motivated model based on a semi-Markov model. Liu et al. (2018) hold the current state-of-the-art results. They encode the table structures by using (a) position and filed embeddings, and (b) structure-aware attention and gating techniques. These techniques are beyond the scope of this work, which focuses mainly on the decoding end.

---

[13] We use the script by Lin (2004) to calculate the ROUGE score, and the mteval script for BLEU: `https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/mteval-v13a.pl`.

Figure 3: Two randomly sampled Gigaword development instances used for qualitative evaluation (§5). `Exemplar 1`'s are retrieved by the system (§3.2), while the remaining ones are produced by the authors. Notable exemplars changes are highlighted in **bold purple**, and output changes in *italic yellow*.

5 Analysis

We now qualitatively evaluate our model, by studying how its outputs are affected by using different exemplars. Figure 3 shows two randomly sampled Gigaword development instances. It compares the outputs by AdaDec (i.e., without attention/copy over exemplars; §4.1) when receiving different exemplars, controlling for the same source inputs. In each example, `Exemplar 1` is retrieved by the system (i.e., a training target; §3.2); while the remaining ones are produced by the authors, by modifying the first one in styles and sometimes introducing distractions in the content.

In the top example, the model includes *people* into the subject (*Three* vs. *Three people*) under the influence by `Exemplar 2`; `Exemplar 3` changes the tense and adds some distraction by changing the place from *Britain* to *Canada*. The model follows the tense switch, but gets confused by the distraction, and decides to let a train in southern Europe collide into North America, which it should not. Looking at the bottom example, the model in general follows the exemplar in using noun adjuncts or prepositional phrases (e.g., *new home sales* vs. *sales of new homes*), except the first one. Perhaps confused by the distraction in `Exemplar 3`, the model makes a judgment on the specific amount of growth, but gets it wrong.

6 Related Work

Exemplar-based generation. Partly inspired by traditional template-based generation (Kukich, 1983; Reiter and Dale, 1997, *inter alia*), many recent efforts have been devoted to augmenting text generation models with retrieved exemplars (Hodosh et al., 2013; Mason and Charniak, 2014; Song et al., 2016; Lin et al., 2017, *inter alia*). Without committing to an explicit slot-filling process, a typical method is to include exemplars as additional inputs to the sequence-to-sequence models (Gu et al., 2018; Pandey et al., 2018; Guu et al., 2018, *inter alia*). Wiseman et al. (2018) took a different approach and used a semi-Markov model to learn templates.

Dynamic parameter construction. The idea of using a smaller network to generate weights for a larger one dues back to Stanley et al. (2009) and Koutnik et al. (2010), mainly under the evolution computing context. It is later revisited with representation learning (Moczulski et al., 2015; Fernando et al., 2016; Al-Shedivat et al., 2017, *inter alia*), and successfully applied to classification (Jia et al., 2016; Liu et al., 2017) and machine translation (Platanios et al., 2018). It also relates to the meta-learning set-up (Thrun and Pratt, 1998).

7 Conclusion

We presented a text generation model using exemplar-informed adaptive decoding. It reparameterizes the decoder using the information gathered from retrieved exemplars. We experimented with text summarization and data-to-text generation, and showed that the proposed model achieves strong performance and outperforms comparable baselines on both. The proposed model can be applicable in other conditioned text generation tasks. We release our implementation at `https://homes.cs.washington.edu/~hapeng`.

Guiding Extractive Summarization with Question-Answering Rewards

Kristjan Arumae and **Fei Liu**
Computer Science Department
University of Central Florida, Orlando, FL 32816, USA
k.arumae@knights.ucf.edu feiliu@cs.ucf.edu

Abstract

Highlighting while reading is a natural behavior for people to track salient content of a document. It would be desirable to teach an extractive summarizer to do the same. However, a major obstacle to the development of a supervised summarizer is the lack of ground-truth. Manual annotation of extraction units is cost-prohibitive, whereas acquiring labels by automatically aligning human abstracts and source documents can yield inferior results. In this paper we describe a novel framework to guide a supervised, extractive summarization system with question-answering rewards. We argue that quality summaries should serve as a document surrogate to answer important questions, and such question-answer pairs can be conveniently obtained from human abstracts. The system learns to promote summaries that are informative, fluent, and perform competitively on question-answering. Our results compare favorably with those reported by strong summarization baselines as evaluated by automatic metrics and human assessors.

1 Introduction

Our increasingly digitized lifestyle calls for summarization techniques to produce short and accurate summaries that can be accessed at any time. These summaries should factually adhere to the content of the source text and present the reader with the key points therein. Although neural abstractive summarization has shown promising results (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017), these methods can have potential drawbacks. It was revealed that abstracts generated by neural systems sometimes alter or falsify objective details, and introduce new meanings not present in the original text (Cao et al., 2018). Reading these abstracts can lead to misinterpretation of the source materials, which is clearly undesirable. In this work, we focus on extractive summarization, where the summaries are guaranteed to remain faithful to the original content. Our system seeks to identify *salient and consecutive sequences of words* from the source document, and highlight them in the text to assist users in browsing and comprehending lengthy documents. An example is illustrated in Table 1.

Former TSA agent sentenced to six months in jail for restroom recording

(CNN) **A judge this week sentenced a former TSA agent to six months in jail for secretly videotaping a female co-worker** while she was in the bathroom, prosecutors said.

During the investigation, detectives with **the Metro Nashville Police Department in Tennessee** also found that the agent, 33-year-old Daniel Boykin, entered **the woman's** home multiple times, where he took videos, photos and other data.

Police found **more than 90 videos and 1,500 photos of the victim** on Boykin's phone and computer.

The victim filed a complaint after seeing images of herself on his phone last year. [...]

Comprehension Questions (Human Abstract):

Former ______ Daniel Boykin, 33, videotaped his female co-worker in the restroom, authorities say.

Authorities say they found 90 videos and 1,500 photos of the victim on ______ and computer.

Table 1: An example extractive summary bolded in the article (top). Highlighted sections indicate salient segments useful for answering fill-in-the-blank questions generated from human abstracts (bottom).

A primary challenge faced by extractive summarizers is the lack of annotated data. The cost of hiring humans to label a necessary amount of source articles with summary words, good for training a modern classifier, can be prohibitive. Previous work has exploited using human abstracts to derive labels for extraction units (Woodsend and Lapata, 2010). E.g., a source word is tagged 1 if it appears in the abstract, 0 otherwise. Although pairs of source articles and human abstracts are abundant, labels derived in this way are not necessarily best since summary saliency can not be easily captured with a rule based categorization. Considering that human abstracts involve generalization, paraphrasing, and can con-

Proceedings of NAACL-HLT 2019, pages 2566–2577
Minneapolis, Minnesota, June 2 - June 7, 2019.

tain words not present in the source text, leveraging them to derive labels for extraction units can be suboptimal. In this work, we investigate a new strategy that seeks to better utilize human abstracts to guide the extraction of summary text units.

We hypothesize that quality extractive summaries should contain informative content so that they can be used as document surrogates to answer important questions, thereby satisfying users' information needs. The question-answer pairs can be conveniently developed from human abstracts. Our proposed approach identifies answer tokens from each sentence of the human abstract, then replaces each answer token with a blank to create a Cloze-style question-answer pair. To answer *all* questions ($\approx$human abstract), the system summary must contain content that is semantically close to and collectively resembles the human abstract.

In this paper, we construct an extractive summary by selecting consecutive word sequences from the source document. To accomplish this we utilize a novel reinforcement learning framework to explore the space of possible extractive summaries and assess each summary using a novel reward function judging the summary's adequacy, fluency, length, and its competency to answer important questions. The system learns to sample extractive summaries yielding the highest expected rewards, with no pre-derived extraction labels needed. This work extends the methodology of Arumae and Liu (2018) with new representations of extraction units and thorough experimental evaluation. The contributions of this research can be summarized as follows:

- we describe a novel framework generating extractive summaries by selecting consecutive sequences of words from source documents. This new system explores various encoding mechanisms, as well as new sampling techniques to capture phrase level data. Such a framework has not been thoroughly investigated in the past;

- We conduct a methodical empirical evaluation from the point of view of information saliency. Rather than solely relying on automatic summarization evaluation methods, we also show the advantages of our system by assessing the summary quality with reading comprehension tasks. Our summaries compare favorably with the automatic metrics against state of the art, and show promising results against baselines when evaluated by humans for question answering.

2 Related Work

Extractive summarization has seen growing popularity in the past decades (Nenkova and McKeown, 2011). The methods focus on selecting representative sentences from the document(s) and optionally deleting unimportant sentence constituents to form a summary (Knight and Marcu, 2002; Radev et al., 2004; Zajic et al., 2007; Martins and Smith, 2009; Gillick and Favre, 2009; Lin and Bilmes, 2010; Wang et al., 2013; Li et al., 2013, 2014; Hong et al., 2014; Yogatama et al., 2015). A majority of the methods are unsupervised. They estimate sentence importance based on the sentence's length and position in the document, whether the sentence contains topical content and its relationship with other sentences. The summarization objective is to select a handful of sentences to maximize the coverage of important content while minimizing summary redundancy. Although unsupervised methods are promising, they cannot benefit from the large-scale training data harvested from the Web (Sandhaus, 2008; Hermann et al., 2015; Grusky et al., 2018).

Neural extractive summarization has focused primarily on extracting sentences (Nallapati et al., 2017; Cao et al., 2017; Isonuma et al., 2017; Tarnpradab et al., 2017; Zhou et al., 2018; Kedzie et al., 2018). These studies exploit parallel training data consisting of source articles and story highlights (i.e., human abstracts) to create ground-truth labels for sentences. A neural extractive summarizer learns to predict a binary label for each source sentence indicating if it is to be included in the summary. These studies build distributed sentence representations using neural networks (Cheng and Lapata, 2016; Yasunaga et al., 2017) and use reinforcement learning to optimize the evaluation metric (Narayan et al., 2018b) and improve summary coherence (Wu and Hu, 2018). However, sentence extraction can be coarse and in many cases, only a part of the sentence is worthy to be added to the summary. In this study, we perform finer-grained extractive summarization by allowing the system to select consecutive sequences of words rather than sentences to form a summary.

Interestingly, studies reveal that summaries generated by recent neural abstractive systems are, in fact, quite "extractive." Abstractive systems often adopt the encoder-decoder architecture with an attention mechanism (Rush et al., 2015; Nallapati et al., 2016; Paulus et al., 2017; Guo et al., 2018; Gehrmann et al., 2018; Lebanoff et al., 2018; Celikyilmaz et al., 2018). The encoder condenses a source sequence to a fixed-length vector and the decoder takes the vector as input and generates a summary by predicting one word at a time. See, Liu, and Manning (2017) suggest that about 35% of the summary sentences occur in the source documents, and 90% of summary n-grams appear in the source. Moreover, the summaries may contain inaccurate factual details and introduce new meanings not present in the original text (Cao et al., 2018; Song et al., 2018). It thus raises concerns as to whether such systems can be used in real-world scenarios to summarize materials such as legal documents. In this work, we choose to focus on extractive summarization where selected word sequences can be highlighted on the source text to avoid change of meaning.

Our proposed method is inspired by the work of Lei et al. (2016) who seek to identify rationales from textual input to support sentiment classification and question retrieval. Distinct from this previous work, we focus on generating generic document summaries. We present a novel supervised framework encouraging the selection of consecutive sequences of words to form an extractive summary. Further, we leverage reinforcement learning to explore the space of possible extractive summaries and promote those that are fluent, adequate, and competent in question answering. We seek to test the hypothesis that successful summaries can serve as document surrogates to answer important questions, and moreover, ground-truth question-answer pairs can be derived from human abstracts. In the following section we describe our proposed approach in details.

3 Our Approach

Let $\mathcal{S}$ be an extractive summary consisting of text segments selected from a source document $\mathbf{x}$. The summary can be mapped to a sequence of binary labels $\mathbf{y}$ assigned to document words. In this section we first present a supervised framework for identifying *consecutive sequences of words* that are summary-worthy, then proceed by describing our question-answering rewards and a deep reinforcement learning framework to guide the selection of summaries so that they can be used as document surrogates to answer important questions.[1]

3.1 Representing an Extraction Unit

How best to decompose a source document into a set of text units useful for extractive summarization remains an open problem. A natural choice is to use words as extraction units. However, this choice ignores the cohesiveness of text. A text chunk (e.g., a prepositional phrase) can be either selected to the summary in its entirety or not at all. In this paper we experiment with both schemes, using either *words* or *chunks* as extraction units. When a text chunk is selected in the summary, all its consisting words are selected. We obtain text chunks by breaking down the sentence constituent parse tree in a top-down manner until each tree fragment governs at most 5 words. A chunk thus can contain from 1 to 5 words. Additionally, word level modeling can be considered a special case of chunks where the length of each phrase is 1. It is important to note that using sentences as extraction units is out of the scope of this paper, because our work focuses on finer-grained extraction units such as words and phrases and this is notably a more challenging task.

The most successful neural models for encoding a piece of text to a fixed-length vector include the recurrent (Hochreiter and Schmidhuber, 1997) and convolutional neural networks (CNN; Kim et al., 2014), among others. A recent study by Khandelwal et al. (2018) reported that the recurrent networks are capable of memorizing a recent context of about 20 tokens and the model is highly sensitive to word order, whereas this is less the case for CNN whose max-pooling operation makes it agnostic to word order. We implement both networks and are curious to compare their effectiveness at encoding extraction units for summarization.

$$\{\mathbf{h}_t^e\} = f_1^{\text{Bi-LSTM}}(\mathbf{x}) \quad (1)$$

$$\text{or} \quad \{\mathbf{h}_t^e\} = f_2^{\text{CNN}}(\mathbf{x}) \quad (2)$$

Our model first encodes the source document using a bidirectional LSTM with the forward and backward passes (Eq. (1)). The representation of the t-th source word $\mathbf{h}_t^e = [\overleftarrow{\mathbf{h}}_t^e || \overrightarrow{\mathbf{h}}_t^e]$ is the concatenation of the hidden states in both directions. A chunk is similarly denoted by $\mathbf{h}_t^e = [\overleftarrow{\mathbf{h}}_t^e || \overrightarrow{\mathbf{h}}_{t+n}^e]$ where t and $t+n$ are the indices of its beginning and ending words. In both cases, a fixed-length vector ($\mathbf{h}_t^e \in \mathbb{R}^m$) is created for the word/chunk. Further, our CNN encoder (Eq. (2)) uses a sliding window of {1,3,5,7} words, corresponding to the kernel sizes, to scan through the source document. We apply a number of filters to each window size

---

[1] We have made our code and models available at `https://github.com/ucfnlp/summ_qa_rewards`

to extract local features. The t-th source word is represented by the concatenation of feature maps (an m-dimensional vector). To obtain the chunk vector we perform max-pooling over the representations of its consisting words (from t to $t+n$). In the following we use $\mathbf{h}^e_t$ to denote the vector representation of the t-th extraction unit, may it be a word or a chunk, generated using either encoder.

3.2 Constructing an Extractive Summary

It is desirable to first develop a supervised framework for identifying summary-worthy text segments from a source article. These segments collectively form an extractive summary to be highlighted on the source text. The task can be formulated as a sequence labeling problem: a source text unit (a word or chunk) is labelled 1 if it is to be included in the summary and 0 otherwise. It is not unusual to develop an auto-regressive model to perform sequence labeling, where the label of the t-th extraction unit (y_t) depends on all previous labels ($\mathbf{y}_{<t}$). Given this hypothesis, we build a framework to extract summary units where the importance of the t-th source unit is characterized by its informativeness (encoded in $\mathbf{h}^e_t$), its position in the document, and relationship with the partial summary. The details are presented below.

We use a positional embedding ($\mathbf{g}_t$) to signify the position of the t-th text unit in the source document. The position corresponds to the index of the source sentence containing the t-th unit, and further, all text units belonging to the same sentence share the same positional embedding. We apply sinusoidal initialization to the embeddings, following Vaswani et al. (2017). Importantly, positional embeddings allow us to inject macro-positional knowledge about words/chunks into a neural summarization framework to offset the natural bias that humans tend to have on putting important content at the beginning of an article.

Next, we build a representation for the partial summary to aid the system in selecting future text units. The representation $\mathbf{s}_t$ is expected to encode the extraction decisions up to time t-1 and it can be realized using a unidirectional LSTM network (Eq. (3)). The t-th input to the network is represented as $y_{t-1} \otimes \mathbf{h}^e_{t-1}$ where y_{t-1} is a binary label serving as a gating mechanism to control if the semantic content of the previous text unit ($\mathbf{h}^e_{t-1}$) is to be included in the summary ("$\otimes$" corresponds to elementwise product). During training, we apply teacher forcing and y_{t-1} is the ground-truth extraction label for the $(t-1)$-th unit; at test time, y_{t-1} is generated on-the-fly by obtaining the label yielding the highest probability according to Eq. (5). In the previous work of Cheng and Lapata (2016) and Nallapati et al. (2017), similar auto-regressive models are developed to identify summary sentences. Different from the previous work, this study focuses on extracting consecutive sequences of words and chunks from the source document, and the partial summary representation is particularly useful for predicting if the next unit is to be included in the summary to improve summary fluency.

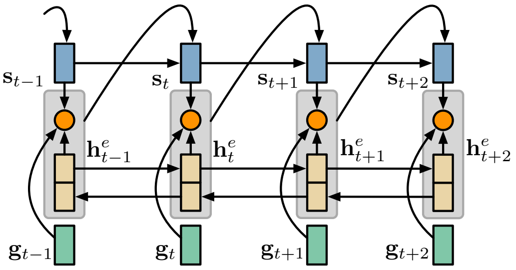

Figure 1: A unidirectional LSTM (blue, Eq. (3)) encodes the partial summary, while the multilayer perceptron network (orange, Eq. (4-5)) utilizes the text unit representation ($\mathbf{h}^e_t$), its positional embedding ($\mathbf{g}_t$), and the partial summary representation ($\mathbf{s}_t$) to determine if the t-th text unit is to be included in the summary. Best viewed in color.

$$\mathbf{s}_t = f_3^{\text{Uni-LSTM}}(\mathbf{s}_{t-1}, y_{t-1} \otimes \mathbf{h}^e_{t-1}) \quad (3)$$

Given the partial summary representation ($\mathbf{s}_t$), and representation of the text unit ($\mathbf{h}^e_t$) and its positional encoding ($\mathbf{g}_t$), we employ a multilayer perceptron to predict how likely the unit is to be included in the summary. This process is described by Eqs. (4-5) and further illustrated in Figure 1.

$$\mathbf{a}_t = f^{\text{ReLU}}(\mathbf{W}^a[\mathbf{h}^e_t; \mathbf{g}_t; \mathbf{s}_t] + \mathbf{b}^a) \quad (4)$$
$$p(y_t|\mathbf{y}_{<t}, \mathbf{x}) = \sigma(\mathbf{w}^y \mathbf{a}_t + b^y) \quad (5)$$

Our model parameters include $\{\mathbf{W}^a, \mathbf{b}^a, \mathbf{w}^y, b^y\}$ along with those required by $f_1^{\text{Bi-LSTM}}$, f_2^{CNN} and $f_3^{\text{Uni-LSTM}}$. It is possible to train this model in a fully supervised fashion by minimizing the negative log-likelihood of the training data. We generate ground-truth labels for source text units as follows. A source *word* receives a label of 1 if both itself and its adjacent word appear in the human abstract (excluding cases where both words are stopwords). This heuristic aims to label consecutive source words (2 or more) as summary-worthy, as opposed to picking single words which can be less informative. A source *text chunk* receives a label of 1 if one of its component words is labelled 1 in the above process.

Because human abstracts are often short and contain novel words not present in source documents, they can be suboptimal for generating ground-truth labels for extraction units. Only a small portion of the source words (about 8% in our dataset) are labelled as positive, whereas the vast majority are negative. Such labels can be ineffective in providing supervision. In the following section, we investigate a new learning paradigm, which encourages extractive summaries to contain informative content useful for answering important questions, while question-answer pairs can be automatically derived from human abstracts.

3.3 Using Summaries to Answer Questions

Our hypothesis is that high-quality summaries should contain informative content making them appropriate to serve as document surrogates to satisfy users' information needs. We train the extractive summarizer to identify source text units necessary for answering questions, and the question-answer (QA) pairs can be conveniently developed from human abstracts.

To obtain QA pairs, we set an answer token to be either a salient word or a named entity to limit the space of potential answers. For any sentence in the human abstract, we identify an answer token from it, then replace the answer token with a blank to create a Cloze-style question-answer pair (see Table 1). When a sentence contains multiple answer tokens, a set of QA pairs can be obtained from it. It is important to note that at least one QA pair should be extracted from each sentence of the abstract. Because a system summary is trained to contain content useful for answering *all* questions ($\approx$human abstract), any missing QA pair is likely to cause the summary to be insufficient.

We collect answer tokens using the following methods: (a) we extract a set of entities with tag {PER, LOC, ORG, MISC} from each sentence using the Stanford CoreNLP toolkit (Manning et al., 2014); (b) we also identify the ROOT word of each sentence's dependency parse tree along with the sentence's subject/object word, whose type is {NSUBJ, CSUBJ, OBJ, IOBJ} (if exists), then add them to the collection of answer tokens. Further, we prune the answer space by excluding those which appear fewer than 5 times overall. Having several methods for question construction allows us to explore the answer space properly. In the results section we perform experiments on root, subject/object, and named entities to see which model provides the best extraction guide.

Given an extractive summary $\mathcal{S}$ containing a set of source text units, and a collection of question-answer pairs $\mathcal{P} = \{(Q_k, e_k^*)\}_{k=1}^K$ related to the source document, we want to develop a mechanism leveraging the extractive summary to answer these questions. We first encode each question Q_k to a vector representation ($\mathbf{q}_k$). This is achieved by concatenating the last hidden states of the forward/backward passes of a bidirectional LSTM (Eq. (6)). Next, we exploit the attention mechanism to locate summary parts that are relevant to answering the k-th question. Given the attention mechanism, an extractive summary $\mathcal{S}$ can be used to answer multiple questions related to the document. We define $\alpha_{t,k}$ to be the semantic relatedness between the t-th source text unit and the k-th question. Following Chen et al. (2016a), we introduce a bilinear term to characterize their relationship ($\alpha_{t,k} \propto \mathbf{h}_t^e \mathbf{W}^\alpha \mathbf{q}_k$; see Eq. (7)). In this process, we consider only those source text units selected in summary $\mathcal{S}$. Using $\alpha_{t,k}$ as weights, we then compute a context vector $\mathbf{c}_k$ condensing summary content related to the k-th question (Eq. (8)).

$$\mathbf{q}_k = f_4^{\text{Bi-LSTM}}(Q_k) \tag{6}$$

$$\alpha_{t,k} = \frac{\exp(\mathbf{h}_t^e \mathbf{W}^\alpha \mathbf{q}_k)}{\sum_t \exp(\mathbf{h}_t^e \mathbf{W}^\alpha \mathbf{q}_k)} \tag{7}$$

$$\mathbf{c}_k = \textstyle\sum_t \alpha_{t,k} \mathbf{h}_t^e \tag{8}$$

$$\mathbf{u}_k = [\mathbf{c}_k; \mathbf{q}_k; |\mathbf{c}_k - \mathbf{q}_k|; \mathbf{c}_k \otimes \mathbf{q}_k] \tag{9}$$

To predict the most probable answer, we construct a fully-connected network as the output layer. The input to the network includes a concatenation of the context vector ($\mathbf{c}_k$), question vector ($\mathbf{q}_k$), absolute difference ($|\mathbf{c}_k - \mathbf{q}_k|$) and element-wise product ($\mathbf{c}_k \otimes \mathbf{q}_k$) of the two vectors (Eq. (9)). A softmax function is used to estimate a probability distribution over the space of candidate answers:

$$P(e_k|\mathcal{S}, Q_k) = \text{softmax}(\mathbf{W}^e f^{\text{ReLU}}(\mathbf{W}^u \mathbf{u}_k + \mathbf{b}^u)).$$

Such a fully-connected output layer has achieved success on natural language inference (Mou et al., 2016; Chen et al., 2018); here we test its efficacy on answer selection. The model parameters include $\{\mathbf{W}^\alpha, \mathbf{W}^e, \mathbf{W}^u, \mathbf{b}^u\}$ and those of $f_4^{\text{Bi-LSTM}}$.

3.4 A Reinforcement Learning Framework

In this section we introduce a reinforcement learning framework to explore the space of possible extractive summaries and present a novel reward function to promote summaries that are adequate, fluent, restricted in length, and competent in question answering. Our reward function consists of four components, whose interpolation weights γ, α, and β are tuned on the dev set.

$$\mathcal{R}(\mathbf{y}) = \mathcal{R}_c(\mathbf{y}) + \gamma\mathcal{R}_a(\mathbf{y}) + \alpha\mathcal{R}_f(\mathbf{y}) + \beta\mathcal{R}_l(\mathbf{y})$$

We define *QA competency* (Eq. (10)) as the average log-likelihood of correctly answering questions using the system summary ($\mathbf{y}$). A high-quality system summary is expected to resemble reference summary by using similar wording. The *adequacy* metric (Eq. (11)) measures the percentage of overlapping unigrams between the system ($\mathbf{y}$) and reference summary ($\mathbf{y}^*$). The *fluency* criterion (Eq. (12)) encourages consecutive sequences of source words to be selected by preventing many 0/1 switches in the label sequence (i.e., $|y_t - y_{t-1}|$). Finally, we limit the summary size by setting the ratio of selected words to be close to a threshold δ (Eq. (13)).

$$\text{QA} \quad \mathcal{R}_c(\mathbf{y}) = \frac{1}{K}\sum_{k=1}^{K} \log P(e_k^* | \mathbf{y}, Q_k) \quad (10)$$

$$\text{Adequ.} \quad \mathcal{R}_a(\mathbf{y}) = \frac{1}{|\mathbf{y}^*|}\mathcal{U}(\mathbf{y}, \mathbf{y}^*) \quad (11)$$

$$\text{Fluency} \quad \mathcal{R}_f(\mathbf{y}) = -\sum_{t=2}^{|\mathbf{y}|} |y_t - y_{t-1}| \quad (12)$$

$$\text{Length} \quad \mathcal{R}_l(\mathbf{y}) = -\left|\frac{1}{|\mathbf{y}|}\sum_t y_t - \delta\right| \quad (13)$$

The reward function $\mathcal{R}(\mathbf{y})$ successfully combines intrinsic measures of summary fluency and adequacy (Goldstein et al., 2005) with extrinsic measure of summary responsiveness to given questions (Dang, 2006; Murray et al., 2008). A reinforcement learning agent finds a policy $P(\mathbf{y}|\mathbf{x})$ to maximize the expected reward $\mathbb{E}_{P(\mathbf{y}|\mathbf{x})}[\mathcal{R}(\mathbf{y})]$. Training the system with policy gradient (Eq. (14)) involves repeatedly sampling an extractive summary $\hat{\mathbf{y}}$ from the source document $\mathbf{x}$. At time t, the agent takes an action by sampling a decision based on $p(y_t|\hat{\mathbf{y}}_{<t}, \mathbf{x})$ (Eq. (5)) indicating whether the t-th source text unit is to be included in the summary. Once the full summary sequence $\hat{\mathbf{y}}$ is generated, it is compared to the ground-truth sequence to compute the reward $\mathcal{R}(\hat{\mathbf{y}})$. In this way, reinforcement learning explores the space of extractive summaries and promotes those yielding high rewards. At inference time, rather than sampling actions from $p(y_t|\mathbf{y}_{<t}, \mathbf{x})$, we choose y_t that yields the highest probability to generate the system summary $\mathbf{y}$. This process is deterministic and no QA is required.

$$\begin{aligned} &\nabla_\theta \mathbb{E}_{P(\mathbf{y}|\mathbf{x})}[\mathcal{R}(\mathbf{y})] \\ &= \mathbb{E}_{P(\mathbf{y}|\mathbf{x})}[\mathcal{R}(\mathbf{y})\nabla_\theta \log P(\mathbf{y}|\mathbf{x})] \\ &\approx \tfrac{1}{N}\textstyle\sum_{n=1}^{N} \mathcal{R}(\hat{\mathbf{y}}^{(n)})\nabla_\theta \log P(\hat{\mathbf{y}}^{(n)}|\mathbf{x}) \end{aligned} \quad (14)$$

4 Experiments

We proceed by discussing the dataset and settings, comparison systems, and experimental results obtained through both automatic metrics and human evaluation in a reading comprehension setting.

4.1 Dataset and Settings

Our goal is to build an extractive summarizer identifying important textual segments from source articles. To investigate the effectiveness of the proposed approach, we conduct experiments on the CNN/Daily Mail dataset using a version provided by See et al. (2017). The reference summaries of this dataset were created by human editors exhibiting a moderate degree of extractiveness. E.g., 83% of summary unigrams and 45% of bigrams appear in source articles (Narayan et al., 2018a). On average, a CNN article contains 761 words / 34 sentences and a DM article contains 653 words / 29 sentences. We report results respectively for the CNN and DM portion of the dataset.

Our hyperparameter settings are as follows. We set the hidden state dimension of the LSTM to be 256 in either direction. A bidirectional LSTM $f_1^{\text{Bi-LSTM}}(\cdot)$ produces a 512-dimensional vector for each content word. Similarly, $f_4^{\text{Bi-LSTM}}(\cdot)$ generates a question vector $\mathbf{q}_k$ of the same size. Our CNN encoder $f_2^{\text{CNN}}(\cdot)$ uses multiple window sizes of $\{1, 3, 5, 7\}$ and 128 filters per window size. $\mathbf{h}_t^e$ is thus a 512-dimensional vector using either CNN or LSTM encoder. We set the hidden state dimension of $\mathbf{s}_t$ to be 128. We also use 100-dimensional word embeddings (Pennington et al., 2014) and sinusoidal positional encodings (Vaswani et al., 2017) of 30 dimensions.

The maximum article length is set to 400 words. Compared to the study of Arumae and Liu (2018), we expand the search space dramatically from 100 to 400 words, which poses a challenge to the RL-based summarizers. We associate each article with at most 10 QA pairs (K=10) and use them to guide the extraction of summary segments. We apply mini-batch training with Adam optimizer (Kingma and Ba, 2014), where a mini-batch contains 128

articles and their QA pairs. The summary ratio δ is set to 0.15, yielding extractive summaries of about 60 words. Following Arumae and Liu (2018), we set hyperparameters $\beta = 2\alpha$; α and γ are tuned on the dev set using grid search.

4.2 Experimental Results

Comparison systems We compare our method with a number of extractive and abstractive systems that have reported results on the CNN/DM datasets. We consider non-neural approaches that extract sentences from the source article to form a summary. These include *LexRank* (Radev et al., 2004), *SumBasic* (Vanderwende et al., 2007), and *KLSum* (Haghighi and Vanderwende, 2009). Such methods treat sentences as bags of words, and then select sentences containing topically important words. We further include the Lead-3 baseline that extracts the first 3 sentences from any given article. The method has been shown to be a strong baseline for summarizing news articles.

Neural extractive approaches focus on learning vector representations for sentences and words, then performing extraction based on the learned representations. Cheng et al. (2016) describe a neural network method composed of a hierarchical document encoder and an attention-based extractor. The system has two variants: *NN-WE* extracts words from the source article and *NN-SE* extracts sentences. *SummaRuNNer* (Nallapati et al., 2017) presents an autoregressive sequence labeling method based on recurrent neural networks. It selects summary sentences based on their content, salience, position, and novelty representations.

Abstractive summarization methods are not directly comparable to our approach, but we choose to include three systems that report results respectively for CNN and DM datasets. *Distraction-M3* (Chen et al., 2016b) trains the summarization system to distract its attention to traverse different regions of the source article. *Graph attention* (Tan et al., 2017) introduces a graph-based attention mechanism to enhance the encoder-decoder framework. *PointerGen+Cov.* (See et al., 2017) allows the system to not only copy words from the source text but also generate summary words by selecting them from a vocabulary. Abstractive methods can thus introduce new words to the summary that are not present in the source article. However, system summaries may change the meaning of the original texts due to this flexibility.

Results We present summarization results of various systems in Tables 2 and 3, evaluated on the standard CNN/DM test sets by R-1, R-2, and R-L metrics (Lin, 2004), which respectively measure the overlap of unigrams, bigrams, and longest common subsequences between system and reference summaries. We investigate four variants of our method: *QASumm+NoQ* does not utilize any question-answer pairs during training. It extracts summary text chunks by learning from ground-truth labels (§3.2) and the chunks are encoded by $f_1^{\text{Bi-LSTM}}$. Other variants initialize their models using pretrained parameters from QASumm+NoQ, then integrate the reinforcement learning objective (§3.4) to exploit the space of possible extractive summaries and reward those that are useful for answering questions. We consider three types of QA pairs: the answer token is the root of a sentence dependency parse tree (+ROOT), a subject or object (+SUBJ/OBJ), or an entity found in the sentence (+NER). In all cases, the question is generated by replacing the answer token with a blank symbol.

As illustrated in Tables 2 and 3, our QASumm methods with reinforcement learning (+ROOT,

	NoText			QASumm+NoQ			GoldSumm			FullText		
	Train	Dev	Gap	Train	Dev	Gap	Train	Dev	Gap	Train	Dev	Gap
SUBJ/OBJ	49.7	24.4	25.3	55.9	31.2	24.7	69.3	48.6	20.7	67.6	43.3	24.3
ROOT	68.1	34.9	33.2	71.6	36.3	35.3	76.9	44.9	32.0	76.0	35.7	40.3
NER	61.0	15.8	45.2	66.0	32.7	33.3	85.2	54.0	31.2	82.4	46.3	36.1

Table 4: Question-answering accuracies using different types of QA pairs (ROOT, SUBJ/OBJ, NER) and different source input (NoText, QASumm+NoQ, GoldSumm, and FullText) as the basis for predicting answers.

+SUBJ/OBJ, +NER) perform competitively with strong baselines. They outperform the counterpart *QASumm+NoQ* that makes no use of the QA pairs by a substantial margin. They outperform or perform at a comparable level to state-of-the-art published systems on the CNN/DM datasets but are generally inferior to PointerGen. We observe that exacting summary chunks is highly desirable in real-world applications as it provides a mechanism to generate concise summaries. Nonetheless, accurately identifying summary chunks is challenging because the search space is vast and spuriousness arises in chunking sentences. Cheng and Lapata (2016) report a substantial performance drop when adapting their system to extract words. Our QASumm methods focusing on chunk extraction perform on par with competitive systems that extract whole sentences. We additionally present human evaluation results of summary usefulness for a reading comprehension task in §4.3.

In Tables 2 and 3, we further show the number of unique answers per QA type. We find that the ROOT-type QA pairs have the least number of unique answers. They are often main verbs of sentences. In contrast, the SUBJ/OBJ-type has the most number of answers. They are subjects and objects of sentences and correspond to an open class of content words. The NER-type has a moderate number of answers compared to others. Note that all answer tokens have been filtered by frequency; those appearing less than 5 times in the dataset are removed to avoid overfitting.

Among variants of the QASumm method, we find that *QASumm+ROOT* achieves the highest scores on DM dataset. *QASumm+NER* performs consistently well on both CNN and DM datasets, suggesting QA pairs of this type are effective in guiding the system to extract summary chunks. We conjecture that maintaining a moderate number of answers is important to maximize performance. To answer questions with missing entities, the summary is encouraged to contain similar content as the question body. Because questions are derived from the human abstract, this in turn requires the system summary to carry similar semantic content as the human abstract.

Question-answering accuracy We next dive into the QA component of our system to investigate question-answering performance when different types of summaries and QA pairs are supplied to the system (§3.3). Given a question, the system predicts an answer using an extractive summary as the source input. Intuitively, an informative summary can lead to high QA accuracy, as the summary content serves well as the basis for predicting answers. With the same summary as input, certain types of questions can be more difficult to answer than others, and the system must rely heavily on the summary to gauge correct answers.

We compare various types of summaries. These include (a) *QASumm+NoQ* which extracts summary chunks without requiring QA pairs; and (b) *GoldSumm*, which are gold-standard extractive summaries generated by collecting source words appearing in human summaries. We further consider *NoText* and *FullText*, corresponding to using no source text or the full source article as input. They represent the two extremes. In all cases the QA component (§3.3) is trained on the training set and we report QA accuracies on the dev set.

In Table 4, we observe that question-answering with *GoldSumm* performs the best for all QA types. It outperforms the scenarios using *FullText* as the source input. This indicates that distilled information contained in a high-quality summary can be useful for answering questions, as searching for answers in a succinct summary can be more efficient than that in a full article. Moreover, we observe that the performance of *QASumm+NoQ* is in between *NoText* and *GoldSumm* for all answer types. The results suggest that extractive summaries with even modest ROUGE scores can prove useful for question-answering. Regarding different types of QA pairs, we find that the ROOT-type can achieve high QA accuracy when using *NoText* input. It suggests that ROOT answers can to some extent be predicted based on the question context. The NER-type QA

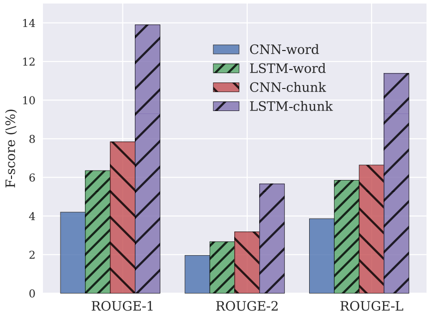

Figure 2: Summarization results using f_1^{LSTM} or f_2^{CNN} encoder with word/chunk as the extraction unit.

pairs work the best for both *GoldSumm* and *FullText*, likely because the source texts contain necessary entities required to correctly answer those questions. We also find the SUBJ/OBJ-type QA pairs have the smallest gap between train/dev accuracies, despite that they have a large answer space. Based on the analysis we would suggest future work to consider using NER-based QA pairs as they encourage the summaries to contain salient source content and be informative.

Extraction units We finally compare the performance of using either words or chunks as extraction units (§3.1). The chunks are obtained by breaking down sentence constituent parse trees in a top-down manner until all tree fragments contain 5 words or less. We observe that 70% of the chunks are 1-grams, and 2/3/4/5-grams are 9%, 7%, 6%, and 8% respectively. We compare the bidirectional LSTM (f_1^{LSTM}) and CNN (f_2^{CNN}) encoders for their effectiveness on generating representations for extraction units. Figure 2 presents the results of the QASumm+NoQ system under various settings. We find that extracting chunks performs superior, and combining chunks with LSTM representations yield the highest scores.

4.3 Human Evaluation

Testing the usefulness of an extractive system driven by reading comprehension is not inherently measured by automatic metrics (i.e. ROUGE). We conducted a human evaluation to assess whether the highlighted summaries contribute to document understanding. Similar to our training paradigm we presented each participant with the document and three fill-in-the-blank questions created from the human abstracts. It was guaranteed that each question was from a unique human abstract to avoid seeing the answer adjacent to the same template. The missing section was randomly generated to be either the root word, the subject or object of the sentence, or a named entity. We compare our reinforced extracted summary (presented as a bold overlay to the document), against our supervised method (section 3.2), abstractive summaries generated by See et al. (2017), and the human abstracts in full. Additionally we asked the participants to rate the quality of the summary presented (1-5, with 5 being most informative). We utilized Amazon Mechanical Turk, and conducted an experiment where we sampled 80 documents from the CNN test set. The articles were evenly split across the four competing systems, and each HIT was completed by 5 turkers. Upon completion the data was analyzed manually for accuracy since turkers entered each answer as free text, and to remove any meaningless datapoints.

Summary	Time	Accuracy	Inform.
Human	69.5s	87.3	4.23
QASumm+NoQ	87.9s	53.7	1.76
Pointer+Cov.	100.9s	52.3	2.14
QASumm+NER	95.0s	**62.3**	**2.14**

Table 5: Amazon mechanical turk experiments. Human abstracts were the goldstandard summaries, Pointer+Cov. were summaries generated by See et al. (2017). Our systems tested were the supervised extractor, and our full model (NER).

Table 5 shows the average time (in seconds) to complete a single question, the overall accuracy of the participants, and the informativeness of a given summary type. Excluding the use of human abstracts, all systems resulted in similar performance times. However we observe a large margin in QA accuracy in our full system compared to the abstractive and our supervised approach. Although participants rated the informativeness of the summaries to be the same our systems yielded a higher performance. This strongly indicates that having a system which makes using of document comprehension has a tangible effect when applied towards a real-world task.

5 Conclusion

We exploited an extractive summarization framework using deep reinforcement learning to identify consecutive word sequences from a document to form an extractive summary. Our reward function promotes adequate and fluent summaries that can serve as document surrogates to answer important questions, directly addressing users' information needs. Experimental results on benchmark datasets demonstrated the efficacy of our proposed method over state-of-the-art baselines, assessed by both automatic metrics and human evaluators.

Abstract

We propose a grounded dialogue state encoder which addresses a foundational issue on how to integrate visual grounding with dialogue system components. As a test-bed, we focus on the *GuessWhat?!* game, a two-player game where the goal is to identify an object in a complex visual scene by asking a sequence of yes/no questions. Our visually-grounded encoder leverages synergies between guessing and asking questions, as it is trained jointly using multi-task learning. We further enrich our model via a cooperative learning regime. We show that the introduction of both the joint architecture and cooperative learning lead to accuracy improvements over the baseline system. We compare our approach to an alternative system which extends the baseline with reinforcement learning. Our in-depth analysis shows that the linguistic skills of the two models differ dramatically, despite approaching comparable performance levels. This points at the importance of analyzing the linguistic output of competing systems beyond numeric comparison solely based on task success.[1]

1 Introduction

Over the last few decades, substantial progress has been made in developing dialogue systems that address the abilities that need to be put to work during conversations: Understanding and generating natural language, planning actions, and tracking the information exchanged by the dialogue participants. The latter is particularly critical since, for communication to be effective, participants need to represent the state of the dialogue and the common ground established through the conversation (Stalnaker, 1978; Lewis, 1979; Clark, 1996).

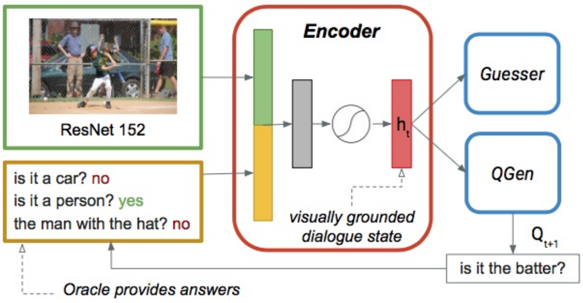

Figure 1: Our questioner model with a single visually grounded dialogue state encoder.

In addition to the challenges above, dialogue is often situated in a perceptual environment. In this study, we develop a dialogue agent that builds a representation of the context and the dialogue state by integrating information from both the *visual* and *linguistic* modalities. We take the *GuessWhat?!* game (de Vries et al., 2017) as our test-bed, a two-player game where a Questioner faces the task of identifying a target object in a visual scene by asking a series of yes/no questions to an Oracle. We model the agent in the Questioner's role.

To model the Questioner, previous work relies on two independent models to learn to ask questions and to guess the target object, each equipped with its own encoder (de Vries et al., 2017; Strub et al., 2017; Zhu et al., 2017; Lee et al., 2017; Shekhar et al., 2018; Zhang et al., 2018). We propose an end-to-end architecture with a single *visually-grounded dialogue state encoder* (cf. Figure 1). Our system is trained jointly in a supervised learning setup, extended with a cooperative learning (CL) regime: By letting the model play the game with self-generated dialogues, the components of the Questioner agent learn to better perform the overall Questioner's task in a cooperative manner. Das et al. (2017b) have explored the use of CL to train two visual dialogue agents that receive joint rewards when they play a game successfully. To our knowledge, ours is the first ap-

proach where cooperative learning is applied to the internal components of a grounded conversational agent.

Our cooperative learning regime can be seen as an interesting alternative to reinforcement learning (RL)—which was first applied to *GuessWhat?!* by Strub et al. (2017)—because it is entirely differentiable and computationally less expensive to train than RL. Little is known on how this learning approach compares to RL not only regarding task success, but also in terms of the quality of the linguistic output, a gap we seek to fill in this paper. In particular, our contributions are:[2]

- The introduction of a single visually-grounded dialogue state encoder jointly trained with the guesser and question generator modules to address a foundational question of how to integrate visual grounding with dialogue system components; this yields up to 9% improvement on task success.
- The effectiveness of cooperative learning, which yields an additional increase of 8.7% accuracy, while being easier to train than RL.
- A first in-depth study to compare cooperative learning to a state-of-the-art RL system. Our study shows that the linguistic skills of the models differ dramatically, despite approaching comparable task success levels. This underlines the importance of linguistic analysis to complement solely numeric evaluation.

2 Related Work

Task-oriented dialogue systems The conventional architecture of task-oriented dialogue systems includes a pipeline of components, and the task of tracking the dialogue state is typically modelled as a partially-observable Markov decision process (Williams et al., 2013; Young et al., 2013; Kim et al., 2014) that operates on a symbolic dialogue state consisting of predefined variables. The use of symbolic representations to characterise the state of the dialogue has some advantages (e.g., ease of interfacing with knowledge bases), but it has also some key disadvantages: the variables to be tracked have to be defined in advance and the system needs to be trained on data annotated with explicit state configurations.

Given these limitations, there has been a shift towards neural end-to-end systems that learn their own representations. Early works focus on non-goal-oriented chatbots (Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a,b). Bordes et al. (2017) propose a memory network to adapt an end-to-end system to task-oriented dialogue. Recent works combine conventional symbolic with neural approaches (Williams et al., 2017; Zhao and Eskenazi, 2016; Rastogi et al., 2018), but all focus on language-only dialogue. We propose a visually grounded task-oriented end-to-end dialogue system which, while maintaining the crucial aspect of the interaction of the various modules at play in a conversational agent, grounds them through vision.

Visual dialogue agents In recent years, researchers in computer vision have proposed tasks that combine visual processing with dialogue interaction. Pertinent datasets created by Das et al. (2017a) and de Vries et al. (2017) include *VisDial* and *GuessWhat?!*, respectively, where two participants ask and answer questions about an image. While impressive progress has been made in combining vision and language, current models make simplifications regarding the integration of these two modalities and their exploitation for task-related actions. For example, the models proposed for *VisDial* by Das et al. (2017a) concern an image guessing game where one agent does not see the target image (thus, no multimodal understanding) and is required to 'imagine' it by asking questions. The other agent does see the image, but only responds to questions without the need to perform additional actions.

In *GuessWhat?!*, the Questioner agent sees an image and asks questions to identify a target object in it. The Questioner's role hence involves a complex interaction of vision, language, and guessing actions. Most research to date has investigated approaches consisting of different models trained independently (de Vries et al., 2017; Strub et al., 2017; Zhu et al., 2017; Lee et al., 2017; Shekhar et al., 2018; Zhang et al., 2018). We propose the first multimodal dialogue agent for the *GuessWhat?!* task where all components of the Questioner agent are integrated into a joint architecture that has at its core a *visually-grounded dialogue state encoder* (cf. Figure 1).

Reinforcement learning for visual dialogue agents was introduced by Das et al. (2017b) for

---

[2] Code and supplementary material are available at `https://vista-unitn-uva.github.io`.

VisDial and by Strub et al. (2017) for *GuessWhat?!*. Our joint architecture allows us to explore a simpler solution based on cooperative learning between the agent's internal modules (see Section 5 for details).

3 Task and Data

The *GuessWhat?!* game (de Vries et al., 2017) is a simplified instance of a referential communication task where two players collaborate to identify a referent—a setting used extensively in human-human collaborative dialogue (Clark and Wilkes-Gibbs, 1986; Yule, 1997; Zarrieß et al., 2016).

The *GuessWhat?!* dataset[3] was collected via Amazon Mechanical Turk by de Vries et al. (2017). The task involves two human participants who see a real-world image, taken from the MS-COCO dataset (Lin et al., 2014). One of the participants (the Oracle) is assigned a target object in the image and the other participant (the Questioner) has to guess it by asking Yes/No questions to the Oracle. There are no time constraints to play the game. Once the Questioner is ready to make a guess, the list of candidate objects is provided and the game is considered successful if the Questioner picks the target object. The dataset consists of around 155k English dialogues about approximately 66k different images. Dialogues contain on average 5.2 questions-answer pairs.

4 Models

We focus on developing an agent who plays the role of the Questioner in *GuessWhat?!*.

4.1 Baseline Model

As a baseline model (BL), we consider our own implementation of the best performing system put forward by de Vries et al. (2017). It consists of two independent models: a Question Generator (QGen) and a Guesser. For the sake of simplicity, QGen asks a fixed number of questions before the Guesser predicts the target object.

QGen is implemented as an Recurrent Neural Network (RNN) with a transition function handled with Long-Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), on which a probabilistic sequence model is built with a Softmax classifier. At each time step in the dialogue, the model receives as input the raw image and the dialogue history and generates the next question one word at a time. The image is encoded by extracting its VGG-16 features (Simonyan and Zisserman, 2014). In our new joint architecture (described below in Section 4.2), we use ResNet152 (He et al., 2016) features instead of VGG, because they tend to yield better performance in image classification and are more efficient to compute. For the baseline model it turns out that the original VGG-16 features lead to better performance (41.8% accuracy for VGG-16 vs. 37.3% with ResNet152 features). While we use ResNet152 features in our models, we keep the original VGG-16 feature configuration as de Vries et al. (2017), which constitutes a stronger baseline.

The Guesser model exploits the annotations in the MS-COCO dataset (Lin et al., 2014) to represent candidate objects by their object category and their spatial coordinates. This yields better performance than using raw image features in this case, as reported by de Vries et al. (2017). The objects' categories and coordinates are passed through a Multi-Layer Perceptron (MLP) to get an embedding for each object. The Guesser also takes as input the dialogue history processed by its own dedicated LSTM. A dot product between the hidden state of the LSTM and each of the object embeddings returns a score for each candidate object.

The model playing the role of the Oracle is informed about the target object o_{target}. Like the Guesser, the Oracle does not have access to the raw image features. It receives as input embeddings of the target object's category, its spatial coordinates, and the current question asked by the Questioner, encoded by a dedicated LSTM. These three embeddings are concatenated and fed to an MLP that gives an answer (Yes or No).

4.2 Visually-Grounded Dialogue State Encoder

In line with the baseline model, our Questioner agent includes two sub-modules, a QGen and a Guesser. As in the baseline, the Guesser guesses after a fixed number of questions, which is a parameter tuned on the validation set. Our agent architecture differs from the baseline model by de Vries et al.: Rather than operating independently, the language generation and guessing modules are connected through a common *grounded dialogue state encoder* (GDSE) which combines linguistic and visual information as a prior for the two modules. Given this representation, we will

---

[3] Dataset: `https://guesswhat.ai/download`.

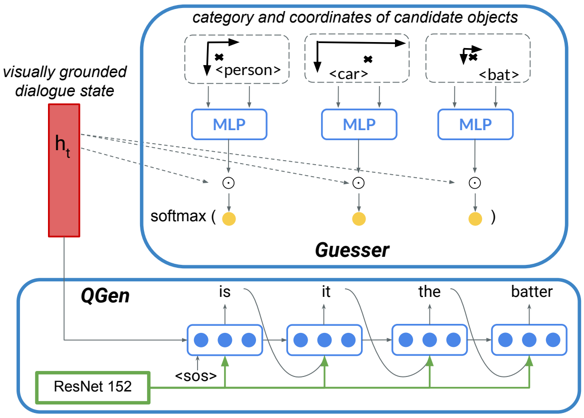

Figure 2: Question Generation and Guesser modules.

refer to our Questioner agent as GDSE.

As illustrated in Figure 1, the encoder receives as input representations of the visual and linguistic context. The visual representation consists of the second to last layer of ResNet152 trained on ImageNet. The linguistic representation is obtained by an LSTM (LSTM$_e$) which processes each new question-answer pair in the dialogue. At each question-answer QA_t, the last hidden state of LSTM$_e$ is concatenated with the image features I, passed through a linear layer and a *tanh* activation to result in the final layer h_t:

$$h_t = \tanh\left(W \cdot [\text{LSTM}_e(qa_{1:t-1});\ I]\right) \qquad (1)$$

where $[\cdot;\cdot]$ represents concatenation, $I \in \mathbb{R}^{2048\times 1}$, LSTM$_e$ $\in \mathbb{R}^{1024\times 1}$ and $W \in \mathbb{R}^{512\times 3072}$ (identical to prior work except for tuning the ResNet-specific parameters). We refer to this final layer as the *dialogue state*, which is given as input to both QGen and Guesser.

As illustrated in Figure 2, our QGen and Guesser modules are like the corresponding modules by de Vries et al. (2017), except for the crucial fact that they receive as input the same grounded dialogue state representation. QGen employs an LSTM (LSTM$_q$) to generate the token sequence for each question conditioned on h_t, which is used to initialise the hidden state of LSTM$_q$. As input at every time step, QGen receives a dense embedding of the previously generated token w_{i-1} and the image features I:

$$p(w_i) = p(w_i | w_1, ..., w_{i-1}, h_t, I) \qquad (2)$$

We optimise QGen by minimising the Negative Log Likelihood (NLL) of the human dialogues and use the Adam optimiser (Kingma and Ba, 2015):

$$\mathcal{L}_Q = \sum_i - \log p(w_i) \qquad (3)$$

Thus, in our architecture the LSTM$_q$ of QGen in combination with the LSTM$_e$ of the Encoder form a sequence-to-sequence model (Sutskever et al., 2014), conditioned on the visual and linguistic context — in contrast to the baseline model, where question generation is performed by a single LSTM on its own.

The Guesser consists of an MLP which is evaluated for each candidate object in the image. It takes the dense embedding of the category and the spatial information of the object to establish a representation $r_j \in \mathbb{R}^{512\times 1}$ for each object. A score is calculated for each object by performing the dot product between the dialogue state h_t and the object representation. Finally, a softmax over the scores results in a probability distribution over the candidate objects:

$$p(o_j) = \frac{e^{h_t^T \cdot r_j}}{\sum_j e^{h_t^T \cdot r_j}} \qquad (4)$$

We pick the object with the highest probability and the game is successful if $o_{guess} = o_{target}$, where $o_{guess} = \arg\max_j p(o_j)$. As with QGen, we optimise the Guesser by minimising the NLL and again make use of Adam:

$$\mathcal{L}_G = -\log p(o_{target}) \qquad (5)$$

The resulting architecture is fully differentiable. In addition, the GDSE agent faces a multi-task optimisation problem: While the QGen optimises $\mathcal{L}_Q$ and the Guesser optimises $\mathcal{L}_G$, the parameters of the Encoder (W, LSTM$_e$) are optimised via both $\mathcal{L}_Q$ and $\mathcal{L}_G$. Hence, both tasks faced by the Questioner agent contribute to the optimisation of the dialogue state h_t, and thus to a more effective encoding of the input context.

5 Learning Approach

We first introduce the supervised learning approach used to train both BL and GDSE, then our cooperative learning regime, and finally the reinforcement learning approach we compare to.

5.1 Supervised Learning

In the baseline model, the QGen and the Guesser modules are trained autonomously with supervised learning (SL): QGen is trained to replicate human questions and, independently, the Guesser is trained to predict the target object. Our new architecture with a common dialogue state encoder allows us to formulate these two tasks as a multi-task problem, with two different losses (Eq. 3 and 5 in Section 4.2). These two tasks are not equally difficult: While the Guesser has to learn the probability distribution of the set of possible objects in the image, QGen needs to fit the distribution of natural language words. Thus, QGen has a harder task to optimize and requires more parameters and training iterations. We address this issue by making the learning schedule task-dependent. We call this setup *modulo-n* training, where *n* indicates after how many epochs of QGen training the Guesser is updated together with QGen.

Using the validation set, we experimented with *n* from 5 to 15 and found that updating the Guesser every 7 epochs worked best. With this optimal configuration, we then train GDSE for 100 epochs (batch size of 1024, Adam, learning rate of 0.0001) and select the Questioner module best performing on the validation set (henceforth, GDSE-SL or simply SL).

5.2 Cooperative Learning

Once the model has been trained with SL, new training data can be generated by letting the agent play new games. Given an image from the training set used in the SL phase, we generate a new training instance by randomly sampling a target object from all objects in the image. We then let our Questioner agent and the Oracle play the game with that object as target, and further train the common encoder using the generated dialogues by backpropagating the error with gradient descent through the Guesser. After training the Guesser and the encoder with generated dialogues, QGen needs to 'readapt' to the newly arranged encoder parameters. To achieve this, we re-train QGen on the human data with SL, but using the new encoder states. Also here, the error is backpropagated with gradient descent through the common encoder.

Regarding *modulo-n*, in this case QGen is updated at every n^{th} epoch, while the Guesser is updated at all other epochs; we experimented with *n* from 3-7 and set it to the optimal value of 5. The GDSE previously trained with SL is further trained with this cooperative learning regime for 100 epochs (batch size of 256, Adam, learning rate of 0.0001), and we select the Questioner module performing best on the validation set (henceforth, GDSE-CL or simply CL).

5.3 Reinforcement Learning

Strub et al. (2017) proposed the first extension of BL (de Vries et al., 2017) with deep reinforcement learning (RL). They present an architecture for end-to-end training using an RL policy. First, the Oracle, Guesser, and QGen models are trained independently using supervised learning. Then, QGen is further trained using a policy gradient.

We use the publicly available code and pre-trained model based on Sampling (Strub et al., 2017), which resulted in the closest performance to what was reported by the authors.[4] This is the RL model we use throughout the rest of the paper.

5.4 Experimental Details

We use the same train (70%), validation (15%), and test (15%) splits as de Vries et al. (2017). The test set contains new images not seen during training. We use two experimental setups for the number of questions to be asked by the question generator, motivated by prior work: 5 questions (5Q) following de Vries et al. (2017), and 8 questions (8Q) as in Strub et al. (2017). As noted in Section 3, on average, there are 5.2 questions per dialogue in the *GuessWhat?!* data set.

For evaluation, we report task success in terms of accuracy (Strub et al., 2017). To neutralize the effect of random sampling in training CL, we trained the model 3 times. RL is tested 3 times with sampling. We report means and standard deviation (for some tables these are provided in the supplementary material; see footnote 2).

6 Results

Table 1 reports the results for all models. There are several take-aways.

Grounded joint architecture First of all, our visually-grounded dialogue state encoder is effective. GDSE-SL outperforms the baseline by de Vries et al. (2017) significantly in both setups (absolute accuracy improvements of 6.6%

---

[4] Their result of 53.3% accuracy published in Strub et al. (2017) is obsolete, as stated on their GitHub page (`https://github.com/GuessWhatGame/guesswhat`) where they report 56.5% for sampling and 58.4% for greedy search. By running their code, we could only replicate their results with sampling, obtaining 56%, while greedy and beam search resulted in similar or worse performance. Our analysis showed that greedy and beam search have the additional disadvantage of learning a smaller vocabulary.

Model	5Q	8Q
Baseline	41.2	40.7
GDSE-SL	47.8	49.7
GDSE-CL	53.7 (±.83)	58.4 (±.12)
RL	56.2 (±.24)	56.3 (±.05)

Table 1: Test set accuracy for each model (for setups with 5 and 8 questions). GDSE-SL is our grounded supervised learning system, GDSE-CL the cooperative learning setup, and RL the results we obtain with the reinforcement learning system by Strub et al. (2017).

and 9%). To evaluate the impact of the multi-task learning aspect, we did an ablation study and used the encoder-decoder architecture to train the QGen and Guesser modules independently. With such a decoupled training we obtain lower results: 44% and 43.7% accuracy for 5Q and 8Q, respectively. Hence, the multi-task component brings an increase of up to 6% over the baseline.[5]

Cooperative learning and RL The introduction of the cooperative learning approach results in a clear improvement over GDSE-SL: +8.7% (8Q: from 49.7 to 58.4) and +5.9% (with 5Q). Despite its simplicity, our GDSE-CL model achieves a task success rate which is comparable to RL: In the 8Q setup, GDSE-CL reaches an average accuracy of 58.4 versus 56.3 for RL, giving CL a slight edge in this setup (+2.1%), while in the 5Q setup RL is slightly better (+2.5%). Overall, the accuracy of the CL and RL models is close. The interesting question is how the linguistic skills and strategy of these two models differ, to which we turn in the next section.

We compared to Strub et al. (2017), but RL has also been put forward by Zhang et al. (2018), who report 60.7% accuracy (5Q). This result is close to our highest GDSE-CL result (60.8 ±0.51, when optimized for 10Q).[6] Their RL system integrates several partial reward functions to increase coherence, which is an interesting aspect. Yet their code is not publicly available. We leave the comparison to Zhang et al. (2018) and adding RL to GDSE to future work.

7 Analysis

In this section, we present a range of analyses that aim to shed light on the performance of the models. They are carried out on the test set data using the 8Q setting, which yields better results than the 5Q setting for the GDSE models and RL. Given that there is only a small difference in accuracy for the baseline with 5Q and 8Q, for comparability we analyse dialogues with 8Q also for BL.

7.1 Quantitative Analysis of Linguistic Output

We analyse the language produced by the Questioner agent with respect to three factors: (1) lexical diversity, measured as type/token ratio over all games, (2) question diversity, measured as the percentage of unique questions over all games, and (3) the number of games with questions repeated verbatim. We compute these factors on the test set for the models and for the human data (H).

As shown in Table 2, the linguistic output of SL & CL is closer to the language used by humans: Our agent is able to produce a much richer and less repetitive output than both BL and RL. In particular, it learns to use a more diverse vocabulary, generates more unique questions, and repeats questions within the same dialogue at a much lower rate than the baseline and RL: 93.5% of the games played by BL contain at least one verbatim question repetition, for RL this happens in 96.47% of the cases, whereas for SL and CL this is for only 55.8% and 52.19% of the games, respectively.

	Lexical diversity	Question diversity	% Games with repeated Q's
BL	0.030	1.60	93.50
SL	0.101	13.61	55.80
CL	0.115 (±.02)	14.15 (±3.0)	52.19 (±4.7)
RL	0.073 (±.00)	1.04 (±.03)	96.47 (±.04)
H	0.731	47.89	—

Table 2: Statistics of the linguistic output of all models with the 8Q setting and of humans (H) in all test games.

7.2 Dialogue Strategy

To further understand the variety of questions asked by the agents, we classify questions into different types. We distinguish between questions that aim at getting the category of the target object (ENTITY questions, e.g., *'is it a vehicle?'*) and questions about properties of the queried objects (ATTRIBUTE questions, e.g., *'is it square?'* or *'are*

---

[5] While de Vries et al. (2017) originally report an accuracy of 46.8%, this result was later revised to 40.8%, as clarified on their GitHub page. Our own implementation of the baseline system achieves an accuracy of 41.2%.

[6] Since our aim is to compare to the best setup for BL (5Q) and RL (8Q), we do not report our results with 10Q in Table 1.

Humans	*[success]*	**GDSE-CL**	*[success]*	**RL**	*[failure]*
1. does it have cereal on it?	no	1. is it a donut?	yes	1. is it food?	yes

Figure 3: Game example where GDSE-CL succeeds and RL fails at guessing the target object (framed).

they standing?'). Within ATTRIBUTE questions, we make a distinction between color, shape, size, texture, location, and action questions. Within ENTITY questions, we distinguish questions whose focus is an object category or a super-category (see the supplementary material for example questions). The classification is done by manually extracting keywords for each question type from the human dialogues, and then applying an automatic heuristic that assigns a class to a question given the presence of the relevant keywords.[7] This procedure allows us to classify 91.41% of the questions asked by humans. The coverage is higher for the questions asked by the models: 98.88% (BL), 94.72% (SL), 94.11% (CL) and 99.51 % (RL).[8]

The statistics are shown in Table 3. We use Kullback-Leibler (KL) divergence to measure how the output of each model differs from the human distribution of fine-grained question classes. The baseline's output has the highest degree of divergence: For instance, the BL model does never ask any SHAPE or TEXTURE questions, and hardly any SIZE questions. The output of the RL model also differs substantially from the human dialogues: It asks a very large number of LOCATION questions (74.8% vs. 40% for humans). Our model, in contrast, generates question types that resemble the human distribution more closely.

Question type	BL	SL	CL	RL	H
ENTITY	**49.00**	**48.07**	**46.51**	**23.99**	**38.11**
SUPER-CAT	19.6	12.38	12.58	14.00	14.51
OBJECT	29.4	35.70	33.92	9.99	23.61
ATTRIBUTE	**49.88**	**46.64**	**47.60**	**75.52**	**53.29**
COLOR	2.75	13.00	12.51	0.12	15.50
SHAPE	0.00	0.01	0.02	0.003	0.30
SIZE	0.02	0.33	0.39	0.024	1.38
TEXTURE	0.00	0.13	0.15	0.013	0.89
LOCATION	47.25	37.09	38.54	74.80	40.00
ACTION	1.34	7.97	7.60	0.66	7.59

KL (wrt human)	0.953	0.042	0.038	0.396	0.0

Table 3: Percentage of questions per question type in all the test set games played by humans (H) and the models with the 8Q setting, and KL divergence from human distribution of fine-grained question types.

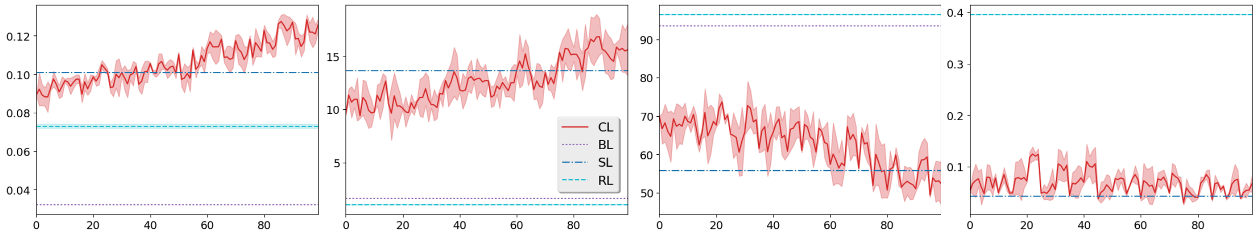
We also analyse the structure of the dialogues in terms of the sequences of question types asked. As expected, both humans and models almost always start with an ENTITY question (around 97% for BL, SL and CL, 98.7% for RL, and 78.48% for humans), in particular a SUPER-CATEGORY (around 70% for BL, SL and CL, 84% for RL, and 52.32% for humans). In some cases, humans start by asking questions directly about an attribute that may easily distinguish an object from others, while this is very uncommon for models. Figure 3 shows an example: The human dialogue begins with an ATTRIBUTE question (*'does it have cereal on it?'*), which in this case is not very effective and leads to a change in strategy at turn 4. The CL model starts by asking an OBJECT question (*'is it a donut?'*) while the RL model begins with a more generic SUPER-CATEGORY question (*'is it food?'*).

We check how the answer to a given question type affects the type of the follow-up question. In principle, we expect to find that question types that are answered positively will be followed by more specific questions. This is indeed what we observe in the human dialogues, as shown in Table 4. For example, when a SUPER-CATEGORY question is answered positively, humans follow up with an OBJECT or ATTRIBUTE question 89.56% of the time. This trend is mirrored by all models. Overall, the models also learn the strategy to move from an OBJECT to an ATTRIBUTE question when an OBJECT question receives a Yes answer. The BL, SL, and CL models do this to a lesser extent than humans, while the RL model systematically

---

[7] A question may be tagged with several attribute classes if keywords of different types are present. E.g., *"Is it the white one on the left?"* is classified as both COLOR and LOCATION.

[8] In the supplementary material we provide details on the question classification procedure: the lists of keywords by class, the procedure used to obtain these lists, as well as the pseudo-code of the heuristics used to classify the questions.



(a) Lexical diversity (b) Question diversity (c) % Games w/ repeated Q's (d) KL-distance from human

Figure 4: Evolution of linguistic factors over 100 training epochs for our GDSE-CL model. Note: lexical and question diversity of the human data fall outside the range in (a) / (b). The same is the case with KL for BL in (d).

Question type shift	BL	SL	CL	RL	H
SUPER-CAT → OBJ/ATT	89.05	92.61	89.75	95.63	89.56
OBJECT → ATTRIBUTE	67.87	60.92	65.06	99.46	88.70

Table 4: Proportion of question type shift vs. no type shift in consecutive questions $Q_t \rightarrow Q_{t+1}$ where Q_t has received a Yes answer.

transitions to attributes (in 99.46% of cases), using mostly LOCATION questions as pointed out above. For example (Figure 3), after receiving an affirmative answer to the OBJECT question 'is it a donut?' both CL and RL shift to a LOCATION question. Once location is established, CL moves on to other attributes while RL keeps asking the same LOCATION question, which leads to failure. Further illustrative examples are given in the supplementary material.

7.3 Analysis of the CL Learning Process

In order to better understand the effect of the cooperative learning regime, we trace the evolution of linguistic factors identified above over the CL epochs. As illustrated in Figure 4 (a) and (b), through the epochs the CL model learns to use a richer vocabulary and more diverse questions, moving away from the levels achieved by BL and RL, overpassing SL and moving toward humans.

The CL model progressively produces fewer repeated questions within a dialogue, improving over SL in the last few epochs, cf. Figure 4 (c). Finally, (d) illustrates the effect of modulo-n training: As the model is trained on generated dialogues, its linguistic output drifts away from the human distribution of question types; every 5^{th} epoch QGen is trained via supervision, which brings the model's behaviour closer back to human linguistic style and helps decrease the drift.

8 Conclusion

We present a new visually-grounded joint Questioner agent for goal-oriented dialogue. First, we show that our architecture archives 6–9% accuracy improvements over the *GuessWhat?!* baseline system (de Vries et al., 2017). This way, we address a foundational limitation of previous approaches that model guessing and questioning separately.

Second, our joint architecture allows us to propose a two-phase cooperative learning approach (CL), which further improves accuracy. It results in our overall best model and reaches state-of-the-art results (cf. Section 6). We compare CL to the system proposed by Strub et al. (2017) which extends the baseline with reinforcement learning (RL). We find that the two approaches (CL and RL) achieve overall relatively similar task success rates. However, evaluating on task success is only one side of the coin. Finally and most importantly, we propose to pursue an in-depth analysis of the quality of the dialogues by visual conversational agents, which is an aspect often neglected in the literature. We analyze the linguistic output of the two models across three factors (lexical diversity, question diversity, and repetitions) and find them to differ substantially. The CL model uses a richer vocabulary and inventory of questions, and produces fewer repeated questions than RL. In contrast, RL highly relies on asking location questions, which might be explained by a higher reliance on spatial and object-type information explicitly given to the Guesser and Oracle models. Limiting rewards to task success or other rewards not connected to the language proficiency does not stimulate the model to learn rich linguistic skills, since a reduced vocabulary and simple linguistic structures may be an efficient strategy to succeed at the game.

Overall, the presence of repeated questions remains an important weakness of all models, resulting in unnatural dialogues. This shows that there is still a considerable gap to human-like conversational agents. Looking beyond task success can provide a good basis for extensions of current architectures, e.g., Shekhar et al. (2018) add a decision-making component that decides when to stop asking questions which results in less repetitive and more human-like dialogues. Our joint architecture could easily be extended with such a component.

Abstract

Visual Dialog is a multi-modal task that requires a model to participate in a multi-turn human dialog grounded on an image, and generate correct, human-like responses. In this paper, we propose a novel Adversarial Multi-modal Feature Encoding (AMFE) framework for effective and robust auxiliary training of visual dialog systems. AMFE can force the language-encoding part of a model to generate hidden states in a distribution closely related to the distribution of real-world images, resulting in language features containing general knowledge from both modalities by nature, which can help generate both more correct and more general responses with reasonably low time cost. Experimental results show that AMFE can steadily bring performance gains to different models on different scales of data. Our method outperforms both the supervised learning baselines and other fine-tuning methods, achieving state-of-the-art results on most metrics of VisDial v0.5/v0.9 generative tasks.

1 Introduction

In recent years, there has been a rising attention in Artificial Intelligence on how to train a model to understand visual inputs from the physical world, and communicate them with human language. Typical problems include Visual Question Answering (VQA) (Antol et al., 2015) and Image Captioning (Xu et al., 2015). These tasks require a model to read an image and generate a proper response, such as answering a question grounded on the image, or generating a sentence to describe the image. As a more difficult extension, Visual Dialog (De Vries et al., 2017; Das et al., 2017a; Mostafazadeh et al., 2017) is a cluster of tasks featuring two agents conducting a multi-turn dialog grounded on an image. A model is usually trained to predict every single response of one agent in the two, based on the image and dialog history. There are also some different task settings such as directly training two agents to complete a goal-driven cooperative task such as Guessing Game (Das et al., 2017b).

Tasks involving both the physical world (visual images) and abstract world (languages) share a core issue: how to establish connections between these two worlds, and is there a framework to leverage these connections for learning? Temporarily, the majority of answers are learning end-to-end models with multi-modal feature fusion (Kim et al., 2016; Fukui et al., 2016; Yu et al., 2018). These methods usually merge the visual and language features into rich representations containing information from both sides. Some cross-modal attention methods (Lu et al., 2016; Nam et al., 2017) formulate the visual-language connections explicitly by parameterizing the attention weights to learn whether there is high correlation within certain pairs of language and visual feature vectors. However, in all these works, the merged representations or attention weights are only learned from pairwise (one image, one sentence) co-occurrence, and serve for the optimization of a loss function only related to the final ground-truth response. In fact, the features from both sides are not truly connected in an aspect of general distributions, but only merged into a new vector for each training/testing sample. We suppose that this is not good enough for a model to distill knowledge from both of the two worlds because the language/visual vectors do not contain knowledge from the other modality in the bottom level before they are merged.

In this paper, we discuss another possibility. We want to establish an unsupervised framework of multi-modal encoding, which directly generates an “image feature distribution” from a language

distribution, or vice versa. For example, when a neural network based model receives a natural language sentence x as input, it encodes x into a sequence of high-dimensional continuous vectors. All these language vectors can be projected into another latent space to have a new distribution p_l. We train the language encoder to let the new distribution p_l be the same as, or very close to, the distribution p_v of all *image features* observed and encoded in the task data. Since we can partly recover a real-world image distribution from the language vectors achieved in this way, these language vectors intrinsically contain both language semantics and real-world image properties. This is a higher-level connection between the two worlds.

In order to train a model to generate samples subject to a certain distribution p_v from an original distribution p_l, Generative Adversarial Networks (GANs) have been proved very effective (Goodfellow et al., 2014; Arjovsky et al., 2017; Miyato et al., 2018). Lample et al. (2018) used adversarial training on the vectors produced by sentence encoders for different languages in unsupervised machine translation. However, different languages in their task are in single modality and share encoder structures, making the same method not directly usable and extendable for multi-modal tasks with largely different prior distributions and complex encoder structures with attention. In our work, we propose Adversarial Multi-modal Feature Encoding (AMFE), a novel GAN-based training schedule with an attention-based sample-selecting method, which can successfully force the multi-modal vectors to have closely related distributions, benefitting the performances of various visual dialog systems.

We test our method on the VisDial (Das et al., 2017a) benchmark (one example is shown in Table 1). A normal sample of VisDial contains an image and 10 turns of question-answering dialog from two people grounded on the image. A series of models have been proposed to solve the task, including memory and attention based models (Das et al., 2017a), reinforcement learning (Das et al., 2017b), knowledge transfer techniques (Lu et al., 2017) and GAN (Wu et al., 2017). Wu et al. (2017) designed a complex attention model and applied GAN in a traditional way to force the generated tokens to mimic real-world language (language vs. language), making their model only trainable through sequence sampling and reinforcement learning. Our work, on the other hand, applies a directly differentiable GAN on continuous vectors as a multi-modal feature encoding method (language vs. image).

Table 1: An example from VisDial dataset.

Our contributions include:

- We propose AMFE: a novel Adversarial Multi-modal Feature Encoding framework to benefit visual dialog models. The core idea is to force features from different modalities to have closely related distributions.
- We develop efficient AMFE implementations, including a novel attention-based sample selecting method, for various commonly-used visual dialog models.
- Experimental results show that AMFE brings robust performance gains to different visual dialog models. We achieve state-of-the-arts on most metrics of VisDial v0.5/v0.9 generative tasks.

2 Related Work

2.1 Visual Dialog

Visual Dialog is a cluster of tasks sharing two properties: multi-turn and cross-modality. VisDial (Das et al., 2017a) is a widely-used benchmark with question-answering style dialogs grounded on real-world images. As a special case of dialog generation tasks, VisDial share some of the research concerns with single-modal natural language dialog generation (Dhingra et al., 2016; Serban et al., 2017; Sordoni et al., 2015; Serban et al., 2016; Liu et al., 2016). Natural language dialogs are usually discrete, state-dependent and style-free, thus some reinforcement learning (RL) methods have been proposed (Li et al., 2016). Das et al. (2017b) built an cooperative image guessing task on VisDial: they train both the questioner and the answerer, making them complete a same goal to help the questioner produce a guessing or "imagination" of the unseen image described by the answerer. The distance between the guessing and the target image is used as reward for reinforcement learning. In some extreme settings, such a task definition can even lead to emergence of a new language between robots (Kottur et al., 2017). After per-training, using their reinforcement learning method as an auxiliary loss can also bring performance gain in standard VisDial metrics such as mean rank.

However, generating a reward based on just one target image for a training sample may lead to a kind of overfitting. Language is highly abstract: one dialog can correctly describe a lot of different scenes in real world, so why should we force a dialog to fit one single example among them? Therefore, generating a reward from adversarial training is a more efficient way because it goes beyond individual samples into distributions. There are two previous works (Wu et al., 2017; Lu et al., 2017) that use GAN-like methods to boost the performances of pre-trained VisDial models. (Wu et al., 2017) proposes to use adversarial reinforcement learning. A discriminator is trained to distinguish the tokens of real/generated answers, and the answerer (generator) is trained via RL using a reward related to the score given by discriminator. This method is very effective, but using both RL Monte Carlo and GAN brings high computational cost. Also, a lot of tricks are involved for a good training. Our method, on the other hand, does not need Monte-Carlo sampling to compute immediate reward while generating each of the N words in a sentence ($O(N)$ time cost). (Lu et al., 2017) uses a knowledge-transferring method between generative and discriminative task settings. However, this requires the models on both settings to be pre-trained well enough. Our work is also an adversarial learning based method, but it is more robust, time-efficient and effective.

2.2 GAN for Generative Tasks

GAN (Goodfellow et al., 2014; Arjovsky et al., 2017; Miyato et al., 2018) has raised much attention because of its ability to directly generate samples subject to a target distribution. Many training techniques have been proposed to solve the unstable training problems of GAN (Gulrajani et al., 2017; Kurach et al., 2018). Wasserstein GAN (WGAN) (Arjovsky et al., 2017) is a successful method using critic learning loss and weight clipping operations. We borrow some ideas from WGAN in the adversarial training of our model.

GAN well suits the image generation tasks because image signals are continuous and thus differentiable, enabling the gradient directly flowing back from the discriminator to generator. In language generation tasks, however, how to deal with the discrete sequence of symbols generated by the generator has long been a problem. A widely-used solution is applying RL with rewards generated by the discriminator (Wang et al., 2018; Li et al., 2017). As mentioned above, this is time-costing because RL needs to explore a large action space by sampling multiple action sequence. Besides, how the immediate reward is computed after generating each word is also a difficult problem.

Another solution is to avoid the discrete problem by applying adversarial training on the hidden states of the generator. This requires that there is a known distribution p for the hidden states we want the model to generate. A successful case is reported by (Lample et al., 2018): using adversarial training to restrict the hidden states of source language and target language (both from vanilla LSTMs) into a same latent space can boost the performance of unsupervised machine translation. Our AMFE framework is also an adversarial training on the language hidden states, but we are the first to use this kind of methods to establish connections between different modalities. Our training procedure is also largely different from (Lample et al., 2018) with our modified WGAN-like algorithm and a novel attention-based sample selection method: they are critical for training convergency on multi-modal tasks, with complex attention-based model structures.

3 Model

We first define the task and our framework formally, and then describe how it is implemented and trained on different visual dialog models.

3.1 VisDial Task Definition

In the VisDial task, each sample contains an image I, a caption sentence C and a dialog D with $T = 10$ turns in total. In each turn t, there is a question q_t about the image, and a ground truth answer a_t. The model needs to read the dialog history $H = \{C, (q_1, a_1), ..., (q_{t-1}, a_{t-1})\}$ and image I, to generate an answer as a response to q_t. We rewrite $H_t = (q_t, a_t)$ and $H_0 = C$. Formally, the dialog agent (named A-Bot) outputs an answer

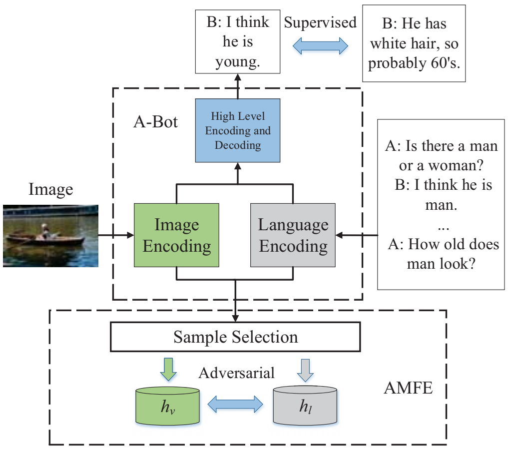

Figure 1: AMFE framework with a generative encoder-decoder model and multi-modal adversarial training.

prediction $\hat{a}_t$:

$$\hat{a}_t = ABot(q_t, I, H_{0\sim t-1}). \tag{1}$$

3.2 AMFE Framework

The goal of our Adversarial Multi-modal Feature Encoding (AMFE) is to restrict the distribution of feature representations from one modality m_1 to be closely related to that from another modality m_2. We take $m_1 = l(anguange)$ and $m_2 = v(isual)$. Specifically, A-Bot encodes language inputs into vectors h_l, and visual inputs into h_v, respectively. We want h_l and h_v to have indistinguishable distributions:

$$h_l, h_v \sim p(h). \tag{2}$$

To achieve this goal, we use a discriminative model (named D-Bot) to classify whether a vector encoded by A-Bot comes from modality l or v. D-Bot is trained with real h_l and h_v samples, while A-Bot is trained to generate language vectors h_l that can confuse D-Bot to classify them as label v. Figure 1 shows our framework.

3.3 A-Bot

We implement our AMFE method on two commonly-used visual dialog models, using them as A-Bot. The two A-Bot models are named Hierarchical Recurrent Encoder (HRE) and History-Conditioned Image Attentive Encoder (HCIAE), respectively. A-Bot learns to predict the right answer in each turn. In this process, it also encodes language and visual inputs into h_l and h_v samples, which we use for AMFE training.

3.3.1 Hierarchical Recurrent Encoder (HRE)

HRE is a hierarchical LSTM (Hochreiter and Schmidhuber, 1997) model used in (Das et al., 2017a,b). In HRE, a pre-trained Convolutional Neural Network (CNN) encodes the image into a single feature vector, which is further mapped into a visual representation I by a trainable Multi-Layer Perceptron (MLP). In each turn t, the question is encoded by a word-level LSTM into a question vector q_t, and the dialog history in the previous step H_{t-1} is encoded by another LSTM into vector f_{t-1}. There is a state-tracker $LSTM^{st}$ on the top level: $LSTM^{st}$ is forwarded one step each turn, integrating all the encoded vectors mentioned above. It reads the encoded history f_{t-1}, image vector I, the question q_t and the previous hidden state s_{t-1} from itself, and produces the new hidden state representation s_t:

$$s_t = LSTM^{st}([q_t, I, f_{t-1}], s_{t-1}), \tag{3}$$

where $[\cdot]$ stands for concatenation.

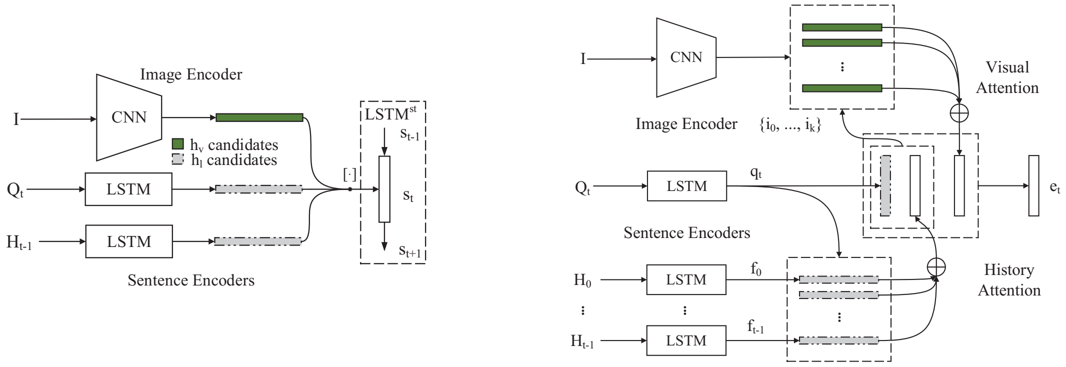
The answer decoder in HRE is an LSTM that takes s_t as initial state, and predicts one word at a time by a softmax probability over the vocabulary, to generate the whole answer sentence. Figure 2(a) shows the encoder structure of HRE. We use image vectors I as h_v samples (dark green) in AMFE, and both the q and f vectors as h_l samples (pink).

3.3.2 History-Conditioned Image Attentive Encoder (HCIAE)

HCIAE model (Lu et al., 2017) contains an textual attention on all history vectors based on the question, and a visual attention based on both the history and the question. In detail, it uses a pre-trained CNN to encode the image into a set of visual feature vectors V. Each vector in V is further passed through a trainable MLP, resulting in a visual feature set $\{i_0, ...i_{K-1}\}$. In each turn t, the question is encoded by an LSTM into vector q_t; the dialog history $\{H_0, H_1, ..., H_{t-1}\}$ is encoded by another word-level LSTM into vectors $\{f_0, ..., f_{t-1}\}$. The attention weight between q_t and each history vector f_j is computed as:

$$\begin{aligned} z_t^j &= \omega_a^T tanh(W_f f_j + W_q q_t), \\ \alpha_t^j &= softmax(z_t^j), \end{aligned} \tag{4}$$

where $\omega_a^T \in \mathbb{R}^{d\times 1}$, $W_f \in \mathbb{R}^{d\times d}$, $W_q \in \mathbb{R}^{d\times d}$ are trainable parameters; d is the length of both



(a) HRE encoder model.

(b) HCIAE encoder model.

Figure 2: A-Bot models we use for AMFE training. The intermediate vectors used as h_v and h_l candidates in AMFE are colored dark green and pink, respectively.

question and history features. A memory vector $\hat{m}_t$ is computed by:

$$\hat{m}_t = \sum_{j=0}^{t-1} \alpha_t^j f_j. \tag{5}$$

The memory vector is further used as a key to compute a similar visual attention over $\{i_0, ...i_{k-1}\}$ to achieve a final image vector $\hat{v}_t$. The final output of the encoder is computed by:

$$e_t = tanh(W_e[q_t, \hat{m}_t, \hat{v}_t]), \tag{6}$$

where $W_e \in \mathbb{R}^{d \times 3d}$ is trainable parameters; $[\cdot]$ stands for concatenation.

The answer decoder is an LSTM like that of HRE, taking e_t as input. Figure 2(b) shows the structure of HCIAE encoder. HCIAE produces more visual vectors for each image than HRE. We take all the q and f vectors as h_l candidates of AMFE, and the spatial visual features $\{i_0, ...i_{k-1}\}$ as candidates for h_v.

3.4 D-Bot

Despite the multiple choices of A-Bot, our D-Bot is always an MLP with two hidden layers of size 512 and ReLU activation. It is used to compute a loss function that forces all the h_l samples to be subject to the same distribution $p(h)$ as the visual vectors h_v. D-Bot takes a vector h in size d as its input, and predicts the probability of h coming from real image distribution and the visual encoder:

$$\hat{p}_v(modality = v|h) = DBot(h). \tag{7}$$

D-Bot is the discriminator from a GAN viewpoint. A-Bot must learn to confuse D-Bot in order to generate language features indistinguishable from image features.

3.5 Training

3.5.1 Loss Functions

To train our model, we use standard supervised training with cross-entropy loss function for pretraining, and add in adversarial training to produce an auxiliary loss to improve feature encoding.

The supervised learning loss is:

$$L_{su} = \frac{1}{N} \sum_{n=1}^{N} -\log(p(w_n^t | w_{<n}^t)), \tag{8}$$

where N is the full length of the decoded sentence.

For adversarial learning, A-Bot is trained to minimize the probability that D-Bot predicts the generated features to be fake samples. Following WGAN (Arjovsky et al., 2017), we do not use logarithm but directly optimize the likelihood itself:

$$L_{adv} = -E_{h_l}[DBot(h_l)]. \tag{9}$$

We sum L_{adv} as an auxiliary loss with a tunable weight λ, making A-Bot minimize:

$$L_G = L_{su} + \lambda L_{adv}. \tag{10}$$

On the other hand, D-Bot maximizes the following objective to distinguish real-world image vectors h_v from the language vectors h_l:

$$L_D = E_{h_v}[DBot(h_v)] - E_{h_l}[DBot(h_l)]. \tag{11}$$

We switch between A-Bot and D-Bot updates for each batch of dialog samples.

3.5.2 Attention-based Sample Selection

We have specified where the h_l and h_v samples come from while using different A-Bots in Section 3.3. Typically, for each batch of samples with batch-size M, in each turn t, there are M question vectors and $M \times t$ history vectors as h_l candidates. For HRE encoder, there are M image vectors as h_v candidates, while the number is $M \times K$ for the HCIAE encoder; K is the number of "pixels" in the final CNN feature-map. Thus, it is impossible to use all the generated samples in AMFE. For a successful training, the selected samples must be efficient, informative and balanced.

While using HCIAE, in order to compute L_{adv}, we use M question vectors and $M * w$ history vectors as h_l samples. The history vectors are selected using textual attention weights α_t^j produced by the temporary model: for each dialog, we pick the top w history vectors with the highest attention weights. We call this Attention-based Sample Selection (AbS). While computing L_D to train D-Bot, we use the same technique on the image, using the top-attended $M * w$ image vectors, together with another M image vectors randomly sampled from the dataset as positive samples h_v. The M question vectors and $M * w$ history vectors are used as a pool of negative samples h_l. In our experiments, $w = 1, 2$ works well.

While using HRE, since the model always "attends" on f_{t-1} by default (Eq. 3), we directly select q_t and f_{t-1} as h_l samples. We use the M image vectors I in this batch, together with another M image vectors randomly sampled from the dataset as the pool of h_v. The full training procedure is specified in Algorithm 1.

Algorithm 1 AMFE Training Procedure.

```
Require: $\alpha$ the learning rate; $c$ the clipping parameter; $M$ the batch size; $w_0$ the initial D-Bot parameters; $\theta_0$ the initial A-Bot parameters; dialog samples.
  Pre-train A-Bot with $L_{su}$ (Eq. 8).
  while $\theta$ has not converged do
      Sample $M$ turns of $(q, H, I, a)$ dialog samples.
      Forward A-Bot and select $h_l$ by attention weights.
      Compute $L_{adv} = -\sum_{k=1}^{M} DBot(h_l^k))$.
      Compute $L_{su}$ with ground-truth answers using (Eq. 8).

      Update $\theta$ to minimize $L_G = L_{su} + \lambda L_{adv}$.
      Switch to D-Bot training.
      Select image vectors $h_v$ by attention weights.
      Re-generate $h_l$ samples using the updated A-Bot.
      Compute $L_D = \sum_{k=1}^{M} DBot(h_v^k) - \sum_{k=1}^{M} DBot(h_l^k)$.
      Update $w$ to maximize $L_D$.
      Clip D-Bot weight $w$ into range $(-c, c)$.
  end while
```

4 Experiments

4.1 The VisDial Dataset

VisDial is a visual dialog dataset based on MS COCO (Lin et al., 2014) images. There are 10 turns of human-posed question-answering dialogs on each image, with the questioner kept not seeing the image during the data collection process. For generative models, a model must give the probability of generating each candidate answer without seeing other candidates, and the rank of the ground-truth answer in the 100 candidates is used to compute different evaluation metrics; for discriminative models, the model can read and encode all the candidate answers and directly assign scores on them. According to the nature of GANs and similarities to real-world application scenarios, we use the generative setting for our model: it is equipped with a sequential decoder instead of a scoring module.

For fair and sufficient comparison, we evaluate our model on both VisDial v0.5 and VisDial v0.9. VisDial v0.5 has 68k COCO images, for a total of 680k QA-pairs. Following (Das et al., 2017a) and (Das et al., 2017b), we use 50,729 images for training, 7,663 for validation and 9,628 for testing. Visdial v0.9 has 123,287 images. There are different splitting of train/valid/test in previous work. We follow (Lu et al., 2017) to use 82k for training, 1k for validation and 40k for testing. [1]

We compare our results to several existing models on the VisDial dataset, including:

- *Answer Prior* (Das et al., 2017a): directly encoding answer candidates with an LSTM and scoring by a linear model that captures the frequency of answers in the training set.
- *NN-QI* (Das et al., 2017a): a k-Nearest Neighborhood method considering only the question and the image. Unlike generative methods, both Answer Prior and NN-QI need to know the answer candidates.
- *LF-QIH-G* (Das et al., 2017a): a Late Fusion encoder that encodes the question, image and history separately. The encoded features are concatenated and linearly transformed to a

---

[1] VisDial has released v1.0 recently, and claims that models trained on v0.9 should also use the new v1.0 test set. Due to lack of baselines in the *generative* task, we follow the original widely-used settings of v0.5 and v0.9.

joint representation. The answer is produced by a generative decoder.

- *HRE* (Das et al., 2017b): the HRE model introduced in Section 3.3.
- *HREA-QIH-G* (Das et al., 2017a): a modified HRE A-Bot with attention to dialog history.
- *MN-QIH-G* (Das et al., 2017a): a Memory Network encoder that stores each piece of dialog history embeddings in an explicit memory. These embeddings can be attended and fused while generating the answer.
- *HCIAE* (Lu et al., 2017): the HCIAE model introduced in Section 3.3.
- *CoAtt* (Wu et al., 2017): this is a previous state-of-the-art model with a more complex co-attention encoder; the decoder is enhanced by adversarial reinforcement learning for better answer generation.

4.2 AMFE for HRE

We first test the efficiency of AMFE on the simpler A-Bot model: HRE. We use VisDial v0.5 as our benchmark for fair comparison with other HRE-based models and auxiliary training methods.

4.2.1 Implementation Details

For Visdial v0.5 dataset, we follow the preprocessing procedure and hyper-parameters described in (Das et al., 2017b). We pass each image through a pre-trained VGG-16 (Simonyan and Zisserman, 2015) CNN, and pick the single f7 vector as input image feature. We limit the maximum lengths of captions, questions and answers to be 40, 20 and 20, respectively; we remove words appearing less than 5 times in the training set, and replace them by a UNK token. We use vector size 300 for word embedding and 512 for all language and visual feature vectors. All LSTMs have two layers.

We pre-train A-Bot with L_{su} for 20 epochs before L_{adv} is added in. The batch-size is set to be 32. After each update of A-Bot, we perform 5 D-Bot updates. We use the 32 encoded image vectors in the batch, together with 32 image vectors randomly sampled from the dataset, to form 64 positive samples; for negative samples, we use the 32 question vectors and 32 history vectors ($t-1$) from the updated A-Bot. We use Adam (Kingma and Ba, 2014) for A-Bot and RMSprop (Tieleman and Hinton, 2012) algorithm for D-Bot to perform gradient descending. The learning rate is set to 1e-3 for pre-training, further decayed to 5e-5; after adversarial training starts, the learning rate is fixed to 5e-5 for both A- and D-Bot. In the weight clipping step of WGAN (Arjovsky et al., 2017), we use a clipping parameter $c = 0.01$.

Model	MRR	R@1	R@5	R@10	Mean
Answer Prior	0.311	19.85	39.14	44.28	31.56
NN-QI	0.385	29.71	46.57	49.86	30.90
LF-QIH-G	0.430	33.27	51.96	58.09	23.04
HREA-QIH-G	0.442	34.47	53.43	59.73	21.83
MN-QIH-G	0.443	**34.62**	53.74	60.18	21.69
HRE-MLE	0.436	33.02	53.41	60.09	21.83
Frozen-Q-Multi	0.437	33.22	53.67	60.48	21.13
HRE-AMFE	**0.445**	**34.62**	**53.95**	**60.76**	**20.98**

Table 2: VisDial v0.5 evaluation results. The five metrics are mean reciprocal rank, recall of the ground-truth answer in the top-1/5/10 ranked candidates (higher is better), and the mean rank of the ground-truth answer (lower is better).

4.2.2 VisDial v0.5 Evaluation Results

On VisDial v0.5, two previous top models are a Memory Network based model (MN-QIH-G) by (Das et al., 2017a) and a multi-loss training on HRE encoder (Frozen-Q-Multi) based on goal-driven reinforcement learning (Das et al., 2017b). We start from the same HRE hyper-parameters and checkpoint as (Das et al., 2017b), but continue with our AMFE instead of reinforcement learning.

Table 2 shows the results on all the five evaluation metrics on VisDial v0.5. Results in the first 4 rows are copied from (Das et al., 2017a). AMFE achieves better performances than the supervised training of A-Bot model (HRE-MLE), especially significant on R@5, R@10 and mean rank, indicating that the adversarial feature encoding results in “generally better” dialogs. It also outperforms the another HRE-like model with history attentions (HREA-QIH-G). While used for multi-loss training, AMFE is significantly better than Frozen-Q-Multi, setting a new state-of-the-art on all metrics. We point out that in Frozen-Q-Multi (Das et al., 2017b), the goal-driven reinforcement leaning reward is computed pair-wise (considering how much can the questioner rebuild the image from the answerer’s words), but the reward computed with a single image is not good enough to evaluate the dialog actions. This is because language is much more abstract than image, and failure to recover an image does not necessarily mean that the dialog is actually bad. Our method could avoid this issue because adversarial training is based on general distributions.

4.3 AMFE for HCIAE

In this section, we test the efficiency of AMFE for the HCIAE model with attention. We use VisDial v0.9 as our benchmark for fair comparison with (Lu et al., 2017).

4.3.1 Implementation Details

For Visdial v0.9 dataset, we follow the preprocessing procedure and HCIAE structure described in (Lu et al., 2017). We pass each image through a pre-trained VGG-19 CNN, resulting in a 512 × 7 × 7 feature-map as visual input. To speed up convergence, we add a Batch Normalization (Ioffe and Szegedy, 2015) after the MLP that further encodes these visual vectors. We limit the maximum lengths of captions, questions and answers to be 24, 16 and 8, respectively. All LSTMs have only one layer.

HCIAE can be trained with either supervised loss (HCIAE-G-MLE) or with multi-loss involving knowledge-transfer (HCIAE-G-DIS). We test AMFE in both settings. For HCIAE-G-MLE, we pre-train HCIAE model with supervised loss for 20 epochs using learning rate 4e-4, and switch to AMFE training with learning rate 5e-5. For HCIAE-G-DIS, we start from the generative model trained with AMFE, together with a pre-trained HCIAE discriminative model. We follow the original knowledge-transfer training schedule, and add our L_{adv} to the original mixed loss function with weight 1. We use batch-size 32 for AMFE training, although the original paper used 128. Other settings are kept the same. For more details please see (Lu et al., 2017).

4.3.2 VisDial v0.9 Evaluation Results

Table 3 shows the results on v0.9. All the HCIAE results are picked from (Lu et al., 2017), and all CoAtt results are picked from (Wu et al., 2017); CoAtt-GAN-TF stands for training a CoAtt model with adversarial reinforcement learning and supervised teacher-forcing; HCIAE-AMFE stands for using AMFE on an HCIAE-G-MLE pre-trained model; HCIAE-GD-AMFE means using AMFE as an additional loss to join the HCIAE-G-DIS multi-loss training.

Model	MRR	R@1	R@5	R@10	Mean
Answer Prior	0.374	23.55	48.52	53.23	26.50
NN-QI	0.427	33.13	50.83	58.69	19.62
LF-QIH-G	0.520	41.83	61.78	67.59	17.07
HREA-QIH-G	0.524	42.28	62.33	68.17	16.79
MN-QIH-G	0.526	42.29	62.85	68.88	17.06
CoAtt-G-MLE	0.541	44.32	63.82	69.75	16.47
CoAtt-GAN-TF	**0.558**	**46.10**	65.69	71.74	14.43
HCIAE-G-MLE	0.539	44.06	63.55	69.24	16.01
HCIAE-G-DIS	0.546	44.35	65.28	71.55	14.23
HCIAE-AMFE	0.547	44.40	65.35	71.69	14.42
HCIAE-GD-AMFE	0.554	45.42	**66.09**	**72.30**	**14.11**

Table 3: VisDial v0.9 evaluation results. The five metrics are mean reciprocal rank, recall of the ground-truth answer in the top-1/5/10 ranked candidates, (higher is better) and the mean rank of the ground-truth answer (lower is better).

On VisDial v0.9, we observe that using AMFE on HCIAE can also boost the performances. Comparing HCIAE-G-MLE and HCIAE-AMFE, we can observe the same advantage over supervised training as on HRE, indicating that our method works for different dataset scales and A-Bot structures; comparing HCIAE-AMFE and HCIAE-G-DIS, AMFE is a competitive method for auxiliary training. Combining AMFE and HCIAE-G-DIS achieves better results than previous state-of-the-art (Wu et al., 2017) on R@5, R@10 and mean rank, and comparable on MRR and R@1. Besides, AMFE trains reasonably faster because we avoid the $O(N)$ time cost for Monte-Carlo sampling while computing temporary rewards (Wu et al., 2017).

We explain the efficiency of AMFE in two aspects. Firstly, AMFE is an adversarial training procedure forcing the language to be encoded into a distribution closely connected to the images. With attention-based sample selection, the most informative samples from both modalities are able to transfer knowledge. Secondly, like Batch Normalization, AMFE contributes to bring better numerical properties to the intermediate tensors in a network, especially on their means and variances, which could potentially benefit model performance.

4.4 Ablation Study

Both the weight of adversarial loss and the attention-based sample selection are critical to good performance. Table 4 shows ablation studies on these factors on HCIAE and VisDial v0.9.

Model	MRR	R@1	R@5	R@10	Mean
HCIAE-G-MLE	0.539	44.06	63.55	69.24	16.01
AMFE-standard	0.547	44.40	65.35	71.69	14.42
w/o AbS	0.537	44.03	63.52	69.33	15.45
$\lambda = 0.1$	0.538	44.10	63.59	69.18	16.07
$\lambda = 10$	0.534	44.01	62.83	68.64	16.56

Table 4: VisDial v0.9 ablation results training with HCIAE-G-MLE and AMFE fine-tuning. AMFE-standard uses $\lambda = 1$ with AbS selection.

#1 Caption: There are several airplanes parked on the tarmac.			
Question	Ground Truth	HRE-MLE	HRE-AMFE
1. are these commercial airplanes	yes they are	yes	yes
2. do they have company names on them	1 says UNK and other looks like it says UNK	yes , but i ca n't read them	yes , but i ca n't read them
3. are all of planes white	they are white 1 has blue and yellow on it and other 2 have red and blue	no they are white	no they are all white
4. are there people visible	yes there are 4 people visible	yes	yes
5. can you tell what sex they are	looks like they are all men	it is male	i think they are both male
6. are any of them wearing sunglasses	i think maybe 1 is it 's hard to tell they are kind of far away	i ca n't tell i can only see their backs	i ca n't tell , they are far away
7. are they dressed for warm or cold weather	looks like warm weather they are wearing their safety gear	they are wearing jackets and shorts	looks warm out
8. are there any trees visible	in far background there are lot of trees	no trees at all	yes there are trees in background
9. can you see any planes taking off or landing	no they all appear to be parked	no i do n't	no i do n't
10. are there any pilots visible inside	no i do not see any	no i do not see any	no there are not
#2 Caption: Some trucks move down a city road , while children play nearby.			
Question	Ground Truth	HRE-MLE	HRE-AMFE
1. how many children are there	i see 2	i can see 3 clearly 3 others are too far away	i see 1
2. girls or boys	bot boys	girls	i think they are boys
3. is there fire	no emergency	not that i can see	not that i can see
4. is anyone on fire truck that you can see	i can barely she driver	no it 's just him	no

6. does it look sunny out	not at all	yes	yes
7. is it black and white picture	no it is not	no	no
8. is it snowing	no it is not	no it is not	no it is not
9. is it raining	no , but it may soon	no it is not	no it is not
10. do you see dark clouds	yes i do	no	no

Table 5: Two examples in VisDial v0.5 dataset for case study.

4.5 Human Evaluation

The above results show that AMFE is especially strong at more "general" metrics such as R@5 and mean rank. To confirm that adversarial training on hidden states can help much to generate responses that are more natural, we randomly select 100 dialog samples from both VisDial v0.5 and v0.9 dataset, and ask two human subjects to vote for the responses generated by two groups of models: HRE-MLE vs. HRE-AMFE on v0.5, and HCIAE-G-MLE vs. HCIAE-AMFE on v0.9, both with beam-size 5. Model names are hidden while voting. We ask the human subjects to consider two metrics separately: (1) the fluency of the generated answer sentences and (2) the correctness of the answers compared to the ground-truths. As shown in Table 6, AMFE wins all the votes with different metric and different models, indicating that AMFE is robust in generating more natural responses.

Models	MLE Wins	AMFE Wins	Tie
HRE-fluency	30	52	18
HCIAE-fluency	34	43	23
HRE-correctness	33	42	25
HCIAE-correctness	29	38	33

Table 6: Human voting result on 100 samples from VisDial v0.5 and v0.9.

5 Case Studies

We randomly sample some dialogs from VisDial v0.5 validation set and illustrate the ground-truth answers and the generated answers with/without AMFE. Two results are shown in Table 5. In the first example, the model trained with AMFE generates a right vs. wrong answer in the 8-th turn, and a grammatically better response in the 5-th turn, compared to supervised pre-training. In the second example, the model trained with AMFE has a generally right understanding of the questions and the image, while the HRE-MLE model is generating response as if it does not see the image. This indicates that encoding language features in the image space leads to better understanding on both modalities.

6 Conclusion

We propose AMFE: an unsupervised multi-modal feature encoding framework and its implementations on different commonly-used visual dialog models. Our core idea is to force features from different modalities to have closely related distributions. Experiments show that AMFE can bring performance gains to both simple and complex models on different scales of VisDial dataset. Future work will possibly be visualizing the visual and language features encoded by AMFE to find more straightforward interpretations, as well as trying our method on more complex structures, discriminative models, and on discriminative tasks such as VQA and visual reasoning.

Abstract

Human language is a rich multimodal signal consisting of spoken words, facial expressions, body gestures, and vocal intonations. Learning representations for these spoken utterances is a complex research problem due to the presence of multiple heterogeneous sources of information. Recent advances in multimodal learning have followed the general trend of building more complex models that utilize various attention, memory and recurrent components. In this paper, we propose two simple but strong baselines to learn embeddings of multimodal utterances. The first baseline assumes a conditional factorization of the utterance into unimodal factors. Each unimodal factor is modeled using the simple form of a likelihood function obtained via a linear transformation of the embedding. We show that the optimal embedding can be derived in closed form by taking a weighted average of the unimodal features. In order to capture richer representations, our second baseline extends the first by factorizing into unimodal, bimodal, and trimodal factors, while retaining simplicity and efficiency during learning and inference. From a set of experiments across two tasks, we show strong performance on both supervised and semi-supervised multimodal prediction, as well as significant (10 times) speedups over neural models during inference. Overall, we believe that our strong baseline models offer new benchmarking options for future research in multimodal learning.

1 Introduction

Human language is a rich multimodal signal consisting of spoken words, facial expressions, body gestures, and vocal intonations (Streeck and Knapp, 1992). At the heart of many multimodal modeling tasks lies the challenge of learning rich representations of spoken utterances from multiple modalities (Papo et al., 2014). However, learning representations for these spoken utterances is a complex research problem due to the presence of multiple heterogeneous sources of information (Baltrušaitis et al., 2017). This challenging yet crucial research area has real-world applications in robotics (Montalvo et al., 2017; Noda et al., 2014), dialogue systems (Johnston et al., 2002; Rudnicky, 2005), intelligent tutoring systems (Mao and Li, 2012; Banda and Robinson, 2011; Pham and Wang, 2018), and healthcare diagnosis (Wentzel and van der Geest, 2016; Lisetti et al., 2003; Sonntag, 2017). Recent progress on multimodal representation learning has investigated various neural models that utilize one or more of attention, memory and recurrent components (Yang et al., 2017; Liang et al., 2018). There has also been a general trend of building more complicated models for improved performance.

In this paper, we propose two simple but strong baselines to learn embeddings of multimodal utterances. The first baseline assumes a factorization of the utterance into unimodal factors conditioned on the joint embedding. Each unimodal factor is modeled using the simple form of a likelihood function obtained via a linear transformation of the utterance embedding. We derive a coordinate-ascent style algorithm (Wright, 2015) to learn the optimal multimodal embeddings under our model. We show that, under some assumptions, maximum likelihood estimation for the utterance embedding can be derived in closed form and is equivalent to computing a weighted average of the language, visual and acoustic features. Only a few linear transformation parameters need to be learned. In order to capture bimodal and trimodal representations, our second baseline extends the first one by assuming a factorization into unimodal, bimodal, and trimodal factors (Zadeh et al., 2017). To summarize, our simple baselines 1) consist primarily of linear functions, 2) have few parameters, and 3) can be approximately solved in a closed form solution. As a result, they demonstrate simplicity and

efficiency during learning and inference.

We perform a set of experiments across two tasks and datasets spanning multimodal personality traits recognition (Park et al., 2014) and multimodal sentiment analysis (Zadeh et al., 2016). Our proposed baseline models 1) achieve competitive performance on supervised multimodal learning, 2) improve upon classical deep autoencoders for semi-supervised multimodal learning, and 3) are up to 10 times faster during inference. Overall, we believe that our baseline models offer new benchmarks for future multimodal research.

2 Related Work

We provide a review of *sentence embeddings*, *multimodal utterance embeddings*, and *strong baselines*.

2.1 Language-Based Sentence Embeddings

Sentence embeddings are crucial for down-stream tasks such as document classification, opinion analysis, and machine translation. With the advent of deep neural networks, multiple network designs such as Recurrent Neural Networks (RNNs) (Rumelhart et al., 1986), Long-Short Term Memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997), Temporal Convolutional Networks (Bai et al., 2018), and the Transformer (Vaswani et al., 2017) have been proposed and achieve superior performance. However, more training data is required for larger models (Peters et al., 2018). In light of this challenge, researchers have started to leverage unsupervised training objectives to learn sentence embedding which showed state-of-the-art performance across multiple tasks (Devlin et al., 2018). In our paper, we go beyond unimodal language-based sentence embeddings and consider multimodal spoken utterances where additional information from the nonverbal behaviors is crucial to infer speaker intent.

2.2 Multimodal Utterance Embeddings

Learning multimodal utterance embeddings brings a new level of complexity as it requires modeling both intra-modal and inter-modal interactions (Liang et al., 2018). Previous approaches have explored variants of graphical models and neural networks for multimodal data. RNNs (Elman, 1990; Jain and Medsker, 1999), LSTMs (Hochreiter and Schmidhuber, 1997), and convolutional neural networks (Krizhevsky et al., 2012) have been extended for multimodal settings (Rajagopalan et al., 2016; Lee et al., 2018). Experiments on more advanced networks suggested that encouraging correlation between modalities (Yang et al., 2017), enforcing disentanglement on multimodal representations (Tsai et al., 2018), and using attention to weight modalities (Gulrajani et al., 2017) led to better performing multimodal representations. In our paper, we present a new perspective on learning multimodal utterance embeddings by assuming a conditional factorization over the language, visual and acoustic features. Our simple but strong baseline models offer an alternative approach that is extremely fast and competitive on both supervised and semi-supervised prediction tasks.

2.3 Strong Baseline Models

A recent trend in NLP research has been geared towards building simple but strong baselines (Arora et al., 2017; Shen et al., 2018; Wieting and Kiela, 2019; Denkowski and Neubig, 2017). The effectiveness of these baselines indicate that complicated network components are not always required. For example, Arora et al. (2017) constructed sentence embeddings from weighted combinations of word embeddings which requires no trainable parameters yet generalizes well to down-stream tasks. Shen et al. (2018) proposed parameter-free pooling operations on word embeddings for document classification, text sequence matching, and text tagging. Wieting and Kiela (2019) discovered that random sentence encoders achieve competitive performance as compared to larger models that involve expensive training and tuning. Denkowski and Neubig (2017) emphasized the importance of choosing a basic neural machine translation model and carefully reporting the relative gains achieved by the proposed techniques. Authors in other domains have also highlighted the importance of developing strong baselines (Lakshminarayanan et al., 2017; Sharif Razavian et al., 2014). To the best of our knowledge, our paper is the first to propose and evaluate strong, non-neural baselines for multimodal utterance embeddings.

3 Baselines for Multimodal Learning

3.1 Notation

Suppose we are given video data where each utterance segment is denoted as $\mathbf{s}$. Each segment contains individual words w in a sequence $\mathbf{w}$, visual features v in a sequence $\mathbf{v}$, and acoustic features a in a sequence $\mathbf{a}$. We aim to learn a representation

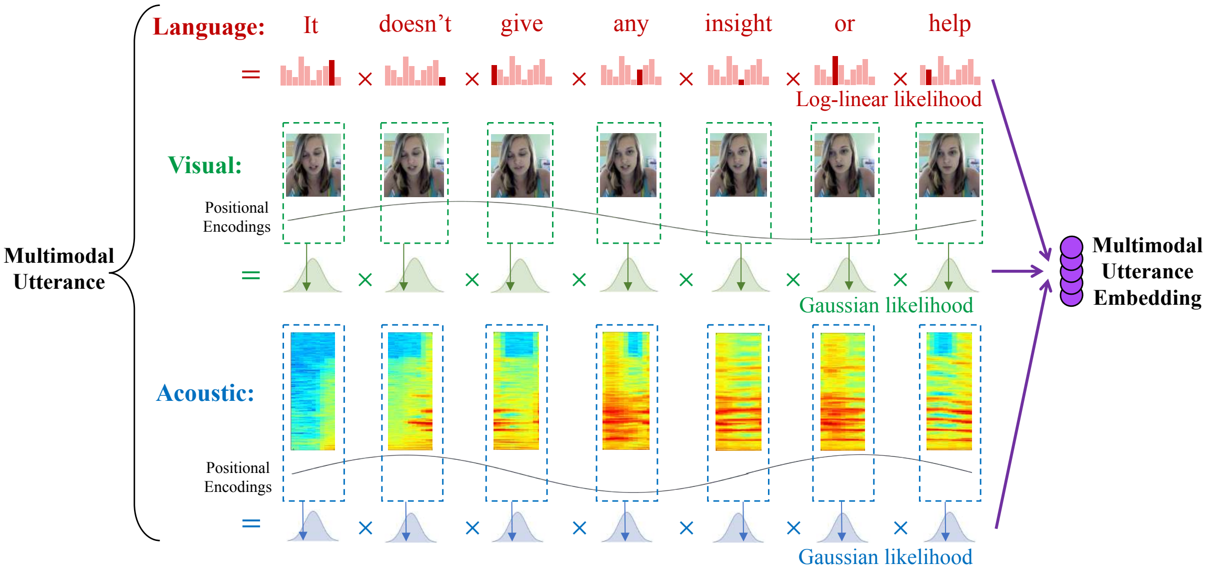

Figure 1: Our baseline model assumes a factorization of the multimodal utterance into unimodal factors conditioned on the joint utterance embedding. Each unimodal factor is modeled using the simple form of a likelihood function obtained via a linear transformation of the utterance embedding. We show that, under some assumptions, maximum likelihood estimation for the utterance embedding can be derived in closed form and is equivalent to taking a weighted average of the language, visual and acoustic features.

$m_{\mathbf{s}}$ for each segment that summarizes information present in the multimodal utterance.

3.2 Background

Our model is related to the work done by Arora et al. (2016) and Arora et al. (2017). In the following, we first provide a brief review of their method. Given a sentence, Arora et al. (2016) aims to learn a sentence embedding c_s. They do so by assuming that the probability of observing a word w_t at time t is given by a log-linear word production model (Mnih and Hinton, 2007) with respect to c_s:

$$\mathbb{P}[w_t|c_s] = \frac{\exp\left(\langle v_{w_t}, c_s\rangle\right)}{Z_{c_s}}, \tag{1}$$

where c_s is the sentence embedding (context), v_{w_t} represents the word vector associated with word w_t and $Z_{c_s} = \sum_{w \in V} \exp\left(\langle v_w, c_s\rangle\right)$ is a normalizing constant over all words in the vocabulary. Given this posterior probability, the desired sentence embedding c_s can be obtained by maximizing Equation (1) with respect to c_s. Under some assumptions on c_s, this maximization yields a closed-form solution which provides an efficient learning algorithm for sentence embeddings.

Arora et al. (2017) further extends this model by introducing a "smoothing term" α to account for the production of frequent stop words or out of context words independent of the discourse vector. Given estimated unigram probabilities $p(w)$, the probability of a word at time t is given by

$$\mathbb{P}[w_t|c_s] = \alpha p(w_t) + (1-\alpha)\frac{\exp\left(\langle v_{w_t}, c_s\rangle\right)}{Z_{c_s}}. \tag{2}$$

Under this model with the additional hyperparameter α, we can still obtain a closed-form solution for the optimal c_s.

3.3 Baseline 1: Factorized Unimodal Model

In this subsection, we outline our method for learning representations of multimodal utterances. An overview of our proposed baseline model is shown in Figure 1. Our method begins by assuming a factorization of the multimodal utterance into unimodal factors conditioned on the joint utterance embedding. Next, each unimodal factor is modeled using the simple form of a likelihood function obtained via a linear transformation of the utterance embedding. Finally, we incorporate positional encodings to represent temporal information in the features. We first present the details of our proposed baseline before deriving a coordinate ascent style optimization algorithm to learn utterance embeddings in our model.

Unimodal Factorization: We use $m_{\mathbf{s}}$ to represent the multimodal utterance embedding. To begin, we simplify the composition of $m_{\mathbf{s}}$ by assuming that the segment $\mathbf{s}$ can be conditionally factorized into words ($\mathbf{w}$), visual features ($\mathbf{v}$), and acoustic features ($\mathbf{a}$). Each factor is also associated with a temperature hyperparameter ($\alpha_{\mathbf{w}}$, $\alpha_{\mathbf{v}}$, $\alpha_{\mathbf{a}}$) that represents the contribution of each factor towards the multimodal utterance. The likelihood of a segment s given the embedding $m_{\mathbf{s}}$ is therefore

$$\begin{aligned}\mathbb{P}[\mathbf{s}|m_{\mathbf{s}}] &= \mathbb{P}[\mathbf{w}|m_{\mathbf{s}}]^{\alpha_{\mathbf{w}}} \left(\mathbb{P}[\mathbf{v}|m_{\mathbf{s}}]\right)^{\alpha_{\mathbf{v}}} \mathbb{P}[\mathbf{a}|m_{\mathbf{s}}]^{\alpha_{\mathbf{a}}} \\ &= \prod_{w\in\mathbf{w}} \mathbb{P}[w|m_{\mathbf{s}}]^{\alpha_{\mathbf{w}}} \prod_{v\in\mathbf{v}} \mathbb{P}[v|m_{\mathbf{s}}]^{\alpha_{\mathbf{v}}} \prod_{a\in\mathbf{a}} \mathbb{P}[a|m_{\mathbf{s}}]^{\alpha_{\mathbf{a}}}.\end{aligned} \tag{3}$$

Choice of Likelihood Functions: As suggested by Arora et al. (2017), given $m_{\mathbf{s}}$, we model the probability of a word w using Equation (2). In order to analytically solve for $m_{\mathbf{s}}$, a lemma is introduced by Arora et al. (2016, 2017) which states that the partition function $Z_{m_{\mathbf{s}}}$ is concentrated around some constant Z (for all $m_{\mathbf{s}}$). This lemma is also known as the "self-normalizing" phenomenon of log-linear models (Andreas and Klein, 2015; Andreas et al., 2015). We use the same assumption and treat $Z_{m_{\mathbf{s}_t}} \approx Z$ for all $m_{\mathbf{s}}$.

Unlike discrete text tokens, the visual features are continuous. We assume that the visual features are generated from an isotropic Gaussian distribution. In section 5.1, we visually analyze the distribution of the features for real world datasets and show that these likelihood modeling assumptions are indeed justified. The Gaussian distribution is parametrized by simple linear transformations $W_v^{\mu}, W_v^{\sigma} \in \mathbb{R}^{|v|\times|m_{\mathbf{s}}|}$ and $b_v^{\mu}, b_v^{\sigma} \in \mathbb{R}^{|v|}$:

$$v|m_{\mathbf{s}} \sim \mathcal{N}(\mu_v, \sigma_v^2), \tag{4}$$

$$\mu_v = W_v^{\mu} m_{\mathbf{s}} + b_v^{\mu}, \tag{5}$$

$$\sigma_v = \operatorname{diag}\left(\exp\left(W_v^{\sigma} m_{\mathbf{s}} + b_v^{\sigma}\right)\right). \tag{6}$$

Similarly, we also assume that the continuous acoustic features are generated from a different isotropic Gaussian distribution parametrized as:

$$a|m_{\mathbf{s}} \sim \mathcal{N}(\mu_a, \sigma_a^2), \tag{7}$$

$$\mu_a = W_a^{\mu} m_{\mathbf{s}} + b_a^{\mu}, \tag{8}$$

$$\sigma_a = \operatorname{diag}\left(\exp\left(W_a^{\sigma} m_{\mathbf{s}} + b_a^{\sigma}\right)\right). \tag{9}$$

Positional Encodings: Finally, we incorporate positional encodings (Vaswani et al., 2017) into the features to represent temporal information. We use d-dimensional positional encodings with entries:

$$PE_{pos,2i} = \sin\left(pos/10000^{2i/d}\right), \tag{10}$$

$$PE_{pos,2i+1} = \cos\left(pos/10000^{2i/d}\right). \tag{11}$$

where pos is the position (time step) and $i \in [1, d]$ indexes the dimension of the positional encodings. We call this resulting model Multimodal Baseline 1 (**MMB1**).

Algorithm 1 Baseline 1

4:         Fix $W^{(k)}, b^{(k)}$, compute $m_{\mathbf{s}}^{(k)}$ by (13).
5:         Fix $m_{\mathbf{s}}^{(k)}$, compute $\nabla_W \mathcal{L}$ by (21-22).
6:         Fix $m_{\mathbf{s}}^{(k)}$, compute $\nabla_b \mathcal{L}$ by (23-24).
7:         Update $W^{(k+1)}$ from $W^{(k)}$ and $\nabla_W \mathcal{L}$.
8:         Update $b^{(k+1)}$ from $b^{(k)}$ and $\nabla_b \mathcal{L}$.
```

3.4 Optimization for Baseline 1

We define our objective function by the log-likelihood of the observed multimodal utterance s. The maximum likelihood estimator of the utterance embedding $m_{\mathbf{s}}$ and the linear transformation parameters W and b can then be obtained by maximizing this objective

$$\mathcal{L}(m_{\mathbf{s}}, W, b; \mathbf{s}) = \log \mathbb{P}[\mathbf{s}|m_{\mathbf{s}}; W, b], \tag{12}$$

where we use W and b to denote all linear transformation parameters.

Coordinate Ascent Style Algorithm: Since the objective (12) is not jointly convex in $m_{\mathbf{s}}$, W and b, we optimize by alternating between: 1) solving for $m_{\mathbf{s}}$ given the parameters W and b at the current iterate, and 2) given $m_{\mathbf{s}}$, updating W and b using a gradient-based algorithm. This resembles the coordinate ascent optimization algorithm which maximizes the objective according to each coordinate separately (Tseng, 2001; Wright, 2015). Algorithm 1 presents our method for learning utterance embeddings. In the following sections, we describe how to solve for $m_{\mathbf{s}}$ and update W and b.

Solving for $m_{\mathbf{s}}$: We first derive an algorithm to solve for the optimal $m_{\mathbf{s}}$ given the log likelihood objective in (12), and parameters W and b.

Theorem 1. *[Solving for $m_{\mathbf{s}}$] Assume the optimal $m_{\mathbf{s}}$ lies on the unit sphere (i.e. $\|m_{\mathbf{s}}\|_2^2 = 1$), then closed form of $m_{\mathbf{s}}$ in line 4 in Algorithm 1 is*

$$\begin{aligned} m_{\mathbf{s}}^* = &\sum_{w\in s} \psi_w w \\ &+ \sum_{v\in s}\left(W_v^{\mu\top}\tilde{v}^{(1)}\psi_v^{(1)} + W_v^{\sigma\top}\tilde{v}^{(2)}\psi_v^{(2)}\right) \\ &+ \sum_{a\in s}\left(W_a^{\mu\top}\tilde{a}^{(1)}\psi_a^{(1)} + W_a^{\sigma\top}\tilde{a}^{(2)}\psi_a^{(2)}\right). \end{aligned} \tag{13}$$

where the shifted visual and acoustic features are:

$$\tilde{v}^{(1)} = v - b_v^{\mu},\ \tilde{v}^{(2)} = (v - b_v^{\mu}) \otimes (v - b_v^{\mu}), \tag{14}$$

$$\tilde{a}^{(1)} = a - b_a^{\mu},\ \tilde{a}^{(2)} = (a - b_a^{\mu}) \otimes (a - b_a^{\mu}), \tag{15}$$

where $\otimes$ denotes Hadamard (element-wise) product and the weights ψ's are given as follows:

$$\psi_w = \frac{\alpha_{\mathbf{w}}(1-\alpha)/(\alpha Z)}{p(w) + (1-\alpha)/(\alpha Z)}, \tag{16}$$

$$\psi_v^{(1)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{v}}}{\exp\left(2b_v^{\sigma}\right)}\right), \tag{17}$$

$$\psi_v^{(2)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{v}}}{\exp\left(2b_v^{\sigma}\right)} - \alpha_{\mathbf{v}}\right), \tag{18}$$

$$\psi_a^{(1)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{a}}}{\exp\left(2b_a^{\sigma}\right)}\right), \tag{19}$$

$$\psi_a^{(2)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{a}}}{\exp\left(2b_a^{\sigma}\right)} - \alpha_{\mathbf{a}}\right). \tag{20}$$

Proof. The proof is adapted from Arora et al. (2017) and involves computing the gradients $\nabla_{m_{\mathbf{s}}} \log \mathbb{P}[\cdot|m_{\mathbf{s}}]^{\alpha_{\cdot}}$. We express $\log \mathbb{P}[\cdot|m_{\mathbf{s}}]$ via a Taylor expansion approximation and we observe that $\log \mathbb{P}[\cdot|m_{\mathbf{s}}] \approx c + \langle m_{\mathbf{s}}, g\rangle$ for a constant c and a vector g. Then, we can obtain $m_{\mathbf{s}}^*$ by computing $\arg\max_{m_{\mathbf{s}}^*} \mathcal{L}(m_{\mathbf{s}}, W, b; \mathbf{s})$ which yields a closed-form solution. Please refer to the supplementary material for proof details. ☐

Observe that the optimal embedding $m_{\mathbf{s}}^*$ is a weighted average of the word features w and the (shifted and transformed) visual and acoustic features, $\tilde{v}$ and $\tilde{a}$. Our choice of a Gaussian likelihood for the visual and acoustic features introduces a squared term $(v - b_v^{\mu}) \otimes (v - b_v^{\mu})$ to account for the ℓ_2 distance present in the pdf. The transformation matrix $W^{\top}$ transforms the visual and acoustic features into the multimodal embedding space. Regarding the weights ψ, note that: 1) the weights are proportional to the global temperatures α assigned to that modality, 2) the weights ψ_w are inversely proportional to $p(w)$ (rare words carry more weight), and 3) the weights ψ_v and ψ_a scale each feature dimension inversely by their magnitude.

Updating W and b: To find the optimal linear transformation parameters W and b to maximize the objective in (12), we perform gradient-based optimization on W and b (in Algorithm 1 line 5-8).

Proposition 1. *[Updating W and b] The gradients $\nabla_W \mathcal{L}(m_{\mathbf{s}}, W, b)$ and $\nabla_b \mathcal{L}(m_{\mathbf{s}}, W, b)$, in each dimension, are:*

$$\nabla_{W_{v\,ij}^{\mu}} \mathcal{L}(m_{\mathbf{s}}, W, b) = \alpha_{\mathbf{v}} \operatorname{tr}\left[\left(\sigma_v^{-2}(v - \mu_v)\right)^{\top} m_{\mathbf{s}j}\right], \tag{21}$$

$$\nabla_{W_{v\,ij}^{\sigma}} \mathcal{L}(m_{\mathbf{s}}, W, b) = -\frac{\alpha_{\mathbf{v}}}{2} \operatorname{tr}\left[\left(\sigma_v^{-2} - \sigma_v^{-2}(v - \mu_v)(v - \mu_v)^{\top}\sigma_v^{-2}\right)^{\top} \sigma_{vii} m_{\mathbf{s}j}\right], \tag{22}$$

$$\nabla_{b_{v\,i}^{\mu}} \mathcal{L}(m_{\mathbf{s}}, W, b) = \alpha_{\mathbf{v}} \operatorname{tr}\left[\left(\sigma_v^{-2}(v - \mu_v)\right)^{\top}\right], \tag{23}$$

$$\nabla_{b_{v\,i}^{\sigma}} \mathcal{L}(m_{\mathbf{s}}, W, b) = -\frac{\alpha_{\mathbf{v}}}{2} \operatorname{tr}\left[\left(\sigma_v^{-2} - \sigma_v^{-2}(v - \mu_v)(v - \mu_v)^{\top}\sigma_v^{-2}\right)^{\top} \sigma_{vii}\right]. \tag{24}$$

Proof. The proof involves differentiating the log likelihood of a multivariate Gaussian with respect to μ and σ before applying the chain rule to $\mu = W^{\mu} m_{\mathbf{s}} + b^{\mu}$ and $\sigma = \operatorname{diag}\left(\exp\left(W^{\sigma} m_{\mathbf{s}} + b^{\sigma}\right)\right)$. ☐

3.5 Baseline 2: Incorporating Bimodal and Trimodal Interactions

So far, we have assumed the utterance segment s can be independently factorized into unimodal features. In this subsection, we extend the setting to take account for bimodal and trimodal interactions. We adopt the idea of early-fusion (Srivastava and Salakhutdinov, 2012), which means the bimodal and trimodal interactions are captured by the concatenated features from different modalities. Specifically, we define our factorized model as:

$$\begin{aligned}
&\mathbb{P}[\mathbf{s}|m_{\mathbf{s}}] = \mathbb{P}[\mathbf{w}|m_{\mathbf{s}}]^{\alpha_{\mathbf{w}}} \mathbb{P}[\mathbf{v}|m_{\mathbf{s}}]^{\alpha_{\mathbf{v}}} \mathbb{P}[\mathbf{a}|m_{\mathbf{s}}]^{\alpha_{\mathbf{a}}} \\
&\mathbb{P}[(\mathbf{w} \oplus \mathbf{v})\,|m_{\mathbf{s}}]^{\alpha_{\mathbf{wv}}} \mathbb{P}[(\mathbf{w} \oplus \mathbf{a})\,|m_{\mathbf{s}}]^{\alpha_{\mathbf{wa}}} \\
&\mathbb{P}[(\mathbf{v} \oplus \mathbf{a})\,|m_{\mathbf{s}}]^{\alpha_{\mathbf{va}}} \mathbb{P}[(\mathbf{w} \oplus \mathbf{v} \oplus \mathbf{a})\,|m_{\mathbf{s}}]^{\alpha_{\mathbf{wva}}},
\end{aligned} \tag{25}$$

where $\oplus$ denotes vector concatenation for bimodal and trimodal features. Each of the individual probabilities factorize in the same way as Equation (3) (i.e. $\mathbb{P}[\mathbf{a}|m_{\mathbf{s}}]^{\alpha_{\mathbf{a}}} = \prod_{a \in \mathbf{a}} \mathbb{P}[a|m_{\mathbf{s}}]^{\alpha_{\mathbf{a}}}$). Similar to baseline 1, we assume a log-linear likelihood (2) for $\mathbb{P}[w|m_{\mathbf{s}}]$ and a Gaussian likelihood (4) for all remaining terms. We call this Multimodal Baseline 2 (**MMB2**).

3.6 Optimization for Baseline 2

The optimization algorithm derived in section 3.4 can be easily extended to learn $m_{\mathbf{s}}$, W and b in Baseline 2. We again alternate between the 2 steps of 1) solving for $m_{\mathbf{s}}$ given the parameters W and b at the current iterate, and 2) given $m_{\mathbf{s}}$, updating W and b using a gradient-based algorithm.

Solving for $m_{\mathbf{s}}$: We state a result that derives the closed-form of $m_{\mathbf{s}}$ given W and b:

Corollary 1. *[Solving for $m_{\mathbf{s}}$] Assume that the optimal $m_{\mathbf{s}}$ lies on the unit sphere (i.e. $\|m_{\mathbf{s}}\|_2^2 = 1$). The closed-form (in Algorithm 1 line 4) for $m_{\mathbf{s}}$ is:*

$$
\begin{aligned}
m_{\mathbf{s}}^* &= \sum_{w\in\mathbf{w}} \psi_w w \\
&+ \sum_{v\in\mathbf{v}} \left(W_v^{\mu\top} \tilde{v}^{(1)} \psi_v^{(1)} + W_v^{\sigma\top} \tilde{v}^{(2)} \psi_v^{(2)} \right) \\
&+ \sum_{a\in\mathbf{a}} \left(W_a^{\mu\top} \tilde{a}^{(1)} \psi_a^{(1)} + W_a^{\sigma\top} \tilde{a}^{(2)} \psi_a^{(2)} \right) \\
&+ \sum_{\substack{\mathbf{f}\in\{\mathbf{w}\oplus\mathbf{v},\mathbf{w}\oplus\mathbf{a},\\ \mathbf{v}\oplus\mathbf{a},\mathbf{w}\oplus\mathbf{v}\oplus\mathbf{a}\}}} \sum_{f\in\mathbf{f}} \left(W_f^{\mu\top} \tilde{f}^{(1)} \psi_f^{(1)} + W_f^{\sigma\top} \tilde{f}^{(2)} \psi_f^{(2)} \right)
\end{aligned}
\tag{26}
$$

where the shifted (and squared) visual features are:

$$\tilde{v}^{(1)} = v - b_v^{\mu},\ \tilde{v}^{(2)} = (v - b_v^{\mu}) \otimes (v - b_v^{\mu}), \tag{27}$$

(and analogously for $\tilde{f}^{(1)}, \tilde{f}^{(2)}, f \in \{a, w \oplus v, w \oplus a, v \oplus a, w \oplus v \oplus a\}$). The weights ψ's are:

$$\psi_w = \frac{\alpha_{\mathbf{w}}(1-\alpha)/(\alpha Z)}{p(w) + (1-\alpha)/(\alpha Z)}, \tag{28}$$

$$\psi_v^{(1)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{v}}}{\exp\left(2 b_v^{\sigma}\right)} \right), \tag{29}$$

$$\psi_v^{(2)} = \operatorname{diag}\left(\frac{\alpha_{\mathbf{v}}}{\exp\left(2 b_v^{\sigma}\right)} - \alpha_{\mathbf{v}} \right). \tag{30}$$

(and analogously for $\psi_f^{(1)}, \psi_f^{(2)}, f \in \{a, w \oplus v, w \oplus a, v \oplus a, w \oplus v \oplus a\}$).

Proof. The proof is a symmetric extension of Theorem 1 to take into account the Gaussian likelihoods for bimodal and trimodal features. □

Updating W and b: The gradient equations for updating W and b are identical to those derived in Proposition 1, Equations (21-24).

3.7 Multimodal Prediction

Given the optimal embeddings $m_{\mathbf{s}}$, we can now train a classifier from $m_{\mathbf{s}}$ to labels y for multimodal prediction. $m_{\mathbf{s}}$ can also be fine-tuned on labeled data (i.e. taking gradient descent steps to update $m_{\mathbf{s}}$ with respect to the task-specific loss functions) to learn task-specific multimodal utterance representations. In our experiments, we use a fully connected neural network for our classifier.

4 Experimental Setup

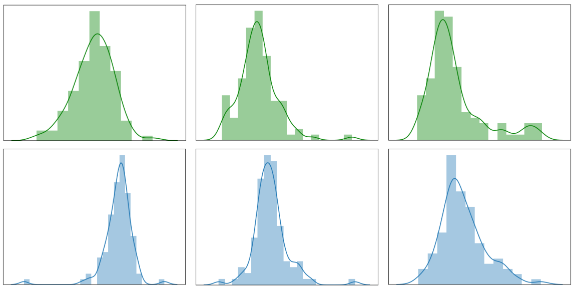

Figure 2: Histogram visualizations of the visual (top) and acoustic (bottom) features in some CMU-MOSI multimodal utterances. Many of the features converge to a Gaussian distribution across the time steps in the utterance, justifying our parametrization for the visual and acoustic likelihood functions.

To evaluate the generalization of our models, we perform experiments on multimodal speaker traits recognition and multimodal sentiment analysis. The code for our experiments is released at `https://github.com/yaochie/multimodal-baselines`, and all datasets for our experiments can be downloaded at `https://github.com/A2Zadeh/CMU-MultimodalSDK`.

4.1 Datasets

All datasets consist of monologue videos where the speaker's intentions are conveyed through the language, visual and acoustic modalities. The multimodal features are described in the next subsection.

Multimodal Speaker Traits Recognition involves recognizing speaker traits based on multimodal utterances. **POM** (Park et al., 2014) contains 903 videos each annotated for speaker traits: confident (con), voice pleasant (voi), dominance (dom), vivid (viv), reserved (res), trusting (tru), relaxed (rel), outgoing (out), thorough (tho), nervous (ner), and humorous (hum). The abbreviations (inside parentheses) are used in the tables.

Multimodal Sentiment Analysis involves analyzing speaker sentiment based on video content. Multimodal sentiment analysis extends conventional language-based sentiment analysis to a multimodal setup where both verbal and non-verbal signals contribute to the expression of sentiment. We use **CMU-MOSI** (Zadeh et al., 2016) which consists of 2199 opinion segments from online videos each annotated with sentiment from strongly negative (-3) to strongly positive ($+3$).

4.2 Multimodal Features and Alignment

GloVe word embeddings (Pennington et al., 2014), Facet (iMotions, 2017) and COVAREP (Degottex et al., 2014) are extracted for the language, visual

Table 1: Results for multimodal personality trait recognition on POM (left) and multimodal sentiment analysis on CMU-MOSI (right). EF-LSTM$^{(\star)}$and HCRF$^{(\star)}$ denote the best result obtained from the LSTM and HCRF variants respectively. The top two results are highlighted in bold. Our proposed baseline model (MMB2), despite its simplicity, often ranks in the top two models and outperforms many large neural models such as C-MKL, DF, SAL-CNN, EF-LSTM, MV-LSTM, BC-LSTM, TFN, and MFN.

and acoustic modalities respectively[1]. Forced alignment is performed using P2FA (Yuan and Liberman, 2008) to obtain the exact utterance times of each word. The video and audio features are aligned by computing the expectation of their features over each word interval (Liang et al., 2018).

4.3 Evaluation Metrics

For classification, we report multiclass classification accuracy A(c) where c denotes the number of classes and F1 score. For regression, we report Mean Absolute Error (MAE) and Pearson's correlation (r). For MAE lower values indicate better performance. For all remaining metrics, higher values indicate better performance.

5 Results and Discussion

5.1 Gaussian Likelihood Assumption

Before proceeding to the experimental results, we perform some sanity checks on our modeling assumptions. We plotted histograms of the visual and acoustic features in CMU-MOSI utterances to visually determine if they resemble a Gaussian distribution. From the plots in Figure 2, we observe that many of the features indeed converge approximately to a Gaussian distribution across the time steps in the utterance, justifying the parametrization for the visual and acoustic likelihood functions in our model.

5.2 Supervised Learning

Our first set of experiments evaluates the performance of our baselines on two multimodal prediction tasks: multimodal sentiment analysis on CMU-MOSI and multimodal speaker traits recognition on POM. On CMU-MOSI (right side of Table 1), our model **MMB2** performs competitively against many neural models including early fusion deep neural networks (Nojavanasghari et al., 2016), several variants of LSTMs (stacked, bidirectional etc.) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997), Multi-view LSTMs (Rajagopalan et al., 2016), and tensor product recurrent models (TFN) (Zadeh et al., 2017). For multimodal personality traits recognition on POM (left side of Table 1), our baseline is able to additionally outperform more complicated memory-based recurrent models such as MFN (Zadeh et al., 2018) on several metrics. We view this as an impressive achievement considering the simplicity of our model and the significantly fewer parameters that our model contains. As we will later show, our model's strong performance comes with the additional benefit of being significantly faster than the existing models.

---

MMB2	**0.00219**	**313000**

Table 3: Average time taken for inference on the CMU-MOSI test set and Inferences Per Second (IPS) on a single Nvidia GeForce GTX 1080 Ti GPU, averaged over 5 trials. Our proposed baselines are more than 10 times faster than the closest neural model (EF-LSTM).

Dataset			**CMU-MOSI**	
Task			**Sentiment**	
Model	PE	FT	A(2)	F1
MMB2, language only	✓	✓	72.3	73.7
MMB2	✗	✗	74.1	73.9
MMB2	✗	✓	74.6	74.6
MMB2	✓	✗	74.6	74.6
MMB2	✓	✓	**75.2**	**75.1**

Table 4: Ablation studies on CMU-MOSI test set. Incorporating nonverbal (visual and acoustic) features, positional encodings (PE), and task-specific fine tuning (FT) are important for good prediction performance.

5.3 Semi-supervised Learning

Our next set of experiments evaluates the performance of our proposed baseline models when there is limited labeled data. Intuitively, we expect our model to have a lower sample complexity since training our model involves learning fewer parameters. As a result, we hypothesize that our model will generalize better when there is limited amounts of labeled data as compared to larger neural models with a greater number of parameters.

We test this hypothesis by evaluating the performance of our model on the CMU-MOSI dataset with only 40%, 60%, 80%, and 100% of the training labels. The remainder of the train set now consists of unlabeled data which is also used during training but in a semi-supervised fashion. We use the entire train set (both labeled and unlabeled data) for unsupervised learning of our multimodal embeddings before the embeddings are fine-tuned to predict the label using limited labeled data. A comparison is performed with two models that also learn embeddings from unlabeled multimodal utterances: 1) deep averaging autoencoder (**AE**) (Iyyer et al., 2015; Hinton and Salakhutdinov, 2006) which averages the temporal dimension before using a fully connected autoencoder to learn a latent embedding, and 2) sequence to sequence autoencoder (**seq2seq**) (Sutskever et al., 2014) which captures temporal information using a recurrent neural network encoder and decoder. For each of these models, an autoencoding model is used to learn embeddings on the entire training set (both labeled and unlabeled data) before the embeddings are fine-tuned to predict the label using limited labeled data. The validation and test sets remains unchanged for fair comparison.

Under this semi-supervised setting, we show prediction results on the CMU-MOSI test set in Table 2. Empirically, we find that our model is able to outperform deep autoencoders and their recurrent variant. Our model remains strong and only suffers a drop in performance of about 3% (75.1% → 72.9% binary accuracy) despite having access to only 40% of the labeled training data.

5.4 Inference Timing Comparisons

To demonstrate another strength of our model, we compare the inference times of our model with existing baselines in Table 3. Our model achieves an inference per second (IPS) of more than 10 times the closest neural model (EF-LSTM). We attribute this speedup to our (approximate) closed form solution for m_s as derived in Theorem 1 and Corollary 1, the small size of our model, as well as the fewer number of parameters (linear transformation parameters and classifier parameters) involved.

5.5 Ablation Study

To further motivate our design decisions, we test some ablations of our model: 1) we remove the modeling capabilities of the visual and acoustic modalities, instead modeling only the language modality, 2) we remove the positional encodings, and 3) we remove the fine tuning step. We provide these results in Table 4 and observe that each component is indeed important for our model. Although the text only model performs decently, incorporating visual and acoustic features under our modeling assumption improves performance. Our results also demonstrate the effectiveness of positional encodings and fine tuning without having to incorporate any additional learnable parameters.

6 Conclusion

This paper proposed two simple but strong baselines to learn embeddings of multimodal utterances. The first baseline assumes a factorization of the utterance into unimodal factors conditioned on the joint embedding while the second baseline extends the first by assuming a factorization into unimodal, bimodal, and trimodal factors. Both proposed models retain simplicity and efficiency during both learning and inference. From experiments across multimodal tasks and datasets, we show that our proposed baseline models: 1) display competitive performance on supervised multimodal prediction, 2) outperform classical deep autoencoders for semi-supervised multimodal prediction and 3) attain significant (10 times) speedup during inference. Overall, we believe that our strong baseline models provide new benchmarks for future research in multimodal learning.

Learning to Navigate Unseen Environments: Back Translation with Environmental Dropout

Hao Tan **Licheng Yu** **Mohit Bansal**

Abstract

A grand goal in AI is to build a robot that can accurately navigate based on natural language instructions, which requires the agent to perceive the scene, understand and ground language, and act in the real-world environment. One key challenge here is to learn to navigate in new environments that are unseen during training. Most of the existing approaches perform dramatically worse in unseen environments as compared to seen ones. In this paper, we present a generalizable navigational agent. Our agent is trained in two stages. The first stage is training via mixed imitation and reinforcement learning, combining the benefits from both off-policy and on-policy optimization. The second stage is fine-tuning via newly-introduced 'unseen' triplets (environment, path, instruction). To generate these unseen triplets, we propose a simple but effective 'environmental dropout' method to mimic unseen environments, which overcomes the problem of limited seen environment variability. Next, we apply semi-supervised learning (via back-translation) on these dropped-out environments to generate new paths and instructions. Empirically, we show that our agent is substantially better at generalizability when fine-tuned with these triplets, outperforming the state-of-art approaches by a large margin on the private unseen test set of the Room-to-Room task, and achieving the top rank on the leaderboard.[1]

1 Introduction

One of the important goals in AI is to develop a robot/agent that can understand instructions from humans and perform actions in complex environments. In order to do so, such a robot is required to perceive the surrounding scene, understand our spoken language, and act in a real-world house. Recent years have witnessed various types of embodied action based NLP tasks being proposed (Correa et al., 2010; Walters et al., 2007; Hayashi et al., 2007; Zhu et al., 2017b; Das et al., 2018; Anderson et al., 2018b).

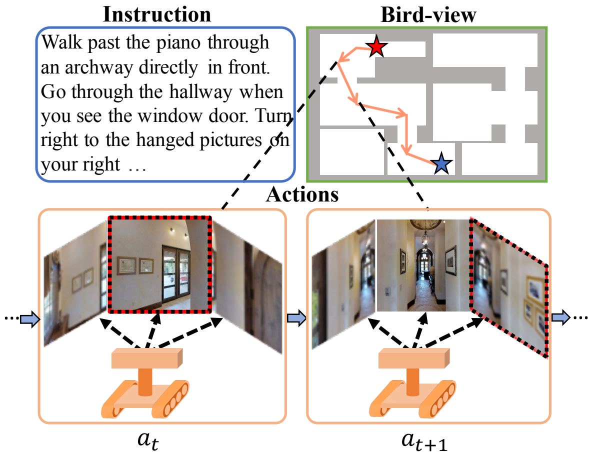

Figure 1: Room-to-Room Task. The agent is given an instruction, then starts its navigation from some staring viewpoint inside the given environment. At time t, the agent selects one view (highlighted as red dotted bounding boxes) from a set of its surrounding panoramic views to step into, as an action a_t.

In this paper, we address the task of instruction-guided navigation, where the agent seeks a route from a start viewpoint to an end viewpoint based on a given natural language instruction in a given environment, as shown in Fig. 1. The navigation simulator we use is the recent Room-to-Room (R2R) simulator (Anderson et al., 2018b), which uses real images from the Matterport3D (Chang et al., 2017) indoor home environments and collects complex navigable human-spoken instructions inside the environments, hence connecting problems in vision, language, and robotics. The instruction in Fig. 1 is *"Walk past the piano through an archway directly in front. Go through the hallway when you see the window door. Turn*

right to the hanged pictures...". At each position (viewpoint), the agent perceives panoramic views (a set of surrounding images) and selects one of them to step into. In this challenging task, the agent is required to understand each piece of the instruction and localize key views (*"piano"*, *"hallway"*, *"door"*, etc.) for making actions at each time step. Another crucial challenge is to generalize the agent's navigation understanding capability to unseen test room environments, considering that the R2R task has substantially different unseen (test) rooms as compared to seen (trained) ones. Such generalization ability is important for developing a practical navigational robot that can operate in the wild.

Recent works (Fried et al., 2018; Wang et al., 2019, 2018a; Ma et al., 2019) have shown promising progress on this R2R task, based on speaker-follower, reinforcement learning, imitation learning, cross-modal, and look-ahead models. However, the primary issue in this task is that most models perform substantially worse in unseen environments than in seen ones, due to the lack of generalizability. Hence, in our paper, we focus on improving the agent's generalizability in unseen environments. For this, we propose a two-stage training approach. The first stage is training the agent via mixed imitation learning (IL) and reinforcement learning (RL) which combines off-policy and on-policy optimization; this significantly outperforms using IL or RL alone.

The second, more important stage is semi-supervised learning with generalization-focused 'environmental dropout'. Here, the model is fine-tuned using additional training data generated via back-translation. This is usually done based on a neural speaker model (Fried et al., 2018) that synthesizes new instructions for additional routes in the *existing* environments. However, we found that the bottleneck for this semi-supervised learning method is the limited variability of given (seen) environments. Therefore, to overcome this, we propose to generate novel and diverse environments via a simple but effective 'environmental dropout' method based on view- and viewpoint-consistent masking of the visual features. Next, the new navigational routes are collected from these new environments, and lastly the new instructions are generated by a neural speaker on these routes, and these triplets are employed to fine-tune the model training.

Overall, our fine-tuned model based on back-translation with environmental dropout substantially outperforms the previous state-of-the-art models, and achieves the most recent rank-1 on the Vision and Language Navigation (VLN) R2R challenge leaderboard's private test data, outperforming all other entries in success rate under all evaluation setups (single run, beam search, and pre-exploration).[2] We also present detailed ablation and analysis studies to explain the effectiveness of our generalization method.

2 Related Work

Embodied Vision-and-Language Recent years are witnessing a resurgence of active vision. For example, Levine et al. (2016) used an end-to-end learned model to predict robotic actions from raw pixel data, Gupta et al. (2017) learned to navigate via mapping and planning, Sadeghi and Levine (2017) trained an agent to fly in simulation and show its performance in the real world, and Gandhi et al. (2017) trained a self-supervised agent to fly from examples of drones crashing. Meanwhile, in the intersection of active perception and language understanding, several tasks have been proposed, including instruction-based navigation (Chaplot et al., 2018; Anderson et al., 2018b), target-driven navigation (Zhu et al., 2017b; Gupta et al., 2017), embodied question answering (Das et al., 2018), interactive question answering (Gordon et al., 2018), and task planning (Zhu et al., 2017a). While these tasks are driven by different goals, they all require agents that can perceive their surroundings, understand the goal (either presented visually or in language instructions), and act in a virtual environment.

Instruction-based Navigation For instruction-based navigation task, an agent is required to navigate from start viewpoint to end viewpoint according to some given instruction in an environment. This task has been studied by many works (Tellex et al., 2011; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013; Andreas and Klein, 2015; Mei et al., 2016; Misra et al., 2017) in recent years. Among them, (Anderson et al., 2018b) differs from the others as it introduced a photo-realistic dataset – Room-to-Room (R2R), where all images are real ones taken by Matterport3D (Chang et al., 2017) and the instructions are also natural. In R2R

---

[2] `https://evalai.cloudcv.org/web/challenges/challenge-page/97/overview`

environments, the agent's ability to perceive real-world images and understanding natural language becomes even more crucial. To solve this challenging task, a lot of works (Fried et al., 2018; Wang et al., 2018a, 2019; Ma et al., 2019) have been proposed and shown some potential. The most relevant work to us is Fried et al. (2018), which proposed to use a speaker to synthesize new instructions and implement pragmatic reasoning. However, we observe there is some performance gap between seen and unseen environments. In this paper, we focus on improving the agent's generalizability in unseen environment.

Back-translation Back translation (Sennrich et al., 2016), a popular semi-supervised learning method, has been well studied in neural machine translation (Hoang et al., 2018; Wang et al., 2018b; Edunov et al., 2018; Prabhumoye et al., 2018). Given paired data of source and target sentences, the model first learns two translators – a forward translator from source to target and a backward translator from target to source. Next, it generates more source sentences using the back translator on an external target-language corpus. The generated pairs are then incorporated into the training data for fine-tuning the forward translator, which proves to improve the translation performance. Recently, this approach (also known as data augmentation) was applied to the task of instruction-based navigation (Fried et al., 2018), where the source and target sentences are replaced with instructions and routes.

3 Method

3.1 Problem Setup

Navigation in the Room-to-Room task (Anderson et al., 2018b) requires an agent to find a route $\mathbf{R}$ (a sequence of viewpoints) from the start viewpoint $\mathbf{S}$ to the target viewpoint $\mathbf{T}$ according to the given instruction $\mathbf{I}$. The agent is put in a photo-realistic environment $\mathbf{E}$. At each time step t, the agent's observation consists of a panoramic view and navigable viewpoints. The panoramic view o_t is discretized into 36 single views $\{o_{t,i}\}_{i=1}^{36}$. Each single view $o_{t,i}$ is an RGB image $v_{t,i}$ accompanied with its orientation $(\theta_{t,i}, \phi_{t,i})$, where $\theta_{t,i}$ and $\phi_{t,i}$ are the angles of heading and elevation, respectively. The navigable viewpoints $\{l_{t,k}\}_{k=1}^{N_t}$ are the N_t reachable and visible locations from the current viewpoint. Each navigable viewpoint $l_{t,k}$ is represented by the orientation $(\hat{\theta}_{t,k}, \hat{\phi}_{t,k})$ from current viewpoint to the next viewpoints. The agent needs to select the moving action a_t from the list of navigable viewpoints $\{l_{t,k}\}$ according to the given instruction $\mathbf{I}$, history/current panoramic views $\{o_\tau\}_{\tau=1}^{t}$, and history actions $\{a_\tau\}_{\tau=1}^{t-1}$. Following Fried et al. (2018), we concatenate the ResNet (He et al., 2016) feature of the RGB image and the orientation as the view feature $f_{t,i}$:

$$\begin{aligned} f_{t,i} = [\, & \mathrm{ResNet}(v_{t,i}); \\ & (\cos\theta_{t,i}, \sin\theta_{t,i}, \cos\phi_{t,i}, \sin\phi_{t,i})\,] \end{aligned} \tag{1}$$

The navigable viewpoint feature $g_{t,k}$ is extracted in the same way.

3.2 Base Agent Model

For our base instruction-to-navigation translation agent, we implement an encoder-decoder model similar to Fried et al. (2018). The encoder is a bidirectional LSTM-RNN with an embedding layer:

$$\hat{w}_j = \text{embedding}(w_j) \tag{2}$$

$$u_1, u_2, \cdots, u_{\mathrm{L}} = \text{Bi-LSTM}(\hat{w}_1, \cdots, \hat{w}_{\mathrm{L}}) \tag{3}$$

where u_j is the j-th word in the instruction with a length of L. The decoder of the agent is an attentive LSTM-RNN. At each decoding step t, the agent first attends to the view features $\{f_{t,i}\}$ computing the attentive visual feature $\tilde{f}_t$:

$$\alpha_{t,i} = \mathrm{softmax}_i(f_{t,i}^{\intercal} W_{\mathrm{F}}\, \tilde{h}_{t-1}) \tag{4}$$

$$\tilde{f}_t = \sum\nolimits_i \alpha_{t,i} f_{t,i} \tag{5}$$

The input of the decoder is the concatenation of the attentive visual feature $\tilde{f}_t$ and the embedding of the previous action $\tilde{a}_{t-1}$. The hidden output h_t of the LSTM is combined with the attentive instruction feature $\tilde{u}_t$ to form the instruction-aware hidden output $\tilde{h}_t$. The probability of moving to the k-th navigable viewpoint $p_t(a_{t,k})$ is calculated as softmax of the alignment between the navigable viewpoint feature $g_{t,k}$ and the instruction-aware hidden output $\tilde{h}_t$.

$$h_t = \mathrm{LSTM}\left([\tilde{f}_t; \tilde{a}_{t-1}], \tilde{h}_{t-1}\right) \tag{6}$$

$$\beta_{t,j} = \mathrm{softmax}_j\left(u_j^{\intercal}\, W_{\mathrm{U}}\, h_t\right) \tag{7}$$

$$\tilde{u}_t = \sum\nolimits_j \beta_{t,j}\, u_j \tag{8}$$

$$\tilde{h}_t = \tanh\left(W\, [\tilde{u}_t;\, h_t]\right) \tag{9}$$

$$p_t(a_{t,k}) = \mathrm{softmax}_k\left(g_{t,k}^{\intercal}\, W_{\mathrm{G}}\, \tilde{h}_t\right) \tag{10}$$

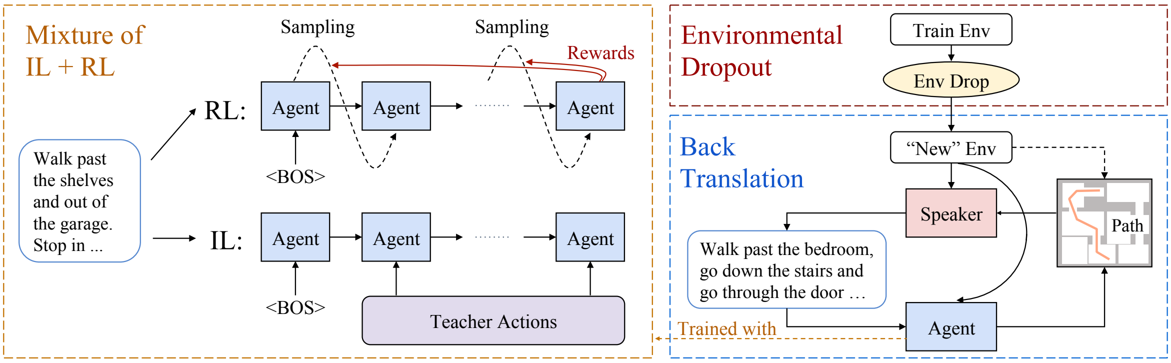

Figure 2: Left: IL+RL supervised learning (stage 1). Right: Semi-supervised learning with back translation and environmental dropout (stage 2).

Different from Fried et al. (2018), we take the instruction-aware hidden vector $\tilde{h}_{t-1}$ as the hidden input of the decoder instead of h_{t-1}. Thus, the information about which parts of the instruction have been attended to is accessible to the agent.

3.3 Supervised Learning: Mixture of Imitation+Reinforcement Learning

We discuss our IL+RL supervised learning method in this section.[3]

Imitation Learning (IL) In IL, an agent learns to imitate the behavior of a teacher. The teacher demonstrates a teacher action a_t^* at each time step t. In the task of navigation, a teacher action a_t^* selects the next navigable viewpoint which is on the shortest route from the current viewpoint to the target $\mathbf{T}$. The off-policy[4] agent learns from this weak supervision by minimizing the negative log probability of the teacher's action a_t^*. The loss of IL is as follows:

$$\mathcal{L}^{\text{IL}} = \sum_t \mathcal{L}_t^{\text{IL}} = \sum_t \text{-}\log p_t(a_t^*) \tag{11}$$

For exploration, we follow the IL method of Behavioral Cloning (Bojarski et al., 2016), where the agent moves to the viewpoint following the teacher's action a_t^* at time step t.

Reinforcement Learning (RL) Although the route induced by the teacher's actions in IL is the shortest, this selected route is not guaranteed to satisfy the instruction. Thus, the agent using IL is biased towards the teacher's actions instead of finding the correct route indicated by the instruction. To overcome these misleading actions, the on-policy reinforcement learning method Advantage Actor-Critic (Mnih et al., 2016) is applied, where the agent takes a sampled action from the distribution $\{p_t(a_{t,k})\}$ and learns from rewards. If the agent stops within $3m$ around the target viewpoint $\mathbf{T}$, a positive reward $+3$ is assigned at the final step. Otherwise, a negative reward -3 is assigned. We also apply reward shaping (Wu et al., 2018): the direct reward at each non-stop step t is the change of the distance to the target viewpoint.

IL+RL Mixture To take the advantage of both off-policy and on-policy learners, we use a method to mix IL and RL. The IL and RL agents share weights, take actions separately, and navigate two independent routes (see Fig. 2). The mixed loss is the weighted sum of $\mathcal{L}^{\text{IL}}$ and $\mathcal{L}^{\text{RL}}$:

$$\mathcal{L}^{\text{MIX}} = \mathcal{L}^{\text{RL}} + \lambda_{\text{IL}}\mathcal{L}^{\text{IL}} \tag{12}$$

IL can be viewed as a language model on action sequences, which regularizes the RL training.[5]

3.4 Semi-Supervised Learning: Back Translation with Environmental Dropout

3.4.1 Back Translation

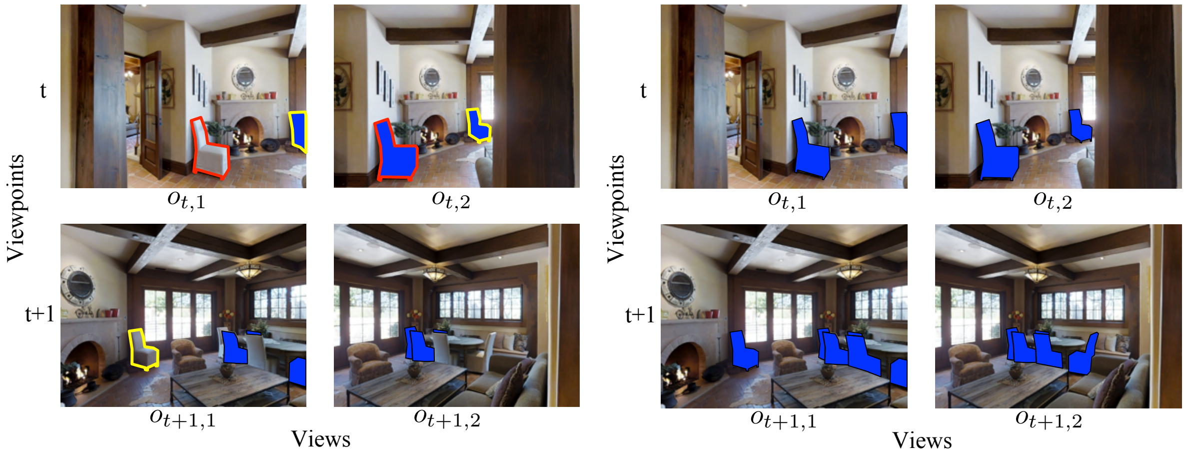
Suppose the primary task is to learn the mapping of $\mathbf{X} \rightarrow \mathbf{Y}$ with paired data $\{(\mathbf{X}, \mathbf{Y})\}$ and unpaired data $\{\mathbf{Y}'\}$. In this case, the back translation method first trains a forward model $P_{\mathbf{X}\rightarrow\mathbf{Y}}$ and a backward model $P_{\mathbf{Y}\rightarrow\mathbf{X}}$, using paired data $\{(\mathbf{X}, \mathbf{Y})\}$. Next, it generates additional datum $\mathbf{X}'$

---

[3] As opposed to semi-supervised methods in Sec. 3.4, in this section we view both imitation learning and reinforcement learning as supervised learning.

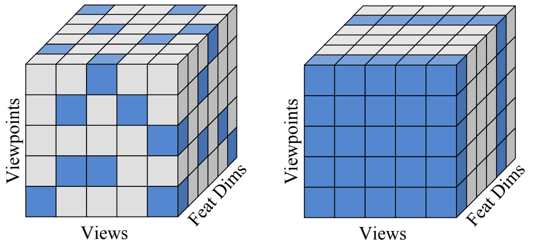
[4] According to Poole and Mackworth (2010), an off-policy learner learns the agent policy independently of the agent's navigational actions. An on-policy learner learns the policy from the agent's behavior including the exploration steps.

[5] This approach is similar to the method ML+RL in Paulus et al. (2018) for summarization. Recently, Wang et al. (2018a) combines purely supervised learning and RL training however, they use a different algorithm named MIXER (Ranzato et al., 2015), which computes cross entropy (XE) losses for the first k actions and RL losses for the remaining.



(a) Feature dropout (b) Environmental dropout

Figure 3: Comparison of the two dropout methods (based on an illustration on an RGB image).



(a) Feature dropout (b) Environmental dropout

Figure 4: Comparison of the two dropout methods (based on image features).

from the unpaired $\mathbf{Y}'$ using the backward model $P_{\mathbf{Y}\to\mathbf{X}}$. Finally, $(\mathbf{X}', \mathbf{Y}')$ are paired to further fine-tune the forward model $P_{\mathbf{X}\to\mathbf{Y}}$ as additional training data (also known as 'data augmentation').

Back translation was introduced to the task of navigation in Fried et al. (2018). The forward model is a navigational agent $P_{\mathbf{E},\mathbf{I}\to\mathbf{R}}$ (Sec. 3.2), which navigates inside an environment $\mathbf{E}$, trying to find the correct route $\mathbf{R}$ according to the given instruction $\mathbf{I}$. The backward model is a *speaker* $P_{\mathbf{E},\mathbf{R}\to\mathbf{I}}$, which generates an instruction $\mathbf{I}$ from a given route $\mathbf{R}$ inside an environment $\mathbf{E}$. Our speaker model (details in Sec. 3.4.3) is an enhanced version of Fried et al. (2018), where we use a stacked bidirectional LSTM-RNN encoder with attention flow.

For back translation, the Room-to-Room dataset labels around 7% routes $\{\mathbf{R}\}$ in the training environments[6], so the rest of the routes $\{\mathbf{R}'\}$ are unlabeled. Hence, we generate additional instructions $\mathbf{I}'$ using $P_{\mathbf{E},\mathbf{R}\to\mathbf{I}}(\mathbf{E}, \mathbf{R}')$, so to obtain the new triplets $(\mathbf{E}, \mathbf{R}', \mathbf{I}')$. The agent is then fine-tuned with this new data using the IL+RL method described in Sec. 3.3. However, note that the environment $\mathbf{E}$ in the new triplet $(\mathbf{E}, \mathbf{R}', \mathbf{I}')$ for semi-supervised learning is still selected from the *seen* training environments. We demonstrate that the limited amount of environments $\{\mathbf{E}\}$ is actually the bottleneck of the agent performance in Sec. 7.1 and Sec. 7.2. Thus, we introduce our environmental dropout method to mimic the "new" environment $\mathbf{E}'$, as described next in Sec. 3.4.2.

3.4.2 Environmental Dropout

Failure of Feature Dropout Different from dropout on neurons to regularize neural networks, we drop raw feature dimensions (see Fig. 4a) to mimic the removal of random objects from an RGB image (see Fig. 3a). This traditional feature dropout (with dropout rate p) is implemented as an element-wise multiplication of the feature f and the dropout mask ξ^f. Each element ξ^f_e in the dropout mask ξ^f is a sample of a random variable which obeys an independent and identical Bernoulli distribution multiplied by $1/(1-p)$. And for different features, the distributions of dropout masks are independent as well.

$$\mathrm{dropout}_p(f) = f \odot \xi^f \tag{13}$$

$$\xi^f_e \sim \frac{1}{1-p}\mathrm{Ber}(1-p) \tag{14}$$

Because of this independence among dropout masks, the traditional feature dropout fails in augmenting the existing environments because the 'removal' is inconsistent in different views at the same viewpoint, and in different viewpoints.

---

[6] The number of all possible routes (shortest paths) in the 60 existing training environments is 190K. Of these, the Room-to-Room dataset labeled around 14K routes with one navigable instruction for each, so the amount of labeled routes is around 7% of 190K.

To illustrate this idea, we take the four RGB views in Fig. 3a as an example, where the chairs are randomly dropped from the views. The removal of the left chair (marked with a red polygon) from view $o_{t,2}$ is inconsistent because it also appears in view $o_{t,1}$. Thus, the speaker could still refer to it and the agent is aware of the existence of the chair. Moreover, another chair (marked with a yellow polygon) is completely removed from viewpoint observation o_t, but the views in next viewpoint o_{t+1} provides conflicting information which would confuse the speaker and the agent. Therefore, in order to make generated environments consistent, we propose our environmental dropout method, described next.

Environmental Dropout We create a new environment $\mathbf{E}'$ by applying environmental dropout on an existing environment $\mathbf{E}$.

$$\mathbf{E}' = \mathrm{envdrop}_p(\mathbf{E}) \tag{15}$$

The view feature $f'_{t,i}$ observed from the new environment $\mathbf{E}'$ is calculated as an element-wise multiplication of the original feature $f_{t,i}$ and the environmental dropout mask $\xi^{\mathbf{E}}$ (see Fig. 4b):

$$f'_{t,i} = f_{t,i} \odot \xi^{\mathbf{E}} \tag{16}$$

$$\xi^{\mathbf{E}}_e \sim \frac{1}{1-p}\mathrm{Ber}(1-p) \tag{17}$$

To maintain the spatial structure of viewpoints, only the image feature $\mathrm{ResNet}(v_{t,i})$ is dropped while the orientation feature $(\cos(\theta_{t,i}), \sin(\theta_{t,i}), \cos(\phi_{t,i}), \sin(\phi_{t,i}))$ is fixed. As illustrated in Fig. 3b, the idea behind environmental dropout is to mimic new environments by removing one specific class of object (e.g., the chair). We demonstrate our idea by running environmental dropout on the ground-truth semantic views in Sec. 7.3, which is proved to be far more effective than traditional feature dropout. In practice, we perform the environmental dropout on image's visual feature where certain structures/parts are dropped instead of object instances, but the effect is similar.

We apply the environmental dropout to the back translation model as mentioned in Sec. 3.4.1. Note the environmental dropout method still preserves the connectivity of the viewpoints, thus we use the same way (Fried et al., 2018) to collect extra unlabeled routes $\{\mathbf{R}'\}$. We take *speaker* to generate an additional instruction $\mathbf{I}'$=$P_{\mathbf{E},\mathbf{R}\rightarrow\mathbf{I}}\,(\mathbf{E}', \mathbf{R}')$ in the new environment $\mathbf{E}'$. At last, we use IL+RL (in Sec. 3.3) to fine-tune the model with this new triplet $(\mathbf{E}', \mathbf{R}', \mathbf{I}')$.

3.4.3 Improvements on Speaker

Our speaker model is an enhanced version of the encoder-decoder model of Fried et al. (2018), with improvements on the visual encoder: we stack two bi-directional LSTM encoders: a route encoder and a context encoder. The route encoder takes features of ground truth actions $\{a^*_t\}_{t=1}^{T}$ from the route as inputs. Each hidden state r_t then attends to surrounding views $\{f_{t,i}\}_{i=1}^{36}$ at each viewpoint. The context encoder then reads the attended features and outputs final visual encoder representations:

$$r_1, ..., r_{\mathrm{T}} = \text{Bi-LSTM}^{\mathrm{RTE}}(g_{1,a^*_1}, ..., g_{\mathrm{T},a^*_{\mathrm{T}}}) \tag{18}$$

$$\gamma_{t,i} = \mathrm{softmax}_i(f_{t,i}^{\intercal} W_{\mathrm{R}}\, r_t) \tag{19}$$

$$\hat{f}_t = \sum\nolimits_i \gamma_{t,i} f_{t,i} \tag{20}$$

$$c_1, ..., c_{\mathrm{T}} = \text{Bi-LSTM}^{\mathrm{CTX}}(\hat{f}_1, ..., \hat{f}_{\mathrm{T}}) \tag{21}$$

The decoder is a regular attentive LSTM-RNN, which is discussed in Sec. 3.2. Empirically, our enhanced speaker model improves the BLEU-4 score by around 3 points.

4 Experimental Setup

Dataset and Simulator We evaluate our agent on the Matterport3D simulator (Anderson et al., 2018b). Navigation instructions in the dataset are collected via Amazon Mechanical Turk by showing them the routes in the Matterport3D environment (Chang et al., 2017). The dataset is split into training set (61 environments, 14,025 instructions), seen validation set (61 environments, 1,020 instructions), unseen validation set (11 environments, 2,349 instructions), and unseen test set (18 environments, 4,173 instructions). The unseen sets only involve the environments outside the training set.

Evaluation Metrics For evaluating our model, Success Rate (SR) is the primary metric. The execution route by the agent is considered a success when the navigation error is less than 3 meters. Besides success rate, we use three other metrics[7] : Navigation Length (NL), Navigation Error (NE), and Success rate weighted by Path Length (SPL) (Anderson et al., 2018a). Navigation Error (NE) is

---

[7] The Oracle Success Rate (OSR) is not included because it's highly correlated with the Navigation Length.

Models	Test Unseen (Leader-Board)								
	Single Run			Beam Search			Pre-Explore		
	NL	SR(%)	*SPL*	NL	*SR(%)*	SPL	NL	SR(%)	*SPL*
Random (Anderson et al., 2018b)	9.89	13.2	0.12	-	-	-	-	-	-
Seq-to-Seq (Anderson et al., 2018b)	8.13	20.4	0.18	-	-	-	-	-	-
Look Before You Leap (Wang et al., 2018a)	9.15	25.3	0.23	-	-	-	-	-	-
Speaker-Follower (Fried et al., 2018)	14.8	35.0	0.28	1257	53.5	0.01	-	-	-
Self-Monitoring (Ma et al., 2019)	18.0	48.0	0.35	373	61.0	**0.02**	-	-	-
Reinforced Cross-Modal (Wang et al., 2019)	12.0	43.1	0.38	358	63.0	**0.02**	9.48	60.5	0.59
Ours	11.7	**51.5**	**0.47**	687	**68.9**	0.01	9.79	**63.9**	**0.61**

the distance between target viewpoint $\mathbf{T}$ and agent stopping position.

Implementation Details Similar to the traditional dropout method, the environmental dropout mask is computed and applied at each training iteration. Thus, the amount of unlabeled semi-supervised data used is not higher in our dropout method. We also find that sharing the environmental dropout mask in different environments inside a batch will stabilize the training. To avoid over-fitting, the model is early-stopped according to the success rate on the unseen validation set. More training details in appendices.

5 Results

In this section, we compare our agent model with the models in previous works on the Vision and Language Navigation (VLN) leaderboard. The models on the leaderboard are evaluated on a private unseen test set which contains 18 new environments. We created three columns in Table 1 for different experimental setups: single run, beam search, and unseen environments pre-exploration. For the result, our model outperforms all other models in all experimental setups.

Single Run Among all three experimental setups, single run is the most general and highly correlated to the agent performance. Thus, it is considered as the primary experimental setup. In this setup, the agent navigates the environment once and is not allowed[8] to: (1) run multiple trials, (2) explore nor map the test environments before starting. Our result is 3.5% and 9% higher than the second-best in Success Rate and SPL, resp.

Beam Search In the beam search experimental setup, an agent navigates the environment, collects multiple routes, re-ranks them, and selects the route with the highest score as the prediction. Besides showing an upper bound, beam search is usable when the environment is explored and saved in the agent's memory but the agent does not have enough computational capacity to fine-tune its navigational model. We use the same beam-search algorithm, state factored Dijkstra algorithm, to navigate the unseen test environment. Success Rate of our model is 5.9% higher than the second best. SPL metric generally fails in evaluating beam-search models because of the long Navigation Length (range of SPL is 0.01-0.02).

Pre-Exploration The agent pre-explores the test environment before navigating and updates its agent model with the extra information. When executing the instruction in the environment, the experimental setup is still "single run". The "pre-exploration" agent mimics the domestic robots (e.g., robot vacuum) which only needs to navigate the seen environment most of the time. For submitting to the leaderboard, we simply train our agent via back translation with environmental dropout on test unseen environments (see Sec.7.2). Our result is 3.4% higher than Wang et al. (2019) in Success Rate and 2.0% higher in SPL. [9]

6 Ablation Studies

Supervised Learning We first show the effectiveness of our IL+RL method by comparing it with the baselines (Table 2). We implement Behavioural Cloning[10] and Advantage Actor-Critic

[8] According to the Vision and Language Navigation (VLN) challenge submission guidelines

[9] To fairly compare with Wang et al. (2019), we exclude the exploration route in calculating Navigation Length.

[10] The Behavioral Cloning (IL) baseline is the same as the panoramic view baseline in Fried et al. (2018) except for two differences: (1) The agent takes the teacher action instead of the sampled action from the distribution (see "imitation learning" of Sec. 3.3), (2) The hidden input of the LSTM is the instruction-aware hidden from the previous step (see Sec. 3.2). We improve our baseline result with these modifi-

Models	Val Seen				Val Unseen			
	NL(m)	NE(m)	SR(%)	SPL	NL(m)	NE(m)	SR(%)	SPL
SUPERVISED LEARNING								
Behavioral Cloning (IL)	10.3	5.39	48.4	0.46	9.15	6.25	43.6	0.40
Advantage Actor-Critic (RL)	73.8	7.11	22.0	0.03	73.8	7.32	24.0	0.03
IL + RL	10.1	4.71	55.3	0.53	9.37	5.49	46.5	0.43
SEMI-SUPERVISED LEARNING								
Back Translation	10.3	4.19	58.1	0.55	10.5	5.43	48.2	0.44
+ Feat Drop	10.3	4.13	58.4	0.56	9.62	5.43	48.4	0.45
+ Env Drop (No Tying)	10.3	4.32	57.3	0.55	9.51	5.27	49.0	0.46
+ Env Drop (Tying)	11.0	3.99	62.1	0.59	10.7	5.22	52.2	0.48
FULL MODEL								
Single Run	11.0	3.99	62.1	0.59	10.7	5.22	52.2	0.48
Beam Search	703	2.52	75.7	0.01	663	3.08	69.0	0.01
Pre-Explore	9.92	4.84	54.7	0.52	9.57	3.78	64.5	0.61

Table 2: For the ablation study, we show the results of our different methods on validation sets. Our full model (single run) gets 8.6% improvement in validation unseen success rate above our baseline. And both the supervised learning (IL+RL) and semi-supervised learning methods (back translation + env drop) have substantial contributions to our final result.

as our imitation learning (IL) and reinforcement learning (RL) baselines, respectively. The mixture of IL+RL (see Sec. 3.3) outperforms the IL-only model and RL-only model by 2.9% and 22.5%, which means that our IL+RL could overcome the misleading teacher actions in IL and significantly stabilize the training of RL.

Semi-Supervised Learning We then fine-tune our best supervised model (i.e., IL+RL) with back translation. Besides providing a warm-up, IL+RL is also used to learn the new generated data triplets in back translation. As shown in Table 2, back translation with environmental dropout improves the best supervised model by 5.7%, where the improvement is 3 times more than the back translation without new environments. We then show the results of the alternatives to environmental dropout. The performance with feature dropout is almost the same to the original back translation, which is 3.8% lower than the environmental dropout. We also prove that the improvement from the environmental dropout method does not only come from generating *diverse* instructions introduced by dropout in the speaker, but also comes from using the same dropout mask in the follower agent too. To show this, we use two independent (different) environmental dropout masks for the speaker and the follower (i.e., no tying of the dropout mask), and the result drops a lot as compared to when we tie the speaker and follower dropout masks.

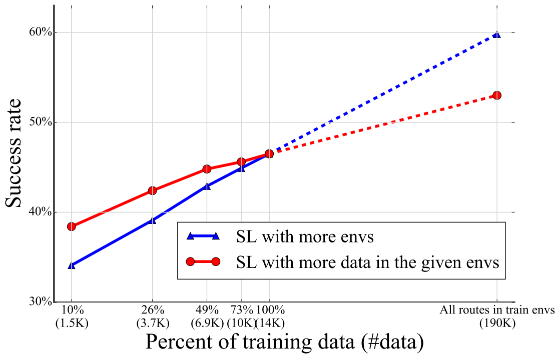

Figure 5: Success rates of agents trained with different amounts of data. X-axis in log-scale. The blue line represents the growth of results by gradually adding new environments to the supervised training method. The red line is trained with the same amounts of data as the blue line, but the data is randomly selected from all 60 training environments. The dashed lines are predicted.

Full Model Finally, we show the performance of our best agent under different experimental setups. The "single run" result is copied from the best semi-supervised model for comparison. The state-factored Dijkstra algorithm (Fried et al., 2018) is used for the beam search result. The method for pre-exploration is described in Sec. 7.2, where the agent applies back translation with environmental dropout on the validation unseen environment.

7 Analysis

In this section, we present analysis experiments that first exposed the limited environments bottleneck to us, and hence inspired us to develop our environmental dropout method to break this bottleneck.

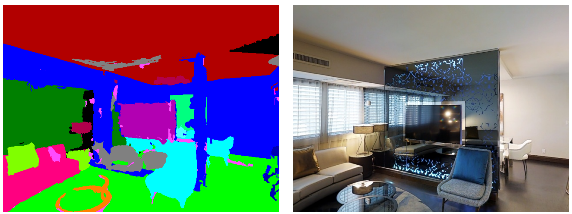
cations.



(a) Semantic View (b) RGB view

Figure 6: Comparison of semantic and raw RGB views.

7.1 More Environments vs. More Data

In order to show that more environments are crucial for better performance of agents, in Fig. 5, we present the result of Supervised Learning (SL) with different amounts of data selected by two different data-selection methods. The first method gradually uses more #environments (see the blue line "SL with more envs") while the second method selects data from the whole training data with all 60 training environments (see the red line "SL with more data"). Note that the amounts of data in the two setups are the same for each plot point As shown in Fig. 5, the "more envs" selection method shows *higher growth rate* in success rate than the "more data" method. We also predict the success rates (in dashed line) with the prediction method in Sun et al. (2017). The predicted result is much higher when training with more environments. The predicted result (the right end of the red line) also shows that the upper bound of Success Rate is around 52% if all the 190K routes in the training environments is labeled by human (instead of being generated by *speaker* via back translation), which indicates the need for "new" environments.

7.2 Back Translation on Unseen Environments

In this subsection, we show that back translation could significantly improve the performance when it uses new data triplets from testing environments — the unseen validation environments where the agent is evaluated in. Back translation (w.o. Env Drop) on these unseen environments achieves a success rate of 61.9%, while the back translation on the training environments only achieves 46.5%. The large margin between the two results indicates the need of "new" environments in back translation. Moreover, our environmental dropout on testing environments could further improve the result to 64.5%, which means that the amount of environments in back translation is far from enough.

7.3 Semantic Views

To demonstrate our intuition of the success of environmental dropout (in Sec. 3.4.2), we replace the image feature $\mathrm{ResNet}(v_{t,i})$ with the semantic view feature. The semantic views (as shown in Fig. 6) are rendered from the Matterport3D dataset (Chang et al., 2017), where different colors indicate different types of objects. Thus, dropout on the semantic view feature would remove the object from the view. With the help of this additional information (i.e., the semantic view), the success rate of IL+RL is 49.5% on the unseen validation set. Back translation (without dropout) slightly improves the result to 50.5%. The result with feature dropout is 50.2% while the environmental dropout could boost the result to 52.0%, which supports our claim in Sec. 3.4.2.

8 Conclusion

We presented a navigational agent which better generalizes to unseen environments. The agent is supervised with a mixture of imitation learning and reinforcement learning. Next, it is fine-tuned with semi-supervised learning, with speaker-generated instructions. Here, we showed that the limited variety of environments is the bottleneck of back translation and we overcome it via 'environmental dropout' to generate new unseen environments. We evaluate our model on the Room-to-Room dataset and achieve rank-1 in the Vision and Language Navigation (VLN) challenge leaderboard under all experimental setups.

A Appendices

A.1 Implementation Details

We use ResNet-152 (He et al., 2016) pretrained on the ImageNet (Russakovsky et al., 2015) to extract the 2048-dimensional image feature. The agent model is first trained with supervised learning via the mixture of imitation and reinforcement learning. The model is then fine-tuned by back translation with environmental dropout. To stabilize the optimization of back translation, we calculate supervised loss for half of the batch and semi-supervised loss for the other half. We find that sharing the environmental dropout mask in different environments inside the same batch will stabilize the training.

The word embedding is trained from scratch with size 256 and the dimension of the action embedding is 64. The size of the LSTM units is set to 512 (256 for the bidirectional LSTM). In RL training, the discounted factor γ is 0.9. We use the reward shaping (Wu et al., 2018): the direct reward r_t at time step t is the change of the distance $d_{t-1} - d_t$, supposing d_t is the distance to the target position at time step t. The maximum decoding action length is set to 35. For optimizing the loss, we use RMSprop (Hinton et al., 2012) (as suggested in Mnih et al. (2016)) with a fixed learning rate $1e-4$ and the batch size is 64. We applying dropout rate 0.4 to the environmental dropout and 0.5 to the dropout layers which regularize the network. The global gradient norm is clipped by 40. We tuned the hyper-parameters based on the Success Rate of the unseen validation set.

When working with the semantic view, the *key* labels (e.g., *wall*, *floor*, *ceil*) are not dropped, because they are the basic structure of the environment. Empirically, no improvement will be achieved when the *key* labels are dropped as well.

Towards Content Transfer through Grounded Text Generation

Abstract

Recent work in neural generation has attracted significant interest in controlling the *form* of text, such as style, persona, and politeness. However, there has been less work on controlling neural text generation for content. This paper introduces the notion of Content Transfer for long-form text generation, where the task is to generate a next sentence in a document that both fits its context and is grounded in a content-rich external textual source such as a news story. Our experiments on Wikipedia data show significant improvements against competitive baselines. As another contribution of this paper, we release a benchmark dataset of 640k Wikipedia referenced sentences paired with the source articles to encourage exploration of this new task.

1 Introduction

Recent work in neural natural language generation (NLG) has witnessed a growing interest in controlling text for various form-related and linguistic properties, such as style (Ficler and Goldberg, 2017), affect (Ghosh et al., 2017), politeness (Sennrich et al., 2016), persona (Li et al., 2016b) voice (Yamagishi et al., 2016), grammatical correctness (Ji et al., 2017), and length (Kikuchi et al., 2016). This trend offers the promise of empowering existing authoring tools such as Grammarly, Google Smart Compose, and Microsoft Word with the ability to control a much greater variety of textual properties, which are currently mostly limited to grammar, spelling, word choice, and wordiness. What has been relatively less explored in neural NLG research is the ability to control the generation of a current sentence not only in its *form*, but also its *content*.[1] Consider for example Fig. 1, which illustrates a situation where an author edits a document (here a Wikipedia article), and the goal is to generate or suggest a next sentence (shown in orange) to the author. This type of unconstrained, long-form text generation task (Mostafazadeh et al., 2016; Fan et al., 2018) is of course extremely difficult. Free-form generation can easily go astray due to two opposing factors. On one hand, ensuring that the generated output is of relatively good quality often comes at the cost of making it bland and devoid of factual content (Li et al., 2016a). On the other hand, existing techniques can help steer neural models away

Monkey selfie copyright dispute

From Wikipedia, the free encyclopedia

On 4 July 2011 several publications picked up the story and quoted Slater as describing the photographs as self-portraits. Slater said reports that a monkey ran off with his camera and "began taking self-portraits" were incorrect and that the portrait was shot when his camera had been on a tripod, with the primates playing around with a remote cable release as he fended off other monkeys.[14]

One of the monkey selfies at issue in the dispute

Ape-rture priority photographer plays down monkey reports

amateurphotographer.co.uk
July 5, 2011

A photographer who says he witnessed monkeys taking pictures of themselves, tells Amateur Photographer (AP) that much of the media coverage has been exaggerated.

Speaking to AP, David explained that his camera had been mounted on a tripod when the primates began playing around with a remote 'cable release' as he was trying to fend off other monkeys.

Figure 1: Example of content transfer: Given existing curated text (yellow) and a document with additional relevant information (green), the task is to update the curated text (orange) to reflect the most salient updates.

---

[1] Historically, NLG has focused on generation from structured content such as a database or semantic representation, but this paper is interested in generation from free-form text.

Proceedings of NAACL-HLT 2019, pages 2622–2632
Minneapolis, Minnesota, June 2 - June 7, 2019.

from blandness in order to produce more contentful outputs (using temperature sampling (Fan et al., 2018), GAN (Goodfellow et al., 2014), etc.), but often at the cost of "hallucinating" (Wiseman et al., 2017) words or concepts that are totally irrelevant. Neither situation provides a compelling experience to the user.

What is clearly missing from the aforementioned authoring scenario is the notion of *grounding*: there is often a profusion of online resources that bear at least some relevance to any given document currently being written. Much of the general-purpose world knowledge is available in the form of encyclopedias (e.g., Wikipedia), books (e.g., Project Gutenberg, Google Books), and news articles. While the generation of good quality texts without any conditioning on "external" sources (Fan et al., 2018) might be an interesting research endeavor on its own, we argue that grounding can make the generation task much easier, e.g., as shown in Fig. 1 where a passage of a news article (green) can be reformulated considering the current context of the document (yellow) in order to produce a natural next sentence (orange). In light of this desideratum, this paper addresses the problem of grounded text generation, where the goal is to infuse the content or knowledge from an external source (e.g., a news article as in Fig. 1) in order to generate a follow-up sentence of an existing document. We see this as a form of *Content Transfer*, as other characteristics of the external source—such as style and linguistic form—are not controlled.

In addition to formulating this new task, our work makes the following contributions: We provide a large dataset of 640k instances that contain parallel data of a source document (news articles), a context, and sentence to be produced. The latter two are extracted from Wikipedia, which is an attractive dataset for grounded generation as many of the statements in Wikipedia cite external sources (i.e., grounded in an external article). Finally, we also provide simple yet efficient models that condition both on the external article and the context of the current document. We compare our models against extractive and abstractive baselines, including summarization methods that simply try to condense the external article without considering the context of the document. Our experiments show that our models which incorporate the context gain 7.0 ROUGE-L F1 points —in other words, treating our task as a summarization problem is not enough. Our human evaluations also show that models that are aware of the context generate relevant and fluent sentences that are coherent to the context.

2 Task

This research is concerned with the general problem of grounded authorship assistance, i.e., the task of suggesting text to insert or append in an existing document draft, in such a way that all the added *content* reflects information from external sources, such as news articles and books. This type of grounded generation task could take many forms, so we decided to formalize the task as follows, while still keeping the task both challenging and practically interesting. Given an external **document** (green in Fig. 1), and some existing **curated text** (yellow), the task is to generate a single **update sentence** (orange). This update sentence should be both relevant to the context and reflective of the information contained in the document.

This task bears some similarity with automatic summarization (Nenkova and McKeown, 2011), as a naïve approach to the above problem is to append a one-sentence summary of the document to the curated text. While indeed related, the two tasks differ in two key points. First, the one-sentence summary must be contextually appropriate given the previous context of the curated text. Second, summarization is mostly concerned with finding *salient* information, but—in the case of our task—information relevant to the context might actually only be auxiliary within the external document. Section 6 (Related Work) further contrasts our task with summarization.

Formally we define our task as follows: given an existing curated text $\boldsymbol{s}$ and a document $\boldsymbol{d}$ describing novel information relevant to that text, the system must produce a revised text $\boldsymbol{s}'$ that incorporates the most salient information from $\boldsymbol{d}$. We restrict our focus to the cases where the revised text $\boldsymbol{s}'$ can be obtained by appending the new information from $\boldsymbol{d}$ to the original curated text $\boldsymbol{s}$.[2] In particular, we assume we can transform the old curated text $\boldsymbol{s}$ into the new text $\boldsymbol{s}'$ by appending one additional update sentence $\boldsymbol{x}$ to $\boldsymbol{s}$.

---

[2] In general, updated information from $\boldsymbol{d}$ might demand substantial changes to $\boldsymbol{s}$: perhaps core assumptions of $\boldsymbol{s}$ were contradicted, necessitating many removed and rewritten sentences. We postpone this complex setting to future work.

3 Models

This paper operates in a conventional supervised learning setting. For training data, we rely on a large dataset of existing curated text $\boldsymbol{S} = \{\boldsymbol{s}_1, \ldots, \boldsymbol{s}_n\}$, corresponding documents with novel information $\boldsymbol{D} = \{\boldsymbol{d}_1, \ldots, \boldsymbol{d}_n\}$, and the update sentences $\boldsymbol{X} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$. Our task is to generate the update sentence $\boldsymbol{x}_i$ that could be appended to the curated text $\boldsymbol{s}_i$ in order to incorporate the additional information from document $\boldsymbol{d}_i$. The goal would be to identify new information (in particular, $\boldsymbol{d}_i \setminus \boldsymbol{s}_i$) that is most salient to the topic or focus of the text, then generate a single sentence that represents this information.

3.1 Generative models

A natural though difficult means of generating this additional update sentence $\boldsymbol{x}$ is to use a generative model conditioned on the information in the curated text $\boldsymbol{s}$ and the new document $\boldsymbol{d}$. Recent methods inspired by successful neural machine translation systems have produced impressive results in abstractive summarization (Nallapati et al., 2016). Hence, our first step is to use the sequence-to-sequence encoder-decoder model (Bahdanau et al., 2015) with attention (Luong et al., 2015) for our task. This kind of model assumes that the output sentence can be generated word-by-word. Each output word $\boldsymbol{x}_i^t$ generated is conditioned on all prior words $\boldsymbol{x}_i^{<t}$ and an encoded representation of the context $\boldsymbol{z}$:

$$\prod_t p(\hat{\boldsymbol{x}}_i^t | \hat{\boldsymbol{x}}_i^{<t}, \boldsymbol{z}) \tag{1}$$

Context Agnostic Generative (CAG) Model: One simple baseline is to train a sequence-to-sequence model for the document $\boldsymbol{d}$ alone that does not directly incorporate information from the curated text $\boldsymbol{s}$. Here, the algorithm is trained to generate the most likely update sentence $\hat{\boldsymbol{x}} = \arg\max p(\boldsymbol{x}|\boldsymbol{d})$. In this setting, we consider the reference document $\boldsymbol{d}_i$ as the source and the update sentence to be generated $\boldsymbol{x}_i$ as the target.

$$\boldsymbol{z} = \text{Encoder}(\boldsymbol{d}_i, \boldsymbol{\theta}) \tag{2}$$

The encoder and decoder do not directly see the information from the curated text $\boldsymbol{s}$, but the update $\boldsymbol{x}$ inherently carries some information about it. The parameters of the model are learned from updates that were authored given the knowledge of the curated text. Hence, the model may capture some generalizations about the kinds of information and locations in $\boldsymbol{d}$ that are most likely to contribute novel information to $\boldsymbol{s}$.

Context Only Generative (COG) Model: This algorithm is trained to generate the most likely update sentence $\hat{\boldsymbol{x}} = \arg\max p(\boldsymbol{x}|\boldsymbol{s})$. This model is similar to CAG except that we consider the curated $\boldsymbol{s}_i$ as the source. In this setting, there is no grounding of the content to be generated.

Context Informed Generative (CIG) Model: An obvious next step is to incorporate information from the curated text $\boldsymbol{s}$ as well. We can concatenate the document and the curated text, and produce an encoded representation of this sequence.

$$\boldsymbol{z} = \text{Encoder}([\boldsymbol{d}_i; \boldsymbol{s}_i], \boldsymbol{\theta}) \tag{3}$$

This approach incorporates information from both sources, though it does not differentiate them clearly. Thus, the model may struggle to identify which pieces of information are novel with respect to the curated text.

To clearly identify the information that is already present in the curated text $\boldsymbol{s}$, a model could encode $\boldsymbol{s}$ and $\boldsymbol{d}$ separately, then incorporate both signals into the generative procedure.

Context Receptive Generative (CRG) Model: Our next step was to condition our generative process more concretely on the curated text $\boldsymbol{s}$. We condition the generative process on the representation of $\boldsymbol{s}$ at each time step. Formally:

$$\begin{aligned} \boldsymbol{z_d} &= \text{Encoder}_{\boldsymbol{d}}(\boldsymbol{d}_i, \boldsymbol{\theta_d}) && (4) \\ \boldsymbol{z_s} &= \text{Encoder}_{\boldsymbol{s}}(\boldsymbol{s}_i, \boldsymbol{\theta_s}) && (5) \\ \hat{\boldsymbol{x}}_{\boldsymbol{i}} &\sim \prod_t p(\hat{x}_i^t | [\hat{\boldsymbol{x}}_i^{<t}; \boldsymbol{z_s}], \boldsymbol{z_d}) && (6) \end{aligned}$$

where, $\boldsymbol{\theta_d}$ and $\boldsymbol{\theta_s}$ are the parameters of the encoder for the document $\boldsymbol{d}$ and encoder for the curated text $\boldsymbol{s}$ respectively, $\boldsymbol{z_d}$ and $\boldsymbol{z_s}$ are the encoded representations of the document $\boldsymbol{d_i}$ and curated text $\boldsymbol{s_i}$ respectively. At each time step of generation, the output is conditioned on the tokens generated up to the time step t concatenated with $\boldsymbol{z_s}$. Hence, the generative process is receptive of the context at each time step.

3.2 Extractive models

Generative models that construct new sentences conditioned on the relevant context are compelling but have a number of modeling challenges. Such a model must both select the most relevant content *and* generate a fluent linguistic realization of this information.

We also consider extractive models: approaches that select the most relevant sentence from the document $\boldsymbol{d}$ to append to the curated text $\boldsymbol{s}$. These approaches can focus solely on the content selection problem and ignore the difficulties of generation. This simplification does come at a cost: the most effective sentence to add might require only a subset of information from some sentence in the document, or incorporate information from more than one sentence.

Sum-Basic (SB): One common baseline is Sum-Basic, an extractive summarization technique that relies on word frequency statistics to select salient sentences (Nenkova and Vanderwende, 2005). As an initial step, unigram probabilities are computed from the set of input documents using relative frequency estimation. Then, sentences are selected one-by-one in greedy rounds until the summary budget is saturated. At each round, this model selects the most likely sentence according to the current unigram distribution. The selected sentence is added to the summary and removed from the pool of available sentences. The unigram probabilities of all words in the selected sentence are heuristically discounted (replaced by square root). Select-then-discount operations continue until the summary is written. Discounting is crucial to prevent repetition: once a word (or ideally a concept) has been selected for the summary, it is much less likely to be picked in a subsequent round.

We use Sum-Basic as a Context Agnostic extractive model: we provide the document $\boldsymbol{d}$ as an input to the model and run Sum-Basic for exactly one round. The selected sentence is considered to be the update sentence $\boldsymbol{x}$.

Context Informed Sum-Basic (CISB): We developed a simple modification of the Sum-basic technique to incorporate information from the curated text $\boldsymbol{s}$ as context. Initial unigram probabilities are computed using word counts from *both* the curated text *and* the document. Next, for each sentence in the curated text, we apply just the discount procedure, updating the probability distribution as if those sentences were selected. Finally, we select the single sentence from the document that is most likely according to the resulting discounted unigram probabilities. This simple modification of Sum-Basic helps select a sentence that is novel with respect to the curated text by lowering the probability of all words already present.

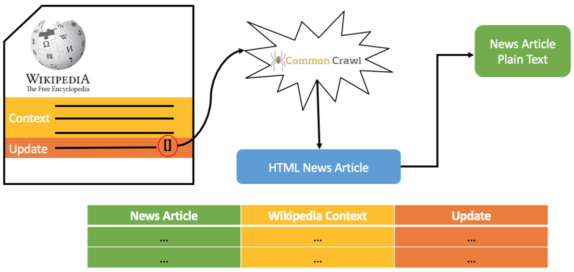

Figure 2: Dataset creation process

Extractive CAG, CIG, CRG Models: Any generative model of $\boldsymbol{x}$ can also be used as an extractive model: we simply estimate the likelihood of each sentence in the document according to the model, and select the most likely one. Generative models may fail because either they are unable to select the most relevant information, or because the resulting sentence is ill-formed. Extractive ranking circumvents all errors due to generation and can help isolate model issues.

Hybrid CAG, CIG, CRG Models: Since the document $\boldsymbol{d}$ can be quite large, a generative model may struggle to pick the most salient information based on the context. To simplify the generative modeling task, we can pre-filter the document toward only the most salient parts. We use the Context Informed Sum-Basic technique to first select the top five sentences from the document. We supply only these five sentences in place of the source document $\boldsymbol{d}$, then apply the CAG, CIG, and CRG techniques described above.

4 Dataset

Our ideal dataset would capture the edits made to some curated reference text in light of a stream of new articles describing changes. For instance, one might maintain reference software documentation about a system, making additions or changes in light of incoming emails describing updates or additions. This type of data is unfortunately difficult to obtain due to privacy considerations.

However, Wikipedia can provide a naturally-occurring body of text with references to primary sources. A substantial fraction of Wikipedia sentences include citations to supporting documentation, a ripe source of data for content transfer. That

Corpus	Input	Output	#Examples	Rouge-1 R
Gigaword (Graff and Cieri, 2003)	10^1	10^1	10^6	78.7
CNN/DailyMail (Nallapati et al., 2016)	10^2–10^3	10^1	10^5	76.1
WikiSum (Liu et al., 2018)	10^2–10^6	10^1–10^3	10^6	59.2
Content Transfer (this paper)	10^1–10^3	10^1–10^2	10^5	66.9

Table 1: Key characteristics of the dataset: approximate size of input and output instances, approximate dataset size, and recall of reference output against the source material, as a measure of dataset difficulty.

said, some of the citations are quite difficult to follow or trust: broken URLs might lead to lost information; citations to books are difficult to consume given the large scope of information; etc. Therefore, we only consider cases where the reference links to some well-known news sources.

Based on citation frequency, we selected a list of 86 domains,[3] primarily news outlets. During the data creation process we only considered citations belonging to one of these eighty six domains. We make this simplifying assumption for several reasons. First, our English Wikipedia dump contained approximately 23.7 million citation URLS belonging to 1.6 million domains; fine-grained filtering would be a daunting task. Our hand-vetted list of domains is a high-precision (albeit low-recall) means of selecting clean data. Second, we wanted to ground the generated text on credible, consistent, and well-written sources of information. Furthermore, well-known domains are readily available on Common Crawl,[4] leading to an easily-reproducible dataset.

Fig. 2 illustrates the procedure used to create a dataset for the task described in Section 2 from Wikipedia. For each Wikipedia article, we extracted the plain text without markdown. When encountering a citation belonging to a selected domain, we considered the sentence just before the citation to be generated based on the content of the citation. This sentence became our reference update sentence: the additional update sentence $\boldsymbol{x}$ added to the curated text $\boldsymbol{s}$ to produce the new text $\boldsymbol{s}'$. The k sentences prior to the target sentence in the Wikipedia article were considered to be the curated text $\boldsymbol{s}$. In our case, we used a window of $k = 3$ sentences to select our context. The cited article acted as the document $\boldsymbol{d}$, from which the appropriate update $\boldsymbol{x}$ can be generated.

The HTML source of the citation was downloaded from Common Crawl for reproducibility and consistency. The HTML derived from Common Crawl is then processed to get the plain text of the news article. The resulting dataset $\boldsymbol{C}$ consists of aligned tuples $\boldsymbol{C} = \left(\boldsymbol{d_i}, \boldsymbol{s_i}, \boldsymbol{x_i}\right)_{i\in[1,n]}$, where n is the total number of samples in the dataset.

Alternatively, one might rely on Wikipedia edit history to create a dataset. In this setting, edits which include a new citation would act as the update $\boldsymbol{x}$. Although this has the upside of identifying potentially complex, multi-sentence updates, preliminary analysis suggested that these edits are noisy. Editors may first generate the content in one edit, then add the citation in a subsequent edit, they may only rephrase a part of the text while adding the citation, or they may check in a range of changes across the document in a single edit. Our simpler sentence-based approach leads to an interesting dataset with fewer complications.

Dataset Statistics and Analysis Table 1 describes some key statistics of our dataset and how it compares with other datasets used for similar tasks. The ROUGE-1 recall scores of reference output $\boldsymbol{x}$ against document $\boldsymbol{d}$ suggest this task will be difficult for conventional extractive summarization techniques.[5] We hypothesize that during content transfer, the language in document $\boldsymbol{d}$ often undergoes substantial transformations to fit the curated text $\boldsymbol{s}$. The average unigram overlap (after stopword removal) between the document $\boldsymbol{d}$ and the reference update sentence $\boldsymbol{x}$ is 55.79%; overlap of the curated text $\boldsymbol{s}$ and the reference update sentence $\boldsymbol{x}$ is 30.12%. This suggests the reference update sentence $\boldsymbol{x}$ can be derived from the document $\boldsymbol{d}$, though not extracted directly. Furthermore, the content of $\boldsymbol{x}$ is very different from the content of $\boldsymbol{s}$ but appears topically related.

Our dataset consists of approximately 290k unique Wikipedia articles. Some heavily-cited

---

[3] This list is provided in the data release of this paper.

[4] `http://commoncrawl.org/`

[5] ROUGE-1 recall was computed on a sample of 50k instances from the entire dataset.

articles include ‘Timeline of investigations into Trump and Russia (2017)’, ‘List of England Test cricketers’, and ‘2013 in science’. We randomly split the dataset into 580k training instances, 6049 validation instances, and 50k test instances, ensuring that any Wikipedia article appearing in the train set must not appear in validation or test.

5 Experimental results

We evaluate our models using both automated metrics and, for a subset of promising systems, human assessment. One key evaluation is the similarity between the model generated update sentence and reference update sentence. We also ask human judges to assess grammaticality and coherence.

Hyper-parameter settings: For all our experiments with generative models, we have used bidirectional encoder, 2 layers in encoder and decoder, RNN size of 128, word vector size of 100. We have used sentencepiece toolkit[6] to use byte-pair-encoding (BPE) with a vocabulary size of 32k. We used stochastic gradient descent optimizer and the stopping criterion was perplexity on the validation set. We filtered our dataset to contain instances which have length of the document between 50 and 2000 tokens, length of the curated text between 20 and 500 tokens and the length of the update sentence between 5 and 200 tokens.

5.1 Automated Evaluation

Our primary automated evaluation metric for system-generated update sentences is ROUGE-L F1 against reference update sentence,[7] though we also include BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2011) as additional indicators. ROUGE is a standard family of metrics for summarization tasks; ROUGE-L measures the longest common subsequence between the system and the reference, capturing both lexical selection and word order.

Table 2 illustrates that this task is quite difficult for extractive techniques. Furthermore, the results emphasize the importance of having curated text as context when generating the update. In all experimental conditions, models aware of context perform much better than models agnostic of it. In contrast to Liu et al. (2018), generative approaches outperformed hybrid, likely because we only had a single input document. Extractive CAG, CIG, and CRG all outperformed both Sum-Basic and the context informed variant. Extractive CAG was on-par with generative CAG, suggesting the generated sentences were of reasonable quality. However, generative CIG and CRG were substantially better: rewriting to match context was beneficial.

Model	ROUGE-L	BLEU	METEOR
SB	5.6 (5.6–5.7)	0.6	2.0
CISB	7.0 (7.0–7.1)	1.0	2.8
CAG	9.1 (9.0–9.2)	1.2	4.6
COG	13.5 (13.4–13.6)	1.7	3.5
CIG	**16.0** (15.9-16.1)	**3.5**	**5.3**
CRG	14.7 (14.6–14.8)	2.6	4.5
Hybrid CAG	8.0 (7.9–8.0)	1.0	3.8
Hybrid CIG	15.0 (14.9–15.1)	2.7	4.7
Hybrid CRG	13.5 (13.4–13.6)	2.3	4.1
Extractive CAG	9.3 (9.2–9.3)	1.1	3.2
Extractive CIG	9.3 (9.2–9.3)	1.1	3.2
Extractive CRG	9.2 (9.1–9.3)	1.1	3.2
Oracle	*28.8* *(28.7–29.0)*	*11.0*	*10.9*

Table 2: Automated metrics; 95% confidence interval in parentheses.

The *Oracle* system of Table 2 aims to establish an upper limit attainable by extractive methods, using the following oracle experiment: For each test instance $(\boldsymbol{d_i}, \boldsymbol{s_i}, \boldsymbol{x_i})$, we enumerate each extracted sentence $\boldsymbol{e}$ of document $\boldsymbol{d_i}$ and select the one with highest ROUGE-L score as *Oracle*’s update sentence $\hat{\boldsymbol{x}}_{\boldsymbol{i}}$ (i.e., $\hat{\boldsymbol{x}}_{\boldsymbol{i}} = \arg\max_{\boldsymbol{e} \in \boldsymbol{d_i}} \text{ROUGE-L}(\boldsymbol{x_i}, \boldsymbol{e})$). Note this yields a very optimistic upper bound, as the same ground truth $\boldsymbol{x_i}$ is used both to select an extractive sentence from a large pool of candidates and for final automatic metric scoring.[8] Nevertheless, these oracle results let us draw two conclusions: (1) They give us better perspective to assess the non-oracle systems, and we believe that their seemingly low

---

[6] https://github.com/google/sentencepiece

[7] We use the pyrouge toolkit along with ROUGE-1.5.5: `https://github.com/bheinzerling/pyrouge`

[8] Previous work has shown that this type of oracle can yield upper bounds that are unrealistically high, and they tend to be above human performance (Och et al., 2004, Table 1). One remedy suggested by Och et al. is a round-robin oracle ensuring that the reference (ground truth) used by the argmax is distinct from that of the final automatic evaluation, but that scheme is only possible with a multi-reference test set.

automatic evaluation scores are quite reasonable relative to the optimistic upper bound (e.g., CIGs ROUGE-Ls score is 55% of the oracle). (2) The oracle results suggest that humans are substantially changing the surface realization as they summarize for Wikipedia, as otherwise the oracle results would be much closer to maximum metric scores (i.e., 100%). This shows that extractive methods are not enough for this task, justifying our use of generation techniques.

5.2 Human Evaluations

For careful evaluation of the performance of the most promising configurations (CAG and CIG models) we also asked human judges for quality assessments. We solicited several types of evaluation, including two relative comparisons between pairs of system outputs and an absolute quality evaluation of individual system outputs.

Close to reference (Relative): The first relative comparison measured how accurately the generated update reflected information in the reference update. Here, the annotators saw only the reference update sentence and the outputs of two systems labeled A and B in a randomized order. We asked the annotators "Which system output is closest in meaning to the reference update?" The annotators could pick system A, system B, or indicate that neither was preferred. This is a simple evaluation task though potentially biased toward the sole reference update.

Coherent to context (Relative): The second relative comparison measured whether the generated output contained salient information from the document written in a manner appropriate to the curated text. The annotators saw the document $\boldsymbol{d}$, the curated text $\boldsymbol{s}$, and the outputs of the two systems A and B, again in a random order. They were asked, "Which system output is more accurate relative to the background information given in the snippet of the article?" Each judge had to consider whether the information fits with the curated text and also whether system-generated content could be supported by the document.

Four human judges each annotated 30 unique output pairs for these two relative comparison settings, a total of 240 relative judgments. Table 3 shows the results: the context-aware CIG system was substantially better in both settings.

	prefer		
Evaluation task	CAG	neither	CIG
Close to reference	15.8%	53.3%	30.8%
Coherent to context	7.5%	53.3%	39.2%

Table 3: Human preferences of CAG vs. CIG.

Model	Grammar	Non-redund.	Ref. clarity	Focus	Structure
CAG	2.6	1.8	2.7	2.6	2.4
CIG	**4.3**	**3.9**	**3.6**	**3.5**	**3.2**

Table 4: Human absolute quality assessments.

DUC Guidelines (Absolute): In addition, we performed an absolute quality evaluation following the guidelines from DUC 2007.[9] Each judge was presented with a single system output, then they were asked to evaluate five aspects of system output: grammaticality, non-redundancy, referential clarity, focus, and structure/coherence. For each aspect, the judge provided an assessment on a five-point scale: (1) Very Poor, (2) Poor, (3) Barely Acceptable, (4) Good, (5) Very Good. We gathered 120 additional judgments in this setting (4 judges, 30 outputs). Again, context-aware CIG substantially outperforms CAG across the board, as seen in Table 4.

Observations: Systems unaware of the curated text $\boldsymbol{s}$ tend to generate long updates with repeated frequent words or phrases. Consider the ratio of unique tokens over the total number of tokens in the generated output, which we denote by $\boldsymbol{R}$. A small $\boldsymbol{R}$ indicates many repeated tokens. We find that 88% of the time this ratio $\boldsymbol{R}$ falls below 0.5 for the CAG model, i.e. for 88% instances, more than 50% of the words in the generated output are repeats. This number is relatively small – 14% for CIG and 20% for CRG – in context aware models. In the reference updates only 0.21% instances repeat more than 50% of words.

Figs. 3 and 4 show good and bad examples generated by the CIG model along with the document, curated text and the reference update. Table 5 has a set of updates generated by the CIG model as

Document (News Article)

anne kirkbride, who portrayed bespectacled, gravelly-voiced deirdre barlow in coronation street for more that four decades, has died. the 60-year-old, whose first appearance in the soap opera was in 1972, died in a manchester hospital after a short illness.... kirkbride had left the soap opera after she was diagnosed with non-hodgkin’s lymphoma in 1993 but returned some months later after treatment and spoke candidly about how she had struggled with depression following the diagnosis...

Curated Text (Wikipedia Context)

in 1993, kirkbride was diagnosis with non-hodgkin’s lymphoma. she spoke to the british press about her bout of depression following the diagnosis. she was cured within a year of being diagnosed.

Reference Update

anne kirkbride died of breast cancer in a manchester hospital on 19 january 2015, aged 60.

Generated Update

she was diagnosed with non-hodgkin’s lymphoma.

Figure 4: Example of lower-quality output: the generated update unnecessarily restates information yet misses the most salient detail from the document.

well as the reference update. As we can see in examples 3 and 4, the CIG model misplaces the date but correctly generates the remaining content. In examples 1 and 2, the CIG model appears to successfully select the correct pronouns for co-reference resolution, though it gets confused as to when to use the pronoun or the named entity. Examples 5 and 6 represent failure cases due to missing words.

6 Related Work

The proposed content transfer task is clearly related to a long series of papers in summarization, including recent work with neural techniques (Rush et al., 2015; Nallapati et al., 2016). In particular, one recent paper casts the the task of generating an entire Wikipedia article as a multi-document summarization problem (Liu et al., 2018). Their best-performing configuration was a two-stage extractive-abstractive framework; a multi-stage approach helped circumvent the difficulties of purely abstractive methods given quite large input token sequences.

Looking beyond the clear task similarity of authoring Wikipedia style content, there are several crucial differences in our approach. First, the goal of that paper is to author the whole page, starting from nothing more than a set of primary sources, such as news articles. In practice, however, Wikipedia articles often contain information outside these primary sources, including common sense knowledge, framing statements to set the article in context, and inferences made from those primary sources. Our task restricts the focus to content where a human editor explicitly decided to cite some external source. Hence, it is much more likely that the resulting summary can be derived from the external source content. Furthermore, we focus on the act of adding information to existing articles, rather than writing a complete article without any context. These two scenarios are clearly useful yet complementary: sometimes people want to produce a new reference text where nothing existed before; in other cases the goal is to maintain and update an existing reference.

Another closely related task is update summarization (Dang and Owczarzak, 2008), where systems attempt to provide a brief summary of the novel information in a new article assuming the user has read a known set of prior documents. Our focus on curating an authoritative resource

Table 5: Example generations from the CIG system, paired with the human generated updates.

is a substantial difference. Also our datasets are substantially larger, enabling generative models to be used in this space, where prior update summarization techniques have been primarily extractive (Fisher and Roark, 2008; Li et al., 2015).

For any generation task, it is important to address both the content ('what' is being said) as well its style ('how' it is being said). Recently, a great deal of research has focused on the 'how' (Li et al., 2018; Shen et al., 2017), including efforts to collect a parallel dataset that differs in politeness (Rao and Tetreault, 2018), to control author characteristics in the generated sentences (Prabhumoye et al., 2018), to control the perceived personality traits of dialog responses (Zhang et al., 2018). We believe this research thread is complementary to our efforts on generating the 'what'.

Another form of content transfer bridges across modalities: text generation given schematized or semi-structured information. Recent research has addressed neural natural language generation techniques given a range of structured sources: selecting relevant database records and generating natural language descriptions of them (Mei et al., 2016), selecting and describing slot-value pairs for task-specific dialog response generation (Wen et al., 2015), and even generating Wikipedia biography abstracts given Infobox information (Lebret et al., 2016). Our task, while grounded in external content, is different in that it leverages *linguistic* grounding as well as prior text context when generating text. This challenging setting enables a huge range of grounded generation tasks: there are vast amounts of unstructured textual data.

7 Conclusions

This article highlights the importance of the task of *content transfer*: generation guided by an existing curated text to set context and tone, and grounded in a new source providing useful information. We demonstrate how multiple models can address this challenging problem on a novel dataset derived from Wikipedia and Common Crawl. This dataset is released to the community along with scripts and models.[10] We find this setting particularly promising given the opportunity for human interaction: in contrast to approaches that do not rely on human-generated context, we establish a collaboration between user and computer. Each newly suggested sentence can be rejected, accepted, or edited before inclusion, and the edits can provide more training data.

We believe there are many natural extensions to this work. The models described here are mostly extensions of existing approaches; approaches targeting novelty detection, focus, and document structure could lead to substantial improvements. We could apply models in series to incorporate changes for a set of documents. Future work could also explore changes that modify existing content rather than simply appending.

Acknowledgments

We are grateful to the anonymous reviewers, as well as Alan W. Black, Chris Brockett, Bill Dolan, Sujay Jauhar, Michael Gamon, Jianfeng Gao, Dheeraj Rajagopal, and Xuchao Zhang for their helpful comments and suggestions on this work. We also thank Emily Ahn, Khyati Chandu, Ankush Das, Priyank Lathwal, and Dheeraj Rajagopal for their help with the human evaluation.

Abstract

Reading strategies have been shown to improve comprehension levels, especially for readers lacking adequate prior knowledge. Just as the process of knowledge accumulation is time-consuming for human readers, it is resource-demanding to impart rich general domain knowledge into a deep language model via pre-training. Inspired by reading strategies identified in cognitive science, and given limited computational resources – just a pre-trained model and a fixed number of training instances – we propose three general strategies aimed to improve non-extractive machine reading comprehension (MRC): (i) BACK AND FORTH READING that considers both the original and reverse order of an input sequence, (ii) HIGHLIGHTING, which adds a trainable embedding to the text embedding of tokens that are relevant to the question and candidate answers, and (iii) SELF-ASSESSMENT that generates practice questions and candidate answers directly from the text in an unsupervised manner.

By fine-tuning a pre-trained language model (Radford et al., 2018) with our proposed strategies on the largest general domain multiple-choice MRC dataset RACE, we obtain a 5.8% absolute increase in accuracy over the previous best result achieved by the same pre-trained model fine-tuned on RACE without the use of strategies. We further fine-tune the resulting model on a target MRC task, leading to an absolute improvement of 6.2% in average accuracy over previous state-of-the-art approaches on six representative non-extractive MRC datasets from different domains (i.e., ARC, OpenBookQA, MCTest, SemEval-2018 Task 11, ROCStories, and MultiRC). These results demonstrate the effectiveness of our proposed strategies and the versatility and general applicability of our fine-tuned models that incorporate these strategies. Core code is available at `https://github.com/nlpdata/strategy/`.

1 Introduction

Recent years have seen a growing interest in machine reading comprehension (MRC) (Rajpurkar et al., 2016; Choi et al., 2018; Kočiskỳ et al., 2018; Reddy et al., 2018). In this paper, we mainly focus on *non-extractive MRC* (Khashabi et al., 2018; Ostermann et al., 2018; Clark et al., 2018), in which a significant percentage of candidate answers are not restricted to text spans from the reference document or corpus. In comparison to *extractive MRC* tasks (Section 2.1), non-extractive MRC (Section 2.2) requires diverse reading skills and, as a result, the performance of machine readers on these tasks more accurately indicates the comprehension ability of machine readers in realistic settings such as exams (Lai et al., 2017).

Recently, significant progress has been achieved on many natural language processing tasks including MRC by fine-tuning a pre-trained general-purpose language model (Radford et al., 2018; Devlin et al., 2018). However, similar to the process of knowledge accumulation for human readers, it is time-consuming and resource-demanding to impart massive amounts of general domain knowledge from external corpora into a deep language model via pre-training. For example, it takes a month to pre-train a 12-layer transformer on eight P100 GPUs over the BooksCorpus (Zhu et al., 2015; Radford et al., 2018); Devlin et al. (2018) pre-train a 24-layer transformer using 64 TPUs for four days on the BooksCorpus plus English Wikipedia, a feat not easily reproducible considering the tremendous computational resources (≈ one year to train on eight P100 GPUs).

From a practical viewpoint, given a limited number of training instances and a pre-trained

Proceedings of NAACL-HLT 2019, pages 2633–2643
Minneapolis, Minnesota, June 2 - June 7, 2019.

model, can we improve machine reading comprehension during fine-tuning instead of imparting more prior knowledge into a model via expensive pre-training? Inspired by reading strategies identified in cognitive science research that have been shown effective in improving comprehension levels of human readers, especially those who lack adequate prior knowledge of the topic of the text (Mokhtari and Sheorey, 2002; Mokhtari and Reichard, 2002; McNamara et al., 2004), we propose three corresponding domain-independent strategies to improve MRC based on an existing pre-trained transformer (Section 3.1):

- BACK AND FORTH READING (*"I go back and forth in the text to find relationships among ideas in it."*):
  consider both the original and reverse order of an input sequence (Section 3.2)
- HIGHLIGHTING (*"I highlight information in the text to help me remember it."*):
  add a trainable embedding to the text embedding of those tokens deemed relevant to the question and candidate answers (Section 3.3)
- SELF-ASSESSMENT (*"I ask myself questions I would like to have answered in the text, and then I check to see if my guesses about the text are right or wrong."*):
  generate practice questions and their associated span-based candidate answers from the existing reference documents (Section 3.4)

By fine-tuning a pre-trained transformer (Radford et al., 2018) according to our proposed strategies on the largest general domain multiple-choice MRC dataset RACE (Lai et al., 2017) collected from language exams, we obtain a 5.8% absolute improvement in accuracy over the previous best result achieved by the same pre-trained transformer fine-tuned on RACE without the use of strategies (Section 4.2). We further fine-tune the resulting model on a target MRC task. Experiments show that our method achieves new state-of-the-art results on six representative non-extractive MRC datasets that require a range of reading skills such as commonsense and multi-sentence reasoning (i.e., ARC (Clark et al., 2016, 2018), OpenBookQA (Mihaylov et al., 2018), MCTest (Richardson et al., 2013), SemEval-2018 Task 11 (Yang et al., 2017), ROCStories (Mostafazadeh et al., 2016), and MultiRC (Khashabi et al., 2018)) (Section 4.4). These results indicate the effectiveness of our proposed strategies and the versatility and generality of our fine-tuned models that incorporate the strategies.

2 Task Introduction

We roughly categorize machine reading comprehension tasks into two groups: extractive (Section 2.1) and non-extractive (Section 2.2) based on the expected answer types.

2.1 Extractive MRC

Recently large-scale extractive MRC datasets have been constructed (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016; Chen and Choi, 2016; Mostafazadeh et al., 2016; Bajgar et al., 2016; Nguyen et al., 2016; Joshi et al., 2017; Ma et al., 2018), such as SQuAD (Rajpurkar et al., 2016) and NewsQA (Trischler et al., 2017). Given a reference document and a question, the expected answer is a short span from the document. In contrast, answers in datasets such as SearchQA (Dunn et al., 2017) and NarrativeQA (Kočiský et al., 2018) are free-form human generated texts based on given documents (Nguyen et al., 2016; Reddy et al., 2018; Choi et al., 2018). However, since annotators tend to directly copy spans as answers, the majority of answers are still extractive (Reddy et al., 2018; Kočiský et al., 2018).

2.2 Non-Extractive MRC

In this section, we primarily discuss multiple-choice MRC datasets, in which answer options are not restricted to extractive text spans. Given a question and a reference document/corpus, multiple answer options are provided, and at least one of them is correct. It involves extensive human efforts to build such a dataset (e.g., MCTest (Richardson et al., 2013), SemEval-2018 Task 11 (Ostermann et al., 2018), MultiRC (Khashabi et al., 2018), and OpenBookQA (Mihaylov et al., 2018)) by crowdsourcing. Besides crowdsourcing, datasets such as RACE (Lai et al., 2017) and ARC (Clark et al., 2018) are collected from language or science exams designed by educational experts (Penas et al., 2014; Shibuki et al., 2014; Tseng et al., 2016) to evaluate the comprehension level of human participants. Compared to questions in extractive MRC tasks, besides surface matching, there are various types of complicated questions such as math word problems, summarization, logical reasoning, and sentiment analysis, requiring advanced read-

Table 1: Statistics of multiple-choice machine reading comprehension datasets. Some values come from Reddy et al. (2018), Kočiský et al. (2018), and Lai et al. (2017) (crowd.: crowdsourcing; †: regarding each sentence/claim as a document (Clark et al., 2018); *: correct answer options that are not text snippets from reference documents).

ing skills and prior world knowledge. Besides, in most cases, we can adopt an objective evaluation criteria such as accuracy to evaluate system performance (Clark et al., 2016; Lai et al., 2017). As these kind of datasets are relatively difficult to construct or collect, most existing datasets are small in size, which hinders the development of state-of-the-art deep neural models.

In response, in this paper we investigate how to make use of limited resources to improve MRC, using seven representative multiple-choice MRC datasets as case studies. As shown in Table 1, the majority of the correct answer options in most of the datasets (except for ARC and MCTest) are non-extractive. Except for MultiRC, there is exactly one correct answer option for each question. For ARC and OpenBookQA, a reference corpus is provided instead of a single reference document associated with each question.

Here we give a formal **task definition**. Given a reference document d, a question q, and associated answer options $\{o_1, o_2, \ldots, o_m\}$, the goal is to select the correct answer option(s). We can easily adapt our method to an MRC task that only provides a reference corpus (Section 4.4).

3 Approach

We first introduce a neural reader based on a pre-trained transformer (Section 3.1) and then elaborate on the strategies that are applied during the fine-tuning stage — back and forth reading (Section 3.2), highlighting (Section 3.3), and self-assessment (Section 3.4).

3.1 Framework Overview

Our neural reader follows the framework of discriminatively fine-tuning a generative pre-trained transformer (GPT) (Radford et al., 2018). It adapts a pre-trained multi-layer transformer (Vaswani et al., 2017; Liu et al., 2018) language model to a labeled dataset $\mathcal{C}$, where each instance consists of a sequence of input tokens $x^1, \ldots, x^n$, along with a label y, by maximizing:

$$\sum_{x,y} \log P(y \,|\, x^1, \ldots, x^n) + \lambda \cdot L(\mathcal{C}) \qquad (1)$$

where L is the likelihood from the language model, λ is the weight of language model, and $P(y \,|\, x^1, \ldots, x^n)$ is obtained by a linear classification layer over the final transformer block's activation of the language model. For multiple-choice MRC tasks, $x^1, \ldots, x^n$ come from the concatenation of a start token, a reference document, a question, a delimiter token, an answer option, and an end token; y indicates the correctness of an answer option. We refer readers to Radford et al. (2018) for more details.

Apart from placing a delimiter to separate the answer option from the document and question, the original framework pays little attention to task-specific structures in MRC tasks. Inspired by reading strategies, with limited resources and a pre-trained transformer, we propose three strategies to improve machine reading comprehension. We show the whole framework in Figure 1.

3.2 Back and Forth Reading (BF)

For simplicity, we represent the original input sequence of GPT during fine-tuning (Radford et al., 2018) as $[dq\,\$\,o]$, where [, \$, and] represent the start token, delimiter token, and end token, respectively. Inspired by back and forth reading, we consider both the original order and the reverse order $[o\,\$\,qd]$. The token order within d, q, and o is still preserved. We fine-tune two GPTs that use $[dq\,\$\,o]$ and $[o\,\$\,qd]$ as the input sequence respectively, and then we ensemble the two models. We also consider other similar pairs of input sequences such as $[qd\,\$\,o]$ and $[o\,\$\,dq]$ in the experiments (Section 4.3).

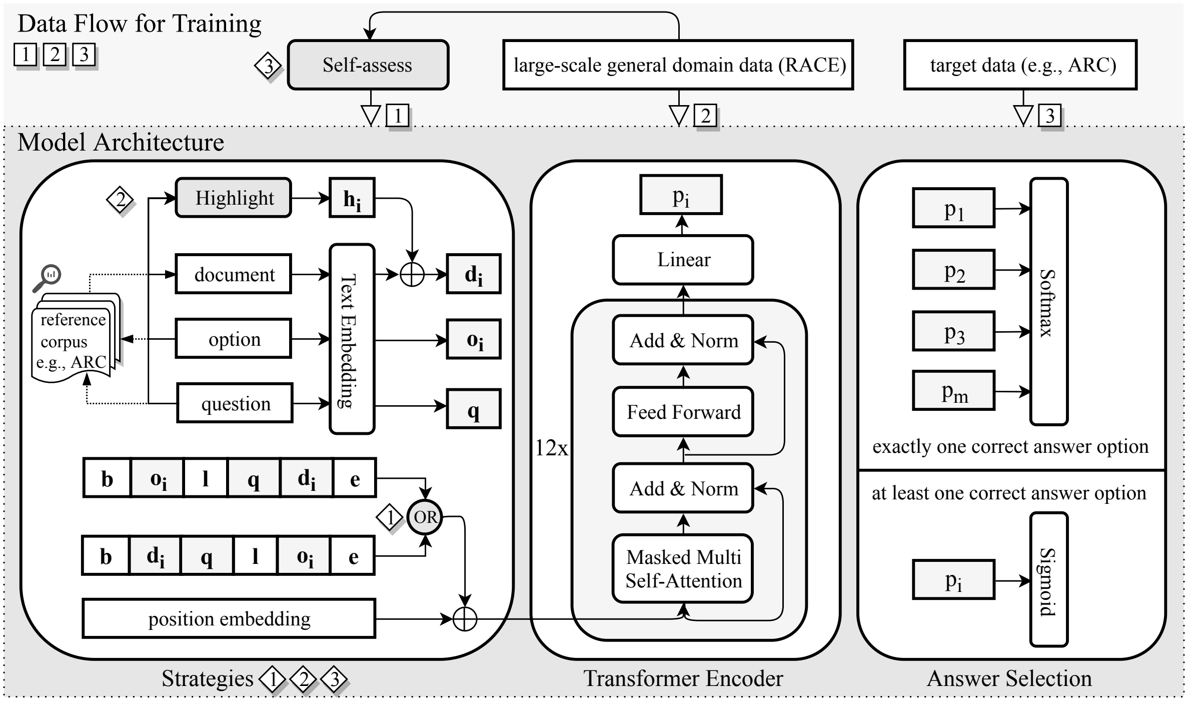

Figure 1: Framework Overview. Strategy 1, 2, and 3 refer to back and forth reading (BF) (Section 3.2), highlighting (HL) (Section 3.3), and self-assessment (SA) (Section 3.4), respectively.

3.3 Highlighting (HL)

In the original implementation (Radford et al., 2018), during the fine-tuning stage of GPT, the text embedding of a document is independent of its associated questions and answer options. Inspired by highlights used in human reading, we aim to make the document encoding aware of the associated question-answer option pair (q, o_i). We focus on the content words in questions and answer options since they appear to provide more useful information (Mirza and Bernardi, 2013), and we identify them via their part of speech (POS) tags, one of: noun, verb, adjective, adverb, numeral, or foreign word.

Formally, we let T be the set of POS tags of the content words. We let $\boldsymbol{d}$ denote the sequence of the text embedding of document d. We use d^j to represent the j^{th} token in d and $\boldsymbol{d^j}$ to denote the text embedding of d^j. Given d and a (q, o_i) pair, we define a *highlight embedding* $\boldsymbol{h_i^j}$ for the j^{th} token in d as:

$$\boldsymbol{h_i^j} = \begin{cases} \boldsymbol{\ell^+} & \text{if the POS tag of } d^j \text{ belongs to } T, \\ & \text{and } d^j \text{ appears in either } q \text{ or } o_i \\ \boldsymbol{\ell^-} & \text{otherwise} \end{cases} \qquad (2)$$

where $\boldsymbol{\ell^+}$ and $\boldsymbol{\ell^-}$ are two trainable vectors of the same dimension as $\boldsymbol{d^j}$.

Following the above definition, the sequence of the highlight embedding $\boldsymbol{h_i} = \boldsymbol{h_i^1}, \boldsymbol{h_i^2}, \ldots, \boldsymbol{h_i^n}$ is of the same length as $\boldsymbol{d}$. We replace $\boldsymbol{d}$ with $\boldsymbol{d_i} = \boldsymbol{d} + \boldsymbol{h_i}$ when we encode a document. More specifically, we use the concatenation of $\boldsymbol{b}$, $\boldsymbol{d_i}$, $\boldsymbol{q}$, $\boldsymbol{l}$, $\boldsymbol{o_i}$, and $\boldsymbol{e}$ as the new input of GPT during fine-tuning (Section 3.1), where $\boldsymbol{b}$, $\boldsymbol{l}$, and $\boldsymbol{e}$ denote the embedding of the start token, delimiter token, and end token, respectively, and $\boldsymbol{q}$ and $\boldsymbol{o_i}$ represent the sequence of the text embedding of q and o_i, respectively.

3.4 Self-Assessment (SA)

While in previous work (Radford et al., 2018), the original GPT is directly fine-tuned on an MRC end task, we instead develop a fine-tuning approach inspired by the self-assessment reading strategy. In particular, we propose a simple method to generate questions and their associated multiple span-based answer options, which cover the content of multiple sentences from a reference document. By first fine-tuning a pre-trained model on these *practice* instances, we aim to render the resulting fine-tuned model more aware of the input structure and to integrate information across multiple sentences as may be required to answer a given question.

Concretely, we randomly generate no more than n_q questions and associated answer options based on each document from the end task (i.e., RACE in this paper). We describe the steps as follows.

- **Input:** a reference document from the end task.
- **Output:** a question and four answer options associated with the reference document.

1. Randomly pick no more than n_s sentences from the document and concatenate these sentences together.
2. Randomly pick no more than n_c non-overlapping spans from the concatenated sentences. Each span randomly contains no more than n_t tokens within a single sentence. We concatenate the selected spans to form the correct answer option. We remove the selected spans from the concatenated sentences and use the remaining text as the question.
3. Generate three distractors (i.e., wrong answer options) by randomly replacing spans in the correct answer option with randomly picked spans from the document.

where n_q, n_s, n_c, and n_t are used to control the number and difficulty level of the questions.

4 Experiment

4.1 Experiment Settings

For most of the hyperparameters, we follow the work of Radford et al. (2018). We use the same preprocessing procedure and the released pretrained transformer. We generate 119k instances based on the reference documents from the training and development set of RACE (Lai et al., 2017), with $n_q = 10$, $n_s = 3$, $n_c = 4$, and $n_t = 4$ (Section 3.4). We first fine-tune the original pretrained model on these automatically generated instances with 1 training epoch (data flow 1 boxed in Figure 1). We then fine-tune the model on a large-scale general domain MRC dataset RACE with 5 training epochs (data flow 2 boxed in Figure 1). Finally, we fine-tune the resulting model on one of the aforementioned six out-of-domain MRC datasets (at max 10 epochs). See data flow 3 boxed in Figure 1. When we fine-tune the model on different datasets, we set the batch size to 8, language model weight λ to 2. We ensemble models by averaging logits after the linear layer. For strategy highlighting (Section 3.3), the content-word POS tagset $T = \{$NN, NNP, NNPS, NNS, VB, VBD, VBG, VBN, VBP, VBZ, JJ, JJR, JJS, RB, RBR, RBS, CD, FW$\}$, and we randomly initialize ℓ^+ and ℓ^-.

Table 2: Accuracy (%) on the test set of RACE (#: number of (ensemble) models; SA: Self-Assessment; HL: Highlighting; BF: Back and Forth Reading; *: our implementation).

4.2 Evaluation on RACE

In Table 2, we first report the accuracy of the state-of-the-art models (MMN and original fine-tuned GPT) and Amazon Turkers (Human performance). We then report the performance of our implemented fine-tuned GPT baselines and our models (GPT+Strategies). Results are shown on the RACE dataset (Lai et al., 2017) and its two subtasks: RACE-M collected from middle school exams and RACE-H collected from high school exams.

Our single and ensemble models outperform previous state-of-the-art (i.e., GPT and GPT (9×)) by a large margin (63.8% vs. 59.0%; 66.7% vs. 60.6%). The two single-model strategies – self-assessment and highlighting – improve over the single-model fine-tuned GPT baseline (58.7%) by 1.7% and 4.5%, respectively. Using the back and forth reading strategy, which involves two models, gives a 3.0% improvement in accuracy compared to the ensemble of two original fine-tuned GPTs (59.6%). Strategy combination further boosts the performance. By combining self-assessment and highlighting, our single model achieves a 5.1% improvement in accuracy over the fine-tuned GPT baseline (63.8% vs. 58.7%). We apply all the strategies by ensembling two such single models that read an input sequence in either the original or the reverse order, leading to a 5.8% improvement in accuracy over the ensemble of two original fine-tuned GPTs (65.4% vs. 59.6%).

To further analyze performance, we roughly divide the question types into five categories: detail (*facts and details*), inference (*reasoning ability*), main (*main idea or purpose of a document*), attitude (*author's attitude toward a topic or tone/source of a document*), and vocabulary (*vocabulary questions*) (Qian and Schedl, 2004; Lai et al., 2017) and annotate all the instances of the RACE development set. As shown in Figure 2, compared to the fine-tuned GPT baseline, our single-model strategies (SA and HL) consistently improve the results across all categories. Compared to other strategies, highlighting is likely to lead to bigger gains for most question types.

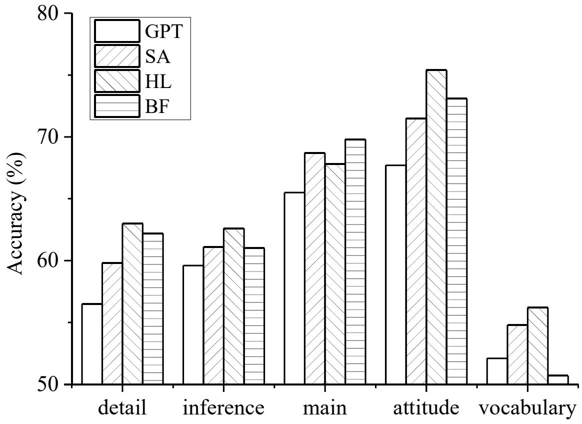

Figure 2: Performance on different question types.

Compared to human performance, there is still a considerable room for improvements, especially on RACE-M. We take a close look at the instances from the RACE-M development set that all our implementations fail to answer correctly. We notice that 82.0% of them require one or multiple types of world knowledge (e.g., negation resolution, commonsense, paraphrase, and mathematical/logic knowledge (Sugawara et al., 2017b,a, 2018)), especially when correct answer options are not explicitly mentioned in the reference document. For example, we need the knowledge — *the type of thing that is written by a writer can probably be a book* — to answer the question *"follow your heart is a _"* from the context *"Follow your heart by Andrew Matthews, an Australian writer, tells us that making our dreams real is life's biggest challenge"*. Besides, 19.7% of these failed instances require coreference resolution. It might be promising to leverage coreference resolvers to connect nonadjacent relevant sentences.

4.3 Further Discussions on Strategies

Besides the strategies introduced in Section 3, we also explore other reading strategies such as SUMMARIZATION (*"I take an overall view of the text to see what it is about before carefully reading it."*) by appending an extractive summary (Boudin et al., 2015) before each reference document, which is shown less effective for machine reading comprehension in our experiments compared to the strategies we focus on. In this section, we further discuss the three strategies.

Back and Forth Reading We notice that the input order difference between two ensemble models is likely to yield performance gains. Besides ensembling two models that use input sequence $[dq\,\$\,o]$ and $[o\,\$\,qd]$ respectively, we also investigate other reverse or almost reverse pairs. For example, we can achieve better results by ensembling $[qd\,\$\,o]$ and $[o\,\$\,dq]$ (61.0%) or $[qd\,\$\,o]$ and $[o\,\$\,qd]$ (61.7%), compared to the ensemble of two original fine-tuned GPTs (both of them use $[d\,\$\,qo]$) on the RACE dataset (59.6% in Table 2).

Highlighting We try two variants to define highlight embeddings (Equation 2 in Section 3.3) by considering the content of questions only or answer options only. Experiments show that using partial information yields a decrease in accuracy (60.6% and 61.0%, respectively) compared to 63.2% (Table 2), achieved by considering the content words in a question and its answer options. We attempt to also highlight the coreferential mentions of the content words, which does not lead to further gains, though.

Self-Assessment We explore alternative approaches to generate questions. For example, we use the Wikipedia articles from SQuAD (Rajpurkar et al., 2016) instead of the general domain documents from the end task RACE. We generate the same number of questions as the number of questions we generate using RACE following the same steps mentioned in Section 3.4. Experiments show that this method also improves the accuracy of the fine-tuned GPT baseline (59.7% vs. 58.7%). As self-assessment can be somehow regarded as a data augmentation method, we investigate other unsupervised question generation methods such as sentence shuffling and paraphrasing via back-translation (Ding and Zhou, 2018; Yu et al., 2018). Our experiments demonstrate that neither of them results in performance improvements on the RACE dataset.

4.4 Adaptation to Other Non-Extractive Machine Reading Comprehension Tasks

We follow the philosophy of transferring the knowledge from a high-performing model pre-trained on a large-scale supervised data of a source task to a target task, in which only a small amount of training data is available (Chung et al., 2018). RACE has been used to pre-train a model for other MRC tasks as it contains the largest number of general domain non-extractive questions (Table 1) (Ostermann et al., 2018; Wang et al., 2018a). In our experiment, we also treat RACE as the source task and regard six representative non-extractive multiple-choice MRC datasets from multiple domains as the target tasks.

We require some task-specific modifications considering the different structures of these datasets. In ARC and OpenBookQA, there is no reference document associated with each question. Instead, a reference corpus is provided, which consists of unordered science-related sentences relevant to questions. We therefore first use Lucene (McCandless et al., 2010) to retrieve the top 50 sentences by using the non-stop words in a question and one of its answer options as a query. The retrieved sentences are used to form the reference document for each answer option. In MultiRC, a question could have more than one correct answer option. Therefore, we use a sigmoid function instead of softmax at the final layer (Figure 1) and regard the task as a binary (i.e., correct or incorrect) classification problem over each (document, question, answer option) instance. When we adapt our method to the non-conventional MRC dataset ROCStories, which aims at choosing the correct ending to a four-sentence incomplete story from two answer options (Mostafazadeh et al., 2016), we leave the question context empty as no explicit questions are provided. Since the test set of MultiRC is not publicly available, we report the performance of the model that achieves the highest micro-average F1 (F1_a) on the development set. For other tasks, we select the model that achieves the highest accuracy on the development set and report the accuracy on the test set.

We first fine-tune GPT using our proposed three strategies on RACE and further fine-tune the resulting model on one of the six target tasks (see Table 3). During the latter fine-tuning stage, besides the *highlighting* embeddings inherited from the previous fine-tuning stage, we also apply the strategy *back and forth reading*, and we do not consider *self-assessment* since the model has already benefited from the high-quality RACE instances during the first fine-tuning stage. We compare with the baselines that are first fine-tuned on RACE and then fine-tuned on a target task without the use of strategies, which already outperform previous state-of-the-art (SOTA) on four out of six datasets (OpenBookQA, SemEval-2018 Task 11, ROCStories, and MultiRC). By using the strategies, we obtain a 7.8% absolute improvement in average accuracy over the ensemble baseline (58.5%) and a 6.2% absolute improvement over previous SOTA (60.1%).

To further investigate the contribution of the strategies, we directly fine-tune GPT on a target task without using the labeled data in RACE (i.e., we only keep data flow 3 in Figure 1). Compared to the baseline that is fine-tuned without using strategies (54.6%), we obtain a 10.4% relative improvement in average accuracy (60.3%) and especially large improvements on datasets ARC, OpenBookQA, and MCTest (Table 4).

5 Related Work

5.1 Methods for Multiple-Choice Machine Reading Comprehension

We primarily discuss methods applied to large-scale datasets such as RACE (Lai et al., 2017). Researchers develop a variety of methods with attention mechanisms (Chen et al., 2016; Dhingra et al., 2017; Xu et al., 2018; Tay et al., 2018; Tang et al., 2019) for improvement such as adding an elimination module (Parikh et al., 2018) or applying hierarchical attention strategies (Zhu et al., 2018; Wang et al., 2018b). These methods seldom take the rich external knowledge (other than pre-trained word embeddings) into considerations. Instead, we investigate different strategies based on an existing pre-trained transformer (Radford et al., 2018) (Section 3.1), which leverages rich linguistic knowledge from external corpora and achieves state-of-the-art performance on a wide range of natural language processing tasks including machine reading comprehension.

5.2 Transfer Learning for Machine Reading Comprehension and Question Answering

Transfer learning techniques have been successfully applied to machine reading comprehension (Golub et al., 2017; Chung et al., 2018) and question answering (Min et al., 2017; Wiese et al., 2017). Compared to previous work, we simply fine-tune our model on the source data and then further fine-tune the entire model on the target data. The investigation of methods such as adding additional parameters or an L2 loss and fine-tuning only part of the parameters is beyond the scope of this work.

5.3 Data Augmentation for Machine Reading Comprehension Without Using External Datasets

Previous methods augment the training data for extractive machine reading comprehension and question answering by randomly reordering words or shuffling sentences (Ding and Zhou, 2018; Li and Zhou, 2018) or generating questions through paraphrasing (Yang et al., 2017; Yuan et al., 2017), which require a large amount of training data or limited by the number of training instances (Yu et al., 2018). In comparison, our problem (i.e., question and answer options) generation method does not rely on any existing questions in the training set, and the generated questions can involve the content of multiple sentences in a reference document.

6 Conclusions

Inspired by previous research on reading strategies for improved comprehension levels of human readers, we propose three strategies (i.e., back and forth reading, highlighting, and self-assessment), aiming at improving machine reading comprehension using limited resources: a pre-trained language model and a limited number of training instances. By applying the proposed three strategies, we obtain a 5.8% absolute improvement in accuracy over the state-of-the-art performance on the RACE dataset. By fine-tuning the resulting model on a new target task, we achieve new state-of-the-art results on six representative non-extractive MRC datasets from multiple domains that require a diverse range of reading skills. These results consistently indicate the effectiveness of our proposed strategies and the general applicability of our fine-tuned model that incorporates these strategies.

Acknowledgments

We would like to thank the anonymous reviewers for their constructive suggestions. We thank Hai Wang, Chengzhu Yu, and Chao Weng for their useful discussions. We especially thank Chao for helping us speed up the release of the preprint[1] with technical supports. We thank Rishi Bommasani for proofreading the paper and Saku Sugawara for sharing annotations with us.

Abstract

We propose a multi-task learning framework to learn a joint Machine Reading Comprehension (MRC) model that can be applied to a wide range of MRC tasks in different domains. Inspired by recent ideas of data selection in machine translation, we develop a novel sample re-weighting scheme to assign sample-specific weights to the loss. Empirical study shows that our approach can be applied to many existing MRC models. Combined with contextual representations from pre-trained language models (such as ELMo), we achieve new state-of-the-art results on a set of MRC benchmark datasets. We release our code at `https://github.com/xycforgithub/MultiTask-MRC`.

1 Introduction

Machine Reading Comprehension (MRC) has gained growing interest in the research community (Rajpurkar et al., 2016; Yu et al., 2018). In an MRC task, the machine reads a text passage and a question, and generates (or selects) an answer based on the passage. This requires the machine to possess strong comprehension, inference and reasoning capabilities. Over the past few years, there has been much progress in building end-to-end neural network models (Seo et al., 2016) for MRC. However, most public MRC datasets (e.g., SQuAD, MS MARCO, TriviaQA) are typically small (less than 100K) compared to the model size (such as SAN (Liu et al., 2018c,b) with around 10M parameters). To prevent over-fitting, recently there have been some studies on using pre-trained word embeddings (Pennington et al., 2014) and contextual embeddings in the MRC model training, as well as back-translation approaches (Yu et al., 2018) for data augmentation.

Multi-task learning (Caruana, 1997) is a widely studied area in machine learning, aiming at better model generalization by combining training datasets from multiple tasks. In this work, we explore a multi-task learning (MTL) framework to enable the training of one universal model across different MRC tasks for better generalization. Intuitively, this multi-task MRC model can be viewed as an implicit data augmentation technique, which can improve generalization on the target task by leveraging training data from auxiliary tasks.

We observe that merely adding more tasks cannot provide much improvement on the target task. Thus, we propose two MTL training algorithms to improve the performance. The first method simply adopts a sampling scheme, which randomly selects training data from the auxiliary tasks controlled by a ratio hyperparameter; The second algorithm incorporates recent ideas of data selection in machine translation (van der Wees et al., 2017). It learns the sample weights from the auxiliary tasks automatically through language models.

Prior to this work, many studies have used upstream datasets to augment the performance of MRC models, including word embedding (Pennington et al., 2014), language models (ELMo) (Peters et al., 2018) and machine translation (Yu et al., 2018). These methods aim to obtain a robust semantic encoding of both passages and questions. Our MTL method is orthogonal to these methods: rather than enriching semantic embedding with external knowledge, we leverage existing MRC datasets across different domains, which help make the whole comprehension process more robust and universal. Our experiments show that MTL can bring further performance boost when combined with contextual representations from pre-trained language models, e.g., ELMo (Peters et al., 2018).

Proceedings of NAACL-HLT 2019, pages 2644–2655
Minneapolis, Minnesota, June 2 - June 7, 2019.

To the best of our knowledge, this is the first work that systematically explores multi-task learning for MRC. In previous methods that use language models and word embedding, the external embedding/language models are pre-trained separately and remain fixed during the training of the MRC model. Our model, on the other hand, can be trained with more flexibility on various MRC tasks. MTL is also faster and easier to train than embedding/LM methods: our approach requires no pre-trained models, whereas back translation and ELMo both rely on large models that would need days to train on multiple GPUs (Jozefowicz et al., 2016; Peters et al., 2018).

We validate our MTL framework with two state-of-the-art models on four datasets from different domains. Experiments show that our methods lead to a significant performance gain over single-task baselines on SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017) and Who-Did-What (Onishi et al., 2016), while achieving state-of-the-art performance on the latter two. For example, on NewsQA (Trischler et al., 2017), our model surpassed human performance by **13.4** (46.5 vs 59.9) and **3.2** (72.6 vs 69.4) absolute points in terms of exact match and F1.

The contribution of this work is three-fold. First, we apply multi-task learning to the MRC task, which brings significant improvements over single-task baselines. Second, the performance gain from MTL can be easily combined with existing methods to obtain further performance gain. Third, the proposed sampling and re-weighting scheme can further improve the multi-task learning performance.

2 Related Work

Studies in machine reading comprehension mostly focus on architecture design of neural networks, such as bidirectional attention (Seo et al., 2016), dynamic reasoning (Xu et al., 2017), and parallelization (Yu et al., 2018). Some recent work has explored transfer learning that leverages outdomain data to learn MRC models when no training data is available for the target domain (Golub et al., 2017). In this work, we explore multi-task learning to make use of the data from other domains, while we still have access to target domain training data.

Multi-task learning (Caruana, 1997) has been widely used in machine learning to improve generalization using data from multiple tasks. For natural language processing, MTL has been successfully applied to low-level parsing tasks (Collobert et al., 2011), sequence-to-sequence learning (Luong et al., 2015), and web search (Liu et al., 2015). More recently, (McCann et al., 2018) proposes to cast all tasks from parsing to translation as a QA problem and use a single network to solve all of them. However, their results show that multi-task learning hurts the performance of most tasks when tackling them together. Differently, we focus on applying MTL to the MRC task and show significant improvement over single-task baselines.

Our sample re-weighting scheme bears some resemblance to previous MTL techniques that assign weights to tasks (Kendall et al., 2018). However, our method gives a more granular score for each sample and provides better performance for multi-task learning MRC.

3 Model Architecture

We call our model Multi-Task-SAN (MT-SAN), which is a variation of SAN (Liu et al., 2018c) model with two main differences: i) we add a highway network layer after the embedding layer, the encoding layer and the attention layer; ii) we use exponential moving average (Seo et al., 2016) during evaluation. The SAN architecture and our modifications are briefly described below and in Section 5.2, and detailed description can be found in (Liu et al., 2018c).

3.1 Input Format

For most tasks we consider, our MRC model takes a triplet (Q, P, A) as input, where $Q = (q_1, ..., q_m), P = (p_1, ..., p_n)$ are the word index representations of a question and a passage, respectively , and $A = (a_{\text{begin}}, a_{\text{end}})$ is the index of the answer span. The goal is to predict A given (Q, P).

3.2 Lexicon Encoding Layer

We map the word indices of P and Q into their 300-dim Glove vectors (Pennington et al., 2014). We also use the following additional information for embedding words: i) 16-dim part-of-speech (POS) tagging embedding; ii) 8-dim named-entity-recognition (NER) embedding; iii) 3-dim exact match embedding: $f_{\text{exact\_match}}(p_i) = \mathbb{I}(p_i \in Q)$, where matching is determined based on the original word, lower case, and lemma form, respectively; iv) Question enhanced passage word embeddings: $f_{\text{align}}(p_i) = \sum_j \gamma_{i,j} h(\text{GloVe}(q_j))$, where

$$\gamma_{i,j} = \frac{\exp(h(\text{GloVe}(p_j)),h(\text{GloVe}(q_i)))}{\sum_{j'}\exp(h(\text{GloVe}(p_{j'})),h(\text{GloVe}(q_i)))} \quad (1)$$

is the similarity between word p_j and q_i, and $g(\cdot)$ is a 300-dim single layer neural net with Rectified Linear Unit (ReLU) $g(x) = \text{ReLU}(W_1 x)$; v) Passage-enhanced question word embeddings: the same as iv) but computed in the reverse direction. To reduce the dimension of the input to the next layer, the 624-dim input vectors of passages and questions are passed through a ReLu layer to reduce their dimensions to 125.

After the ReLU network, we pass the 125-dim vectors through a highway network (Srivastava et al., 2015), to adapt to the multi-task setting: $g_i = \text{sigmoid}(W_2 p_i^t), p_i^t = \text{ReLU}(W_3 p_i^t) \odot g_i + g_i \odot p_i^t$, where p_i^t is the vector after ReLU transformation. Intuitively, the highway network here provides a neuron-wise weighting, which can potentially handle the large variation in data introduced by multiple datasets.

3.3 Contextual Encoding Layer

Both the passage and question encodings go through a 2-layer Bidirectional Long-Short Term Memory (BiLSTM, Hochreiter and Schmidhuber, 1997) network in this layer. We append a 600-dim CoVe vector (McCann et al., 2017) to the output of the lexicon encoding layer as input to the contextual encoders. For the experiments with ELMo, we also append a 1024-dim ELMo vector. Similar to the lexicon encoding layer, the outputs of both layers are passed through a highway network for multi-tasking. Then we concatenate the output of the two layers to obtain $H^q \in \mathbb{R}^{2d\times m}$ for the question and $H^p = \mathbb{R}^{2d\times n}$ the passage, where d is the dimension of the BiLSTM.

3.4 Memory/Cross Attention Layer

We fuse H^p and H^q through cross attention and generate a working memory in this layer. We adopt the attention function from (Vaswani et al., 2017) and compute the attention matrix as $C = \text{dropout}\left(f_{\text{attention}}(\hat{H}^q, \hat{H}^p)\right) \in \mathbb{R}^{m\times n}$. We then use C to compute a question-aware passage representation as $U^p = \text{concat}(H^p, H^q C)$. Since a passage usually includes several hundred tokens, we use the method of (Lin et al., 2017) to apply self attention to the representations of passage to rearrange its information: $\hat{U}^p = U^p \text{drop}_{\text{diag}}(f_{\text{attention}}(U^p, U^p))$, where $\text{drop}_{\text{diag}}$ means that we only drop diagonal elements on the similarity matrix (i.e., attention with itself). Then, we concatenate U^p and $\hat{U}^p$ and pass them through a BiLSTM: $M = \text{BiLSTM}([U^p]; \hat{U}^p])$. Finally, output of the BiLSTM (after concatenating two directions) goes through a highway layer to produce the memory.

3.5 Answer Module

The base answer module is the same as SAN, which computes a distribution over spans in the passage. Firstly, we compute an initial state s_0 by self attention on H^q: $s_0 \leftarrow \text{Highway}\left(\sum_j \frac{\exp(w_4 H_j^q)}{\sum_{j'}\exp w_4 H_{j'}^q} \cdot H_j^q\right)$. The final answer is computed through T time steps. At step $t \in \{1, ..., T-1\}$, we compute the new state using a Gated Recurrent Unit (GRU, Cho et al., 2014) $s_t = \text{GRU}(s_{t-1}, x_t)$, where x_t is computed by attention between M and s_{t-1}: $x_t = \sum_j \beta_j M_j, \beta_j = \text{softmax}(s_{t-1} W_5 M)$. Then each step produces a prediction of the start and end of answer spans through a bilinear function: $P_t^{\text{begin}} = \text{softmax}(s_t W_6 M)$, $P_t^{\text{end}} = \text{softmax}(s_t W_7 M)$. The final prediction is the average of each time step: $P^{\text{begin}} = \frac{1}{T}\sum_t P_t^{\text{begin}}, P^{\text{end}} = \frac{1}{T}\sum_t P_t^{\text{end}}$. We randomly apply dropout on the step level in each time step during training, as done in (Liu et al., 2018c). During training, the objective is the log-likelihood of the ground truth: $l(Q, P, A) = \log P^{\text{begin}}(a_{\text{begin}}) + \log P^{\text{end}}(a_{\text{end}})$.

4 Multi-task Learning Algorithms

We describe our MTL training algorithms in this section. We start with a very simple and straightforward algorithm that samples one task and one mini-batch from that task at each iteration. To improve the performance of MTL on a target dataset, we propose two methods to re-weight samples according to their importance. The first proposed method directly lowers the probability of sampling from a particular auxiliary task; however, this probability has to be chosen using grid search. We then propose another method that avoids such search by using a language model.

Suppose we have K different tasks, the simplest version of our MTL training procedure is shown in Algorithm 1. In each epoch, we take all the mini-batches from all datasets and shuffle them for

Algorithm 1 Multi-task Learning of MRC

```
Input: k different datasets $\mathcal{D}_1, ..., \mathcal{D}_K$, max_epoch
Initialize the model $\mathcal{M}$
for epoch= $1, 2, ...,$ max_epoch do
    Divide each dataset $\mathcal{D}_k$ into $N_k$ mini-batches $\mathcal{D}_k = \{b_1^k, ..., b_{N_k}^k\}, 1 \leq k \leq K$
    Put all mini-batches together and randomly shuffle the order of them, to obtain a sequence $B = (b_1, ..., b_L)$, where $L = \sum_k N_k$
    for each mini-batch $b \in B$ do
        Perform gradient update on $\mathcal{M}$ with loss $l(b) = \sum_{(Q,P,A) \in b} l(Q, P, A)$
    end for
    Evaluate development set performance
end for
Output: Model with best evaluation performance
```

model training, and the same set of parameters is used for all tasks. Perhaps surprisingly, as we will show in the experiment results, this simple baseline method can already lead to a considerable improvement over the single-task baselines.

4.1 Mixture Ratio

One observation is that the performance of our model using Algorithm 1 starts to deteriorate as we add more and more data from other tasks into our training pool. We hypothesize that the external data will inevitably bias the model towards auxiliary tasks instead of the target task.

To avoid such adverse effect, we introduce a mixture ratio parameter during training. The training algorithm with the mixture ratio is presented in Algorithm 2, with $\mathcal{D}_1$ being the target dataset. In each epoch, we use all mini-batches from $\mathcal{D}_1$, while only a ratio α of mini-batches from external datasets are used to train the model. In our experiment, we use hyperparameter search to find the best α for each dataset combination. This method resembles previous methods in multi-task learning to weight losses differently (e.g., Kendall et al., 2018), and is very easy to implement. In our experiments, we use Algorithm 2 to train our network when we only use 2 datasets for MTL.

4.2 Sample Re-Weighting

The mixture ratio (Algorithm 2) dramatically improves the performance of our system. However, it requires to find an ideal ratio by hyperparameter search which is time-consuming. Furthermore, the ratio gives the same weight to every auxiliary data, but the relevance of every data point to the target task can vary greatly.

Algorithm 2 Multi-task Learning of MRC with mixture ratio, targeting $\mathcal{D}_1$

```
Input: K different datasets $\mathcal{D}_1, ..., \mathcal{D}_K$, max_epoch, mixture ratio $\alpha$
Initialize the model $\mathcal{M}$
for epoch= $1, 2, ...,$ max_epoch do
    Divide each dataset $\mathcal{D}_k$ into $N_k$ mini-batches $\mathcal{D}_k = \{b_1^k, ..., b_{N_k}^k\}, 1 \leq k \leq K$
    $S \leftarrow \{b_1^1, ..., b_{N_1}^1\}$
    Randomly pick $\lfloor \alpha N_1 \rfloor$ mini-batches from $\bigcup_{k=2}^K \mathcal{D}_k$ and add to $S$
    Assign mini-batches in $S$ in a random order to obtain a sequence $B = (b_1, ..., b_L)$, where $L = N_1 + \lfloor \alpha N_1 \rfloor$
    for each mini-batch $b \in B$ do
        Perform gradient update on $\mathcal{M}$ with loss $l(b) = \sum_{(Q,P,A) \in b} l(Q, P, A)$
    end for
    Evaluate development set performance
end for
Output: Model with best evaluation performance
```

We develop a novel re-weighting method to resolve these problems, using ideas inspired by data selection in machine translation (Axelrod et al., 2011; van der Wees et al., 2017). We use (Q^k, P^k, A^k) to represent a data point from the k-th task for $1 \leq k \leq K$, with $k = 1$ being the target task. Since the passage styles are hard to evaluate, we only evaluate data points based on Q^k and A^k. Note that only data from auxiliary task ($2 \leq k \leq K$) is re-weighted; target task data always have weight 1.

Our scores consist of two parts, one for questions and one for answers. For questions, we create language models (detailed in Section 5.2) using questions from each task, which we represent as LM_k for the k-th task. For each question Q^k from auxiliary tasks, we compute a cross-entropy score:

$$H_{C,Q}(Q^k) = -\frac{1}{m} \sum_{w \in Q^k} \log(LM_C(w)), \quad (2)$$

where $C \in \{1, k\}$ is the target or auxiliary task, m is the length of question Q^k, and w iterates over all words in Q^k.

It is hard to build language models for answers since they are typically very short (e.g., answers

Dataset	SQuAD(v1)	NewsQA	MS MARCO(v1)	WDW
# Training Questions	87,599	92,549	78,905	127,786
Text Domain	Wikipedia	CNN News	Web Search	Gigaword Corpus
Avg. Document Tokens	130	638	71	365
Answer type	Text span	Text span	Natural sentence	Cloze
Avg. Answer Tokens	3.5	4.5	16.4	N/A

Table 1: Statistics of the datasets. Some numbers come from (Sugawara et al., 2017).

on SQuAD includes only one or two words in most cases). We instead just use the length of answers as a signal for scores. Let l_a^k be the length of A^k, the cross-entropy answer score is defined as:

$$H_{C,A}(A^k) = -\log \text{freq}_C(l_a^k), \tag{3}$$

where freq_C is the frequency of answer lengths in task $C \in \{1, k\}$.

The cross entropy scores are then normalized over all samples in task C to create a comparable metric across all auxiliary tasks:

$$H'_{C,Q}(Q^k) = \frac{H_{C,Q}(Q^k) - \min(H_{C,Q})}{\max(H_{C,Q}) - \min(H_{C,Q})} \tag{4}$$

$$H'_{C,A}(A^k) = \frac{H_{C,A}(A^k) - \min(H_{C,A})}{\max(H_{C,A}) - \min(H_{C,A})} \tag{5}$$

for $C \in \{1, 2, ..., K\}$. For $C \in \{2, ..., K\}$, the maximum and minimum are taken over all samples in task k. For $C = 1$ (target task), they are taken over all available samples.

Intuitively, $H'_{C,Q}$ and $H'_{C,A}$ represents the similarity of text Q, A to task C; a low $H'_{C,Q}$ (resp. $H'_{C,A}$) means that Q^k (resp. A^k) is easy to predict and similar to C, and vice versa. We would like samples that are most similar from data in the target domain (low H'_1), and most different (informative) from data in the auxiliary task (high H'_k). We thus compute the following cross-entropy difference for each external data:

$$\begin{aligned}\text{CED}(Q^k, A^k) =&(H'_{1,Q}(Q^k) - H'_{k,Q}(Q^k)) + \\ &(H'_{1,A}(A^k) - H'_{k,A}(A^k))\end{aligned} \tag{6}$$

for $k \in \{2, ..., K\}$. Note that a low CED score indicates high importance. Finally, we transform the scores to weights by taking negative, and normalize between $[0, 1]$:

$$\text{CED}'(Q^k, A^k) = 1 - \frac{\text{CED}(Q^k, A^k) - \min(\text{CED})}{\max(\text{CED}) - \min(\text{CED})}. \tag{7}$$

Here the maximum and minimum are taken over all available samples and task. Our training algorithm is the same as Algorithm 1, but for mini-batch b we instead use the loss

$$l(b) = \sum_{(P,Q,A) \in b} \text{CED}'(Q, A) l(P, Q, A) \tag{8}$$

in step 6. We define $\text{CED}'(Q^1, A^1) \equiv 1$ for all target samples (P^1, Q^1, A^1).

5 Experiments

Our experiments are designed to answer the following questions on multi-task learning for MRC:
1. Can we improve the performance of existing MRC systems using multi-task learning?
2. How does multi-task learning affect the performance if we combine it with other external data?
3. How does the learning algorithm change the performance of multi-task MRC?
4. How does our method compare with existing MTL methods?

We first present our experiment details and results for MT-SAN. Then, we provide a comprehensive study on the effectiveness of various MTL algorithms in Section 5.4. At last, we provide some additional results on combining MTL with DrQA (Chen et al., 2017) to show the flexibility of our approach [1].

5.1 Datasets

We conducted experiments on SQuAD (Rajpurkar et al., 2016), NewsQA(Trischler et al., 2017), MS MARCO (v1, Nguyen et al.,2016) and WDW (Onishi et al., 2016). Dataset statistics is shown in Table 1. Although similar in size, these datasets are quite different in domains, lengths of text, and types of task. In the following experiments, we will validate whether including external datasets as additional input information (e.g., pre-trained language model on these datasets) helps boost the performance of MRC systems.

---

[1] We include the results in the appendix due to space limitations.

Model	Dev Set Performance
Single Model without Language Models	EM,F1
BiDAF (Seo et al., 2016)	67.7, 77.3
SAN (Liu et al., 2018c)	76.24, 84.06

BERT (Devlin et al., 2018)	**84.2, 91.1**
Human Performance (test set)	82.30, 91.22

Table 2: Performance of our method to train SAN in multi-task setting, competing published results, leaderboard results and human performance, on SQuAD dataset (single model). Note that BERT uses a much larger language model, and is not directly comparable with our results. We expect our test performance is roughly similar or a bit higher than our dev performance, as is the case with other competing models.

5.2 Experiment Details

We mostly focus on span-based datasets for MT-SAN, namely SQuAD, NewsQA, and MS MARCO. We convert MS MARCO into an answer-span dataset to be consistent with SQuAD and NewsQA, following (Liu et al., 2018c). For each question, we search for the best span using ROUGE-L score in all passage texts and use the span to train our model. We exclude questions with maximal ROUGE-L score less than 0.5 during training. For evaluation, we use our model to find a span in all passages. The prediction score is multiplied with the ranking score, trained following Liu et al. (2018a)'s method to determine the final answer.

We train our networks using algorithms in Section 4, using SQuAD as the target task. For experiments with two datasets, we use Algorithm 2; for experiments with three datasets we find the re-weighting mechanism in Section 4.2 to have a better performance (a detailed comparison will be presented in Section 5.4).

For generating sample weights, we build a LSTM language model on questions following the implementation of Merity et al. (2017) with the same hyperparameters. We only keep the 10,000 most frequent words, and replace the other words with a special out-of-vocabulary token.

Parameters of MT-SAN are mostly the same as in the original paper (Liu et al., 2018c). We utilize spaCy[2] to tokenize the text and generate part-of-speech and named entity labels. We use a 2-layer BiLSTM with 125 hidden units as the BiLSTM throughout the model. During training, we drop the activation of each neuron with 0.3 probability. For optimization, we use Adamax (Kingma and Ba, 2014) with a batch size of 32 and a learning rate of 0.002. For prediction, we compute an exponential moving average (EMA, Seo et al. 2016) of model parameters with a decay rate of 0.995 and use it to compute the model performance. For experiments with ELMo, we use the model implemented by AllenNLP [3]. We truncate passage to contain at most 1000 tokens during training and eliminate those data with answers located after the 1000th token. The training converges in around 50 epochs for models without ELMo (similar to the single-task SAN); For models with ELMo, the convergence is much faster (around 30 epochs).

5.3 Performance of MT-SAN

In the following sub-sections, we report our results on SQuAD and MARCO development sets,

---

[2] https://spacy.io

[3] https://allennlp.org/

as well as on the development and test sets of NewsQA [4]. All results are single-model performance unless otherwise noted.

The multi-task learning results of SAN on SQuAD are summarized in Table 2. By using MTL on SQuAD and NewsQA, we can improve the exact-match (EM) and F1 score by (2%, 1.5%), respectively, both with and without ELMo. The similar gain indicates that our method is orthogonal to ELMo. Note that our single-model performance is slightly higher than the original SAN, by incorporating EMA and highway networks. By incorporating with multi-task learning, it further improves the performance. The performance gain by adding MARCO is relatively smaller, with 1% in EM and 0.5% in F1. We conjecture that MARCO is less helpful due to its differences in both the question and answer style. For example, questions in MS MARCO are real web search queries, which are short and may have typos or abbreviations; while questions in SQuAD and NewsQA are more formal and well written.

Using 3 datasets altogether provides another marginal improvement. Our model obtains the best results among existing methods that do not use a large language model (e.g., ELMo). Our ELMo version also outperforms any other models which are under the same setting. We note that BERT (Devlin et al., 2018) uses a much larger model than ours(around 20x), and we leave the performance of combining BERT with MTL as interesting future work.

The results of multi-task learning on NewsQA are in Table 3. The performance gain with multi-task learning is even larger on NewsQA, with over 2% in both EM and F1. Experiments with and without ELMo give similar results. What is worth noting is that our approach not only achieves new state-of-art results with a large margin but also surpasses human performance on NewsQA.

Finally we report MT-SAN performance on MS MARCO in Table 4. Multi-tasking on SQuAD and NewsQA provides a similar performance boost in terms of BLEU-1 and ROUGE-L score as in the case of NewsQA and SQuAD. Our method does not achieve very high performance compared to previous work, probably because we do not apply common techniques like yes/no classification or cross-passage ranking (Wang et al., 2018b).

such questions in SQuAD is 12.9%. Moreover, WDW is a cloze dataset, whereas in SQuAD and NewsQA answers are spans in the passage. We use a task-specific answer layer in this experiment and use Algorithm 2; the WDW answer module is the same as in AS Reader (Kadlec et al., 2016), which we describe in the appendix for completeness. Despite these large difference between datasets, our results (Table 5) show that MTL can still provide a moderate performance boost when jointly training on SQuAD (around 0.7%) and WDW (around 1%).

Comparison of methods using external data. As a method of data augmentation, we compare our approach to previous methods for MRC in Table 6. Our model achieves better performance than back translation. We also observe that language models such as ELMo obtain a higher performance gain than multi-task learning, however, combining it with multi-task learning leads to the most significant performance gain. This validates our assumption that multi-task learning is more robust and is different from previous methods such as language modeling.

5.4 Comparison of Different MTL Algorithms

In this section, we provide ablation studies as well as comparisons with other existing algorithms on the MTL strategy. We focus on MT-SAN without ELMo for efficient training.

Model	Performance

Mixture Ratio	78.4, 85.7
Sample Re-weighting	**78.8**, **86.0**

Table 7: Comparison of different MTL strategies on MT-SAN. Performance is on SQuAD. Loss Uncertainty is from Kendall et al. (2018).

Table 7 compares different multi-task learning strategies for MRC. Both the mixture ratio (Sec 4.1) and sample re-weighting (Sec 4.2) improves over the naive baseline of simply combining all the data (Algorithm 1). On SQuAD+MARCO, they provide around 0.6% performance boost in terms of both EM and F1, and around 1% on all 3 datasets. We note that this accounts for around a half of our overall improvement. Although sample re-weighting performs similar as mixture ratio, it significantly reduces the amount of training time as it eliminates the need for a grid searching the best ratio. Kendal et al., (2018) use task uncertainty to weight tasks differently for MTL; our experiments show that this has some positive effect, but does not perform as well as our proposed two techniques. We note that Kendal et al. (as well as other previous MTL methods) optimizes the network to perform well for all the tasks, whereas our method focuses on the target domain which we are interested in, e.g., SQuAD.

Sensitivity of mixture ratio. We also investigate the effect of mixture ratio on the model performance. We plot the EM/F1 score on SQuAD dev set vs. mixture ratio in Figure 1 for MT-SAN when trained on all three datasets. The curve peaks at $\alpha = 0.4$; however if we use $\alpha = 0.2$ or $\alpha = 0.5$, the performance drops by around 0.5%, well behind the performance of sample re-weighting. This shows that the performance of MT-SAN is sensitive to changes in α, making the hyperparameter search even more difficult. Such sensitivity suggests a preference for using our sample re-weighting technique. On the other hand, the ratio

	Samples/Groups	CED$'$	H_Q	H_A
Examples	(NewsQA) Q: Where is the drought hitting? A: Argentina	0.824	0.732	0.951
	(MARCO) Q: thoracic cavity definition A: is the chamber of the human body ... and fascia.	0.265	0.332	0.240
Averages	Samples in NewsQA	0.710	0.593	0.895
	Samples in MARCO	0.587	0.550	0.669
	MARCO Questions that start with “When” or “Who”	0.662	0.605	0.761
	All samples	0.654	0.573	0.791

Table 8: Scores for examples from NewsQA and MS MARCO and average scores for specific groups of samples. CED$'$ is as in (7), while H_Q and H_A are normalized version of question and sample scores. “Sum” are the actual scores we use, and “LM”, “Answer” are scores from language models and answer lengths.

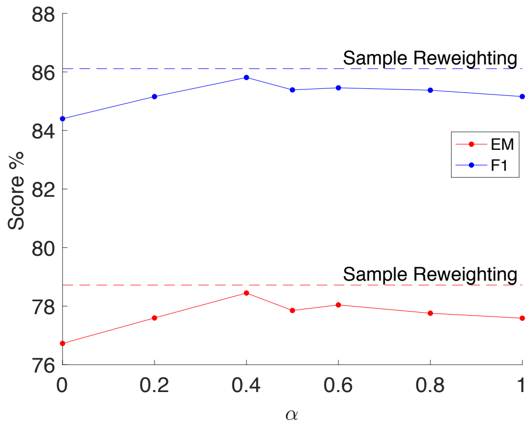

Figure 1: Effect of the mixture ratio on the performance of MT-SAN. Note that $\alpha = 0$ is equivalent to single task learning, and $\alpha = 1$ is equivalent to simple combining.

based approach is pretty straightforward to implement.

Analysis of sample weights. Dataset comparisons in Table 1 and performance in Table 2 suggests that NewsQA share more similarity with SQuAD than MARCO. Therefore, a MTL system should weight NewsQA samples more than MARCO samples for higher performance. We try to verify this in Table 8 by showing examples and statistics of the sample weights. We present the CED$'$ scores, as well as normalized version of question and answer scores (resp. $(H'_{1,Q} - H'_{k,Q})$ and $(H'_{1,A} - H'_{k,A})$ in (6), and then negated and normalized over all samples in NewsQA and MARCO in the same way as in (7)). A high H_Q score indicates high importance of the question, and H_A of the answer; CED$'$ is a summary of the two. We first show one example from NewsQA and one from MARCO. The NewsQA question is a natural question (similar to SQuAD) with a short answer, leading to high scores both in questions and answers. The MARCO question is a phrase, with a very long answer, leading to lower scores. From overall statistics, we also find samples in NewsQA have a higher score than those in MARCO. However, if we look at MARCO questions that start with “when” or “who” (i.e., probability natural questions with short answers), the scores go up dramatically.

6 Conclusion

We proposed a multi-task learning framework to train MRC systems using datasets from different domains and developed two approaches to re-weight the samples for multi-task learning on MRC tasks. Empirical results demonstrated our approaches outperform existing MTL methods and the single-task baselines as well. Interesting future directions include combining with larger language models such as BERT, and MTL with broader tasks such as language inference (Liu et al., 2019) and machine translation.

A Answer Module for WDW

We describe the answer module for WDW here for completeness. For WDW we need to choose an answer from a list of candidates; the candidates are people names that have appeared in the passage. We use the same way to summary information in questions as in span-based models: $s_0 \leftarrow \text{Highway}\left(\sum_j \frac{\exp(w_4 H^q_j)}{\sum_{j'} \exp w_4 H^q_{j'}} \cdot H^q_j\right)$. We then compute an attention score via simple dot product: $s = \text{softmax}(s_0^T M)$. The probability of a candidate being the true answer is the aggregation of attention scores for all appearances of the candidate:

$$\Pr(c|Q,P) \propto \sum_{1 \leq i \leq n} s_i \mathbb{I}(p_i \in C)$$

Setup	SQuAD (v1)	SQuAD (v2)	NewsQA	WDW
Single Dataset	69.5,78.8 (paper) 68.6, 77.8 (ours)	61.9, 65.2	51.9, 64.6	**75.8**
MT-DrQA on Sv1+NA	70.2, 79.3	-,-	52.8, 65.8	-
MT-DrQA on Sv1+W	69.2, 78.4	-,-	-,-	75.7
MT-DrQA on Sv1+N+W	**70.2, 79.3**	-,-	**53.1, 65.7**	75.4
MT-DrQA on Sv2+N	-,-	**63.6, 66.7**	52.7, 65.7	-
MT-DrQA on Sv2+W	-,-	63.5, 66.3	-,-	75.4
MT-DrQA on Sv2+N+W	-,-	63.1, 66.3	52.5, 65.6	75.3
SOTA (Single Model)	80.0, 87.0	72.3, 74.8	48.4, 63.7 (test)	71.7 (test)
MT-DrQA Best Performance	**70.2, 79.3**	**63.6, 66.7**	**53.0, 66.2(test)**	**75.4 (test)**
Human Performance (test set)	82.3, 91.2	86.8, 89.5	46.5, 69.4	84

Table 9: Single model performance of our method to train DrQA on multi-task setting, as well as state-of-the-art (SOTA) results and human performance. SQuAD and NewsQA performance are measured by (EM, F1), and WDW by accuracy percentage. All results are on development set unless otherwise noted. Published SOTA results come from (Wang et al., 2018a; Hu et al., 2018; Kundu and Ng, 2018; Yang et al., 2016) respectively.

for each candidate C. Recall that n is the length of passage P, and p_i is the i-th word; therefore $\mathbb{I}(p_i \in C)$ is the indicator function of p_i appears in candidate C. The candidate with the largest probability is chosen as the predicted answer.

B Experiment Results on DrQA

To demonstrate the flexibility of our approach, we also adapt DrQA (Chen et al., 2017) into our MTL framework. We only test DrQA using the basic Algorithm 2, since our goal is mainly to test the MTL framework.

B.1 Model Architecture

Similar to MT-SAN, we add a highway network after the lexicon encoding layer and the contextual encoding layer and use a different answer module for each dataset. We apply MT-DrQA to a broader range of datasets. For span-detection datasets such as SQuAD, we use the same answer module as DrQA. For cloze-style datasets like Who-Did-What, we use the attention-sum reader (Kadlec et al., 2016) as the answer module. For classification tasks required by SQuAD v2.0 (Rajpurkar et al., 2018), we apply a softmax to the last state in the memory layer and use it as the prediction.

B.2 Performance of MT-DrQA

We apply MT-DrQA to SQuAD (v1.1 and v2.0), NewsQA, and WDW. We follow the setup of (Chen et al., 2017) for model architecture and hyperparameter setup. We use Algorithm 1 to train all MT-DrQA models. Different than (Rajpurkar et al., 2018), we do not optimize the evaluation score by changing the threshold to predict unanswerable question for SQuAD v2.0; we just use the argmax prediction. As a result, we expect the gap between dev and test performance to be lower for our model. The results of MT-DrQA are presented in Table 9. The results of combining SQuAD and NewsQA obtain similar performance boost as our SAN experiment, with a performance boost between 1-2% in both EM and F1 for the two datasets. The results of MTL including WDW is different: although adding WDW to SQuAD still brings a marginal performance boost to SQuAD, the performance on WDW drops after we add SQuAD and NewsQA into the training process. We conjecture that this negative transfer phenomenon is probably because of the drastic difference between WDW and SQuAD/NewsQA, both in their domain, answer type, and task type; and DrQA might not be capable of caputuring all these features using just one network. We leave the problem of further preventing such negative transfer to future work.

Semantically-Aligned Equation Generation for Solving and Reasoning Math Word Problems

Ting-Rui Chiang **Yun-Nung Chen**
National Taiwan University, Taipei, Taiwan
`r07922052@csie.ntu.edu.tw` `y.v.chen@ieee.org`

Abstract

Solving math word problems is a challenging task that requires accurate natural language understanding to bridge natural language texts and math expressions. Motivated by the intuition about how human generates the equations given the problem texts, this paper presents a neural approach to automatically solve math word problems by operating symbols according to their semantic meanings in texts. This paper views the process of generating equations as a bridge between the semantic world and the symbolic world, where the proposed neural math solver is based on an encoder-decoder framework. In the proposed model, the encoder is designed to understand the semantics of problems, and the decoder focuses on tracking semantic meanings of the generated symbols and then deciding which symbol to generate next. The preliminary experiments are conducted in a benchmark dataset Math23K, and our model significantly outperforms both the state-of-the-art single model and the best non-retrieval-based model over about 10% accuracy, demonstrating the effectiveness of bridging the symbolic and semantic worlds from math word problems.[1]

1 Introduction

Automatically solving math word problems has been an interesting research topic and also been viewed as a way of evaluating machines' ability (Mandal and Naskar, 2019). For human, writing down an equation that solves a math word problem requires the ability of reading comprehension, reasoning, and sometimes real world understanding. Specifically, to solve a math word problem, we first need to know the goal of the given problem, then understand the semantic meaning of each numerical number in the problem, perform reasoning based on the comprehension in the previous step, and finally decide what to write in the equation.

Most prior work about solving math word problems relied on hand-crafted features, which required more human knowledge. Because those features are often in the lexical level, it is not clear whether machines really understand the math problems. Also, most prior work evaluated their approaches on relatively small datasets, and the capability of generalization is concerned.

This paper considers the reasoning procedure when writing down the associated equation given a problem. Figure 1 illustrates the problem solving process. The illustration shows that human actually assigns the semantic meaning to each number when manipulating symbols, including operands (numbers) and operators ($+ - \times \div$). Also, we believe that the semantic meaning of operands can help us decide which operator to use. For example, the summation of "*price of one pen*" and "*number of pens Tom bought*" is meaningless; therefore the addition would not be chosen.

Following the observation above, this paper proposes a novel encoder decoder model, where the encoder extracts semantic meanings of numbers in the problem, and the decoder is equipped with a stack that facilitates tracking the semantic meanings of operands. The contributions of this paper are 4-fold:

- This paper is the first work that models semantic meanings of operands and operators for math word problems.
- This paper proposes an end-to-end neural math solver with a novel decoding process that utilizes the stack to generate associated equations.

---

Proceedings of NAACL-HLT 2019, pages 2656–2668
Minneapolis, Minnesota, June 2 - June 7, 2019.

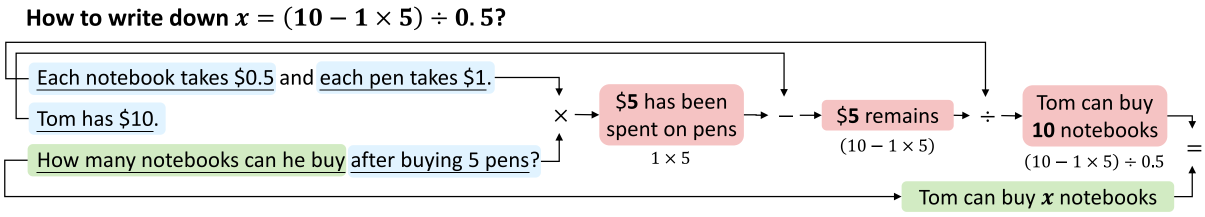

Figure 1: The solving process of the math word problem "*Each notebok takes $0.5 and each pen takes $1. Tom has $10. How many notebook can he buy after buying 5 pens?*" and the associated equation is $x = (10 - 1 \times 5) \div 0.5$. The associated equation is $x = (10 - 1 \times 5) \div 0.5$.

- This paper achieves the state-of-the-art performance on the large benchmark dataset Math23K.
- This paper is capable of providing interpretation and reasoning for the math word problem solving procedure.

2 Related Work

There is a lot of prior work that utilized hand-crafted features, such as POS tags, paths in the dependency trees, keywords, etc., to allow the model to focus on the quantities in the problems (Kushman et al., 2014; Hosseini et al., 2014; Roy et al., 2015; Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Roy et al., 2016; Upadhyay et al., 2016; Upadhyay and Chang, 2017; Roy and Roth, 2018; Wang et al., 2018). Recently, Mehta et al.; Wang et al.; Ling et al. attempted at learning models without predefined features. Following the recent trend, the proposed end-to-end model in this paper does not need any hand-crafted features.

Kushman et al. first extracted templates about math expressions from the training answers, and then trained models to select templates and map quantities in the problem to the slots in the template. Such two-stage approach has been tried and achieved good results (Upadhyay and Chang, 2017). The prior work highly relied on human knowledge, where they parsed problems into equations by choosing the expression tree with the highest score calculated by an operator classifier, working on a hand-crafted "trigger list" containing quantities and noun phrases in the problem, or utilizing features extracted from text spans (Roy et al., 2015, 2016; Koncel-Kedziorski et al., 2015). Shi et al. defined a Dolphin language to connect math word problems and logical forms, and generated rules to parse math word problems. Upadhyay et al. parsed math word problems without explicit equation annotations. Roy and Roth classified math word problems into 4 types and used rules to decide the operators accordingly. Wang et al. trained the parser using reinforcement learning with hand-crafted features. Hosseini et al. modeled the problem text as transition of world states, and the equation is generated as the world states changing. Our work uses a similar intuition, but hand-crafted features are not required and our model can be trained in an end-to-end manner. Some end-to-end approaches have been proposed, such as generating equations directly via a seq2seq model (Wang et al., 2017). Ling et al. tried to generate solutions along with its rationals with a seq2seq-like model for better interpretability.

This paper belongs to the end-to-end category, but different from the previous work; we are the first approach that generates equations with stack actions, which facilitate us to simulate the way how human solves problems. Furthermore, the proposed approach is the first model that is more interpretable and provides reasoning steps without the need of rational annotations.

3 End-to-End Neural Math Solver

Our approach composes of two parts, an encoder and a decoder, where the process of solving math word problems is viewed as transforming multiple text spans from the problems into the target information the problems ask for. In the example shown in Figure 1, all numbers in the problem are attached with the associated semantics. Motivated by the observation, we design an encoder to extract the semantic representation of each number in the problem text. Considering that human usually manipulates those numbers and operators (such as addition, subtraction, etc.) based on their semantics for problem solving, a decoder is designed to construct the equation, where the semantics is aligned with the representations extracted by the encoder. The idea of the proposed model

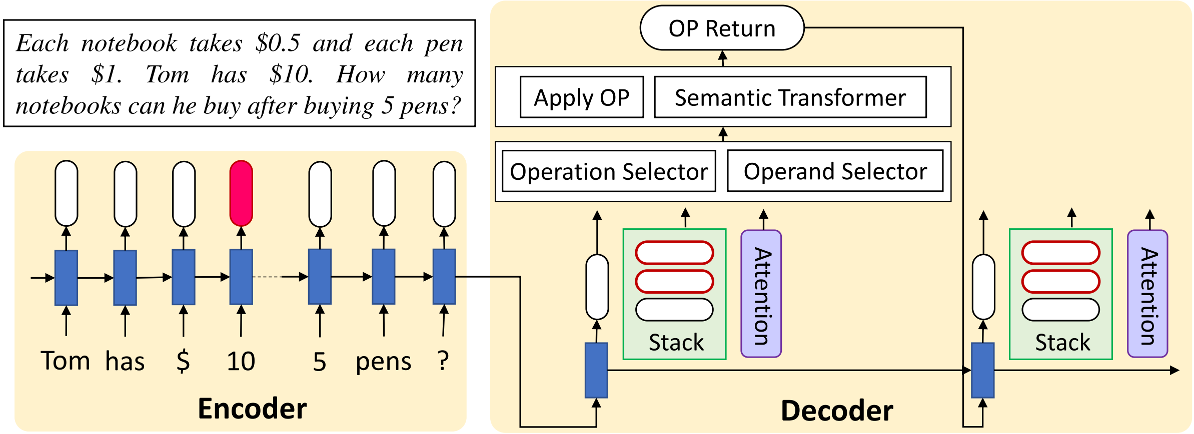

Figure 2: The encoder-decoder model architecture of the proposed neural solver machine.

is to imitate the human reasoning process for solving math word problems. The model architecture is illustrated in Figure 2.

3.1 Encoder

The encoder aims to extract the semantic representation of each constant needed for solving problems. However, the needed constants may come from either the given problem texts or domain knowledge, so we detail these two procedures as follows.

3.1.1 Constant Representation Extraction

For each math word problem, we are given a passage consisting of words $\{w_t^P\}_{t=1}^m$, whose word embeddings are $\{e_t^P\}_{t=1}^m$. The problem text includes some numbers, which we refer as constants. The positions of constants in the problem text are denoted as $\{p_i\}_{i=1}^n$. In order to capture the semantic representation of each constant by considering its contexts, a bidirectional long short-term memory (BLSTM) is adopted as the encoder (Hochreiter and Schmidhuber, 1997):

$$h_t^E, c_t^E = \text{BLSTM}(h_{t-1}^E, c_{t-1}^E, e_t^P), \quad (1)$$

and then for the i-th constant in the problem, its semantic representation e_i^c is modeled by the corresponding BLSTM output vector:

$$e_i^c = h_{p_i}^E. \quad (2)$$

3.1.2 External Constant Leveraging

External constants, including 1 and π, are leveraged, because they are required to solve a math word problem, but not mentioned in the problem text. Due to their absence from the problem text, we cannot extract their semantic meanings by BLSTM in (2). Instead, we model their semantic representation e^π, e^1 as parts of the model parameters. They are randomly initialized and are learned during model training.

3.2 Decoder

The decoder aims at constructing the equation that can solve the given problem. We generate the equation by applying stack actions on a stack to mimic the way how human understands an equation. Human knows the semantic meaning of each term in the equation, even compositing of operands and operators like the term ”$(10-1\times5)$” in Figure 1. Then what operator to apply on a pair operands can be chosen based on their semantic meanings accordingly. Hence we design our model to generate the equation in a postfix manner: a operator is chosen base on the semantic representations of two operands the operator is going to apply to. Note that the operands a operator can apply to can be any results generated previously. That is the reason why we use “stack” as our data structure in order to keep track of the operands a operator is going to apply to. The stack contains both symbolic and semantic representations of operands, denoted as

$$S = [(v_{l_t}^S, e_{l_t}^S), (v_{l_t-1}^S, e_{l_t-1}^S), \cdots, (v_1^S, e_1^S)], \quad (3)$$

where v^S of each pair is the symbolic part, such as $x+1$, while e^S is the semantic representation, which is a vector. The components in the decoder are shown in the right part of Figure 2, each of which is detailed below.

3.3 Decoding State Features

At each decoding step, decisions are made based on features of the current state. At each step, fea-

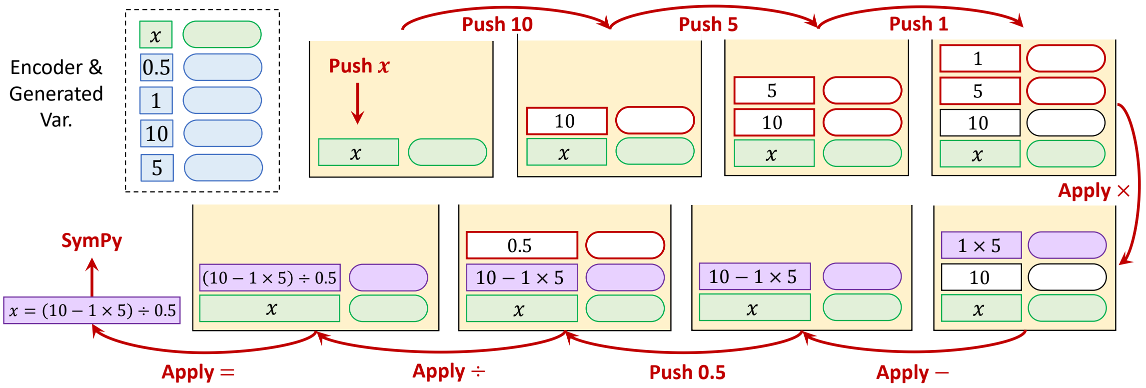

Figure 3: Illustration of the inference process. The purple round blocks denote the transformed semantics, while the green ones are generated by the variable generator.

tures r^{sa} and r^{opd} are extracted to select a stack action (section 3.3.2) and an operand to push (section 3.3.3). Specifically, the features are the gated concatenation of following vectors:

- h_t^D is the output of an LSTM, which encodes the history of applied actions:

  $$h_t^D, c_t^D = \mathrm{LSTM}(h_{t-1}^D, c_{t-1}^D, \mathrm{res}_{t-1}), \quad (4)$$

  where res_{t-1} is the result from the previous stack action similar to the seq2seq model (Sutskever et al., 2014). For example, if the previous stack action o_{t-1} is "push", then res_{t-1} is the semantic representation pushed into the stack. If the previous stack action o_{t-1} is to apply an operator $\diamond$, then res_{t-1} is the semantic representation generated by $f_\diamond$.

- s_t is the stack status. It is crucial because some operators are only applicable to certain combinations of operand semantics, which is similar to the type system in programming languages. For example, operating multiplication is applicable to the combination of "*quantity of an item*" and "*price of an item*", while operating addition is not. Considering that all math operators supported here $(+, -, \times, \div)$ are binary operators, the semantic representations of the stack's top 2 elements at the time $t-1$ are considered:

  $$s_t = [e_{l_t}^S; e_{l_t}^S]. \quad (5)$$

- q_t incorporates problem information in the decision. It is believed that the attention mechanism (Luong et al., 2015) can effectively capture dependency for longer distance. Thus, the attention mechanism over the encoding problem $h_1^E, h_2^E, \cdots$ is adopted:

  $$q_t = \mathrm{Attention}(h_t^D, \{h_i^E\}_{i=1}^m), \quad (6)$$

  where the attention function in this paper is defined as a function with learnable parameters w, W, b:

  $$\mathrm{Attention}(u, \{v_i\}_{i=1}^m) = \sum_{i=1}^m \alpha_i h_i, \quad (7)$$

  $$\alpha_i = \frac{\exp(s_i)}{\sum_{l=1}^m \exp(s_i)}, \quad (8)$$

  $$s_i = w^\intercal \tanh(W^T[u; v_i] + b). \quad (9)$$

In order to model the dynamic features for different decoding steps, features in r_t^{sa} is gated as follows:

$$r_t^{sa} = [g_{t,1}^{sa} \cdot h_t^D; g_{t,2}^{sa} \cdot s_t; g_{t,3}^{sa} \cdot q_t], \quad (10)$$

$$g_t^{sa} = \sigma(W^{sa} \cdot [h_t^D; s_t; q_t]), \quad (11)$$

where σ is a sigmoid function and W^{sa} is a learned gating parameter. r_t^{opd} is defined similarly, but with a different learned gating parameter W^{opd}.

3.3.1 Stack Action Selector

The stack action selector is to select an stack action at each decoding step (section 3.3.2) until the unknowns are solved. The probability of choosing action a at the decoding step t is calculated with a network NN constituted of one hidden layer and ReLU as the activation function:

$$\begin{aligned} P(Y_t \mid \{y_i\}_{i=1}^{t-1}, \{w_i\}_{i=1}^m) \quad (12) \\ = \mathrm{StackActionSelector}(r_t^{sa}) \\ = \mathrm{softmax}(\mathrm{NN}(r_t^{sa})), \end{aligned}$$

where r_t^{sa} is decoding state features as defined in section 3.3.

3.3.2 Stack Actions

The available stack actions are listed below:

- **Variable generation**: The semantic representation of an unknown variable x is generated dynamically as the first action in the decoding process. Note that this procedure provides the flexibility of solving problems with more than one unknown variables. The decoder module can decide how many unknown variables are required to solve the problem, and the semantic representation of the unknown variable is generated with an attention mechanism:

$$e^x = \mathrm{Attention}(h_t^D, \{h_i^E\}_{i=1}^m). \tag{13}$$

- **Push**: This stack action pushes the operand chosen by the operand selector (section 3.3.3). Both the symbolic representation v_* and semantic representation e_* of the chosen operand would be pushed to the stack S in (3). Then the stack state becomes

$$S = [(v_*^S, e_*^S), (v_{l_t}^S, e_{l_t}^S), \cdots, (v_1^S, e_1^S)]. \tag{14}$$

- **Operator $\diamond$ application** ($\diamond \in \{+, -, \times, \div\}$): One stack action pops two elements from the top of the stack, which contains two pairs, (v_i, e_i) and (v_j, e_j), and then the associated symbolic operator, $v_k = v_i \diamond v_j$, is recorded. Also, a semantic transformation function $f_\diamond$ for that operator is invoked, which generates the semantic representation of v_k by transforming semantic representations of v_i and v_j to $e_k = f_\diamond(e_i, e_j)$. Therefore, after an operator is applied to the stack specified in (3), the stack state becomes

$$\begin{aligned} S =[&(v_{l_t}^S \diamond v_{l_t-1}^S, f_\diamond(e_{l_t}^S, e_{l_t-1}^S)), \\ &(v_{l_t-2}^S, e_{l_t-2}^S), \cdots, (v_1^S, e_1^S)]. \end{aligned} \tag{15}$$

- **Equal application**: When the equal application is chosen, it implies that an equation is completed. This stack action pops 2 tuples from the stack, $(v_i, e_i), (v_j, e_j)$, and then $v_i = v_j$ is recorded. If one of them is an unknown variable, the problem is solved. Therefore, after an OP is applied to the stack specified in (3), the stack state becomes

$$S = [(v_{l_t-2}^S, e_{l_t-2}^S), \cdots, (v_1^S, e_1^S)]. \tag{16}$$

3.3.3 Operand Selector

When the stack action selector has decided to push an operand, the operand selector aims at choosing which operand to push. The operand candidates e include constants provided in the problem text whose semantic representations are $e_1^c, e_2^c, \cdots, e_n^c$, unknown variable whose semantic representation is e^x, and two external constants 1 and π whose semantic representations are e^1, e^π:

$$e = [e_1^c, e_2^c, \cdots, e_n^c, e^1, e^\pi, e^x]. \tag{17}$$

An operand has both symbolic and semantic representations, but the selection focuses on its semantic meaning; this procedure is the same as what human does when solving math word problems.

Inspired by addressing mechanisms of neural Turing machine (NTM) (Graves et al., 2014), the probability of choosing the i-th operand candidate is the attention weights of r_t over the semantic representations of the operand candidates as in (8):

$$\begin{aligned} &P(Z_t \mid \{y_i\}_{i=1}^{t-1}, \{w_i\}_{i=1}^m) \qquad (18) \\ &= \mathrm{OperandSelector}(r_t^{opd}) \\ &= \mathrm{AttentionWeight}(r_t^{opd}, \{e_i\}_{i=1}^m \cup \{e^1, e^\pi, e^x\}), \end{aligned}$$

and r_t^{opd} is defined in section 3.3.

3.3.4 Semantic Transformer

A semantic transformer is proposed to generate the semantic representation of a new symbol resulted from applying an operator, which provides the capability of interpretation and reasoning for the target task. The semantic transformer for an operator $\diamond \in \{+, -, \times, \div\}$ transforms semantic representations of two operands e_1, e_2 into

$$f_\diamond(e_1, e_2) = \tanh(U_\diamond \mathrm{ReLU}(W_\diamond[e_1; e_2] + b_\diamond) + c_\diamond), \tag{19}$$

where $W_\diamond, U_\diamond, b_\diamond, c_\diamond$ are model parameters. Semantic transformers for different operators have different parameters in order to model different transformations.

3.4 Training

Both stack action selection and operand selection can be trained in a fully supervised way by giving problems and associated ground truth equations. Because our model generates the equation with stack actions, the equation is first transformed into its postfix representation. Let the postfix representation of the target equation be $y_1, \cdots y_t, \cdots, y_T$, where y_t can be either an operator $(+, -, \times, \div, =)$ or a target operand. Then for each time step t, the loss can be computed as

$$L(y_t) = \begin{cases} L_1(\text{push\_op}) + L_2(y_t) & y_t \text{ is an operand} \\ L_1(y_t) & \text{otherwise} \end{cases},$$

where L_1 is the stack action selection loss and L_2 is the operand selection loss defined as

$$L_1(y_t) = -\log P(Y_t = y_t \mid \{o_i\}_{i=1}^{t-1}, \{w_i\}_{i=1}^{m}),$$
$$L_2(y_t) = -\log P(Z_t = y_t \mid r_t).$$

The objective of our training process is to minimize the total loss for the whole equation, $\sum_{t=1}^{T} L(y_t)$.

3.5 Inference

When performing inference, at each time step t, the stack action with the highest probability $P(Y_t|\{\tilde{y}_i\}_{i=1}^{t-1}, \{w_i\}_{i=1}^{m})$ is chosen. If the chosen stack action is "*push*", the operand with the highest probability $P(Z_t|\{\tilde{Y}_i\}_{i=1}^{t-1}, \{w_i\}_{i=1}^{m})$ is chosen. When the stack has less than 2 elements, the probability of applying operator $+, -, \times, \div, =$ would be masked out to prevent illegal stack actions, so all generated equations must be legal math expressions. The decoder decodes until the unknown variable can be solved. After the equations are generated, a Python package SymPy (Meurer et al., 2017) is used to solve the unknown variable. The inference procedure example is illustrated in Figure 3. The detailed algorithm can be found in Algorithm 1.

Algorithm 1 Training and Inference

```
function SOLVEPROBLEM(problem_text)
    $v \leftarrow$ ExtractConstants(problem_text)
                        ▷ $v$ is a list of constants in the problem.

        $h_t^D \leftarrow$ LSTM($h_{t-1}^D, c_{t-1}$, ret)
        $s_t \leftarrow S$.get_top2()
        $h^E \leftarrow$ Attention($h_{t-1}^D, h^E$)
        $r_t \leftarrow [h_t^D, s_t, h^E]$
        $p_{sa} \leftarrow$ StackActionSelector($r_t$)
        $p_{opd} \leftarrow$ OperandSelector($r_t$)
        if training then
            ▷ Target equation $y$ is available when training.
            $Y_t \leftarrow y_t$
            if $y_t$ is operand then
                loss $\leftarrow$ loss + $L_1$(push) + $L_2(y_t)$
            else
                loss $\leftarrow$ loss + $L_1(y_t)$
            end if
        else
            $Y_t \leftarrow$ StackActionSelector($r_t^{sa}$)
            if $Y_t$ = push then
                $Z_t \leftarrow$ OperandSelector($r_t^{opd}$)
            end if
        end if
        if $Y_t$ = gen_var then
            $e^x \leftarrow$ Attention($h_t^D, h^E$)
            ret $\leftarrow e^x$
        else if $Y_t$ = push then
            $S$.push($v_{Z_t}, e_{Z_t}$)
            ret $\leftarrow e_{Z_t}$
        else if $Y_t \in \{+, -, \times, \div\}$ then
            $(v_a, e_a), (v_b, e_b) = S$.pop(), $S$.pop()
            $S$.push($v_a Y_t v_b, f_{Y_t}(e_a, e_b)$)
            ret $\leftarrow f_{Y_t}(e_a, e_b)$
        else if $Y_t$ = equal then
            $(v_a, e_a), (v_b, e_b) = S$.pop(), $S$.pop()
            equations = equations $\cup$ "$v_a = v_b$"
            ret $\leftarrow S$.top()
        end if
    end while
    return solve(equations)
end function
```

4 Experiments

To evaluate the performance of the proposed model, we conduct the experiments on the benchmark dataset and analyze the learned semantics.

4.1 Settings

The experiments are benchmarked on the dataset Math23k (Wang et al., 2017), which contains 23,162 math problems with annotated equations. Each problem can be solved by a single-unknown-variable equation and only uses operators $+, -, \times, \div$. Also, except π and 1, quantities in the equation can be found in the problem text. There are also other large scale datasets like Dolphin18K (Shi et al., 2015) and AQuA (Ling et al., 2017), containing 18,460 and 100,000 math word problems respectively. The reasons about not evaluating on these two datasets are 1) Dolphin18k contains some unlabeled math word problems and some incorrect labels, and 2) AQuA contains rational for solving the problems, but the equations in the rational are not formal (e.g. mixed with texts, using x to represent $\times$, etc.) and inconsistent. Therefore, the following experiments are performed and analyzed using Math23K, the only large scaled, good-quality dataset.

4.2 Results

The results are shown in Table 1. The retrieval-based methods compare problems in test data with problems in training data, and choose the most

Model		Accuracy
Retrieval	Jaccard	47.2%
	Cosine	23.8%
Classification	BLSTM	57.9%
	Self-Attention	56.8%
Generation	Seq2Seq w/ SNI	58.1%
	Proposed Word-Based	**65.3%**
	Proposed Char-Based	**65.8%**
Hybrid	Retrieval + Seq2Seq	64.7%

Table 1: 5-fold cross validation results on Math23K.

Model	Accuracy
Char-Based	65.8%
Word-Based	65.3%
Word-Based - Gate	64.1%
Word-Based - Gate - Attention	62.5%
Word-Based - Gate - Attention - Stack	60.1%
Word-Based - Semantic Transformer	64.1%
Word-Based - Semantic Representation	61.7%

Table 2: 5-fold cross validation results of ablation tests.

similar one's template to solve the problem (Kushman et al., 2014; Upadhyay and Chang, 2017). The classification-based models choose equation templates by a classifier trained on the training data. Their performance are reported in Robaidek et al.. The seq2seq and hybrid models are from Wang et al., where the former directly maps natural language into symbols in equations, and the latter one ensembles prediction from a seq2seq model and a retrieval-based model. The ensemble is the previous state-of-the-art results of Math23K.

Our proposed end-to-end model belongs to the generation category, and the single model performance achieved by our proposed model is new state-of-the-art ($> 65\%$) and even better than the hybrid model result (64.7%). In addition, we are the first to report character-based performance on this dataset, and the character-based results are slightly better than the word-based ones. Among the single model performance, our models obtain about more than 7% accuracy improvement compared to the previous best one (Wang et al., 2017). The performance of our character-based model also shows that our model is capable of learning the relatively accurate semantic representations without word boundaries and achieves better performance.

4.3 Ablation Test

To better understand the performance contributed by each proposed component, we perform a series of ablation tests by removing components one by one and then checking the performance by 5-fold cross validation. Table 2 shows the ablation results.

Char-Based v.s. Word-Based As reported above, using word-based model instead of character-based model only causes 0.5% performance drop. To fairly compare with prior word-based models, the following ablation tests are performed on the word-based approach.

Word-Based - Gate It uses r_t instead of r_t^{sa} and r_t^{opr} as the input of both $\mathrm{StackActionSelector}$ and $\mathrm{OperandSelector}$.

Word-Based - Gate - Attention Considering that the prior generation-based model (seq2seq) did not use any attention mechanism, we compare the models with and without the attention mechanism. Removing attention means excluding q_{t-1} in (11), so the input of both operator and operand selector becomes $r_t = [h_t^D; s_t]$. The result implies that our model is not better than previous models solely because of the attention.

Word-Based - Gate - Attention - Stack To check the effectiveness of the stack status (s_t in (11)), the experiments of removing the stack status from the input of both operator and operand selectors ($r_t = h_t^D$) are conducted. The results well justify our idea of choosing operators based on semantic meanings of operands.

Word-Based - Semantic Transformer To validate the effectiveness of the idea that views an operator as a semantic transformer, we modify the semantic transformer function of the operator $\diamond$ into $f_\diamond(e_1, e_2) = e_\diamond$, where $e_\diamond$ is a learnable parameter and is different for different operators. Therefore, $e_\diamond$ acts like the embedding of the operator $\diamond$, and the decoding process is more similar to a general seq2seq model. The results show that the semantic transformer in the original model encodes not only the last operator applied on the operands but other information that helps the selectors.

Word-Based - Semantic Representation To explicitly evaluate the effectiveness of operands' semantic representations, we rewrite semantic representation of the i-th operand in the problem texts

	58.0	quantifier 个	banana 香蕉	,	every 每	(basket) <unk>	6.0	quantifier 个	,	take off 拿掉	how many 多少	quantifier 个	,	then 就	can 可以	exactly 正好	fill 装	9.0	quantifier 个	baskets 篮子	了	<unk>	.
58.0	.02	.15	.02	.03	.26	.14	.01	.02	.00	.02	.31	.00	.00	.00	.00	.00	.01	.00	.01	.00	.00	.00	.00
6.0	.01	.00	.00	.00	.01	.09	.42	.21	.02	.05	.13	.00	.00	.00	.00	.00	.01	.01	.02	.00	.01	.00	.00
9.0	.00	.00	.00	.00	.00	.00	.00	.00	.00	.01	.01	.00	.00	.00	.00	.08	.65	.21	.01	.01	.01	.00	.00

Figure 4: The self-attention map visualization of operands' semantic expressions for the problem "*There are 58 bananas. Each basket can contain 6 bananas. How many bananas are needed to be token off such that exactly 9 baskets are filled?*".

from (2) to $e^c_i = b^c_i$, where b^c_i is a parameter. Thus for every problem, the representation of the i-th operand is identical, even though their meanings in different problems may be different. This modification assumes that no semantic information is captured by b^c_i, which can merely represent a symbolic placeholder in an equation. Because the semantic transformer is to transform the semantic representations, applying this component is meaningless. Here the semantic transformer is also replaced with $f_\diamond(e_1, e_2) = e_\diamond$ as the setting of the previous ablation test. The results show that the model without using semantic representations of operands causes a significant accuracy drop of 3.5%. The main contribution of this paper about modeling semantic meanings of symbols is validated and well demonstrated here.

5 Qualitative Analysis

To further analyze whether the proposed model can provide interpretation and reasoning, we visualize the learned semantic representations of constants to check where the important cues are,

5.1 Constant Embedding Analysis

To better understand the information encoded in the semantic representations of constants in the problem, a self-attention is performed when their semantic representations are extracted by the encoder. Namely, we rewrite (2) as

$$e^c_i = \text{Attention}(h^E_{p_i}, \{h^E_t\}^m_{t=1}. \quad (20)$$

Then we check the trained self-attention map (α in the attention function) on the validation dataset.

For some problems, the self-attention that generates semantic representations of constants in the problem concentrates on the number's quantifier or unit, and sometimes it also focuses on informative verbs, such as "*gain*", "*get*", "*fill*", etc., in the sentence. For example, Figure 4 shows the attention weights for an example math word problem, where lighter colors indicate higher weights. The numbers "*58*" and "*6*" focus more on the quantifier-related words (e.g. "*every*" and "*how many*"), while "*9*" pays higher attention to the verb "*fill*". The results are consistent with those handcraft features for solving math word problems proposed by the prior research (Hosseini et al., 2014; Roy and Roth, 2015; Roy et al., 2015). Hence, we demonstrate that the automatically learned semantic representations indeed capture critical information that facilitates solving math word problems without providing human-crafted knowledge.

5.2 Decoding Process Visualization

We visualize the attention map (q_t in (6)) to see how the attention helps the decoding process. An example is shown in the top of Figure 5, where most attention focuses on the end of the sentence. Unlike the machine translation task, the attention shows the word-level alignment between source and target languages, solving math word problems requires high-level understanding due to the task complexity.

To further analyze the effectiveness of the proposed gating mechanisms for stack action and operand selection, the activation of gates g^{sa}, g^{opd} at each step of the decoding process is shown in the bottom of Figure 5. It shows that most of time, the gate activation is high, demonstrating that the proposed gating mechanisms play an important role during decoding. We also observe a common phenomenon that the activation g^{sa}_2, which controls how much attention the stack action selector puts on the stack state when deciding an stack action, is usually low until the last "operator application" stack action. For example, in the example of Figure 5, g^{sa}_2 is less than 0.20 till the last argument selection stack action, and activates when deciding the *division operator application* ($\div$) and the *equal application* ($=$). It may result from the higher-level semantics of the operand $(6.75-2.75)$ on the stack when selecting the stack action *division operator application* ($\div$). In terms

What is the unknown number?*", where the associated equation is $x = (6.75 - 2.75) \div 5$. Note that g^{opd} is meaningful only when the t-th stack action is push_op.

of the activation of g^{opd}, we find that three features are important in most cases, demonstrating the effectiveness of the proposed mechanisms.

5.3 Error Analysis

We randomly sample some results predicted incorrectly by our model shown in Table 3. In the first example, the error is due to the language ambiguity, and such ambiguity cannot be resolved without considering the exact value of the number. From the second example, although our model identifies the problem as a comparison problem successfully, it handles the order of the operands incorrectly. For the third problem, it cannot be solved by using only the surface meaning but requires some common sense. Therefore, above phenomena show the difficulty of solving math word problems and the large room for improvement.

6 Conclusion

We propose an end-to-end neural math solver using an encoder-decoder framework that incorporates semantic representations of numbers in order to generate mathematical symbols for solving math word problems. The experiments show that the proposed model achieves the state-of-the-art performance on the benchmark dataset, and empirically demonstrate the effectiveness of each component in the model. In sum, the proposed neural math solver is designed based on how human performs reasoning when writing equations, providing better interpretation without the need of labeled rationals.

A Algorithm Detail

The training and inference procedures are shown in Algortihm 1.

B Hyperparameter Setup

The model is trained with the optimizer `adam` (Kingma and Ba, 2014), and the learning rate is set to 0.001. Pretrained embeddings using FastText (Joulin et al., 2016) are adopted. The hidden state size of LSTM used in the encoder and decoder is 256. The dimension of hidden layers in attention, semantic transformer and operand/stack action selector is 256. The dropout rate is set as 0.1 before inputting the decoder LSTM, before the stack action selector and after the hidden layer of the stack action selector and attention. The reported accuracy is the result of 5-fold cross-validation, same as Wang et al. for fair comparison.

C Error Analysis between Seq2Seq

We implement the seq2seq model as proposed by Wang et al. and compare the performance difference between our proposed model and the baseline seq2seq model. Table 4 shows the generated results seq2seq predicts correctly but our model predicts incorrectly. Table 5 show the results our model can predict correctly but seq2seq cannot.

Problem & Results
小红前面 5 人，后面 7 人，一共有多少人？ (There are 5 people in front of Little Red and 7 people behind. How many persons are there in total?) *Proposed Model*: $5 + 7$ *Seq2Seq Model*: $5 + 7 + 1$
两个数相差28，如果被减数减少3，减数增加5，那么它们的差=？ (The difference between two numbers is 28. If the minuend is reduced by 3, and the subtrahend is increased by 5, then their difference=?) *Proposed Model*: $(28 - 3) \div 5$ *Seq2Seq Model*: $28 - (3 + 5)$
机床厂第一车间有55人，第二车间有45人，每人每天平均生产261个零件，这两个车间每天共生产多少个零件？ (There are 55 people in the first workshop of the machine tool factory and 45 people in the second workshop. Each person produces 261 small components per day in average. How many components do the two workshops produce every day in total?) *Proposed Model*: $(55 + 45) \div 261$ *Seq2Seq Model*: $(55 + 45) \times 261$
箭鱼游动时的速度是28米/秒，8秒可以游多少米？ (The swordfish swims at speed 28 meters/sec. How many meters can it swim in 8 seconds?) *Proposed Model*: $28 \div 8$ *Seq2Seq Model*: 28×8
水果店有梨子387千克，卖出205千克后，又运来一批，现在水果店共有梨子945千克．水果店又运来梨子多少千克？ (The fruit shop has 387 kilograms of pears . After selling 205 kilograms, some pears arrive. Now the fruit shop has 945 kilograms of pears in total. How many kilograms of pears does the fruit shop get?) *Proposed Model*: $945 \times (387 - 205)$ *Seq2Seq Model*: $945 - (387 - 205)$
王老师买排球用了40元，买篮球用的钱数是排球的3倍．王老师买球一共用了多少元？ (Teacher Wang spent 40 dollars buying volleyballs and 3 times of money for basketballs. How many dollars did Teacher Wang spend for the balls?) *Proposed Model*: $40 \div 3 + 40$ *Seq2Seq Model*: $40 + 40 \times 3$
筑路队修筑一条长1200米的公路，甲队单独修40天可以完成任务，乙队单独修30天可以完成任务．甲队每天修的比乙队少多少米？ (The road construction team built a road with a length of 1200 meters. Team A can complete the task in 40 days alone, and team B can complete the task in 30 days alone. How many meters does team A construct more than team B every day?) *Proposed Model*: $1200 \div 40 - 1200 \div 30$ *Seq2Seq Model*: $1200 \div 30 - 1200 \div 40$
一共1800本，我们六年级分得2/9，分给五年级的本数相当于六年级的4/5，五年级分得多少本？ (There are 1800 books in total. We sixth grade get 2/9. The number of books given to the fifth grade is equal to 4/5 of the number to the sixth grade. How many books does the fifth grade get?) *Proposed Model*: $1800 \times \frac{2}{9} \div \frac{4}{5}$ *Seq2Seq Model*: $1800 \times \frac{2}{9} \times \frac{4}{5}$
有一批布料，如果只做上衣可以做10件，如果只做裤子可以做15条，那么这批布料可以做几套这样的衣服？ (There is a batch of fabrics. If all is used for making shirts, 10 pieces can be made, and 15 pieces if used to make pants only. Then how many suits of such clothes can be made with this batch of fabric?) *Proposed Model*: $10 \times 1 \div 15$ *Seq2Seq Model*: $1 \div (1 \div 10 + 1 \div 15)$
贝贝的钱买一本5.9元笔记本差0.6元，他买一本4.8元的，剩下的钱正好买一只圆珠笔，这只圆珠笔多少钱？ (Beibei needs 0.6 dollars more to buy a notebook of 5.9 dollars. If he buys one of 4.8 dollars, the remaining money allows her to buy exactly one ball pen. How much is the ball pen?) *Proposed Model*: $5.9 + 0.6 - 4.8$ *Seq2Seq Model*: $5.9 - 0.6 - 4.8$

Table 4: Examples that Seq2Seq predicts correctly while our proposed model predicts incorrectly.

Problem & Results
医院里经常要给病人输入葡萄糖水，这种葡萄糖水是把葡萄糖和水按1：19配制的，根据这些信息，你能知道什么？ (In hospital, it is often necessary to give glucose injection to patient. This glucose water is prepared by mixing glucose and water at 1:19. Based on this information, what do you know?) *Proposed Model*: $1 \div (1 + 19.0)$ *Seq2Seq Model*: $1 \times (1 + 19.0)$
一根长2.45米的木桩打入河底，现在测得木桩水上部分长0.75米，水中长1.05米，求这根桩打在泥中的长度=多少米？ (A wooden pile of 2.45 meters long is hammered into the bottom of a river. Now the part above water is measured as 0.75 meters long, and the part in the water is measured as 1.05 meters long. How long is the part of the pile in the mud?) *Proposed Model*: $2.45 - 0.75 - 1.05$ *Seq2Seq Model*: $2.45 + 0.75 + 1.05$
李强6月份的生活费为255元，比计划节省了15%，节省了多少元． (Li Qiang's living expenses in June were 255 dollars, 15% savings over the plan. How much did he save?) *Proposed Model*: $(255.0 \div (1 - 0.15)) \times 0.15$ *Seq2Seq Model*: $0.15 = 6.0/(1 - 255.0) - 6.0$
小芳在计算一个数除以10时，将除号看成了乘号，结果得3.2，正确的结果应该=． (When Xiaofang calculates a number divided by 10 , the division sign is mistakenly treated as a multiplication sign, and the result is 3.2. The correct result should be = .) *Proposed Model*: $3 \div 10 \div 10$ *Seq2Seq Model*: $3.2 \div (1 + 10)$
24 + 91 的 2/13，所得的和再除 19/20，商 = ？ (2/13 of 91 + 24, and the sum is divided by 19/20, quotient = ?) *Proposed Model*: $\frac{19}{20} \div (24 + 91 \times \frac{2}{13})$ *Seq2Seq Model*: $\frac{19}{20} \div (24 \times 91 - \frac{2}{13})$
1/3 + 0.25 = ？ (1/3 + 0.25 = ?) *Proposed Model*: $\frac{1}{3} + 0.25$ *Seq2Seq Model*: $\frac{1}{3} \times 0.25$
商店运来鸡蛋和鸭蛋各7箱．鸡蛋每箱重26千克，鸭蛋每箱重31千克，商店一共运来的鸡蛋和鸭蛋共多少千克？ (The store shipped 7 boxes of eggs and duck eggs respectively. Eggs weigh 26 kilograms per box, duck eggs weigh 31 kilograms per box. How many kilograms of eggs and duck eggs are shipped from the store in total?) *Proposed Model*: $26 \times 7 + 31 \times 7$ *Seq2Seq Model*: $26 \times 7 + 31$
3.8 - 2.54 + 1.46 = ？ (3.8 - 2.54 + 1.46 =) *Proposed Model*: $3.8 - 2.54 + 1.46$ *Seq2Seq Model*: $3.8 + 2.54 + 1.46$
有一池水，第一天放出200吨，第二天比第一天多放20%，第3天放了整池水的36%，正好全部放完．这池水共 有多少吨？ (There was a pool of water, which released 200 tons of water in the first day, 20% more in the second day than the first day, and 36% of the whole pool on the third day. Then the water is gone. How many tons of water did this pool have?) *Proposed Model*: $(200.0 + 200.0 \times (1 + 0.2)) \div (1 - 0.36)$ *Seq2Seq Model*: $(200.0 + 0.2) \times 3.0 + 0.2 \times (1 - 0.36)$
16 的 5/12 比一个数的 7 倍多 2 ， 这个数 = ？ (5/12 of 16 is more than 7 times of a number by 2. What is the number=?) *Proposed Model*: $(16 \times \frac{5}{12} - 2) \div 7$ *Seq2Seq Model*: $(16 \times \frac{5}{12} + 7) \div 2$

Table 5: Examples that Seq2Seq predicts incorrectly while our proposed model predicts correctly.

Iterative Search for Weakly Supervised Semantic Parsing

Abstract

Training semantic parsers from question-answer pairs typically involves searching over an exponentially large space of logical forms, and an unguided search can easily be misled by spurious logical forms that coincidentally evaluate to the correct answer. We propose a novel iterative training algorithm that alternates between searching for consistent logical forms and maximizing the marginal likelihood of the retrieved ones. This training scheme lets us iteratively train models that provide guidance to subsequent ones to search for logical forms of increasing complexity, thus dealing with the problem of spuriousness. We evaluate these techniques on two hard datasets: WIKITABLEQUESTIONS (WTQ) and Cornell Natural Language Visual Reasoning (NLVR), and show that our training algorithm outperforms the previous best systems, on WTQ in a comparable setting, and on NLVR with significantly less supervision.

1 Introduction

Semantic parsing is the task of translating natural language utterances into machine-executable meaning representations, often called *programs* or *logical forms*. These logical forms can be executed against some representation of the context in which the utterance occurs, to produce a *denotation*. This setup allows for complex reasoning over contextual knowledge, and it has been successfully used in several natural language understanding problems such as question answering (Berant et al., 2013), program synthesis (Yin and Neubig, 2017) and building natural language interfaces (Suhr et al., 2018).

Recent work has focused on training semantic parses via *weak supervision* from denotations alone (Liang et al., 2011; Berant et al., 2013). This is because obtaining logical form annotations is generally expensive (although recent work has addressed this issue to some extent (Yih et al., 2016)), and not assuming full supervision lets us be agnostic about the logical form language. The second reason is more important in open-domain semantic parsing tasks where it may not be possible to arrive at a complete set of operators required by the task. However, training semantic parsers with weak supervision requires not only searching over an exponentially large space of logical forms (Berant et al., 2013; Artzi and Zettlemoyer, 2013; Pasupat and Liang, 2015; Guu et al., 2017, *inter alia*) but also dealing with *spurious* logical forms that evaluate to the correct denotation while not being semantically equivalent to the utterance. For example, if the denotations are binary, 50% of all syntactically valid logical forms evaluate to the correct answer, regardless of their semantics. This problem renders the training signal extremely noisy, making it hard for the model to learn anything without some additional guidance during search.

We introduce two innovations to improve learning from denotations. Firstly, we propose an iterative search procedure for gradually increasing the complexity of candidate logical forms for each training instance, leading to better training data and better parsing accuracy. This procedure is implemented via training our model with two interleaving objectives, one that involves searching for logical forms of limited complexity during training (online search), and another that maximizes the marginal likelihood of retrieved logical forms. Second, we include a notion of coverage over the question in the search step to guide the training algorithm towards logical forms that not only evaluate to the correct denotation, but also have some connection to the words in the utterance.

We demonstrate the effectiveness of these two techniques on two difficult reasoning tasks: WIK-

Proceedings of NAACL-HLT 2019, pages 2669–2680
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

iTableQuestions(WTQ) (Pasupat and Liang, 2015), an open domain task with significant lexical variation, and Cornell Natural Language Visual Reasoning (NLVR) (Suhr et al., 2017), a closed domain task with binary denotations, and thus far less supervision. We show that: 1) interleaving online search and MML over retrieved logical forms (§4) is a more effective training algorithm than each of those objectives alone; 2) coverage guidance during search (§3) is helpful for dealing with weak supervision, more so in the case of NLVR where the supervision is weaker; 3) a combination of the two techniques yields 44.3% test accuracy on WTQ, outperforming the previous best single model in a comparable setting, and 82.9% test accuracy on NLVR, outperforming the best prior model, which also relies on greater supervision.

2 Background

2.1 Weakly supervised semantic parsing

We formally define semantic parsing in a weakly supervised setup as follows. Given a dataset where the i^{th} instance is the triple $\{x_i, w_i, d_i\}$, representing a sentence x_i, the world w_i associated with the sentence, and the corresponding denotation d_i, our goal is to find y_i, the translation of x_i in an appropriate logical form language (see §5.3), such that $[\![y_i]\!]^{w_i} = d_i$; i.e., the execution of y_i in world w_i produces the correct denotation d_i. A semantic parser defines a distribution over logical forms given an input utterance: $p(Y|x_i;\theta)$.

2.2 Training algorithms

In this section we describe prior techniques for training semantic parsers with weak supervision: maximizing marginal likelihood, and reward-based methods.

2.2.1 Maximum marginal likelihood

Most work on training semantic parsers from denotations maximizes the likelihood of the denotation given the utterance. The semantic parsing model itself defines a distribution over *logical forms*, however, not *denotations*, so this maximization must be recast as a *marginalization* over logical forms that evaluate to the correct denotation:

$$\max_{\theta} \prod_{x_i, d_i \in \mathcal{D}} \sum_{y_i \in Y | [\![y_i]\!]^{w_i} = d_i} p(y_i|x_i;\theta) \qquad (1)$$

This objective function is called *maximum marginal likelihood* (MML). The inner summation is in general intractable to perform during training, so it is only approximated.

Most prior work (Berant et al., 2013; Goldman et al., 2018, *inter alia*) approximate the intractable marginalization by summing over logical forms obtained via beam search during training. This typically results in frequent search failures early during training when model parameters are close to random, and in general may only yield spurious logical forms in the absence of any guidance. Since modern semantic parsers typically operate without a lexicon, new techniques are essential to provide guidance to the search procedure (Goldman et al., 2018).

One way of providing this guidance during search is to perform some kind of heuristic search up front to find a set of logical forms that evaluate to the correct denotation, and use those logical forms to approximate the inner summation (Liang et al., 2011; Krishnamurthy et al., 2017). The particulars of the heuristic search can have a large impact on performance; a smaller candidate set has lower noise, while a larger set makes it more likely that the correct logical form is in it, and one needs to strike the right balance. In this paper, we refer to the MML that does search during training as *dynamic MML*, and the one that does an offline search as *static MML*.

The main benefit of dynamic MML is that it adapts its training signal over time. As the model learns, it can increasingly focus its probability mass on a small set of very likely logical forms. The main benefit of static MML is that there is no need to search during training, so there is a consistent training signal even at the start of training, and it is typically more computationally efficient than dynamic MML.

2.2.2 Reward-based methods

When training weakly supervised semantic parsers, it is often desirable to inject some prior knowledge into the training procedure by defining arbitrary reward or cost functions. There exists prior work that use such methods, both in a reinforcement learning setting (Liang et al., 2017, 2018), and otherwise (Iyyer et al., 2017; Guu et al., 2017). In our work, we define a customized cost function that includes a coverage term, and use a Minimum Bayes Risk (MBR) (Goodman, 1996; Goel and Byrne, 2000; Smith and Eisner,

2006) training scheme, which we describe in §3.

3 Coverage-guided search

Weakly-supervised training of semantic parsers relies heavily on lexical cues to guide the initial stages of learning to good logical forms. Traditionally, these lexical cues were provided in the parser's lexicon. Neural semantic parsers remove the lexicon, however, and so need another mechanism for obtaining these lexical cues. In this section we introduce the use of coverage to inject lexicon-like information into neural semantic parsers.

Coverage is a measure of relevance of the candidate logical form y_i to the input x_i, in terms of how well the productions in y_i map to parts of x_i. We use a small manually specified lexicon as a mapping from source language to the target language productions, and define coverage of y_i as the number of productions triggered by the input utterance, according to the lexicon, that are included in y_i.

We use this measure of coverage to augment our loss function, and train using an MBR based algorithm as follows. We use beam search to train a model to minimize the expected value of a cost function $\mathcal{C}$:

$$\min_{\theta} \sum_{i=1}^{N} \mathbb{E}_{\tilde{p}(y_i|x_i;\theta)} \mathcal{C}(x_i, y_i, w_i, d_i) \tag{2}$$

where $\tilde{p}$ is a *re-normalization*[1] of the probabilities assigned to all logical forms on the beam.

We define the cost function $\mathcal{C}$ as:

$$\mathcal{C}(x_i, y_i, w_i, d_i) = \lambda \mathcal{S}(y_i, x_i) + (1-\lambda) \mathcal{T}(y_i, w_i, d_i) \tag{3}$$

where the function $\mathcal{S}$ measures the number of items that y_i is missing from the actions (or grammar production rules) triggered by the input utterance x_i given the lexicon; and the function $\mathcal{T}$ measures the consistency of the evaluation of y_i in w_i, meaning that it is 0 if $[\![y_i]\!]^{w_i} = d_i$, or a value e otherwise. We set e as the maximum possible value of the coverage cost for the corresponding instance, to make the two costs comparable in magnitude. λ is a hyperparameter that gives the relative weight of the coverage cost.

4 Iterative search

In this section we describe the iterative technique for refining the set of candidate logical forms associated with each training instance.

As discussed in §2.2, most prior work on weakly-supervised training of semantic parsers uses dynamic MML. This is particularly problematic in domains like NLVR, where the supervision signal is binary—it is very hard for dynamic MML to bootstrap its way to finding good logical forms. To solve this problem, we interleave static MML, which has a consistent supervision signal from the start of training, with the coverage-augmented MBR algorithm described in §3.

In order to use static MML, we need an initial set of candidate logical forms. We obtain this candidate set using a bounded-length exhaustive search, filtered using heuristics based on the same lexical mapping used for coverage in §3. A bounded-length search will not find logical forms for the entire training data, so we can only use a subset of the data for initial training. We train a model to convergence using static MML on these logical forms, then use that model to initialize coverage-augmented MBR training. This gives the model a good starting place for the dynamic learning algorithm, and the search at training time can look for logical forms that are longer than could be found with the bounded-length exhaustive search. We train MBR to convergence, then use beam search on the MBR model to find a new set of candidate logical forms for static MML on the training data. This set of logical forms can have a greater length than those in the initial set, because this search uses model scores to not exhaustively explore all possible paths, and thus will likely cover more of the training data. In this way, we can iteratively improve the candidate logical forms used for static training, which in turn improves the starting place for the online search algorithm.

Algorithm 1 concretely describes this process. `Decode` in the algorithm refers to running a beam search decoder that returns a set of consistent logical forms (i.e. $\mathcal{T} = 0$) for each of the input utterances. We start off with a seed dataset $\mathcal{D}^0$ for which consistent logical forms are available.

5 Datasets

We will now describe the two datasets we use in this work to evaluate our methods – Cornell NLVR

---

[1] Note that without this re-normalization, and with a -1/0 cost function based on denotation accuracy, MBR will maximize the likelihood of correct logical forms on the beam, which is equivalent to dynamic MML.

```
Input  : Dataset $\mathcal{D} = \{X, W, D\}$; and
         seed set $\mathcal{D}^0 = \{X^0, Y^0\}$ such that
         $X^0 \subset X$ and $\mathcal{C}(x_i^0, y_i^0, W_i, D_i) = 0$
Output: Model parameters $\theta^{\text{MBR}}$
Initialize dataset $\mathcal{D}^{\text{MML}} = \mathcal{D}^0$;
while $Acc(\mathcal{D}_{dev})$ is increasing do
    $\theta^{\text{MML}} = \texttt{MML}(\mathcal{D}^{\text{MML}})$;
    Initialize $\theta^{\text{MBR}} = \theta^{\text{MML}}$;
    Update $\theta^{\text{MBR}} = \texttt{MBR}(\mathcal{D}; \theta^{\text{MBR}})$;
    Update $\mathcal{D}^{\text{MML}} = \texttt{Decode}(\mathcal{D}; \theta^{\text{MBR}})$;
end
```

and WIKITABLEQUESTIONS.

5.1 Cornell NLVR

Cornell NLVR is a language-grounding dataset containing natural language sentences provided along with synthetically generated visual contexts, and a label for each sentence-image pair indicating whether the sentence is true or false in the given context. Figure 1 shows two example sentence-image pairs from the dataset (with the same sentence). The dataset also comes with structured representations of images, indicating the color, shape, size, and x- and y-coordinates of each of the objects in the image. While we show images in Figure 1 for ease of exposition, we use the structured representations in this work.

Following the notation introduced in §2.1, x_i in this example is *There is a box with only one item that is blue*. The structured representations associated with the two images shown are two of the worlds (w_i^1 and w_i^2), in which x_i could be evaluated. The corresponding labels are the denotations d_i^1 and d_i^2 that a translation y_i of the sentence x_i is expected to produce, when executed in the two worlds respectively. That the same sentence occurs with multiple worlds is an important property of this dataset, and we make use of it by defining the function $\mathcal{T}$ to be 0 only if $\forall_{w_i^j, d_i^j} [\![y_i]\!]^{w_i^j} = d_i^j$.

5.2 WIKITABLEQUESTIONS

WIKITABLEQUESTIONS is a question-answering dataset where the task requires answering complex questions in the context of Wikipedia tables. An example can be seen in Figure 2. Unlike NLVR, the answers are not binary. They can instead be cells in the table or the result of numerical or set-theoretic operations performed on them.

5.3 Logical form languages

For NLVR, we define a typed variable-free functional query language, inspired by the GeoQuery language (Zelle and Mooney, 1996). Our language contains six basic types: `box` (referring to one of the three gray areas in Figure 1), `object` (referring to the circles, triangles and squares in Figure 1), `shape`, `color`, `number` and `boolean`. The constants in our language are color and shape names, the set of all boxes in an image, and the set of all objects in an image. The functions in our language include those for filtering objects and boxes, and making assertions, a higher order function for handling negations, and a function for querying objects in boxes. This type specification of constants and functions gives us a grammar with 115 productions, of which 101 are terminal productions (see Appendix A.1 for the complete set of rules in our grammar). Figure 1 shows an example of a complete logical form in our language.

For WTQ, we use the functional query language used by (Liang et al., 2018) as the logical form language. Figure 2 shows an example logical form.

5.4 Lexicons for coverage

The lexicon we use for the coverage measure described in §3 contains under 40 rules for each logical form language. They mainly map words and phrases to constants and unary functions in the target language. The complete lexicons are shown in the Appendix. Figures 1 and 2 also show the actions triggered by the corresponding lexicons for the utterances shown. We find that small but precise lexicons are sufficient to guide the search process away from spurious logical forms. Moreover, as shown empirically in §6.4, the model for NLVR does not learn much without this simple but crucial guidance.

6 Experiments

We evaluate both our contributions on NLVR and WIKITABLEQUESTIONS.

6.1 Model

In this work, we use a grammar-constrained encoder-decoder neural semantic parser for our experiments. Of the many variants of this basic architecture (see §7), all of which are essentially seq2seq models with constrained outputs and/or re-parameterizations, we choose to use the parser of Krishnamurthy et al. (2017), as it is particularly well-suited to the WIKITABLEQUESTIONS dataset, which we evaluate on.

The encoder in the model is a bi-directional recurrent neural network with Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) cells, and the decoder is a grammar-constrained decoder also with LSTM cells. Instead of directly outputting tokens in the logical form, the decoder outputs *production rules* from a CFG-like grammar. These production rules sequentially build up an abstract syntax tree, which determines the logical form. The model also has an entity linking component for producing table entities in the logical forms; this component is only applicable to WIKITABLEQUESTIONS, and we remove it when running experiments on NLVR. The particulars of the model are not the focus of this work, so we refer the reader to the original paper for more details.

In addition, we slightly modify the constrained decoding architecture from (Krishnamurthy et al., 2017) to bias the predicted actions towards those that would decrease the value of $\mathcal{S}(y_i, x_i)$. This is done using a coverage vector, $v_i^{\mathcal{S}}$ for each training instance that keeps track of the production rules triggered by x_i, and gets updated whenever one of those desired productions is produced by the decoder. That is, $v_i^{\mathcal{S}}$ is a vector of 1s and 0s, with 1s indicating the triggered productions that are yet to be produced by the decoder. This is similar to the idea of checklists used by Kiddon et al. (2016). The decoder in the original architecture scores output actions at each time step by computing a dot product of the predicted action representation with the embeddings of each of the actions. We add a weighted sum of all the actions that are yet to produced:

$$s_i^a = e^a.(p_i + \gamma * v_i^{\mathcal{S}}.E) \tag{4}$$

where s_i^a is the score of action a at time step i, e^a is the embedding of that action, p_i is the predicted action representation, E is the set of embeddings of all the actions, and γ is a learned parameter for regularizing the bias towards yet-to-be produced triggered actions.

6.2 Experimental setup

NLVR We use the standard train-dev-test split for NLVR, containing 12409, 988 and 989 sentence-image pairs respectively. NLVR contains most of the sentences occurring in multiple worlds (with an average of 3.9 worlds per sentence). We set the word embedding and action embedding sizes to 50, and the hidden layer size of both the encoder and the decoder to 30. We initialized all the parameters, including the word and action embeddings using Glorot uniform initialization (Glorot and Bengio, 2010). We found that using pretrained word representations did not help. We added a dropout (Srivastava et al., 2014) of 0.2 on the outputs of the encoder and the decoder and before predicting the next action, set the beam size to 10 both during training and at test time, and trained the model using ADAM (Kingma and Ba, 2014) with a learning rate of 0.001. All the hyper-parameters are tuned on the validation set.

WIKITABLEQUESTIONS This dataset comes with five different cross-validation folds of training data, each containing a different 80/20 split for training and development. We first show results aggregated from all five folds in §6.3, and then show results from controlled experiments on fold 1. We replicated the model presented in Krishnamurthy et al. (2017), and only changed the training algorithm and the language used. We used a beam size of 20 for MBR during training and decoding, and 10 for MML during decoding, and trained the model using Stochastic Gradient Descent (Kiefer et al., 1952) with a learning rate of 0.1, all of which are tuned on the validation sets.

Specifics of iterative search For our iterative search algorithm, we obtain an initial set of candidate logical forms in both domains by exhaustively searching to a depth of 10[2]. During search we retrieve the logical forms that lead to the correct denotations in all the corresponding worlds, and sort them based on their coverage cost using the coverage lexicon described in §5.4, and choose the top-k[3]. At each iteration of the search step in our iterative training algorithm, we increase the maximum depth of our search with a step-size of 2, finding more complex logical forms and covering a larger proportion of the training data. While exhaustive search is prohibitively expensive beyond a fixed number of steps, our training process that uses beam search based approximation can go deeper.

Implementation We implemented our model and training algorithms within the AllenNLP (Gardner et al., 2018) toolkit. The code and models are publicly available at `https://github.com/allenai/iterative-search-semparse`.

6.3 Main results

WIKITABLEQUESTIONS Table 1 compares the performance of a single model trained using Iterative Search, with that of previously published single models. We excluded ensemble models since there are differences in the way ensembles are built for this task in previous work, either in terms of size or how the individual models were chosen. We show both best and average (over 5 folds) single model performance from Liang et al. (2018) (Memory Augmented Policy Optimization). The best model was chosen based on performance on the development set. Our single model performances are computed in the same way. Note that Liang et al. (2018) also use a lexicon similar to ours to prune the seed set of logical forms used to initialize their memory buffer.

Approach	Dev	Test
Pasupat and Liang (2015)	37.0	37.1
Neelakantan et al. (2017)	34.1	34.2
Haug et al. (2018)	-	34.8
Zhang et al. (2017)	40.4	43.7
Liang et al. (2018) (MAPO) (avg.)	42.3	43.1
Liang et al. (2018) (MAPO) (best)	42.7	43.8
Iterative Search (avg.)	42.1	43.9
Iterative Search (best)	**43.1**	**44.3**

Table 1: Comparison of single model performances of Iterative Search with previously reported single model performances

Algorithm	Dev acc.	Test acc.
MAPO	42.1	42.7
Static MML	40.0	42.2
Iterative MML	42.5	43.1
Iterative Search	**43.0**	**43.8**

Table 2: Comparison of iterative search with static MML, iterative MML, and the previous best result from (Liang et al., 2018), all trained on the official split 1 of WIKITABLEQUESTIONS and tested on the official test set.

In Table 2, we compare the performance of our iterative search algorithm with three baselines: 1) Static MML, as described in §2.2.1 trained on the candidate set of logical forms obtained through the heuristic search technique described in §6.2; 2) Iterative MML, also an iterative technique but unlike iterative search, we skip MBR and iteratively train static MML models while increasing the number of decoding steps; and 3) MAPO (Liang et al., 2018), the current best published system on WTQ. All four algorithms are trained and evaluated on the first fold, use the same language, and the bottom three use the same model and the same set of logical forms used to train static MML.

---

[2] It was prohibitively expensive to search beyond depth of 10.

[3] k is a hyperparameter that is chosen on the dev set at each iteration in iterative search, and is typically 10 or 20

NLVR In Table 3, we show a comparison of the performance of our *iterative coverage-guided search* algorithm with the previously published approaches for NLVR. The first two rows correspond to models that are not semantic parsers. This shows that semantic parsing is a promising direction for this task. The closest work to ours is the weakly supervised parser built by (Goldman et al., 2018). They build a lexicon similar to ours for mapping surface forms in input sentences to abstract clusters. But in addition to defining a lexicon, they also manually annotate complete sentences in this abstract space, and use those annotations to perform data augmentation for training a supervised parser, which is then used to initialize a weakly supervised parser. They also explicitly use the abstractions to augment the beam during decoding using caching, and a separately-trained discriminative re-ranker to re-order the logical forms on the beam. As a discriminative re-ranker is orthogonal to our contributions, we show their results with and without it, with "Abs. Sup." being more comparable to our work. Our model, which uses no data augmentation, no caching during decoding, and no discriminative re-ranker, outperforms their variant without reranking on the public test set, and outperforms their best model on the hidden test set, achieving a new state-of-the-art result on this dataset.

6.4 Effect of coverage-guided search

To evaluate the contribution of coverage-guided search, we compare the the performance of the NLVR parser in two different settings: with and without coverage guidance in the cost function. We also compare the performance of the parser in the two settings, when initialized with parameters from an MML model trained to maximize the likelihood of the set of logical forms obtained from exhaustive search. Table 4 shows the results of this comparison. We measure accuracy and consistency of all four models on the publicly available test set, using the official evaluation script. Consistency here refers to the percentage of logical forms that produce the correct denotation in all the corresponding worlds, and is hence a stricter metric than accuracy. The cost weight (λ in Equation 3) was tuned based on validation set performance for the runs with coverage, and we found that $\lambda = 0.4$ worked best.

It can be seen that both with and without initialization, coverage guidance helps by a big margin, with the gap being even more prominent in the case where there is no initialization. When there is neither coverage guidance nor a good initialization, the model does not learn much from unguided search and get a test accuracy not much higher than the majority baseline of 56.2%.

We found that coverage guidance was not as useful for WTQ. The average value of the best performing λ was around 0.2, and higher values neither helped nor hurt performance.

6.5 Effect of iterative search

To evaluate the effect of *iterative search*, we present the accuracy numbers from the search (S) and maximization (M) steps from different iterations in Tables 5 and 6, showing results on NLVR and WTQ, respectively. Additionally, we also show number of decoding steps used at each iterations, and the percentage of sentences in the training data for which we were able to obtain consistent logical forms from the S step, the set that was used in the M step of the same iteration. It can be seen in both tables that a better MML model gives a better initialization for MBR, and a better MBR model results in a larger set of utterances for which we can retrieve consistent logical forms, thus improving the subsequent MML model. The improvement for NLVR is more pronounced (a gain of 21% absolute) than for WTQ (a gain of 3% absolute), likely because the initial exhaustive search provides a much higher percentage of spurious logical forms for NLVR, and thus the starting place is relatively worse.

Complexity of Logical Forms We analyzed the logical forms produced by our iterative search algorithm at different iterations to see how they differ. As expected, for NLVR, allowing greater depths lets the parser explore more complex logical forms. Table 7 shows examples from the validation set that indicate this trend.

7 Related Work

Most of the early methods used for training semantic parsers required the training data to come with annotated logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005). The primary limitation of such methods is that manually producing these logical forms is expensive, making it hard to scale these methods across domains.

Table 6: Iterative search on WIKITABLEQUESTIONS. M and S refer to Maximization and Search steps.

More recent research has focused on training semantic parsers with *weak supervision* (Liang et al., 2011; Berant et al., 2013), or trying to automatically infer logical forms from denotations (Pasupat and Liang, 2016). However, matching the performance of a fully supervised semantic parser with only weak supervision remains a significant challenge (Yih et al., 2016).

The main contributions of this work deal with training semantic parsers with weak supervision, and we gave a detailed discussion of related training methods in §2.2.

We evaluate our contributions on the NLVR and WIKITABLEQUESTIONS datasets. Other work that evaluates on on these datasets include Goldman et al. (2018), Tan and Bansal (2018), Neelakantan et al. (2017), Krishnamurthy et al. (2017), Haug et al. (2018), and (Liang et al., 2018). These prior works generally present modeling contributions that are orthogonal (and in some cases complementary) to the contributions of this paper. There has also been a lot of recent work on neural semantic parsing, most of which is also orthogonal to (and could probably benefit from) our contributions (Dong and Lapata, 2016; Jia and Liang, 2016; Yin and Neubig, 2017; Krishnamurthy et al., 2017; Rabinovich et al., 2017). Recent attempts at dealing with the problem of spuriousness include Misra et al. (2018) and Guu et al. (2017).

Coverage has recently been used in machine translation (Tu et al., 2016) and summarization (See et al., 2017). There have also been many methods that use coverage-like mechanisms to give lexical cues to semantic parsers. Goldman et al. (2018)'s abstract examples is the most recent and related work, but the idea is also related to lexicons in pre-neural semantic parsers (Kwiatkowski et al., 2011).

0	*There is a tower with four blocks* `(box_exists (member_count_equals all_boxes 4))`
1	*Atleast one black triangle is not touching the edge* `(object_exists (black (triangle ((negate_filter touch_wall) all_objects))))`
2	*There is a yellow block as the top of a tower with exactly three blocks.* `(object_exists (yellow (top (object_in_box (member_count_equals all_boxes 3)))))`
3	*The tower with three blocks has a yellow block over a black block* `(object_count_greater_equals (yellow (above (black (object_in_box (member_count_equals all_boxes 3))))) 1)`

Table 7: Complexity of logical forms produced at different iterations, from iteration 0 to iteration 3; each logical form could not be produced at the previous iterations

8 Conclusion

We have presented a new technique for training semantic parsers with weak supervision. Our key insights are that lexical cues are crucial for guiding search during the early stages of training, and that the particulars of the approximate marginalization in maximum marginal likelihood have a large impact on performance. To address the first issue, we used a simple coverage mechanism for including lexicon-like information in neural semantic parsers that do not have lexicons. For the second issue, we developed an iterative procedure that alternates between statically-computed and dynamically-computed training signals. Together these two contributions greatly improve semantic parsing performance, leading to new state-of-the-art results on NLVR and WIKITABLEQUESTIONS. As these contributions are to the learning algorithm, they are broadly applicable to many models trained with weak supervision. One potential future work direction is investigating whether they extend to other structured prediction problems beyond semantic parsing.

Acknowledgments

We would like to thank Jonathan Berant and Noah Smith for comments on earlier drafts and Chen Liang for helping us with implementation details of MAPO. Computations on beaker.org were supported in part by credits from Google Cloud.

A Logical form language and lexicon for NLVR

Basic Types: `bool (t),box (b),object (o),shape (s),color (c),number (n)`

In the grammar and lexicon that follow we use the following placeholders,

quantifier ∈ {any, all, none}

comparator ∈ {equals, not_equals, lesser, lesser_equals, greater, greater_equals}

color ∈ {yellow, blue, black}

shape ∈ {square, triangle, circle}

size ∈ {big, medium, small}

location ∈ {above, below, top, left, right, bottom, corner, wall}

number ∈ {1...9}

A.1 Grammar

Constants

```
b -> all_boxes
c -> color_black,
     color_blue, color_yellow
n -> 1, 2, ..., 9
o -> all_objects
s -> shape_circle,
     shape_square, shape_triangle
```

Object filtering functions

```
<o,o> -> [location], [color],
 [shape], [size], same_color,
 same_shape, touch_object,
 touch_bottom, touch_top,
 touch_left, touch_right,
 touch_corner, touch_wall,
```

Box filtering functions

```
<b,<s,b>> ->
  member_shape_[quantifier]_equals
<b,<c,b>> ->
  member_color_[quantifier]_equals
<b,<n,b>> ->
  member_count_[comparator]
  member_color_count_[comparator],
  member_shape_count_[comparator]
<b,b> -> member_color_different,
 member_color_same,
 member_shape_different,
 member_shape_same
```

Assertion functions

```
<b,t> -> box_exists
<o,t> -> object_exists
<b,<n,t>> -> box_count_[comparator]
<o,<c,t>> ->
  object_color_[quantifier]_equals
<o,<s,t>> ->
  object_shape_[quantifier]_equals
<o,<n,t>> ->
  object_color_count_[comparator],
  object_shape_count_[comparator],
  object_count_[comparator]
```

Other functions

```
<b,o> -> object_in_box
<<o,o>,<o,o>> -> negate_filter
```

A.2 Lexicon for NLVR

there is a box → box_exists

Alignment over Heterogeneous Embeddings for Question Answering

Vikas Yadav, Steven Bethard, Mihai Surdeanu
University of Arizona, Tucson, AZ, USA
`{vikasy,bethard,msurdeanu}@email.arizona.edu`

Abstract

We propose a simple, fast, and mostly-unsupervised approach for non-factoid question answering (QA) called Alignment over Heterogeneous Embeddings (AHE). AHE simply aligns each word in the question and candidate answer with the most similar word in the retrieved supporting paragraph, and weighs each alignment score with the inverse document frequency of the corresponding question/answer term. AHE's similarity function operates over embeddings that model the underlying text at different levels of abstraction: character (FLAIR), word (BERT and GloVe), and sentence (InferSent), where the latter is the only supervised component. Despite its simplicity and lack of supervision, AHE obtains a new state-of-the-art performance on the "Easy" partition of the AI2 Reasoning Challenge (ARC) dataset (64.6% accuracy), top-two performance on the "Challenge" partition of ARC (34.1%), and top-three performance on the WikiQA dataset (74.08% MRR), outperforming many other complex, supervised approaches. Our error analysis indicates that alignments over character, word, and sentence embeddings capture substantially different semantic information. We exploit this with a simple meta-classifier that learns how much to trust the predictions over each representation, which further improves the performance of unsupervised AHE[1].

1 Introduction

Question - Which sequence of energy transformations occurs after a battery-operated flashlight is turned on?

1. *electrical → light → chemical*
2. *electrical →chemical → light*
3. *chemical → light → electrical*
4. **chemical → electrical → light**

Supporting paragraph(s): "a chemical cell converts chemical energy into electrical energy; a flashlight chemical energy to light energy"

Figure 1: A multiple-choice question from the ARC dataset with the correct answer in bold font. This question is answered correctly by our alignment method that relies on contextualized word embeddings that capture the correct sequence, and cannot be answered correctly when relying on uncontextualized embeddings.

The "deep learning tsunami"(Manning, 2015) has had a major impact on important natural language processing (NLP) applications such as question answering (QA). Many neural approaches for QA have been proposed in the past few years, with impressive results on several QA tasks (Seo et al., 2016; Wang and Jiang, 2016; Wang et al., 2017b; Tymoshenko et al., 2017; Xiong et al., 2016a; Wang et al., 2018; Radford et al., 2018; Li et al., 2018, inter alia). However, an undesired effect of this focus on neural approaches was that other methods have fallen out of focus, including strong unsupervised benchmarks that are necessary to highlight the true gains of supervised approaches. For instance, alignment approaches have received considerably less interest recently, despite their initial successes (Echihabi and Marcu, 2003; Surdeanu et al., 2011, inter alia). While a few recent efforts have adapted these alignment methods to operate over word representations (Kenter and De Rijke, 2015; Kim et al., 2017; Yadav et al., 2018), they generally underperfom supervised neural methods due to their underlying bag-of-word (BoW) assumptions and reliance on uncontextualized word representations such as GloVe (Pennington et al., 2014).

In this work we argue that alignment approaches are more meaningful today after the advent of *contextualized* word representations, which mitigate the above BoW limitations. For example, Figure 1 shows an example of a question from AI2's Reasoning Challenge (ARC) dataset (Clark et al., 2018),

which is not answered correctly by a state-of-the-art BoW alignment method (Yadav et al., 2018), but is correctly answered by our alignment approach when operating over Bidirectional Encoder Representations from Transformers (BERT) embeddings (Devlin et al., 2018).

We propose a simple, fast, and mostly-unsupervised approach for non-factoid QA called Alignment over Heterogeneous Embeddings (AHE). AHE uses an off-the-shelf information retrieval (IR) component to retrieve likely supporting paragraphs from a knowledge base (KB) given a question and candidate answer. Then AHE aligns each word in the question and candidate answer with the most similar word in the retrieved supporting paragraph, and weighs each alignment score with the inverse document frequency (IDF) of the corresponding question/answer term. AHE's overall alignment score is the sum of the IDF weighted scores of each of the question/answer term.

Importantly, AHE's alignment function operates over contextualized embeddings that model the underlying text at different levels of abstraction: character (FLAIR) (Akbik et al., 2018), word (BERT) (Devlin et al., 2018), and sentence (InferSent) (Conneau et al., 2017), where the latter is the only supervised component in the proposed approach. The different representations are combined through an ensemble approach that by default is unsupervised (using a variant of the NoisyOr formula), but can be replaced with a supervised meta-classifier.

The contributions of our work are the following:

1. To our knowledge, this is the first unsupervised alignment approach for QA that: (a) operates over contextualized embeddings, and (b) captures text at multiple levels of abstraction, including character, word, and sentence.
2. We obtain (near) state-of-the-art results (top three or higher) on three QA datasets: WikiQA (Yang et al., 2015) (74.08 mean reciprocal rank), ARC the Challenge partition (34.1% precision at 1 (P@1)) and ARC Easy (64.6 P@1). Our approach outperforms information retrieval methods, other unsupervised alignment approaches, and many supervised, neural approaches, despite the fact that it is mostly unsupervised and much simpler. Importantly, unlike many neural approaches, our results are robust across several datasets. Minimally, these results indicate that the work proposed here should be considered as a new, strong baseline for the task.
3. Our analysis indicates that alignments over character, word, and sentence embeddings capture substantially different semantic information. We highlight this complementarity with an oracle system that chooses the correct answer when it is proposed by any of the AHE's representations, which achieves 68% P@1 on ARC Challenge, 86% on ARC Easy, and 93.7% mean average precision (MAP) on WikiQA. We exploit this complementarity with a simple meta-classifier that learns when and how much to trust the predictions over each representation, which further improves the performance of unsupervised AHE.

2 Related Work

We highlight major trends in the field, and how our work compares with them. We focus mostly on non-factoid QA, which is usually implemented in two forms: multiple-choice QA such as AI2's Reasoning Challenge (ARC), where the answer must be selected from multiple candidates and (optionally) supported by explanatory texts extracted from external knowledge bases (Clark et al., 2018); or answer sentence selection, where candidate answer sentences are provided and the task is to select the sentences containing the correct answers (Yang et al., 2015). Alignment models have also been proposed for other types of QA, such as reading comprehension (RC) QA (Chakravarti et al., 2017). We believe AHE can be similarly extended to RC, but, in this work, we have limited our experiments to answer selection and multiple-choice QA tasks.

Most QA approaches today use neural, supervised methods. Most use stacked architectures usually coupled with attention mechanisms (He and Lin, 2016; Yin et al., 2015; Seo et al., 2016; Xiong et al., 2016b; Kumar et al., 2016; Tan et al., 2015; Wang et al., 2017a; Chen et al., 2016; Cheng et al., 2016; Golub and He, 2016). Some of these works also rely on structured knowledge bases (Zhong et al., 2018a; Ni et al., 2018) such as ConceptNet (Speer et al., 2017). Some approaches use query expansion methods in addition to the above methods (Musa et al., 2018; Nogueira and Cho, 2017; Ni et al., 2018). For example, Musa et al. (2018) used a sequence to sequence model (Sutskever et al., 2014) to generate an enhanced query for ARC which retrieves better supporting passages.

However, in general, all these approaches rely on annotated training data, and, some, on structured KBs, which are expensive to create (Jauhar et al., 2016). Further, as we demonstrate in Section 5, these methods tend to be tailored to a specific dataset and do not port well to other domains or even within different splits of the same dataset. In contrast, our method is mostly unsupervised and does not require training. Even then, our approach performs well on three distinct QA datasets, with top three performance in all.

Our work is inspired by previous efforts on using alignment methods for NLP (Echihabi and Marcu, 2003). Unsupervised alignment models have been proposed for several NLP tasks such as short text similarity (Kenter and De Rijke, 2015), answer phrase/sentence selection in reading comprehension (RC) (Chakravarti et al., 2017), document retrieval (Kim et al., 2017), etc. Other works have utilized word alignments as features in supervised models (Surdeanu et al., 2011; Wang and Ittycheriah, 2015). For example, Wang and Ittycheriah (2015) utilized the alignment of words between two questions as a feature in a feedforward neural network that matches similar FAQ questions. Recently, Yadav et al. (2018) showed that alignment methods remain competitive for non-factoid QA.

However, the majority of alignment models that rely on representation learning utilize uncontextualized word embeddings such as GloVe, coupled with other BoW models such as IBM Model 1 (Brown et al., 1993) for alignment (Kenter and De Rijke, 2015; Kim et al., 2017; Yadav et al., 2018). To our knowledge, we are the first to adapt these ideas to contextualized embeddings, which mitigates the BoW limitations of previous efforts (as shown in Figure 1). While contextualized representations have been shown to be extremely useful for multiple NLP tasks (Devlin et al., 2018; Peters et al., 2018; Howard and Ruder, 2018), our work is the first to apply them to an unsupervised alignment approach. Further, we show that different contextualized representations of text (character, word, sentence) capture complementary information, and combining them improves performance further.

3 Approach

The core component of our approach computes the score of a candidate answer by aligning two texts. For multiple-choice questions, the first text consists of the question concatenated with the candidate answer, and the second is a supporting paragraph such as the one shown in Figure 1, which consists of one or more sentences retrieved from a larger textual KB using an off-the-shelf IR system (Section 3.1). For answer selection tasks, the first text is the question and the second is the sentence that contains the candidate answer. Answer candidates are then sorted in descending order of their alignment scores. In both cases, the alignment approach operates over multiple contextualized embeddings that model the two texts at different levels of abstraction: character, word, and sentence. The overall architecture is illustrated in Figure 2. We detail the alignment method in §3.2, the multiple representations of text considered in §3.3, and the ensemble strategies over these representations in §3.4.

3.1 Retrieving Supporting Paragraphs

For multiple-choice question datasets such as ARC, we retrieve supporting information from external KBs using Lucene, an off-the-shelf IR system[2]. We use as query the question concatenated with the corresponding answer candidate, and BM25 (Robertson et al., 2009) as the ranking function[3]. For each query, we keep the top C Lucene documents, where each document consists of a sentence retrieved from the ARC corpus. Similar to our previous work (Yadav et al., 2018), we boost candidate answer terms by a factor of 3 while keeping question terms as it is in the BM25 ranking function. All texts were preprocessed by discarding the case of the tokens, removing the stop words from Lucene's list, and lemmatizing the remaining tokens using NLTK (Bird, 2006). For all experiments reported on the ARC dataset we used $C = 20$.

Here we also calculate the IDF of each query term q_i (required later during alignment):

$$idf(q_i) = \log \frac{N - docfreq(q_i) + 0.5}{docfreq(q_i) + 0.5} \quad (1)$$

where N is the number of documents (e.g., 14.3M for the ARC KB) and $docfreq(q_i)$ is the number of documents that contain q_i.

3.2 Alignment Algorithm

For representations that produce word embeddings (e.g., FLAIR, BERT, GloVe), we use the alignment algorithm in Figure 3. Our method computes the alignment score of each query token with every token in the given KB paragraph, using the cosine

[3] https://lucene.apache.org/core/7_0_1/core/org/apache/lucene/search/similarities/BM25Similarity.html

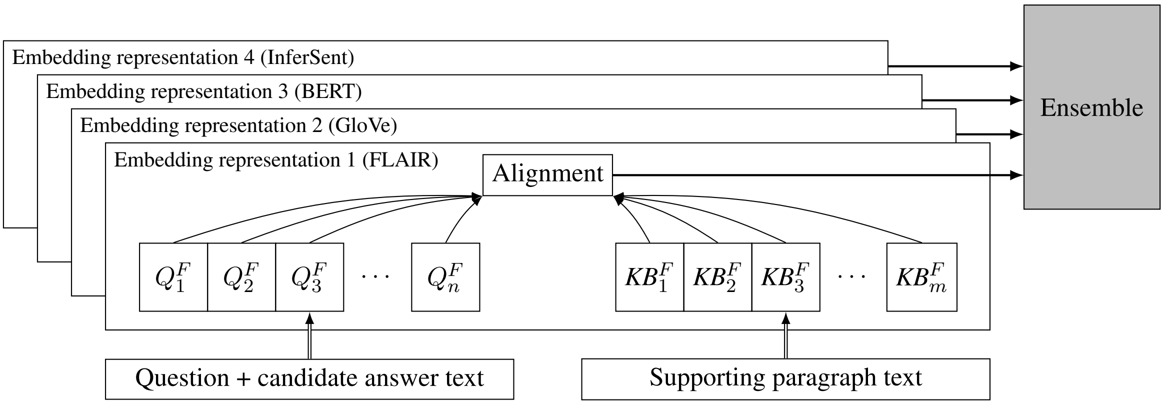

Figure 2: AHE architecture illustrated for the multiple-choice question setting. The left text consists with of the question concatenated with the answer candidate; the right text is a supporting paragraph retrieved from an external KB. The same alignment score is computed over multiple representations of text, and then aggregated through an ensemble model.

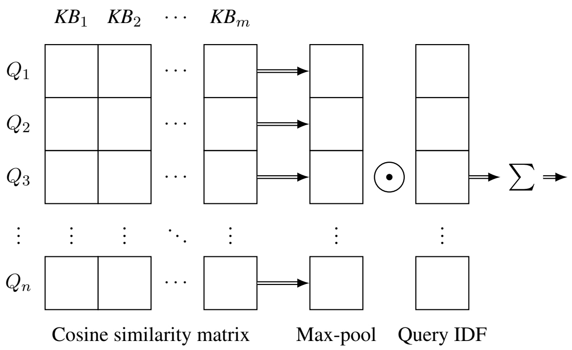

Figure 3: Alignment component of AHE, where a cosine similarity matrix is constructed by comparing token embeddings of input query tokens (Q_i) and supporting KB paragraph tokens (KB_j), and the maximal alignment cosine score for each input query token is weighted by its IDF.

similarity of the two embedding vectors. Then, a max-pooling layer over this cosine similarity matrix is used to retrieve the most similar token in the supporting passage for each query token. Lastly, this max-pooled vector of similarity scores is multiplied with the vector containing the IDF values of the query tokens and the resultant vector is summed to produce the overall alignment score s for the given query Q_a (formed from question Q and candidate answer a) and the supporting paragraph P_j:

$$s(Q_a, P_j) = \sum_{i=1}^{|Q_a|} idf(q_i) \cdot align(q_i, P_j) \qquad (2)$$

$$align(q_i, P_j) = \max_{k=1}^{|P_j|} cosSim(q_i, p_k) \qquad (3)$$

$$cosSim(q_i, p_k) = \frac{\vec{q_i} \cdot \vec{p_k}}{||\vec{q_i}|| \cdot ||\vec{p_k}||} \qquad (4)$$

where $\vec{q_i}$ and $\vec{p_k}$ are the embedding vectors of the terms q_i and p_k.

In addition to alignments over word-level embeddings, we include InferSent (Conneau et al., 2017), which generates sentence-level embeddings (see §3.3 for details). For InferSent, the alignment score between a query Q_a and a supporting paragraph P_j is computed as the dot product of the two corresponding sentence vectors, $\vec{Q_a}$ and $\vec{P_j}$, normalized using softmax over all candidate answers:

$$s(Q_a, P_j) = softmax(\vec{Q_a} \cdot \vec{P_j}) \qquad (5)$$

For ARC, the above alignment scores are computed for each supporting paragraph in the set of C paragraphs retrieved in §3.1. For WikiQA, this score is computed just for the sentence containing the candidate answer.

To aggregate the retrieved ARC paragraph scores (for ARC) into an overall score for the corresponding candidate answer, we consider:

Max: selects the maximum alignment score between all available paragraphs as the final score for candidate answer a:

$$S(cand_a) = \max_{j=1}^{C}(s(Q_a, P_j)) \qquad (6)$$

Weighted average: averages all available paragraph scores, using as weights the inverse IR ranks of the corresponding paragraphs:

$$S(cand_a) = \sum_{j=1}^{C} \frac{1}{j}(s(Q_a, P_j)) \qquad (7)$$

During tuning, we observed that the max strategy is better for ARC Challenge, while the weighted average is better for ARC Easy. We conjecture that this happens because Challenge questions require information that is sparser in the collection, and, thus, including more than the top paragraph tends to introduce noise.

3.3 Text Representations

AHE computes alignments over four different embedding representations that model the text at different levels of abstraction: character, word, and sentence (as detailed below). Although all these embeddings can be tuned for specific domains to improve performance, here we highlight the potential of publicly-available, pre-trained embeddings. Hence, we did not train embeddings on any domain specific corpus, and directly used off-the-shelf embeddings in all but one situation. The details of all four component embeddings of AHE are discussed below.

Character-based embeddings: We used the FLAIR contextual character language model of Akbik et al. (2018). They used long short-term memory (LSTM) networks that operate at character level over the entire text to generate character embeddings (in both forward and backward directions). Similar to them, to generate the embedding for token i, we concatenate the embedding from the forward LSTM for the character following the token, with the embedding from the backward LSTM for the character preceding the token:

$$\mathbf{w}_i^{FLAIR} := \begin{bmatrix} \mathbf{h}^f_{t_i+1-1} \\ \mathbf{h}^b_{t_i-1} \end{bmatrix} \quad (8)$$

where t_i is the character offset of the i^{th} token in the input text, and $\mathbf{h}$ is the corresponding LSTM's hidden state. We used the "mix-forward" and "mix-backward" pretrained models provided by the authors to produce two character embeddings, each of size 2048, resulting in word embeddings of size 4096.

Word-based embeddings: We incorporated two different word-based embeddings:

BERT – we used the Bidirectional Encoder Representations from Transformers (BERT) embedding model of Devlin et al. (2018). We concatenated the last four layers (as suggested by the authors[4]) of the BERT Large language model, where each layer has size 1024, summing up to size 4096 embeddings for each token:

$$\mathbf{w}_i^{BERT} := [Layer_{-1}, ..., Layer_{-4}] \quad (9)$$

GloVe – we also include GloVe embeddings (Pennington et al., 2014), under the hypothesis that these uncontextualized word embeddings will provide complementary information to the contextualized BERT embeddings. We used GloVe embeddings of size 300, trained over 840B tokens from Wikipedia, resulting in 2.2M words vocabulary.

Sentence-based embeddings: Lastly, we used InferSent, the sentence-based embeddings of Conneau et al. (2017). InferSent was originally trained on several natural language inference (NLI) datasets to generate the sentence representations that maximize the probability of correct inference. This model achieved poor performance on our QA tasks (see rows 8a in Table 1 and row 7a in Table 2).

Therefore, rather than using this NLI model, we trained InferSent on our data by maximizing the inference probability from the input query[5] to the supporting paragraph. We used the same number of supporting passages ($C = 20$) and the same scoring functions as explained in Section 3.2. We trained InferSent using batches of size 32, the Adam optimizer, learning rate = 0.001, and 50 epochs. We used max pooling over the token's LSTM hidden states to generate an overall sentence embedding. We tuned the sentence representation size on the development sets,[6] which resulted in 128 for WikiQA and 384 for ARC.

3.4 Aggregating Multiple Representations

We aggregate the scores of candidate answers over the four different embedding representations using an unsupervised variant of the NoisyOr formula:

$$NoisyOr_M(i) = 1 - (\prod_{m=0}^{M} (1 - \alpha^m * S_i^m)) \quad (10)$$

which computes the overall score for answer candidate i. M is the total number of representations (e.g., 4 in our case), and S_i^m is the score of answer candidate i under representation m. Lastly, α^m is a hyperparameter used to dampen peaky distributions of answer probabilities. We included this hyperparameter because we observed that InferSent produces a probability distribution over candidate answers where one answer tends to take most of the probability mass, and these scores dominate in the NoisyOr. Thus, the α^m weights are set to 1 for

---

Italic font indicates which AHE components are supervised, e.g., *InferSent* is the InferSent model trained on ARC data; *AHE* is the AHE variant that uses the supervised meta-classifier ensemble. Line 8a shows performance of alignment over the original InferSent embeddings (trained on NLI datasets); line 8b shows performance when using *InferSent* embeddings trained on ARC training data. The "minimal" supervision configurations (lines 20 and 21) include the supervised *InferSent*, but use the unsupervised NoisyOr strategy for aggregation.

all representations with the exception of InferSent, for which we tuned its value to 0.2.

Of course, other types of aggregation are possible. To explore this space, we also implemented a supervised meta-classifier, which aims to learn the aggregation function directly from data. We implemented this multi-classifier as a feed forward network with two fully connected dense layers of hidden size 16 and K respectively, where K is the maximum number of candidate answers for the given dataset. The activation function of the first dense layer was tanh; we used a softmax in the second output layer. The input to this network was a vector of size $M \times K$. For example, for ARC this vector has a size $4 \times 5 = 20$. For WikiQA this vector has size $4 \times 22 = 88$. Each element in the input vector is the score of one candidate answer under a given representation. Additionally, for ARC we used an extra position in the input vector to indicate the grade of the corresponding exam question (provided in the dataset) with the intuition that the meta-classifier will learn to trust different representations for different grade levels.

4 Empirical Results

We evaluate AHE on two QA tasks:

AI2's Reasoning Challenge (ARC): this is a multiple-choice question dataset, containing science exam questions (Clark et al., 2018). The dataset is split in two partitions: Easy and Challenge, where the latter partition contains the more difficult questions that require reasoning. Each partition is split into train/development/test as follows: Easy contains 2251/570/2376 questions, and Challenge 1119/299/1172. Most of the questions have 4 answer choices, with only $< 1\%$ of all the questions having either 3 or 5 answer choices. ARC also includes a textual KB of 14.3M passages suitable for solving ARC questions. Note that we use solely this KB for retrieving supporting paragraphs,

Table 2: Performance on the WikiQA dataset, measured using mean average precision (MAP) and mean reciprocal rank (MRR). Italic font indicates which AHE components are supervised, e.g., *InferSent* is the InferSent model trained on WikiQA data; *AHE* is the AHE variant that uses the supervised meta-classifier ensemble. The "minimal" supervision configurations (lines 23 and 24) include the supervised *InferSent*, but use the unsupervised NoisyOr strategy for aggregation.

unlike many other approaches that use additional structured KBs such as ConceptNet (Zhong et al., 2018b) (see column 3 in Table 1).

WikiQA: is an open-domain answer selection dataset (Yang et al., 2015). It was constructed from Bing queries and candidate answer sentences from Wikipedia articles. It contains 1040/140/293 questions in train/development/test, and each question has an average of 9.6 candidate answer sentences.

Results and discussion: Tables 1 and 2 summarize the performance of multiple AHE variants, compared against several baselines and previous works, on two datasets. We draw several observations from these:

(1) The mostly unsupervised AHE, i.e., with the only supervised component being the InferSent embeddings, has solid and stable performance across the three datasets: best on ARC Easy, second best on ARC Challenge (see lines 18 – 21 in Table 1), and top three on WikiQA for MRR (see lines 21 – 24 in Table 2). We find these results encouraging: AHE outperforms many complex supervised neural approaches, including methods having multiple RNNs and stacked attention layers (Wang et al., 2017b; He and Lin, 2016; Miller et al., 2016; Yin et al., 2015; Miao et al., 2016; Musa et al., 2018; Mihaylov et al., 2018), despite the fact that it relies mostly on simple, unsupervised components.

(2) AHE ports well between different partitions (Easy and Challenge) of same dataset (ARC), unlike many of the previous approaches. For example, neural architectures that perform well on ARC Challenge perform worse than a simple IR baseline on ARC Easy (see, e.g., rows 14 and 15 in Table 1) or vice versa (see lines 9 – 12). This lack of portability occurs despite these models being trained/tested within the same partition in Table 1. To emphasize this issue, we explore more aggressive domain transfer settings in Section 5.2.

(3) Ablation analysis – The alignment performance from individual components of AHE are shown in the baseline blocks of Tables 1 and 2, while the combinations of AHE's components are shown in the corresponding unsupervised and supervised blocks, i.e.: rows 5–8 in table 1 and rows 4–7 in table 2 show performance from individual embeddings of AHE, while rows 18–23 and rows 21–25, respectively, show performance from combinations of AHE components. This comparison indicates that the combination of two or more embedding types are always better than individual embeddings. Further, we see that word embeddings such as GloVe are useful for ARC Easy but not for the Challenge partition of ARC (row 19). In contrast, sentence-level embeddings (InferSent) show the opposite behavior (row 20), suggesting that the more complex the task, the more high-level representations are required.

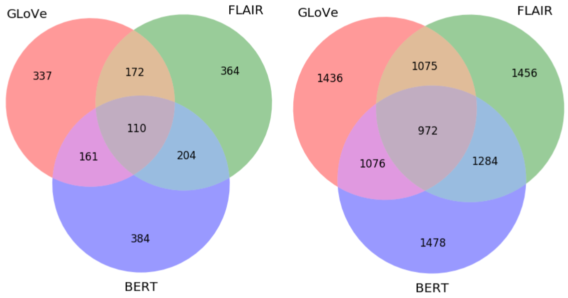
(4) The oracle system (line 24 in table 1 and line 26 in table 2) indicates that the different representations of text are to a large extent complementary: when selecting the correct answer when at least one of the representations proposes it, the oracle system achieves 85.1 P@1 on ARC Easy, 68.1 P@1 on ARC Challenge, and 93.71 MAP on WikiQA. The supervised AHE, which uses a feed-forward neural network to learn when to trust each representation demonstrates that (some of) this complementarity can be learned: the supervised AHE consistently outperforms its unsupervised counterpart, albeit by small amounts. Further, line 23 in Table 1 indicates that additional information about the questions (i.e., grade information) is beneficial, as it provides the meta-classifier more grounding on when to trust which representation. We analyze this complementarity further in Section 5.1.

5 Analysis

To explore the potential of AHE and further understand its individual components, we conducted the following analyses:

5.1 Complementarity of Representations

We calculated the overlap of questions answered correctly by each component of AHE to investigate the complementarity of the different representations. The results are visualized in Figure 4. For simplicity, the figure shows the number of questions answered correctly by the first three (unsupervised) components of AHE, but we found similar trends for the InferSent as well. As shown in the figure, the overlap between any two components is within the range [42 - 53]% in the Challenge partition (GloVe and BERT overlap = (161/384 = 42%), FLAIR and BERT overlap = (204/384 = 53%)) and [73 - 86]% in the Easy partition. Our current meta-classifier only begins to mine this complementarity, but it is limited because it has no information about the question and candidate answers (other than their scores). We conjecture that considerable performance improvements are possible when such a meta-classifier includes additional information such as question type, question encoding, etc. Our initial results that include grade information (line 23 in Table 1) support this hypothesis. We leave a further exploration of this direction as future work.



ARC Challenge ARC Easy

Figure 4: Overlap of correct questions answered by AHE models when they operate over different embeddings. This was a post-hoc analysis on the test partitions; we observed similar trends on training and development. This figure is best viewed in color.

5.2 Domain Transfer

As shown in Table 1 and discussed in the previous section, many supervised neural methods do not perform robustly across different partitions (Easy and Challenge) of the same ARC dataset, even though they were trained within each partition. This raises the question of how stable is their performance when trained/tested in different domains, which is closer to a real-world deployment scenario? To answer this question, we trained and tested two state-of-the-art neural models, BiLSTM Max-out (Mihaylov et al., 2018; Conneau et al., 2017) and BiMPM (Wang et al., 2017b), across three domains: ARC Easy, ARC Challenge, and WikiQA. We selected these two approaches because of they are end-to-end neural methods, and they achieve good performance on all datasets. Further, BiMPM is reminiscent of a supervised alignment method, since it computes the overall similarity of question and answers by aligning the

Train \Test	ARC Easy (P@1)	ARC Challenge (P@1)	WikiQA (MAP, MRR)
ARC Easy	34.26, 38.84	23.12, 24.10	(38.71, 40.51), (52.13, 53.87)
ARC Challenge	27.02, 36.17	33.87, 26.39	(39.05, 40.68), (40.09,41.48)
WikiQA	25.84, 38.40	24.32, 25.36	(67.40, 69.08), (69.20, 71.19)
Unsupervised AHE	64.60	33.87	(67.31, 68.53)

Table 3: Performance of two neural QA methods, BiLSTM Max-out and BiMPM, when trained/tested across datasets. The first value in each cell corresponds to BiLSTM Max-out, and the second to BiMPM. The last row contains the best unsupervised performance of AHE, which was *not* trained on any of these three datasets.

tokens' LSTM hidden states.

The results are summarized in Table 3. The table highlights that the performance of these systems varies considerably based on the training domain, even underperforming a random baseline in some configurations. In contrast, the unsupervised AHE does not require training, and obtains state-of-the-art, stable performance across the three datasets. This analysis suggests that future QA evaluations should consider domain transfer as another evaluation measure, to quantify the performance of QA systems under realistic scenarios.

5.3 Brief Qualitative Analysis

We manually analyzed the questions answered incorrectly by AHE and observed that many of the candidate answers were partially answering the questions. As shown in Figure 5, candidate answers 2 and 5 are partially answering the question, while candidate answers 1 and 3 provide topically relevant information. To select the correct answer in such complex questions, especially for short questions, a successful method would have to incorporate inference, e.g., recognizing process questions such as the one in the figure and coupling with it with a dedicated problem solving method (Clark et al., 2013). We leave the integration of inference methods with AHE as future work.

6 Conclusion

We proposed a simple, mostly-unsupervised alignment model for non-factoid QA, which operates over multiple contextualized embedding representations that model the text at different levels of abstraction. Despite its simplicity, our approach obtains good performance (top three or higher) that is stable across three QA datasets. Our analysis indicates that the different levels of abstraction (character, word, sentence) capture distinct semantics. We showed that this can be modeled with a meta-classifier that learns when and how much to trust the predictions over each representation, and that this has a beneficial impact on performance.

Question - how a water pump works?

1. *A large, electrically driven pump (electropump) for waterworks near the Hengsteysee , Germany.*
2. *A pump is a device that moves fluids (liquids or gases), or sometimes slurries , by mechanical action.*
3. *Pumps can be classified into three major groups according to the method they use to move the fluid: direct lift, displacement, and gravity pumps.*
4. **Pumps operate by some mechanism (typically reciprocating or rotary), and consume energy to perform mechanical work by moving the fluid.**
5. *Pumps operate via many energy sources, including manual operation, electricity, engines , or wind power .*

Figure 5: A question with correct answer in bold font from the WikiQA dataset, which was incorrectly answered by AHE, BiLSTM Max-out and BiMPM.

All in all, our work indicates that the first, and possibly best, investment in the design of a QA system should be on contextualized embeddings rather than custom, complex neural architectures.

When such embeddings are available, state-of-the-art performance that is competitive with modern neural approaches for QA can be obtained with simple alignment-based aggregation strategies. Minimally, our work should be regarded as a new, strong baseline for non-factoid question answering or answer sentence selection.

Abstract

We introduce a new method to tag Multiword Expressions (MWEs) using a linguistically interpretable language-independent deep learning architecture. We specifically target discontinuity, an under-explored aspect that poses a significant challenge to computational treatment of MWEs. Two neural architectures are explored: Graph Convolutional Network (GCN) and multi-head self-attention. GCN leverages dependency parse information, and self-attention attends to long-range relations. We finally propose a combined model that integrates complementary information from both, through a gating mechanism. The experiments on a standard multilingual dataset for verbal MWEs show that our model outperforms the baselines not only in the case of discontinuous MWEs but also in overall F-score.[1]

1 Introduction

Multiword expressions (MWEs) are linguistic units composed of more than one word whose meanings cannot be fully determined by the semantics of their components (Sag et al., 2002; Baldwin and Kim, 2010). As they are fraught with syntactic and semantic idiosyncrasies, their automatic identification remains a major challenge (Constant et al., 2017). Occurrences of discontinuous MWEs are particularly elusive as they involve relationships between non-adjacent tokens (e.g. ***put*** *one of the blue masks* ***on***).

While some previous studies disregard discontinuous MWEs (Legrand and Collobert, 2016), others stress the importance of factoring them in (Schneider et al., 2014). Using a CRF-based and a transition-based approach respectively, Moreau et al. (2018) and Al Saied et al. (2017) try to capture discontinuous occurrences with help from dependency parse information. Previously explored neural MWE identification models (Gharbieh et al., 2017) suffer from limitations in dealing with discontinuity, which can be attributed to their inherently sequential nature. More sophisticated architectures are yet to be investigated (Constant et al., 2017).

Graph convolutional neural networks (GCNs) (Kipf and Welling, 2017) and attention-based neural sequence labeling (Tan et al., 2018) are methodologies suited for modeling non-adjacent relations and are hence adapted to MWE identification in this study. Conventional GCN (Kipf and Welling, 2017) uses a global graph structure for the entire input. We modify it such that GCN filters convolve nodes of dependency parse tree on a per-sentence basis. Self-attention, on the other hand, learns representations by relating different parts of the same sequence. Each position in a sequence is linked to any other position with $O(1)$ operations, minimising maximum path (compared to RNN's $O(n)$) which facilitates gradient flow and makes it theoretically well-suited for learning long-range dependencies (Vaswani et al., 2017).

The difference in the two approaches motivates our attempt to incorporate them into a hybrid model with an eye to exploiting their individual strengths. Other studies that used related syntax-aware methods in sequence labeling include Marcheggiani and Titov (2017) and Strubell et al. (2018) where GCN and self-attention were separately applied to semantic role labelling.

Our contribution in this study, is to show for the first time, how GCNs can be successfully applied to MWE identification, especially to tackle discontinuous ones. Furthermore, we propose a novel architecture that integrates GCN with self-attention outperforming state-of-the-art. The resulting models not only prove superior to existing

methods in terms of overall performance but also are more robust in handling cases with gaps.

2 Methodology

To specifically target discontinuity, we explore two mechanisms both preceding a Bi-LSTM: 1) a GCN layer to act as a syntactic ngram detector, 2) an attention mechanism to learn long-range dependencies.

2.1 Graph Convolution as Feature Extraction

Standard convolutional filters act as sequential ngram detectors (Kim, 2014). Such filters might prove inadequate in modeling complex language units like discontinuous MWEs. One way to overcome this problem is to consider non-sequential relations by attending to syntactic information in parse trees through the application of GCNs.

GCN is defined as a directed multi-node graph $G(V, E)$ where $v_i \in V$ and $(v_i, r, v_j) \in E$ are entities (words) and edges (relations) respectively. By defining a vector x_v as the feature representation for the word v, the convolution equation in GCN can be defined as a non-linear activation function f and a filter W with a bias term b as:

$$c = f(\sum_{i \in r(v)} W x_i + b) \qquad (1)$$

where $r(v)$ shows all words in relation with the given word v in a sentence, and c represents the output of the convolution.

Following Kipf and Welling (2017) and Schlichtkrull et al. (2017), we represent graph relations using adjacency matrices as mask filters for inputs. We derive associated words from the dependency parse tree of the target sentence. Since we are dealing with a sequence labelling task, there is an adjacency matrix representing relations among words (as nodes of the dependency graph) for each sentence. We define the sentence-level convolution operation with filter W_s and bias b_s as follows:

$$C_s = f(W_s X^T A + b_s) \qquad (2)$$

where X, A, and C are representation of words, adjacency matrix, and the convolution output, all at the level of sentence. The above formalism considers only one relation type, while depending on the application, multiple relations can be defined.

Kipf and Welling (2017) construct separate adjacency matrices corresponding to each relation type and direction. Given the variety of dependency relations in a parse tree (e.g. obj, nsubj, advcl, conj, etc), and per-sentence adjacency matrices, we would end up with an over-parametrised model in a sequence labeling task. In this work, we simply treat all relations equally, but consider only three types of relations: 1) the head to the dependents, 2) the dependents to the head, and 3) each word to itself (self-loops). The final output is obtained by aggregating the outputs from the three relations.

2.2 Self-Attention

Attention (Bahdanau et al., 2014) helps a model address the most relevant parts of a sequence through weighting. As attention is designed to capture dependencies in a sequence regardless of distance, it is complementary to RNN or CNN models where longer distances pose a challenge. In this work we employ multi-head self-attention with a weighting function based on scaled dot product which makes it fast and computationally efficient.

Based on the formulation of Transformer by Vaswani et al. (2017), in the encoding module an input vector x is mapped to three equally sized matrices K, Q, and V (representing key, query and value) and the output weight matrix is then computed as follows:

$$\text{Att}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d}})V \qquad (3)$$

The timing signal required for the self-attention to work is already contained in the preceding CNN layers alleviating the need for position encoding.

2.3 Model Architecture

The overall scheme of the proposed model, composed of two parallel branches, is depicted in Figure 1. We employ multi-channel CNNs as the step preceding self-attention. One channel is comprised of two stacked 1D CNNs and the other is a single 1D CNN. After concatenation and batch normalisation, a multi-head self attention mechanism is applied (Section 2.2).

Parallel to the self-attention branch, GCN learns a separate representation (Section 2.1). Since the GCN layer retains important structural information and is sensitive to positional data from the syntax tree, we consider it as a position-based approach. On the other hand, the self-attention layer

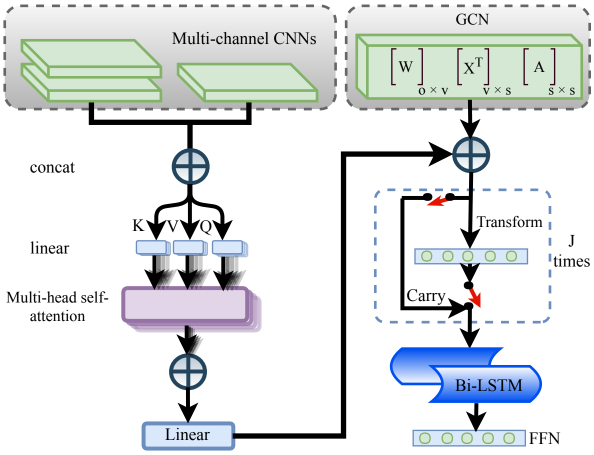

Figure 1: A hybrid sequence labeling approach integrating GCN (o: output dimension; v: word vectors dimension; s: sentence length) and Self-Attention.

is intended to capture long-range dependencies in a sentence. It relates elements of the same input through a similarity measure irrespective of their distance. We therefore regard it as a content-based approach. As these layers represent different methodologies, we seek to introduce a model that combines their complementary traits in our particular task.

Gating Mechanism. Due to the considerable overlap between the GCN and self-attention layers, a naive concatenation introduces redundancy which significantly lowers the learning power of the model. To effectively integrate the information, we design a simple gating mechanism using feed-forward highway layers (Srivastava et al., 2015) which learn to regulate information flow in consecutive training epochs. Each highway layer consists of a Carry (Cr) and a Transform (Tr) gate which decide how much information should pass or be modified. For simplicity Cr is defined as $1 - Tr$. We apply a block of J stacked highway layers (the section inside the blue dotted square in Figure 1). Each layer regulates its input x using the two gates and a feedforward layer H as follows:

$$y = Tr \odot H + (1 - Tr) \odot x \qquad (4)$$

where $\odot$ denotes the Hadamard product and Tr is defined as $\sigma(W_{Tr}x + b_{Tr})$. We set b_{Tr} to a negative number to reinforce carry behavior which helps the model learn temporal dependencies early in the training.

Our architecture bears some resemblance to Marcheggiani and Titov (2017) and Zhang et al. (2018) in its complementary view of GCN and BiLSTM. However there are some important differences. In these works, BiLSTM is applied prior to GCN in order to encode contextualised information and to enhance the teleportation capability of GCN. Marcheggiani and Titov (2017) stack a few BiLSTM layers with the idea that the resulting representation would enable GCN to consider nodes that are multiple hops away in the input graph. Zhang et al. (2018) use a similar encoder, however the model employs single BiLSTM and GCN layers, and the graph of relations is undirected.

In our work, we use pre-trained contextualised embeddings that already contain all the informative content about word order and disambiguation. We put BiLSTM on top of GCN, in line with how CNNs are traditionally applied as feature generating front-ends to RNNs. Furthermore, Marcheggiani and Titov (2017) use an edge-wise gating mechanism in order to down-weight uninformative syntactic dependencies. This method can mitigate noise when parsing information is deemed noisy, however in Zhang et al. (2018) it caused performance to drop. Given our low-resource setting, in this work we preferred not to potentially down-weight contribution of individual edges, therefore treating them equally. We rely on gating as the last step when we combine GCN and self-attention.

3 Experiments

Data. We experiment with datasets from the shared task on automatic identification of verbal Multiword Expressions (Ramisch et al., 2018). The datasets are tagged for different kinds of verbal MWEs including idioms, verb particle constructions, and light verb constructions among others. We focus on annotated corpora of four languages: French (FR), German (DE), English (EN), and Persian (FA) due to their variety in size and proportion of discontinuous MWEs. Tags in the datasets are converted to a variation of IOB which includes the tags `B` (beginning of MWEs), `I` (other components of MWEs), and `O` (tokens outside MWEs), with the addition of `G` for arbitrary tokens in between the MWE components e.g. $make_{\texttt{[B]}}$ $important_{\texttt{[G]}}$ $decisions_{\texttt{[I]}}$.

ELMo. In our experiments, we make use of ELMo embeddings (Peters et al., 2018) which are contextualised and token-based as opposed to

		All		Discontinuous			
		Token-based	MWE-based		MWE-based

Table 1: Model performance (P, R and F) for development sets for all MWE and only discontinuous ones (%: proportion of discontinuous MWES)

type-based word representations like `word2vec` or `GLoVe` where each word type is assigned a single vector. Token-based embeddings better reflect the syntax and semantics of each word in its context compared to traditional type-based ones. We use the implementation by Che et al. (2018) to train ELMo embeddings on our data.

Validation. In the validation phase, we start with a strong baseline which is a CNN + Bi-LSTM model based on the top performing system in the VMWE shared task (Taslimipoor and Rohanian, 2018). Our implemented baseline differs in that we employ ELMo rather than `word2vec` resulting in a significant improvement. We perform hyper-parameter optimisation and make comparisons among our systems, including GCN + Bi-LSTM (GCN-based), CNN + attention + Bi-LSTM (Att-based), and their combination using a highway layer (H-combined) in Table 1.

4 Evaluation and Results

Systems are evaluated using two types of precision, recall and F-score measures: strict MWE-based scores (every component of an MWE should be correctly tagged to be considered as true positive), and token-based scores (a partial match between a predicted and a gold MWE would be considered as true positive). We report results for all MWEs as well as discontinuous ones specifically.

According to Table 1, GCN-based outperforms Att-based and they both outperform the strong baseline in terms of MWE-based F-score in three out of four languages. Combining GCN with attention using highway networks results in further improvements for EN, FR and FA. The H-combined model consistently exceeds the baseline for all languages. As can be seen in Table 1, GCN and H-combined models each show significant improvement with regard to discontinuous MWEs, regardless of the proportion of such expressions.

In Table 2 we show the superior performance (in terms of MWE-based F-score) of our top systems on the test data compared to the baseline and state-of-the-art systems, namely, ATILF-LLF (Al Saied et al., 2017) and SHOMA (Taslimipoor and Rohanian, 2018). GCN works the best for discontinuous MWEs in EN and FA, while H-combined outperforms based on results for all MWEs except for FA. The findings are further discussed in Section 5.

5 Discussion and Analysis

The overall results confirm our assumption that a hybrid architecture can mitigate errors of individual models and bolster their strengths. To demonstrate the effectiveness of the models in detecting discontinuous MWEs, in Figure 2 we plot their performance for FR and EN given a range of different gap sizes. As an ablation study, we show the results for the baseline, GCN-based, Att-based only, as well as H-combined models. GCN and Att-based models each individually outperform the baseline, and the combined model clearly improves the results further.

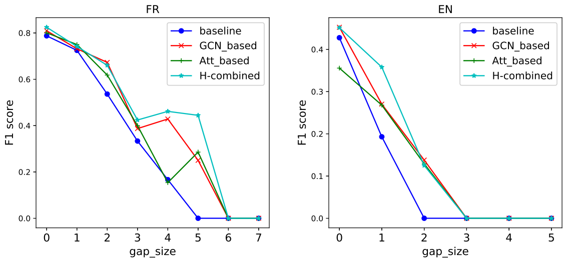

Figure 2: Model performance given different gap sizes

The example in Figure 3 taken from the English dataset demonstrates the way GCN considers relations between non-adjacent tokens in the sentence. Our baseline is prone to disregarding these links. Similar cases captured by both GCN and H-combined (but not the baseline) are ***take*** *a final* ***look***, ***picked*** *one* ***up***, and ***cut*** *yourself* ***off***.

	All | Discontinuous			
	EN	DE	FR	FA
baseline	33.01 | 16.53	54.12 | 53.94	67.66 | 58.70	**81.62** | 61.73
GCN-based	36.27 | **24.15**	56.96 | 54.87	70.79 | 59.95	81.00 | **62.35**
H-combined	**41.91** | 22.73	**59.29** | **55.00**	**70.97** | **63.90**	80.04 | 61.90
ATILF-LLF	31.58 | 09.91	54.43 | 40.34	58.60 | 51.96	77.48 | 53.85
SHOMA	26.42 | 01.90	48.71 | 40.12	62.00 | 51.43	78.35 | 56.10

Table 2: Comparing the performance of the systems on test data in terms of MWE-based F-score

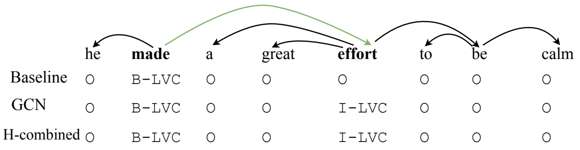

Figure 3: Sample sentence with a discontinuous occurrence of an English MWE, *make an effort*.

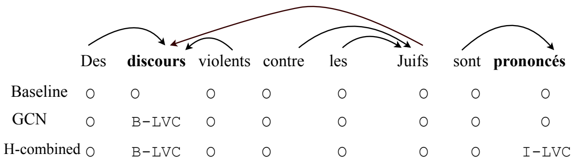

Figure 4: Example sentence with a discontinuous occurrence of a French MWE, *prononcer un discours* 'to make a speech'.

In more complicated constructs where syntactic dependencies might not directly link all constituents, GCN alone is not always conducive to optimal performance. In Figure 4, the French sentence is in the passive form and MWE parts are separated by 5 tokens. This is an MWE skipped by GCN but entirely identified by the H-combined model.

It is important to note that model performance is sensitive to factors such as percentage of seen expressions and variability of MWEs (Pasquer et al., 2018). In FA for instance, 67% of the MWEs in the test set are seen at training time, making them easy to be captured by the baseline (Taslimipoor et al., 2018). Furthermore, only 21% of MWEs in FA and 15% in EN are discontinuous as opposed to 44% in FR and 38% in DE. In this case, a sequential model can already learn the patterns with high accuracy and the potential of a GCN and self-attention is not fully exploited.

Also in DE, a sizable portion of MWEs are verbal idioms (VIDs) which are known for their lexico-syntactic fixedness and prevalence of tokens that lack a standalone meaning and occur only in a limited number of contexts (also known as cranberry words). Furthermore, MWEs in the Persian dataset are all Light Verb Constructions (LVCs), which can be modelled using lexical semantic templates (Megerdoomian, 2004). For such MWEs, our models compete with strong sequential baselines.

6 Conclusion and Future Work

In this paper, we introduced the application of GCN and attention mechanism to identification of verbal MWEs and finally proposed and tested a hybrid approach integrating both models. Our particular point of interest is discontinuity in MWEs which is an under-explored area. All the individual and combined models outperform state-of-the-art in all considered criteria. In future, we will further develop our system using structured attention (Kim et al., 2017) and try to improve the accuracy of parsers in multi-tasking scenarios.

Abstract

Neural network models have been actively applied to word segmentation, especially Chinese, because of the ability to minimize the effort in feature engineering. Typical segmentation models are categorized as character-based, for conducting exact inference, or word-based, for utilizing word-level information. We propose a character-based model utilizing word information to leverage the advantages of both types of models. Our model learns the importance of multiple candidate words for a character on the basis of an attention mechanism, and makes use of it for segmentation decisions. The experimental results show that our model achieves better performance than the state-of-the-art models on both Japanese and Chinese benchmark datasets.[1]

1 Introduction

Word segmentation is the first step of natural language processing (NLP) for most East Asian languages, such as Japanese and Chinese. In recent years, neural network models have been widely applied to word segmentation, especially Chinese, because of their ability to minimize the effort in feature engineering. These models are categorized as character-based or word-based. Word-based models (Zhang et al., 2016; Cai and Zhao, 2016; Cai et al., 2017; Yang et al., 2017) directly segment a character sequence into words and can easily achieve the benefits of word-level information. However, these models cannot usually conduct exact inference because of strategies, such as beam-search decoding and constraints of maximum word length, which are necessary as the number of candidate segmentations increases exponentially with the sentence length. On the other hand, character-based models (Zheng et al., 2013; Mansur et al., 2013; Pei et al., 2014; Chen et al., 2015a) treat word segmentation as sequence labeling. These models typically predict optimal label sequences while considering adjacent labels.

Limited efforts have been devoted to leveraging the advantages of both types of models, such as utilizing word information and conducting exact inference, which are complementary characteristics. In particular, the candidate word information for a character is beneficial to disambiguate word boundaries because a character in the sentence has multiple candidate words that contain the character. For example, there are three or four candidate words for characters x_3, x_4 and x_5 in a sentence $x_{1:5}$ in Figure 1. A feasible solution to develop a model with both characteristics is to incorporate word information into a character-based framework. An example of such work is that of Wang and Xu (2017). They concatenated embeddings of a character and candidate words and used it in their convolutional neural network (CNN)-based model. They treated candidate words equivalently, although the plausibility of a candidate word differs in the context of a target character.

In this paper, we propose a character-based word segmentation model that utilizes word information. Our model is based on a BiLSTM-CRF architecture that has been successfully applied to sequence labeling tasks (Huang et al., 2015; Chen et al., 2015b). Differing from the work of Wang and Xu (2017), our model learns and distinguishes the importance of candidate words for a character in a context, by applying an attention mechanism (Bahdanau et al., 2015).

Our contributions are as follows:

- We introduce word information and an attention mechanism into a character-based word segmentation framework, to distinguish and leverage the importance of candidate words

---

Proceedings of NAACL-HLT 2019, pages 2699–2709
Minneapolis, Minnesota, June 2 - June 7, 2019.

Sentence:

$x_{1:5}$ = 彼は日本人 ⟨*kare wa nihonjin*⟩ (He is a Japanese.)

Candidate words $\{w_j\}$ for characters $\{x_i\}$ in the sentence:

i	$x_i \diagdown w_j$ j	1 彼 ⟨*kare*⟩ (he)	2 は ⟨*wa*⟩ (NOM)	3 日 ⟨*hi*⟩ (day)	4 本 ⟨*hon*⟩ (book)	5 人 ⟨*hito*⟩ (person)	6 日本 ⟨*nihon*⟩ (Japan)	7 本人 ⟨*honnin*⟩ (the person)	8 日本人 ⟨*nihonjin*⟩ (Japanese)	No. of candidate words
1	彼	1	0	0	0	0	0	0	0	1
2	は	0	1	0	0	0	0	0	0	1
3	日	0	0	1	0	0	1	0	1	3
4	本	0	0	0	1	0	1	1	1	4
5	人	0	0	0	0	1	0	1	1	3

Figure 1: An example of candidate words $w_{1:8}$ retrieved from a vocabulary for a sentence $x_{1:5}$. Strings in angle brackets "⟨⟩" and in parentheses "()" respectively indicate (typical) readings and English translations of words. The value in each (i, j) represents whether the i-th character is contained by the j-th word (i.e., δ_{ij} in Eq. (4)).

in different contexts.

- We empirically reveal that accurate attention to proper candidate words leads to correct segmentations.
- Our model outperforms the state-of-the-art word segmentation models on both Japanese and Chinese datasets.

2 Task Definition

Word segmentation can be regarded as a character-level sequence labeling task. Given a sentence $x = x_{1:n} := (x_1, \dots, x_n)$ of length n, each character x_i will be assigned a segmentation label y_i of tag set $\mathcal{T}$, and a label sequence $y = y_{1:n}$ will be predicted. We employ tag set $\mathcal{T} = \{\text{B}, \text{I}, \text{E}, \text{S}\}$, where B, I and E, respectively, represent the beginning, inside and end of a multi-character word, and S represents a single character word (Xue, 2003).

3 Baseline Model

We use a BiLSTM-CRF architecture for our baseline model. The model consists of a character embedding layer, recurrent layers based on long short-term memory (LSTM) and a conditional random fields (CRF) layer as in Figure 2.

Character Embedding Layer Let $\mathcal{V}_c$ be a character vocabulary. Each character in a given sentence is transformed into a character embedding $\mathbf{e}^c$ of d_c-dimensional vector by a lookup operation that retrieves the corresponding column of the embedding matrix $E_c \in \mathbb{R}^{d_c \times |\mathcal{V}_c|}$.

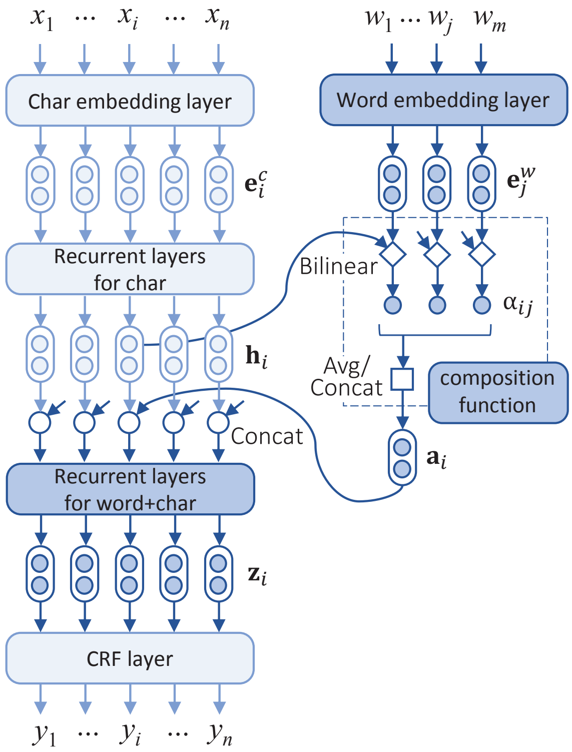

Figure 2: Architecture of our proposed model, which comprises the common components to the baseline model (light blue) and additional ones (dark blue).

Recurrent Layers for Character Representation A sequence of character embeddings $\mathbf{e}^c_{1:n}$ is fed into a recurrent neural network (RNN) to derive contextualized representations $\mathbf{h}_{1:n}$, which we call *character context vectors*. We adopt a stacked (multi-layer) and bidirectional variant of an LSTM (Hochreiter and Schmidhuber, 1997) network, which addresses the issue of learning long-term dependencies and the gradient vanishing problem.

Hidden vectors $\mathbf{h}^{(l)}_{1:n}$ of l-th bidirectional LSTM (BiLSTM) layer are calculated by forward LSTM

(LSTM_f) and backward LSTM (LSTM_b):

$$\begin{aligned}\mathbf{h}_i^{(l)} &= \mathrm{BiLSTM}(\mathbf{h}_{1:n}^{(l-1)}, i) \qquad (1)\\ &:= \mathrm{LSTM}_f(\mathbf{h}_{1:n}^{(l-1)}, i)\\ &\quad \oplus \mathrm{LSTM}_b(\mathbf{h}_{n:1}^{(l-1)}, n-i+1)\ ,\end{aligned}$$

where $\mathbf{h}_i^{(0)} = \mathbf{e}_i^c$ and $\oplus$ denotes a concatenation operation, and $\mathbf{h}_{n:1}^{(l-1)}$ denotes the reversed sequence of the original vectors $\mathbf{h}_{1:n}^{(l-1)}$.

More concretely, each forward or backward LSTM calculates hidden vectors $\mathbf{h}_{1:n}$ from an input sequence $\mathbf{v}_{1:n}$ of d_v-dimensional vectors as follows:

$$\begin{aligned}\mathbf{h}_i &= \mathrm{LSTM}(\mathbf{v}_{1:n}, i) := \mathbf{o}_i \odot \tanh(\mathbf{c}_i)\ ,\\ \mathbf{c}_i &= \mathbf{i}_i \odot \mathbf{t}_i + \mathbf{f}_i \odot \mathbf{c}_{i-1},\\ \mathbf{g}_i &= \sigma(W_g \mathbf{v}_i + U_g \mathbf{h}_{i-1} + \mathbf{b}_g)\ ,\\ \mathbf{t}_i &= \tanh(W_t \mathbf{v}_i + U_t \mathbf{h}_{i-1} + \mathbf{b}_t)\ ,\end{aligned}$$

where σ is sigmoid function, $\odot$ denotes element-wise multiplication, $\mathbf{g}$ indicates an input gate $\mathbf{i}$, a forget gate $\mathbf{f}$ or an output gate $\mathbf{o}$, $W_g, U_g \in \mathbb{R}^{d_r \times d_v}$ and $\mathbf{b}_g \in \mathbb{R}^{d_r}$ are trainable parameters for each gate $g \in \{i, f, o\}$, and d_r is a hyperparameter.

CRF Layer A character context vector $\mathbf{h}_i$ is mapped into a $|\mathcal{T}|$-dimensional vector representing scores of segmentation labels:

$$\mathbf{s}_i = W_s \mathbf{h}_i + \mathbf{b}_s\ ,$$

where $W_s \in \mathbb{R}^{|\mathcal{T}| \times 2d_r}$ and $b \in \mathbb{R}^{|\mathcal{T}|}$ are trainable parameters. Following previous sequence labeling work (Collobert et al., 2011), we introduce a CRF (Lafferty et al., 2001) layer, which has a transition matrix $A \in \mathbb{R}^{|\mathcal{T}| \times |\mathcal{T}|}$ to give transition scores of adjacent labels. Thus, the score of a label sequence $y = y_{1:n}$ for a sentence $x = x_{1:n}$ is calculated as follows:

$$\mathrm{score}(x, y; \theta) = \sum_{i=1}^{n} (A_{y_{i-1}, y_i} + \mathbf{s}_i[y_i])\ ,$$

where θ denotes all the parameters and $\mathbf{s}[y]$ indicates the dimension of a vector $\mathbf{s}$ corresponding to a label y. We can find the best label sequence $y^\star$ by maximizing the sentence score:

$$y^\star = \mathrm{argmax}_{y \in \mathcal{T}^n}\ \mathrm{score}(x, y; \theta)\ . \qquad (2)$$

Training Objective During training, parameters θ of the network are learned by minimizing the negative log likelihood over all the sentences in training data $\mathcal{D}$ w.r.t θ:

$$\begin{aligned}\min_\theta \quad &- \sum_{(x,y)\in\mathcal{D}} \log p(y|x,\theta)\ ,\\ p(y|x,\theta) &= \frac{\mathrm{score}(x, y; \theta)}{\sum_{y'} \mathrm{score}(x, y'; \theta)}\ . \qquad (3)\end{aligned}$$

Note that the Viterbi algorithm can be used for efficient calculation of the probability of a label sequence in Eq. (3) similarly to decoding in Eq. (2).

4 Proposed Model

To disambiguate word boundaries more effectively, we integrate word information into the character-based framework. More concretely, we transform embeddings of multiple candidate words for each character into a fixed size word vector, which we call a *word summary vector*, by a *word feature composition function*. We show the architecture of our model in Figure 2. In addition to the layers of the baseline model, the model comprises a word embedding layer, a word feature composition function, and additional recurrent layers.

Word Embedding Layer Given a character sequence $x = x_{1:n}$, we search for all words corresponding to subsequences of the input sequence from a word vocabulary $\mathcal{V}_w$ within a maximum word length. Then, we obtain a unique list[2] $\mathcal{W}_x$ of candidate words of size m. For example, for a given sentence $x_{1:5}$ in Figure 1, candidate words $\{w_1, \cdots, w_8\}$ will be found. Each word $w \in \mathcal{W}_x \subseteq \mathcal{V}_w$ is transformed into a d_w-dimensional vector $\mathbf{e}^w$ by the embedding matrix $E_w \in \mathbb{R}^{d_w \times |V_w|}$.

We can construct a word vocabulary to search candidate words by using external dictionaries or auto-segmented texts processed by any segmenter. Regarding the construction method used in our experiments, refer to §5.1.

Composition Functions of Word Features For a character x_i, the embeddings of all the candidate words that contain it are aggregated into a word summary vector $\mathbf{a}_i$ by a composition function. We introduce two attention-based composition functions, weighted average (WAVG) and

---

[2] List indicates set where each element has a unique number from 1 to the size of the set.

weighted concatenation (WCON), which enable a model to pay more or less attention according to the importance of candidate words.

Both functions calculate the importance score u_{ij} from a character x_i to a word w_j in $\mathcal{W}_x$ by a bilinear transformation, which indicates the interaction between the character context vector $\mathbf{h}_i$ and the word embedding $\mathbf{e}_j^w$. Then the weight $\alpha_{ij} \in [0, 1]$ is obtained by a softmax operation to normalize the scores:

$$\begin{aligned} u_{ij} &= \mathbf{h}_i^T W_a \mathbf{e}_j^w \ , \\ \alpha_{ij} &= \frac{\delta_{ij} \exp(u_{ij})}{\sum_{k=1}^{m} \delta_{ik} \exp(u_{ik})} \ , \end{aligned} \tag{4}$$

where $W_a \in \mathbb{R}^{2d_r \times d_w}$ is a trainable parameter. For simplification of equations, we introduce an indicator variable $\delta_{ij} \in \{0, 1\}$ that indicates whether the character x_i is included in the word w_j as Figure 1 illustrates.

Next, WAVG and WCON calculate a word summary vector $\mathbf{a}_i$ as the weighted average and the weighted concatenation of word embeddings, respectively:

$$\mathbf{a}_i = \mathrm{WAVG}(x_i, \{w_j\}_{j=1}^m) = \sum_{j=1}^{m} \alpha_{ij} \mathbf{e}_j^w \ , \tag{5}$$

$$\mathbf{a}_i = \mathrm{WCON}(x_i, \{w_j\}_{j=1}^m) = \bigoplus_{l=1}^{L} \alpha_{i,i_l} \mathbf{e}_{i_l}^w \ , \tag{6}$$

where $\{w_j\} = \mathcal{W}_x$ and $\bigoplus(\cdot)$ indicates concatenation of given arguments. Let K be the maximum word length, $L = \sum_{k=1}^{K} k$, and i_l for the character x_i denotes the corresponding index in $\mathcal{W}_x$ of l-th words w'_l in the list $\{w'_1, \dots, w'_L\} = \bigcup_{k=1}^{K} \bigcup_{p=-k+1}^{0} \{x_{i+p:i+p+k-1}\}$. If $w'_l \notin \mathcal{V}_w$, we use a zero vector as the l-th argument in Eq. (6). For example, if $K = 3$, WCON concatenates embeddings of words corresponding to x_i (length 1), $x_{i-1:i}$, $x_{i:i+1}$ (length 2), $x_{i-2:i}$, $x_{i-1:i+1}$ and $x_{i:i+2}$ (length 3) in this order, into a single vector for the character x_i. WAVG and WCON finally output a summary vector of size d_w and Ld_w, respectively. Note that we use zero vector as a summary vector if no candidate words are found for a character.

We also use two more variants of composition functions without the attention mechanism, the average function (AVG) and the concatenation function (CON). AVG is a special case of WAVG, where $\alpha_{ij} = \delta_{ij} / \sum_k \delta_{ik}$ for all (i, j) in Eq. (5). CON is the equivalent function to the word features used in Wang and Xu (2017) and a special case of WCON, where $\alpha_{i,i_l} = 1$ for all (i, i_l) in Eq. (6).

Recurrent Layers for Word-Integrated Character Representation The summary vector $\mathbf{a}_i$ and the context vector $\mathbf{h}_i$ for a character are together fed into additional recurrent layers, which are BiLSTM layers, to further contextualize character representations using word information of surrounding characters. Given the input $\mathbf{h}_i \oplus \mathbf{a}_i$, BiLSTMs calculate hidden vectors, and the hidden vectors $\mathbf{z}_{1:n}$ of the last BiLSTM layer are fed into the CRF layer.

5 Experiments

5.1 Settings

Datasets We evaluated our model on three datasets, CTB6 and MSR for Chinese word segmentation and BCCWJ (short unit word annotation) for Japanese word segmentation. CTB6 is Chinese Penn Treebank 6.0 (Xue et al., 2005). MSR is provided by the second International Chinese Word Segmentation Bakeoff (Emerson, 2005). BCCWJ is Balanced Corpus of Contemporary Written Japanese 1.1 (Maekawa et al., 2014). We followed the same training/development/test split as in previous work (Yang and Xue, 2012; Chen et al., 2015b) for CTB6, official training/test split for MSR, and the same training/test split as in the Project Next NLP[3] for BCCWJ. We randomly selected 90% of the sentences in the training data as a training set and used the other 10% as a development set, respectively for MSR and BCCWJ.

Word Vocabulary Construction Apart from the given training and development sets for each dataset, we assumed no annotated information, including external dictionaries and third-party segmenters, was available in our experiments. Therefore, we used the training set and large unlabeled texts to obtain a word vocabulary to be used in our proposed model.

First, we trained a baseline model from each training set and applied it to large unlabeled texts. Then we collected auto-segmented words appearing in the texts[4] and gold words in the training set, and regarded the union of both kinds of words as a

---

[4] We discarded words occurring less than five times in auto-segmented texts, since their pre-trained embeddings were not learned by Word2Vec with the default minimum frequency of five as described later.

Parameter	Value
Character embedding size	300
Number of BiLSTM-C layers	2
Number of BiLSTM-C hidden units	600
Mini-batch size	100
Initial learning rate	1.0
Learning rate decay ratio	0.9

The result with $*$ is from our run on their released implementation.

word vocabulary. We used the non-core section of BCCWJ (BCCWJ-NC)[5] for the Japanese dataset and Chinese Gigaword Fifth Edition[6] for the Chinese datasets as unlabeled texts.

Pre-training of Embedding Parameters Following previous work (Collobert et al., 2011), we pre-trained word embeddings from large texts and used them to initialize the word embedding matrix in our proposed segmenter. To pre-train word embeddings, we used the gensim (Řehůřek and Sojka, 2010) implementation of Word2Vec (Mikolov et al., 2013) and applied it to the same texts as ones used to construct the word vocabularies, i.e., the auto-segmented BCCWJ-NC or Chinese Gigaword texts processed by the baseline segmenters. We used the toolkit with a skip-gram model, embedding size 300, the number of iterations one, and other default parameters. For words occurring only in a training set, we randomly initialized their embeddings. We fine-tuned all word embeddings during training of the proposed segmenter.

In contrast, we randomly initialized all character embeddings, since pre-trained character embeddings did not improve performance in our preliminary experiments.

Hyperparameter Setting Table 1 gives the hyperparameters for the proposed model. The same dropout strategy as in Zaremba et al. (2015) was applied to non-recurrent connections of recurrent layers. We used word vector dropout, which randomly replaces a word embedding $\mathbf{e}^{w}$ to a zero vector when calculating a word summary vector in Eq. (5) or (6). A mini-batch stochastic gradient descent was used to optimize parameters and decayed the learning rate with a fixed decay ratio every epoch after the first five epochs. We trained models for up to 20 epochs and selected the best model on the development set.

5.2 Results on the Test Sets

We evaluated our baseline and proposed model variants on the test sets of the three benchmark datasets. Table 2 shows the mean of F1 scores of three runs for each dataset and each model. Among the proposed model variants, WCON achieved the best performance in almost all cases. We observed the following three findings from the results.

First, all the word-integrated model variants consistently outperformed the pure character-based baseline. We conducted McNemar's tests in a similar manner to Kudo et al. (2004), and the improvement of each variant over the base-

---

Table 4: Attention accuracy, segmentation accuracy and F1-score on the development sets. The table also shows segmentation accuracy based on the cases where attention is correct (Acc-CA) and incorrect (Acc-IA), the average number of candidate words for a character (NoC) and lower and upper bounds of attention accuracy.

line was significant at 0.001 level. Second, the attention-based variants further boosted performance in comparison with their counterparts without attention. The improvements of WCON over CON on BCCWJ and CTB, and that of WAVG over AVG were statistically significant according to the McNemar's tests. We discuss the reason for the slight and insignificant performance difference between CON and WCON on MSR in §5.3. Third, the concatenation-based variants performed better than the average-based counterparts in almost all cases. This is probably because CON and WCON keep word length and character position information. For example, (d_w+1)-th to $2d_w$-th dimensions of a summary vector always represent a word whose length is two and which ends with a target character (namely $x_{i-1:i}$ for x_i), while AVG and WAVG lose this kind of information.

Table 3 shows the performance of state-of-the-art models without additional annotated data. We listed only the WCON results in Table 3 since it performed the best among all variants on the development sets. In comparison with the best previous models, we obtained better performance on BCCWJ and CTB6, and achieved approximately 31% and 3% error reductions, respectively. On MSR, we obtained a comparable performance with the character-based model with word features in Wang and Xu (2017), which used different unlabeled texts from ours to pre-train word embeddings. To our knowledge, our model is the first neural network-based model that has achieved state-of-the-art results on both Japanese and Chinese word segmentation.

5.3 Analysis of Word Attention

To analyze how the attention mechanism affected segmentation performance, we show in Table 4 attention accuracy of the proposed model with the attention-based functions of the development sets. Attention accuracy regards a predicted result as correct if a character x_i most strongly attends to the word corresponding to the gold segmentation. The table also shows the segmentation performance, where accuracy indicates character-level accuracy of segmentation label prediction.

Note that the attention accuracy of a model falls between lower and upper bounds shown in the table. The upper bound indicates the ratio of characters whose candidate words contain the gold word (then attention can be correctly paid) and the lower bound indicates the ratio of characters whose candidate words consist only of the gold word (then attention is always correctly paid). For example, assuming that the gold segmentation of the sentence in Figure 1 is "$x_1|x_2|x_3x_4x_5$ $(= w_1|w_2|w_8)$", candidate words for all characters contain their gold words, and those for characters x_1 and x_2 consist only of respective gold words w_1 and w_2. Thus, the upper and lower bounds for the sentence are $5/5$ and $2/5$, respectively.

Both WAVG and WCON achieved approximately $\geq$80% attention accuracy over more than two candidate words on average. The "Acc-CA" ("Acc-IA") column denotes the segmentation accuracy in cases where the attention was correctly (incorrectly) paid. We obtained particularly high segmentation accuracy (close to or higher than 99%). However, incorrect attention led to a large drop in segmentation accuracy. Moreover, we can see a clear tendency for WCON resulting in poorer segmentation accuracy in cases with incorrect attention, compared with WAVG. This suggests that attention by WCON is more sensitive to segmentation decisions; information on attended words is more directly propagated to succeeding layers. As for the slight performance difference between CON and WCON on MSR in Table 2, a possible explanation is that existence of fewer gold words (observed from the upper bound of accuracy) leads to inaccurate attention and segmentation.

(f)

Figure 4: Weight α_{ij}, which indicates the importance from character x_i to word w_i, learned by WCON for sentences (a)-(f) in Figure 3. Weights to gold words are highlighted with blue.

5.4 Segmentation Examples

To examine segmentation results of actual sentences by different methods, we picked up sentence segments (a)-(f) from the BCCWJ development set. We show in Figure 3 the results obtained by BASE, WCON, and CON, which are selected as the character-based baseline, the best of our model variants, and its counterpart without attention, respectively. In addition, we also show values of weight α_{ij} learned by WCON in Figure 4.

In examples (a) and (b), BASE resulted in a wrong segmentation. However, both word-integrated methods correctly segmented words with the benefit of word information corresponding to gold segmentations (*adoresu*, *bar* and *hītewa*). This suggests that word information enables a model to utilize information on distant characters with target characters directly. From WCON results, we confirmed that all characters strongly attended to correct words, as in Figure 4. This suggests that accurate attention contributed to predicting correct segmentations.

In examples (c) and (d), only WCON predicted correct segmentations. The existence of correct words in the vocabulary and correct attention probably resulted in the correct segmentation for (c). As for (d), although parts of characters attended to a wrong word (*kankin*), correct attention regarding surrounding characters (*hikikae* and *kingaku*) seems to lead to the correct segmentation.

In examples (e) and (f), WCON predicted the wrong results. The wrong results of (e) by CON and WCON are probably due to the non-existence of the gold word *ochanomizu*, which is a location name, in the vocabulary. As for (f), WCON paid incorrect attention and predicted the wrong segmentation, even though the correct word *chūya* exists in the vocabulary. The model learned the incorrect weights likely due to the infrequent occurrence of the correct words; the single words *hiru* and *yoru* occur in the training set tens or hundreds of times while the compound word *chūya* occurs only twice. We may reduce these errors due to no or infrequent occurrences of gold words by increasing word vocabulary size, e.g., using larger texts to pre-train word embeddings.

6 Related Work

Word Segmentation For both Chinese and Japanese, word segmentation has been traditionally addressed by applying linear statistical algorithms, such as maximum entropy (Xue, 2003), CRF (Peng et al., 2004; Kudo et al., 2004; Zhao and Kit, 2008), and logistic regression (Neubig et al., 2011).

Various neural network architectures have been explored for Chinese word segmentation to reduce the burden of manual feature engineering. Specifically, character-based neural models have been developed to model the task as a sequence labeling problem, starting with earlier work by (Zheng et al., 2013) and (Mansur et al., 2013), which applied feed-forward neural networks. Pei et al. (2014) used a neural tensor network to capture interactions between tags and characters. More sophisticated architectures have also been used as standard components of word segmentation models to derive effective features automatically. Chen et al. (2015a) proposed gated recursive neural networks to model complicated combinations of characters. Chen et al. (2015b) used LSTM to capture long distance dependencies. Xu and Sun (2016) combined LSTM and GRNN to capture long term information better by utilizing chain and tree structures. CNNs have been used to extract complex features such as character n-grams (Chen et al., 2017) and graphical features of Chinese characters (Shao et al., 2017).

On the other hand, word-based neural models have also been proposed. Typical word-based models (Zhang et al., 2016; Cai and Zhao, 2016; Cai et al., 2017; Yang et al., 2017) sequentially determine whether or not to segment each character on the basis of word-level features and segmentation history, while keeping multiple segmentation candidates by beam search decoding. Liu et al. (2016) combined neural architectures for segment (i.e., word) representations into a semi-CRF framework, which searches for an optimal segmentation sequence consisting of variable length segments. Sun et al. (2017) proposed a gap-based model to predict whether or not to segment two consecutive characters, using a deep CNN consisting of more than ten layers.

Recent works utilized word information on a character-based framework. Zhou et al. (2017) pre-trained character embeddings using word boundary information from auto-segmented texts. Wang and Xu (2017) explicitly introduced word information into their CNN-based model. They concatenated embeddings of a character and multiple words corresponding to n-grams (n ranging from 1 to 4) that include the target character.

For Japanese, less work employed neural models for word segmentation than for Chinese. Morita et al. (2015) integrated an RNN language model into a statistical Japanese morphological analysis framework, which simultaneously segments a sentence into words and predicts word features, such as POS and lemma. Kitagawa and Komachi (2018) applied a pure neural model based on LSTM and achieved a better performance than a popular statistical Japanese segmenter (Neubig et al., 2011).

Around the same time as our work, two other character-based models for word segmentation have been proposed. Ma et al. (2018) showed a standard BiLSTM model can achieve state-of-the-art results when combined with deep learning best practices, including dropout to recurrent connections (Gal and Ghahramani, 2016) and pre-trained embeddings of character bigrams. These techniques can also be applied to and can further boost performance of our model. Yang et al. (2018) proposed a lattice LSTM-based model with subsequence (word or subword) information. Their model also considers the importance of multiple words by integrating character and word information into an LSTM cell vector using a gate-mechanism. However, their model might not fully exploit word information, since word information is given to only the first and last characters of the word.

LSTM-CRF LSTM-CRF is a popular neural architecture, which has been applied to various tagging tasks, including word segmentation (Chen et al., 2015b), POS tagging and NER (Huang et al., 2015; Ma and Hovy, 2016; Rei et al., 2016). Ma and Hovy (2016) and Rei et al. (2016) introduced the internal character information of words on word-level labeling tasks in contrast to our work introducing candidate word information of characters in the character-level labeling task.

Attention Mechanism An attention mechanism (Bahdanau et al., 2015) was first introduced in machine translation to focus on appropriate parts of a source sentence during decoding. This mechanism has been widely applied to various NLP tasks, including question answering (Sukhbaatar et al., 2015), constituency parsing (Vinyals et al., 2015), relation extraction (Lin et al., 2016) and natural language inference (Parikh et al., 2016). Rei et al. (2016) introduced a gate-like attention mechanism on their word-based sequence labeling model to determine the importance between the word itself and the internal characters for each word.

7 Conclusion and Future Work

In this paper, we proposed a word segmentation model that integrates word-level information into a character-based framework, aiming to take the advantages of both character- and word-based models. The experimental results show that our model with an attention-based composition function outperforms the state-of-the-art models on both Japanese and Chinese benchmark datasets.

Our analysis suggests that a word vocabulary with larger coverage can reduce errors deriving from unknown words. In future work, we will explore (1) the relationship between vocabulary coverage and segmentation performance, and (2) the effect of using pre-trained word vectors learned from different domain texts in domain adaptation scenarios.

Acknowledgments

We would like to thank Atsushi Fujita, Rui Wang, and the anonymous reviewers for their helpful feedback on this work.

Abstract

Chinese is a logographic writing system, and the shape of Chinese characters contain rich syntactic and semantic information. In this paper, we propose a model to learn Chinese word embeddings via three-level composition: (1) a convolutional neural network to extract the intra-character compositionality from the visual shape of a character; (2) a recurrent neural network with self-attention to compose character representation into word embeddings; (3) the Skip-Gram framework to capture non-compositionality directly from the contextual information. Evaluations demonstrate the superior performance of our model on four tasks: word similarity, sentiment analysis, named entity recognition and part-of-speech tagging.[1]

1 Introduction

Distributed representations of words, namely word embeddings, encode both semantic and syntactic information into a dense vector. Currently, word embeddings have been playing a pivotal role in many natural language processing (NLP) tasks. Most of these NLP tasks also benefit from the pre-trained word embeddings, such as *word2vec* (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014), which are based on the distributional hypothesis (Harris, 1954): words that occur in the same contexts tend to have similar meanings. Earlier word embeddings often take a word as a basic unit, and they ignore compositionality of its sub-word information such as morphemes and character n-grams, and cannot competently handle the rare words. To improve the performance of word embeddings, sub-word information has been employed (Luong et al., 2013; Qiu et al., 2014; Cao and Rei, 2016; Sun et al., 2016a; Wieting et al., 2016; Bojanowski et al., 2016).

Compositionality is more critical for Chinese, since Chinese is a logographic writing system. In Chinese, each word typically consists of fewer characters and each character also contains richer semantic information. For example, Chinese character "休" (rest) is composed of the characters for "人" (person) and "木" (tree), with the intended idea of someone leaning against a tree, i.e., resting.

Based on the linguistic features of Chinese, recent methods have used the character information to improve Chinese word embeddings. These methods can be categorized into two kinds:

1) One kind of methods learn word embeddings with its constituent character (Chen et al., 2015), radical[2] (Shi et al., 2015; Yin et al., 2016; Yu et al., 2017) or strokes[3] (Cao et al., 2018). However, these methods usually use simple operations, such as averaging and n-gram, to model the inherent compositionality within a word, which is not enough to handle the complicated linguistic compositionality.

2) The other kind of methods learns word embeddings with the visual information of the character. Liu et al. (2017) learn character embedding based on its visual characteristics in the text classification task. Su and Lee (2017) also introduce a pixel-based model that learns character features from font images. However, their model is not shown to be better than *word2vec* model because it has little flexibility and fixed character features.

Besides, most of these methods pay less attention to the non-compositionality. For example, the

semantic of Chinese word “沙发” (sofa) cannot be composed by its contained characters “沙” (sand) and “发” (hair).

In this paper, we fully consider the compositionality and non-compositionality of Chinese words and propose a visual character-enhanced word embedding model (VCWE) to learn Chinese word embeddings. VCWE learns Chinese word embeddings via three-level composition:

- The first level is to learn the intra-character composition, which gains the representation of each character from its visual appearance via a convolutional neural network;
- The second level is to learn the inter-character composition, where a bidirectional long short-term neural network (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) with self-attention to compose character representation into word embeddings;
- The third level is to learn the non-compositionality, we can learn the contextual information because the overall framework of our model is based on the skip-gram.

Evaluations demonstrate the superior performance of our model on four tasks such as word similarity, sentiment analysis, named entity recognition and part-of-speech tagging.

2 Related Work

In the past decade, there has been much research on word embeddings. Bengio et al. (2003) use a feedforward neural network language model to predict the next word given its history. Later methods (Mikolov et al., 2010) replace feedforward neural network with the recurrent neural network for further exploration. The most popular word embedding system is *word2vec*, which uses continuous-bag-of-words and Skip-gram models, in conjunction with negative sampling for efficient conditional probability estimation (Mikolov et al., 2013a).

A different way to learn word embeddings is through factorization of word co-occurrence matrices such as GloVe embeddings (Pennington et al., 2014), which have been shown to be intrinsically linked to Skip-gram and negative sampling (Levy and Goldberg, 2014).

The models mentioned above are popular and useful, but they regard individual words as atomic tokens, and the potentially useful internal structured information of words is ignored. To improve the performance of word embedding, sub-word information has been employed (Luong et al., 2013; Qiu et al., 2014; Cao and Rei, 2016; Sun et al., 2016a; Wieting et al., 2016; Bojanowski et al., 2016). These methods focus on alphabetic writing systems, but they are not directly applicable to logographic writing systems.

For the alphabetic writing systems, research on Chinese word embedding has gradually emerged. These methods focus on the discovery of making full use of sub-word information. Chen et al. (2015) design a CWE model for jointly learning Chinese characters and word embeddings. Based on the CWE model, Yin et al. (2016) present a multi-granularity embedding (MGE) model, additionally using the embeddings associated with radicals detected in the target word. Xu et al. (2016) propose a similarity-based character-enhanced word embedding (SCWE) model, exploiting the similarity between a word and its component characters with the semantic knowledge obtained from other languages. Shi et al. (2015) utilize radical information to improve Chinese word embeddings. Yu et al. (2017) introduce a joint learning word embedding (JWE) model and Cao et al. (2018) represent Chinese words as sequences of strokes and learn word embeddings with stroke n-grams information.

From another perspective, Liu et al. (2017) provide a new way to automatically extract character-level features, creating an image for the character and running it through a convolutional neural network to produce a visual character embedding. Su and Lee (2017) also introduce a pixel-based model that learns character features from its image.

Chinese word embeddings have recently begun to be explored, and have so far shown great promise. In this paper, we propose a visual character-enhanced word embedding (VCWE) model that can learn Chinese word embeddings from corpus and images of characters. The model combines the semantic information of the context with the image features of the character, with superior performance in several benchmarks.

3 Proposed Model

In this section, we introduce the visual character-enhanced word embedding (VCWE) model for Chinese word representation.

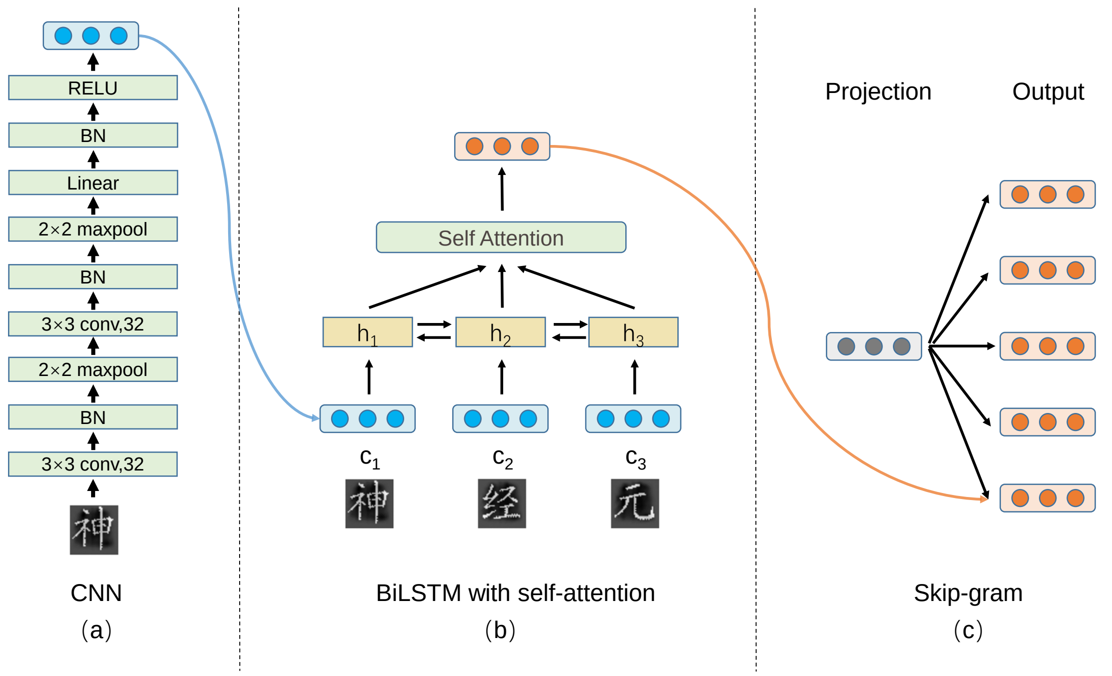

Figure 1: The overall architecture of our approach.

Given a Chinese word w consisting of n characters $c_1, \cdots, c_n$, its semantic may come from either its contained characters or its contexts. Therefore, we use the two-level hierarchical composition to compose the word embedding, which further learned according to its context.

The overall architecture of our approach is on Figure 1. We first use a convolutional neural network (CNN) to model the intra-character compositionality of character from its visual shape information. We use the output of CNN as the embeddings of the character. Then the character embeddings are used as the input of the bidirectional LSTM network to model the inter-character compositionality. After a self-attention layer, we can get the representation of the word. Finally, based on the Skip-Gram framework, we learn the word embeddings with the visual character-enhanced embedding of the context.

3.1 Intra-Character Composition

Since the shape of a Chinese character provides rich syntactic and semantic information, the representation of a character can be composed by its intrinsic visual components. Following the success of the convolutional neural network (CNN) (LeCun et al., 1995) in computer vision, we use CNN to directly model the natural composition of a character from its image.

We first convert each character into an image of size 40×40, a deep CNN is used to fuse its visual information fully. The specific structure of the CNN is shown in Figure 1(a), which consists of two convolution layers and one linear layer. Each convolution layer is followed by a max pooling layer and a batch normalization layer. The lower layers aim to capture the stroke-level information, and the higher layers aim to capture the radical-level and component-level information.

The output of CNN can be regarded as the representation of the character. The character representation by its visual information can fully capture its intrinsic syntactic and semantic information with the intra-character compositionality.

The parameters of CNN are learned through backpropagation in end-to-end fashion.

3.2 Inter-Character Composition

After obtaining the representation of characters, we combine them into word embedding. The word embedding need to capture the character-level compositionality fully. Here, we use the bidirectional LSTM (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) with self-attention to fuse the inter-character information of a word.

The structure of our Bi-LSTM with self-attention is shown in Figure 1(b).

Given a word w consisting of n characters $c_1, \cdots, c_n$, we use $\mathbf{e}_1, \cdots, \mathbf{e}_n$ denote is the character representations, which are the output of the CNN rather than randomly initialized.

The word w is firstly encoded using a Bi-LSTM:

$$\mathbf{h}_i^F = \text{LSTM}(\mathbf{h}_{i-1}^F, \mathbf{e}_i), \tag{1}$$

$$\mathbf{h}_i^B = \text{LSTM}(\mathbf{h}_{i+1}^B, \mathbf{e}_i), \tag{2}$$

$$\mathbf{h}_i = [\mathbf{h}_i^F; \mathbf{h}_i^B], \tag{3}$$

$$H = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n], \tag{4}$$

where $\mathbf{h}_i$ is the hidden state of the i-th character in w.

Then we use self-attention to obtain the inter-character compositionality. Following the self-attention proposed by (Lin et al., 2017), we compute an attention vector α:

$$\alpha = \text{softmax}(\mathbf{v} \tanh(U \mathbf{h}_i^{\mathrm{T}})), \tag{5}$$

where $\mathbf{v}$ and U are learnable weight parameters.

Finally, the representation of word w is:

$$\mathbf{m} = \sum_{i=1}^{n} \alpha_i \mathbf{h}_i. \tag{6}$$

Since the Bi-LSTM's hidden state of each character is different according to its contexts, we believe the hidden state can capture both the compositional and non-compositional relations of the characters within a word.

After obtaining the word representation, Skip-Gram (Mikolov et al., 2013a) is used to learn the word embedding with its context information. Skip-Gram is a useful framework for learning word vectors, which aims to predict context words given a target word in a sentence.

Given a pair of words (w, c), we denote $p(c|w)$ as the probability that the word c is observed in the context of the target word w.

With the negative-sampling approach, skip-gram formulates the probability $p(c|w)$ as follows:

Given a pair of words (w, c), the probability that the word c is observed in the context of the target word w is given by

$$p(D = 1|w, c) = \sigma(\mathbf{w}^{\mathrm{T}}\mathbf{c}), \tag{7}$$

where $\mathbf{w}$ and $\mathbf{c}$ are embedding vectors of w and c respectively, σ is the sigmoid function.

The probability of not observing word c in the context of w is given by:

$$p(D = 0|w, c) = 1 - \sigma(\mathbf{w}^{\mathrm{T}}\mathbf{c}). \tag{8}$$

4 Training

4.1 Objective Function

Given the target word w, its context word c and k negative words $\tilde{c}_1, ..., \tilde{c}_k$. The word w is a word selected from a sentence in the corpus, and the context c is a nearby word within a window size l. The negative sample $\tilde{c}_i$ is a word that is randomly sampled at a certain frequency in the vocabulary.

The loss function of VCWE model is as follows:

$$L = L_1 + L_2, \tag{9}$$

$$L_1 = \log \sigma(\mathbf{w}^{\mathrm{T}}\mathbf{c}) + \sum_{i=1}^{k} \log \sigma(-\mathbf{w}^{\mathrm{T}}\tilde{\mathbf{c}}_i), \tag{10}$$

$$L_2 = \log \sigma(\mathbf{w}^{\mathrm{T}}\mathbf{m}_c) + \sum_{i=1}^{k} \log \sigma(-\mathbf{w}^{\mathrm{T}}\tilde{\mathbf{m}}_i), \tag{11}$$

where $\mathbf{w}$ is the lookup embedding of target word; $\mathbf{c}$ and $\tilde{\mathbf{c}}_i$ are the lookup embeddings of the context and negative words respectively; $\mathbf{m}_c$ and $\tilde{\mathbf{m}}_i$ are visual enhanced word embeddings of the context and negative words respectively.

Here, we use the visually enhanced word embedding as the representation of context word instead of the target word. The final embedding of the target word is indirectly affected by the visual information. Thus, the final word embedding can have an advantage of fully utilizing intra-character compositionality from CNN, inter-character compositionality from LSTM, and context information from Skip-gram.

4.2 Word Sampling

We use a word sampling scheme similar to the implementation in word2vec (Mikolov et al., 2013a,b) to balance the importance of frequent words and rare words. Frequent words such as "的"(of), "是"(is), "这"(this) are not as meaningful as relatively less frequent words such as "猫"(cat), "喜欢"(like), "水果"(fruit). To improve the performance of word embeddings, we use subsampling(Mikolov et al., 2013b) to discard the word w with the probability of $P(w) = 1 - \sqrt{\frac{t}{f(w)}}$ when generating the batch, where $f(w)$ is the frequency of word w and t is a chosen threshold, typically around 10^{-5}.

To generate negative context words, we sample each word w according to distribution $P(w) \propto U(w)^{\frac{3}{4}}$, where $U(w)$ is the unigram distribution, which is the frequency of single words appearing in the corpus. This method also plays a role in reducing the frequency of occurrence of high-frequency words.

5 Experiments

5.1 Preparation for training data

We download Chinese Wikipedia dump[4] on May 20, 2018, which consists of 278K Chinese Wikipedia articles. We use the WikiExtractor toolkit[5] to convert data from XML into text format. We find that the corpus consists of both simplified and traditional Chinese characters. Hence we utilize the opencc toolkit[6] to normalize all characters as simplified Chinese. We remove non-Chinese characters such as punctuation marks by retaining the characters whose Unicode falls into the range between 0x4E00 and 0x9FA5. We use THULAC [7](Sun et al., 2016b) for word segmentation.

We discard words that appeared less than 100 times and obtain a vocabulary of size 66,856. We count the frequency of occurrence of each word to prepare for the subsampling work.

In all 66,856 words, we extract 5030 unique characters. We use a Chinese character image generation software to generate the images of these Chinese characters. We subtract a mean image from each input image to center it before feeding it into the CNN. The pre-processed Chinese character images are shown in Figure 2.

Figure 2: The pre-processed Chinese character images.

5.2 Hyperparameters

Models used for evaluation have dimension $D = 100$ and use context window $l = 5$ unless stated otherwise. We use the threshold $t = 10^{-5}$ for subsampling, which is the recommended value for word2vec Skip-gram (Mikolov et al., 2013a) on large datasets. The number of negative samples per word is 5.

We use mini-batch asynchronous gradient descent with Adam (Kingma and Ba, 2014). The initial learning rate is 0.001.

5.3 Baselines

We compare our model to the following open source state-of-art models:

- word2vec[8] (Mikolov et al., 2013a) is arguably the most popular word embedding, which uses continuous-bag-of-words (CBOW) and Skip-gram models. We train word2vec with both Skip-gram and CBOW models. We did not train Glove(Pennington et al., 2014) because it did not perform well in many previous Chinese word embedding papers.
- CWE[9] (Chen et al., 2015) is character-enhanced word embeddings which introduce internal character information into word embedding methods to alleviate excessive reliance on the external information.
- GWE[10](Su and Lee, 2017) is a pixel-based Chinese word embedding model, which exploits character features from font images by convolutional autoencoders.
- JWE[11](Yu et al., 2017) is a model to jointly learn the embeddings of Chinese words, characters, and sub character components.

For a fair comparison between different algorithms, we use the same corpus and the same hyperparameters mentioned in previous subsections.

5.4 Word Similarity Task

We evaluate our embeddings on the Chinese word similarity datasets wordsim-240 and wordsim-296 provided by (Chen et al., 2015). Besides, we translate two English word similarity datasets MC-30

Table 2: Accuracy for Sentiment analysis task. The configurations are the same of the ones used in Table 1.

(Miller and Charles, 1991) and RG-65 (Rubenstein and Goodenough, 1965) to Chinese[12]. Each dataset contains a list of word pairs with a human score of how related or similar the two words are.

We calculate the Spearman correlation (Spearman, 1904) between the labels and our scores generated by the embeddings. The Spearman correlation is a rank-based correlation measure that assesses how well the scores describe the true labels. The evaluation results of our model and baseline methods on word similarity datasets are shown in Table 1.

From the results, we can see that VCWE outperforms other baseline models. The effect of CBOW is much better than Skip-gram. The impact of GWE and CWE are relatively close. The JWE model works better than other benchmark models. In the VCWE model, when we remove the CNN and the image information, the result falls by 2.91. When we replace Bi-LSTM network and self-attention with the averaging operation, the result drops by 1.42.

In the last subsection, we will qualitatively analyze the results of word similarity for different models.

5.5 Sentiment Analysis Task

To evaluate the quality of our vectors regarding semantics, we use datasets[13] collected by (Peng et al., 2018), which contain Chinese reviews in four domains: notebook, car, camera, and phone. They manually labeled the sentiment polarity towards each aspect target as either positive or negative. It is a binary classification task. Similar to how we process the training data, we remove non-Chinese characters and use THULAC for performing Chinese word segmentation. We build classifiers with the bidirectional LSTM (Hochreiter and Schmidhuber, 1997) network with self-attention (Lin et al., 2017). We use the standard training/dev/test split and report accuracy using different embeddings generated by different meth-

---

[13] http://sentic.net/chinese-review-datasets.zip

ods in Table 2.

As shown in Table 2, Skip-gram performs well on the combination of the four groups, but it does not perform well in the works of a particular group. JWE outstrips other baseline methods by around 1.1 points. The VCWE model has achieved outstanding results in the car, camera and phone category, with an accuracy rate of at least 3 points higher than other models, indicating that this method of training word embeddings with visual character-level features can achieve better results on downstream tasks.

5.6 Named Entity Recognition Task

We evaluate our model on the named entity recognition task. We use an open source Chinese NER model to test our word embeddings on MSRA dataset[14]. MSRA is a dataset for simplified Chinese NER. It comes from SIGHAN 2006 shared task for Chinese NER (Levow, 2006). We pretrain word embeddings from different models and feed them into the input layer as features.

The key to the task is to extract named entities and their associated types. Better word embeddings could get a higher F1 score of NER. The results in Table 3 show that our model also outperforms baseline models in this task. The performance of CWE and GWE models are similar, both slightly lower than Skip-gram and CBOW models. The F1 score of the JWE model exceeds that of other baseline models and is similar to our model. When removing the CNN and image information, our LSTM with the self-attention model can also achieve the best results on this task, indicating that the learned inter-character composition is practical.

5.7 Part-of-speech Tagging Task

The evaluation is performed on the PKU's People's Daily [15] (PPD) (Yu et al., 2001) with the standard training/dev/test split. The model is trained with the bidirectional LSTM model using the same hyper-parameters. Results on the POS accuracy on the test set are reported in Table 3.

The gap between the usage of different embeddings is not significant, and our model has achieved the best results with a slight advantage.

Model	NER			POS Tag
	Prec.	Recall	F1	Acc
Skip-gram	85.30	84.18	84.74	95.87
CBOW	85.64	82.98	84.29	95.79
CWE	83.89	82.57	83.23	95.45
GWE	84.06	82.52	83.28	95.45
JWE	85.74	84.87	85.30	95.91
VCWE	86.93	84.64	**85.77**	**96.00**
-CNN	86.73	84.83	**85.77**	95.92
-LSTM	85.98	84.53	85.25	95.96

Table 3: Chinese NER and POS tagging results for different pretrained embeddings. The configurations are the same of the ones used in Table 1.

5.8 Qualitative analysis

To better understand the quality of the learning word embedding for each model, we conduct a qualitative analysis by doing some case studies in Table 4 to illustrate the most similar words for certain target words under different methods. Explicitly, we present the top 10 words that are most similar to our target word. The similar words are retrieved based on the cosine similarity calculated using the learned embeddings.

The first example word we consider is "唐诗(Tang poetry)". It refers to poetry written in or around the time of or in the characteristic style of China's Tang Dynasty.

All the top-ranked words identified by GWE contain the character "唐(Tang)" and "诗(poetry)", but in addition to the Tang Dynasty, "唐(Tang)" also has other meanings such as surnames. GWE yields several words such as "唐璜(Don Juan)", "唐寅(Tang Yin)", "唐僧(Monk Tang)" and "唐括(Tang Ku)", which do not appear to be semantically close to the target word. In Skip-gram and JWE, certain words such as "佚(anonymity)" and "古今(ancient and modern)" do not appear to be semantically very closely related to the target word. In our VCWE model, all the top-ranked words are semantically related to the target word, including the genre of poetry, poets of the Tang Dynasty, and so on.

We choose the "沙发(sofa)" as the second target word. Like the first two words, GWE only pays attention to the character "沙(sand)". Skip-gram and JWE have some irrelevant words such as "电话亭(telephone box)" and "广告牌(billboard)". VCWE pays more attention to

Table 4: Case study for qualitative analysis. Given the target word, we list the top 10 similar words from each algorithm so as to observe the differences.

the non-compositionality, and the results are better than other models.

Limited to the width of the table, we do not show the results of CWE model. The results of the GWE model are not much different from the CWE model, indicating that the image features obtained by pre-training of GWE may not play a decisive role. However, our model does not pre-train image information, but jointly trains and dynamically updates image feature information and it works better. JWE model is similar to Skip-gram model in that they pay more attention to contextual information, but sometimes the model gets some irrelevant words.

6 Discussion

Unlike phonograms, logograms have word and phrase meanings singularly. The images of Chinese characters contain rich semantic information. Since logographic languages are more closely associated with images than alphabet languages, it makes sense to mine the characteristics of these images.

Liu et al. (2017) provide a new way to automatically extract character-level features, creating an image for the character and running it through a convolutional neural network to produce a visual character embedding. However, this method does not utilize the rich semantic information of contextual words. Our model extracts both image features and contextual semantic information.

Su and Lee (2017) introduce a pixel-based model that learns character features from font images. However, they use convolutional auto-encoder(convAE) to extract image features in advance, and then add these features to the CWE (Chen et al., 2015) model. In the end, the effect of the model is not much different from CWE. Our model is an end-to-end model. We update the image's feature parameters in real time during training, and our model achieves better results than the GWE model.

Our research focuses on simplified Chinese word embeddings, and the idea can also be applied to other languages that share a similar writing system, such as traditional Chinese, Japanese, and so on.

7 Conclusion and Future Work

In this paper, we proposed a pixel-based model to learn Chinese word embeddings with character embeddings that are compositional in the components of the characters. We utilized the visual features of Chinese characters to enhance the word embedding. We showed that our model outperforms the baseline model in the word similarity, sentiment analysis, named entity recognition and part-of-speech tagging tasks.

In summary, we optimized our pixel-based word embedding method to make the model end-to-end and make full use of the contextual information. In the future, we hope to apply our model to other downstream tasks and other logographic writing systems.

Abstract

We investigate subword information for Chinese word segmentation, by integrating sub word embeddings trained using byte-pair encoding into a Lattice LSTM (LaLSTM) network over a character sequence. Experiments on standard benchmark show that subword information brings significant gains over strong character-based segmentation models. To our knowledge, this is the first research on the effectiveness of subwords on neural word segmentation.

1 Introduction

Chinese word segmentation (CWS) is a traditional NLP task (Sproat et al., 1996), the features for which have been a central research topic. Statistical methods consider characters (Xue et al., 2003), subwords (Zhang et al., 2006), and words (Zhang and Clark, 2007) as input features. Among these, both characters (Chen et al., 2015a) and words (Zhang et al., 2016; Cai and Zhao, 2016; Yang et al., 2017) have also shown useful in recent neural models. However, how to utilize the subword features in neural networks has not been investigated yet.

In this paper, we fill this gap by proposing a subword-based neural word segmentor, by integrating two strands of works: the byte pair encoding (BPE) algorithm (Gage, 1994) and the lattice LSTM structure (Zhang and Yang, 2018). The BPE algorithm constructs a subword list from raw data and lattice LSTM introduces subwords into character LSTM representation. In particular, our baseline is a BiLSTM-CRF segmentor (Chen et al., 2015b) and we replace LSTM with lattice LSTM using subwords to encode character composition information. Our code[1] is based on NCRF++ (Yang and Zhang, 2018).

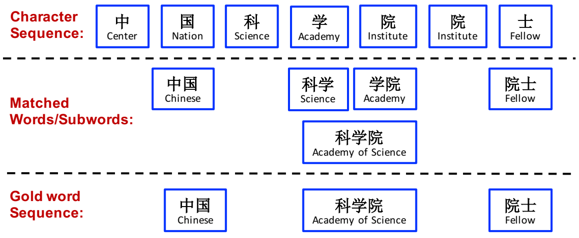

Figure 1: Segmentation with ambiguous words.

Compared with character-based neural segmentors, our model can utilize abundant character combination (subword) information, which is effective to disambiguate characters. For example, in Figure 1, the subword “学院(Academy)” ensures that the character “学” means “Academy(noun)” rather than “study(verb)”. Compared with the word-based neural models (Zhang et al., 2016; Cai and Zhao, 2016), ambiguous subwords in a context can provide additional information for disambiguation. For instance, the subword “科学院(Academy of Sciences)” and “学院(Academy)” can be useful in determining the correct segmentation, which is “科学院/(Academy of Sciences/)”.

To our knowledge, we are the first to use subwords in a neural network segmentor. We investigate the contributions of subword lexicons and their pretrained embeddings through controlled experiments. Results on four benchmarks show that the proposed model can give comparable results with state-of-the-art models.

2 Related Work

State-of-the-art statistical segmentors use either sequence labeling methods e.g. CRF (Lafferty et al., 2001) with character features (Peng et al., 2004; Zhao et al., 2006) or the transition-based models with word features (Zhang and Clark, 2007; Sun, 2010). Neural segmentors (Chen et al.,

Proceedings of NAACL-HLT 2019, pages 2720–2725
Minneapolis, Minnesota, June 2 - June 7, 2019.

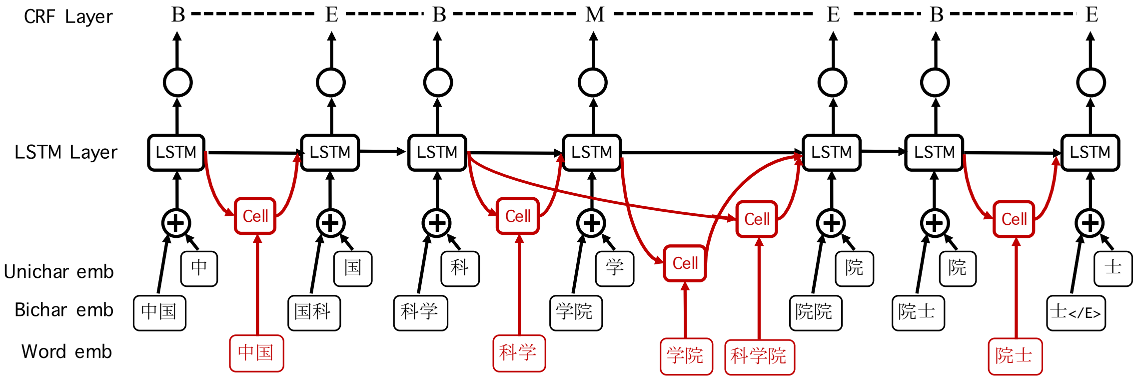

Figure 2: Models. Only forward LSTM is illustrated here.

2015a; Cai and Zhao, 2016) generally take the same framework except using neural networks as automatic feature extractor.

Lattice LSTM was proposed by Zhang and Yang (2018) for Chinese named entity recognition (NER). It integrates the character sequence features and all lexicon word embeddings that match a character subsequence in the input into a sequence labeling model. Zhu et al. (2016) proposed a DAG-structured LSTM structure which is similar to the lattice LSTM model but binarizing the paths in the merging process. Chen et al. (2017) also built a DAG-LSTM structure for word segmentation but without memory cells. Our model consistently gives better performance.

BPE is a data compression algorithm (Gage, 1994) which has been used in neural machine translation (NMT) by capturing the most frequent subwords instead of words (Sennrich et al., 2016). Here we use it for collecting subwords in Chinese, similar to the use in Chinese NMT.

3 Models

We take the state-of-the-art LSTM-CRF framework as our baseline. For an input sentence with m characters $s = c_1, c_2, \ldots, c_m$, where c_i denotes the ith character, the segmentor is to assign each character c_i with a label l_i. Figure 2 shows the segmentor framework on input character sequence "中国科学院院士 (Fellow of the Chinese Academy of Sciences)", where the black part represents the baseline LSTM-CRF model and the red part shows the lattice structure.

3.1 Baseline Model

As shown in Figure 2, for each input character c_i, the corresponding character unigram embeddings and character bigram embeddings are represented as $\mathbf{e}_{c_i}$ and $\mathbf{e}_{c_i c_{i+1}}$, respectively. The character representation is calculated as following:

$$\mathbf{x}_i = \mathbf{e}_{c_i} \oplus \mathbf{e}_{c_i c_{i+1}}, \qquad (1)$$

where $\oplus$ represents *concatenate* operation.

Unlike Zhang et al. (2016) which uses a window to strengthen the local features, or Zhou et al. (2017) which adds a non-linear layer before the LSTM layer, we feed $\{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m\}$ into a bidirectional LSTM:

$$\begin{aligned} \overrightarrow{\mathbf{h}}_1, \overrightarrow{\mathbf{h}}_2, \ldots, \overrightarrow{\mathbf{h}}_m &= \overrightarrow{LSTM}(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m) \\ \overleftarrow{\mathbf{h}}_1, \overleftarrow{\mathbf{h}}_2, \ldots, \overleftarrow{\mathbf{h}}_m &= \overleftarrow{LSTM}(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m), \end{aligned} \qquad (2)$$

where $\overrightarrow{LSTM}$ and $\overleftarrow{LSTM}$ represent the forward and backward LSTM, respectively. The detailed equations are listed in *Appendix*. The hidden vector of character c_i is

$$\mathbf{h}_i = \overrightarrow{\mathbf{h}}_i \oplus \overleftarrow{\mathbf{h}}_i \qquad (3)$$

3.2 Lattice LSTM

The lattice LSTM adds "shortcut paths" (red part in Figure 2) to LSTM. The input of the lattice LSTM model is character sequence and all subsequences which are matched words in a lexicon $\mathbb{D}$, collected from BPE. Following Zhang and Yang (2018), we use $w_{b,e}$ to represent the subsequence that has a start character index b and a end character index e, and the embeddings of the subsequence is represented as $\mathbf{e}_{w_{b,e}}$.

During the forward lattice LSTM calculation, the "cell" in Figure 2 of a subsequence $w_{b,e}$ takes the hidden vector of the start character $\mathbf{h}_b$ and the subsequence embeddings $\mathbf{e}_{w_{b,e}}$ as input, an extra

Parameter	Value	Parameter	Value
char emb size	50	bigram emb size	50
word emb size	50	subword emb size	50
char dropout	0.5	lattice dropout	0.5
LSTM layer	1	LSTM hidden	200
learning rate *lr*	0.01	*lr* decay	0.05

Table 1: Hyper-parameter values.

LSTM cell is applied to calculate the memory vector of the sequence $\mathbf{c}_{w_{b,e}}$:

$$\mathbf{c}_{w_{b,e}} = LSTMCell(\mathbf{h}_b, \mathbf{e}_{w_{b,e}}), \tag{4}$$

where the $LSTMCell$ is a simplified LSTM unit which calculate the memory only. The output memory vector $\mathbf{c}_{w_{b,e}}$ links to the end character c_e to calculate its hidden vector $\overrightarrow{\mathbf{h}}_e$. For character with multiple memory cell inputs[2], we assign a gate for each subsequence input to control its contribution. The detailed equations are listed in *Appendix*. The final output $\overrightarrow{\mathbf{h}}_i$ includes both the character sequence history information and all the matched subsequence information.

3.3 Decoding and Training

We use a standard CRF layer for inference (details in *Appendix*). Viterbi (1967) is used to find the highest scored label sequence over the input. During training, we choose sentence-level log-likelihood as the loss function.

$$Loss = \sum_{i=1}^{N} log(P(y_i|s_i)), \tag{5}$$

where y_i is the gold labels of sentence s_i.

4 Experiments

4.1 Experimental Settings

Data. We evaluate our model on four standard Chinese word segmentation datasets: CTB6, PKU, MSR, and Weibo. PKU and MSR are taken from the SIGHAN 2005 bake-off (Emerson, 2005) and Weibo dataset is the NLPCC 2016 shared task (Qiu et al., 2016), standard split are used. We take CTB6 as the main dataset and split the train/dev/test following Zhang et al. (2016). The statistics of the datasets are listed in *Appendix*.

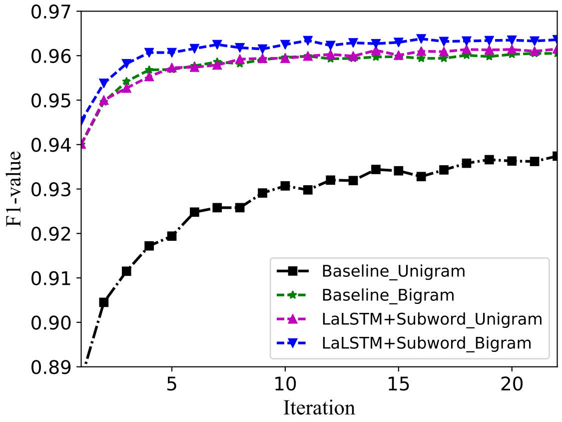

Figure 3: F1-value against training iterations.

Hyperparameters. We keep the hyperparameters the same among all datasets. Standard gradient descent (SGD) with a learning rate decay is used as the optimizer. The embedding sizes of character unigram/bigram and subword are all 50. Dropout (Srivastava et al., 2014) is used on both the character input and the subword input to prevent overfitting. Details are listed in Table 1.

Embeddings. We take the same character unigram and bigram embeddings as Zhang et al. (2016), who pretrain embeddings using word2vec (Mikolov et al., 2013) on Chinese Gigaword[3]. The vocabulary of subword is constructed with 200000 merge operations and the subword embeddings are also trained using word2vec (Heinzerling and Strube, 2018). Trie (Fredkin, 1960) is used to accelerate lattice building. All the embeddings are fine-tuned during training.

4.2 Development Experiments

We perform experiments on the CTB6 development dataset to investigate the contribution of character bigram information and the subword information. Figure 3 shows the iteration curve of F-scores against different numbers of training iterations with different character representations. “_Bigram” represents the model using both character unigram and bigram information (embedding concatenation). Character bigram information can improve the baseline significantly. When the “LaLSTM+Subword” structure is added, the model performance is further improved. This shows that subword information has a great ability to disambiguate the characters.

Table 3: Lexicon and embeddings on CTB6.

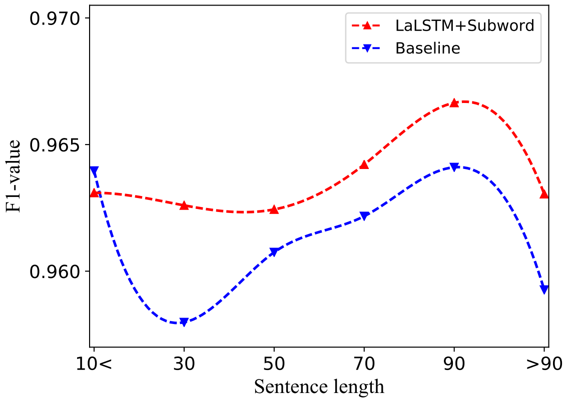

Figure 4: F1-value against the sentence length.

Zhang and Yang (2018) observed that character bigram information has a negative effect in lattice LSTM on Chinese NER task, while we find a different result on Chinese word segmentation where character bigram information gives significant improvements in the lattice LSTM. This is likely because character bigrams are informative but ambiguous. They can provide more useful character disambiguation evidence in segmentation than in NER where lattice LSTM works well in disambiguating characters.

4.3 Results

Table 2 shows the main results and the recent state-of-the-art neural CWS models. Zhang et al. (2016) integrated both discrete features and neural features in a transition-based framework. Xu and Sun (2016) proposed the dependency-based gated recursive neural network to utilize long distance dependencies. Yang et al. (2017)† utilized pretrained character representations from multitasks. We examine their non-pretrained model performance for fair comparison. Ma et al. (2018) built a bidirectional LSTM model with carefully hyperparameter selection. These methods are orthogonal to and can be integrated into our lattice structure.

As shown in Table 2, the subword lattice LSTM gives significant improvements on all evaluated datasets. In the PKU dataset, our model is slightly behind Xu and Sun (2016) which preprocesses the dataset by replacing all the Chinese idioms, leading the comparison not entirely fair. Our model gives the best performance on MSR and Weibo datasets, which demonstrates that subword encoding can help the lattice LSTM model gives comparable performance to the state-of-the-art word segmentation models.

4.4 Analysis

Lexicon and Embeddings. To distinguish the contribution of subword lexicon and their pretrained embeddings, we conduct a set of experiments by using the same subword lexicon with randomly initialized embeddings[4] on CTB6 data. As shown in Table 3, the contribution of the error reduction by the lexicon is 4.5%. While 6.9% error reduction comes from both lexicon and pretrained embeddings. We can estimate that the contribution of pretraining is $(6.9\% - 4.5\%) = 2.4\%$. This roughly shows that both lexicon and pretraining are useful to lattice LSTM, and the former contributes more than the latter.

OOV Analysis. Table 3 also shows the recall of in-vocabulary ($\mathbf{R}_{IV}$) and out-of-vocabulary ($\mathbf{R}_{OOV}$) words, respectively. As shown in the table, the $\mathbf{R}_{OOV}$ can be largely improved with the lattice structure (2.43% absolute improvement).

Sentence Length. We compare the baseline model with our proposed model on the sentence length distribution in Figure 4. The performance of the baseline has a valley in around 30-character length and decreases when the sentence length over 90. This phenomenon has also been observed in transition-based neural segmentor Yang et al. (2017). While ”LaLSTM+Subword” gives a more stable performance along sentence length.

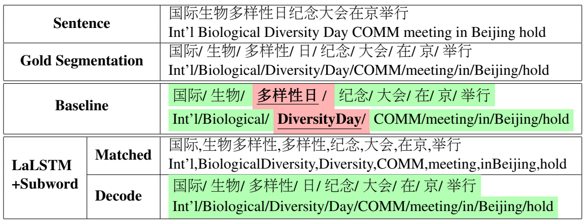
Table 4: Subword coverage.



Sentence		国际生物多样性日纪念大会在京举行 Int'l Biological Diversity Day COMM meeting in Beijing hold
Gold Segmentation		国际/ 生物/ 多样性/ 日/ 纪念/ 大会/ 在/ 京/ 举行 Int'l/Biological/Diversity/Day/COMM/meeting/in/Beijing/hold
Baseline		🟩 国际/ 生物/ 🟥 多样性日 / 🟩 纪念/ 大会/ 在/ 京/ 举行 🟩 Int'l/Biological/ 🟥 **DiversityDay/** 🟩 COMM/meeting/in/Beijing/hold
LaLSTM +Subword	**Matched**	国际,生物多样性,多样性,纪念,大会,在京,举行 Int'l,BiologicalDiversity,Diversity,COMM,meeting,inBeijing,hold
	Decode	🟩 国际/ 生物/ 多样性/ 日/ 纪念/ 大会/ 在/ 京/ 举行 🟩 Int'l/Biological/Diversity/Day/COMM/meeting/in/Beijing/hold

Figure 5: Example.

Subword Coverage in lexicon. Table 4[5] shows the subword coverage rate in four datasets. Subword level coverage is consistently higher than the entity level coverage in Zhang and Yang (2018). We can see that higher subword coverage (PKU/MSR, $> 90\%$) gives better error reduction rate. Weibo dataset gets the minimum improvement due to the low subword coverage.

Case Study. Figure 5 shows an example of CTB6 test dataset. In this example, there are two matched subwords "生物多样性(BiologicalDiversity)" and "多样性(Diversity)" which can guide the segmentor to get the right split of "多样性日(DiversityDay)", which is segmented incorrectly by the baseline.

5 Conclusion

We examined the effectiveness of subwords for neural CWS. Subwords are deduced using BPE, and then integrated into a character-based neural segmentor through lattice LSTM. Results on four benchmarks show that subword brings significant improvements over a character baseline, and our proposed model gives comparable performances to the best systems on all datasets. Our experiments also showed that the matched subwords contribute more than embedding pertaining, which indicates that the lattice LSTM structure with domain lexicons can be useful for cross-domain segmentation training.

Abstract

Cross-domain Chinese Word Segmentation (CWS) remains a challenge despite recent progress in neural-based CWS. The limited amount of annotated data in the target domain has been the key obstacle to a satisfactory performance. In this paper, we propose a semi-supervised word-based approach to improving cross-domain CWS given a baseline segmenter. Particularly, our model only deploys word embeddings trained on raw text in the target domain, discarding complex hand-crafted features and domain-specific dictionaries. Innovative subsampling and negative sampling methods are proposed to derive word embeddings optimized for CWS. We conduct experiments on five datasets in special domains, covering domains in novels, medicine, and patent. Results show that our model can obviously improve cross-domain CWS, especially in the segmentation of domain-specific noun entities. The word F-measure increases by over 3.0% on four datasets, outperforming state-of-the-art semi-supervised and unsupervised cross-domain CWS approaches with a large margin. We make our code and data available on Github.

1 Introduction

Chinese Word Segmentation (CWS) is the first step for many Chinese Natural Language Processing (NLP) tasks (Cai and Zhao, 2016; Zhao et al., 2017). Approaches to CWS could be categorized into two categories: character-based and word-based. The former treats CWS as a sequence labeling problem, labeling each character in a sequence with *B/I/E/S* (*Beginning, Internal, End, Single*) labels (Tseng et al., 2005). Traditional character-based approaches often use Conditional Random Fields (CRF) models to label sequences, with complex hand-crafted discrete features (Peng et al., 2004; Tseng et al., 2005). Unlike character based CWS, word-based CWS operates on a word-level, directly exploiting word-level features. Typical CRF models are replaced with semi-CRF models, in which labels are assigned to subsequences instead of characters (Sarawagi and Cohen, 2005; Liu et al., 2014). Transition-based approaches have also been used to exploit larger feature contexts (Zhang and Clark, 2007). More recent approaches exploit neural networks including Recurrent Neural Networks (RNN) to replace hand-crafted discrete features with real-valued features (Cai and Zhao, 2016; Chen et al., 2015, 2017).

Existing studies have achieved satisfactory results for in-domain CWS, with F-scores over 96.0% in the newspaper domain (Chen et al., 2017). Nevertheless, cross-domain CWS remains a big challenge (Liu et al., 2014; Liu and Zhang, 2012). The main reason is the lack of annotated data in the target domain, which makes supervised approaches less useful. To tackle this problem, some unsupervised and semi-supervised approaches have been proposed. One way is to exploit complex features including character types, lexical features and accessor varieties (Wu et al., 2014), which requires much efforts on feature engineering. Another way is to deploy machine learning algorithms including self-training and model ensemble (Gao and Stephan, 2010; Liu and Zhang, 2012; Qiu and Zhang, 2015), which is time-consuming and inefficient.

In this paper, we investigate a different approach to deploying unsupervised data for cross-domain CWS, in order to completely break free from the reliance on manual annotation, complex feature engineering, and even parametric training to some extent. We propose a Word-Embedding-

Based CWS (WEB-CWS) model, which aims to improve the performance of an existing baseline segmenter in cross-domain CWS. WEB-CWS is a conceptually simple word-based model, using word embeddings, which are expected to carry semantic and syntax information (Mitchell and Lapata, 2010), as the only input of a non-parametric word segmentor. The basic intuition is that embeddings of words within a same context window should be close to each other (Goldberg and Levy, 2014; Mikolov et al., 2013). If a sequence is incorrectly segmented, those incorrectly segmented words are likely to be semantically and syntactically inconsistent with their surrounding words. Consequently, the embedding of an incorrectly segmented word should be far away from embeddings of its surrounding words.

Based on the hypothesis above, we propose WEB-CWS. Word embeddings are first derived with a CWS-oriented word embedding model with innovative subsampling and negative sampling methods. A word-embedding-based decoder is then used for segmentation, with cosine similarities among word embeddings as the metric for probability calculation. WEB-CWS is a *semi-supervised* model, because it only uses word embeddings trained on raw text in the target domain, which is first automatically segmented by the baseline segmenter. The model is also *cross-domain* in the sense that it can improve the performance of the baseline segmenter, when the source text for training the baseline segmenter and the target text to be segmented are in different domains.

The main contributions of this paper include:

- To our knowledge, we are the first to directly use word embeddings for CWS, without any neural structures, which makes our model conceptually simpler and run faster.
- We have proposed novel sampling methods to make the embeddings optimized for CWS, which has never been used for embedding training.
- Our model can be used on top of any existing CWS models to improve their performances, without the need to re-train those models with annotated domain specific data.
- On four datasets in different special domains, our model improves the word F-measure by more than 3.0%, compared with the state-of-the-art baseline segmenter. We release our code and data on Github[1].

2 Related Work

Our work is related with existing research on word-based CWS, cross-domain CWS, and embedding-based CWS.

2.1 Word-Based CWS

Instead of labeling a sequence character-wise, word-based CWS tries to pick the most probable segmentation of a sequence. Zhang and Clark (2007) design a statistical method for word-based CWS, extracting word-level features directly from segmented text. The perceptron algorithm (Collins, 2002) is used for training and beam-search is used for decoding. Cai and Zhao (2016) use Gated Combination Neural Networks and LSTM to present both character sequences and partially segmented word sequences, combining word scores and link scores for segmentation. Our work is in line with their work in directly using word information for CWS. In contrast, our method is conceptually simpler by directly using word embeddings. In addition, our work aims at domain-adaptation, rather than training from scratch.

2.2 Cross-Domain CWS

Supervised, semi-supervised and unsupervised approaches have been proposed for domain adaptation for CWS. Chen et al. (2017) use an Adversarial Network to learn shared knowledge for different segmentation criteria and domains. This approach requires annotated data in the target domain.

However, one challenge for cross-domain CWS is the lack of such annotated data. Liu and Zhang (2012) propose an unsupervised model, in which they use features derived from character clustering, together with a self-training algorithm to jointly model CWS and POS-tagging. This approach is highly time-consuming (Qiu and Zhang, 2015). Another challenge is the segmentation of domain-specific noun entities. In a task of segmenting Chinese novels, Qiu and Zhang (2015) design a double-propagation algorithm with complex feature templates to iteratively extract noun entities and their context, to improve segmentation

---

[1] https://github.com/vatile/CWS-NAACL2019

performance. This approach still relies heavily on feature templates. Similarly, our model does not require any annotated target data. In contrast to their work, our model is efficient and feature-free.

2.3 CWS Using Embeddings

There are CWS models deploying embeddings. Ma and Hinrichs (2015) and Deng and Sun (2018) propose embedding matching CWS models, in which embeddings of characters in a sequence are compared with high dimensional representations of CWS-specific actions (e.g., separation and combination) or CWS-specific labels (e.g., *B/M/E/S*). Then each character is labeled according to the similarity between its embedding and the high dimensional representation.

Particularly, Zhou et al. (2017) propose to use character embeddings trained on a word-based context to improve the performance of existing neural CWS models, which is similar to our approach in terms of making use of CWS-oriented word embeddings derived with automatically segmented raw corpus. However, in their work, when doing cross-domain CWS, word embeddings are fed into the baseline neural model trained on a large annotated general corpus, with annotated special domain data as the development set. In our model, on the contrary, word embeddings are used directly for CWS with a non-parametric decoder, which does not require to re-construct the baseline model, and annotation is not required at all for the special domain data.

3 Word-Embedding-Based CWS

The overall architecture of our method is shown in Figure 1. Given a baseline segmenter and a target domain raw corpus T, we obtain an automatically segmented corpus $T^{'}$ by applying the baseline segmenter to the target corpus. We then execute our CWS-oriented word embedding model (Section 3.1) on $T^{'}$ to derive a set of word embeddings E. In addition, all tokens from $T^{'}$ are collected as a target domain dictionary D. Finally, E and D are used to re-segment T with our word-embedding-based segmenter (Section 3.2).

3.1 CWS-Oriented Word Embedding Model

We use a CWS-oriented model modified from the Skip-gram model (Mikolov et al., 2013) to derive word embeddings. A typical Skip-gram model using negative sampling tries to maximize the following objective (Mikolov et al., 2013):

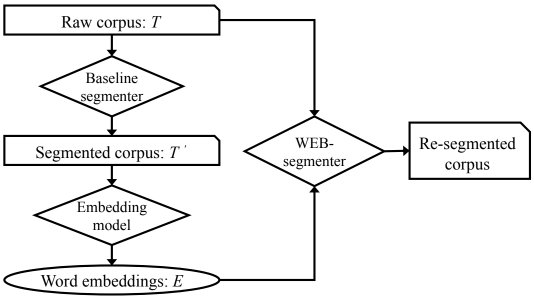

Figure 1: The pipeline of WEB-CWS.

$$\sum_{(w,c)\in P} \log \sigma(v_w \cdot v_c^{\top}) + \sum_{(w,c^{'})\in N} \log \sigma(-v_w \cdot v_{c^{'}}^{\top}) \tag{1}$$

with P being the set of positive samples (w, c) consisting of a target word w and a context word c, N being the set of negative samples $(w, c^{'})$ consisting of a target word w and a word $c^{'}$ drawn randomly from a noise distribution $P_n(w)$, v_w being the word embedding of w, and σ being the sigmoid activation function.

Subsampling is applied when choosing the target word w to reduce training time and to improve the quality of embeddings of rare words (Mikolov et al., 2013). For a natural language, the frequency distribution of all words is expected to obey Zipf's law: a word's frequency is inversely proportional to its rank in the frequency table (Newman, 2005). This highly biased distribution makes the training of the Skip-gram model inefficient, in that very frequent words can make a large portion of training samples, but their embeddings may not change much after being seen for a certain time (Mikolov et al., 2013). Therefore, a subsampling method is used by Mikolov et al. (2013), with the probability for a word w being sampled as:

$$p_{sub}(w) = min(1, \sqrt{\frac{\epsilon}{f(w)}}) \tag{2}$$

where ϵ is an arbitrarily chosen threshold, and $f(w)$ is the frequency of w.

Since word embeddings in our model are used for segmentation, we cannot directly use the training objective in Mikolov et al. (2013), which is designed for language modeling. To make the training objective more consistent with the goal of CWS, we modify the negative sampling Skip-gram model in various ways, including adding

CWS-oriented negative samples, changing the method for subsampling multi-character words, normalizing the dot product of embeddings, and smoothing the weights of positive and negative samples in training.

3.1.1 Context Negative Sampling

When training a typical Skip-gram model, a target word and a word within its context window are taken together as a positive sample (Mikolov et al., 2013). From the perspective of CWS, it can be perceived as teaching the model how to correctly segment a sequence. From this perspective, we develop a method to generate negative samples from a word's context (i.e., words within the context window), in order to tell the model what the incorrect segmentations of a sequence are.

Given a target word w and its context C, and SL/SR as the sequence of characters on the left/right of w within C, the proposed context negative sampling method generates negative samples in the following way: for any substring $s^{'}$ of SL and SR, if $s^{'}$ is in the dictionary D but not in C, (w, $s^{'}$) will be generated as a negative sample.

3.1.2 In-Word Negative Sampling

Another way to generate negative samples concerning CWS is to split multi-character words and combine its substrings as negative samples. For instance, given a multi-character target word $w = c_1c_2c_3$, supposing that all its substrings are in D, the proposed in-word negative sampling method will then generate the following negative samples: $(c_1, c_2), (c_1, c_3), (c_2, c_3), (c_1c_2, c_3)$ and (c_1, c_2c_3). By doing so, our model is expected to learn not to split those multi-character words when segmenting.

3.1.3 Subsampling Multi-Character Words

In the Chinese language, there are some frequent multi-character words consisting of substrings which are also very frequent words themselves. For example, the Chinese word 'dànshì (but)' can be decomposed into two words 'dàn (but)' and 'shì (be)'. Due to the nature of the Skip-gram model, embeddings of frequent words are relatively close to each other since they co-occur with other words more frequently. This nature makes our model inclined to split such multi-character words when segmenting. Although the in-word negative sampling method proposed above is expected to prevent our model from incorrectly splitting multi-character words, we still want our model to pay more attention to the segmentation of such words. As a result, for subsampling, we will not discard a multi-character word w if:

$$p_{sub}(w) < \frac{\mu}{N} \sum_{w_{sub} \in S \cap D} p_{sub}(w_{sub}) \tag{3}$$

where S is the set of substrings of w, and N is the size of all $w_{sub} \in S \cap D$, which is smoothed by a threshold μ (which is empirically set to 0.5 in our model). By doing so, we can keep those multi-character words whose substrings are more frequent words themselves. Our model is thus expected to learn better how to segment such words through samples generated with in-word negative sampling.

3.1.4 Dot Product Normalization

In the original Skip-gram model, the dot product of embeddings of two words is directly used as the input for the sigmoid layer (Mikolov et al., 2013). To make word embeddings derived from the CWS-oriented word embedding model more consistent with the metric used for segmentation as described in Section 3.2.2, we modify the training objective described in Equation (1) as follows:

$$\sum_{(w,c) \in P} \log \sigma(||v_w \cdot v_c^{\top}||) + \sum_{(w,c^{'}) \in N} \log \sigma(-||v_w \cdot v_{c^{'}}^{\top}||) \tag{4}$$

3.1.5 Smoothing Class Weights

For any target word, when training the CWS-oriented word embedding model, only one positive sample but many negative samples are generated. To balance the influence of positive and negative samples, a different weight is assigned to each class as follows:

$$class\_weight = \begin{cases} 1.0 & , positive \\ (\frac{N_{pos}}{N_{neg}} + \eta)/(1 + \eta) & , negative \end{cases} \tag{5}$$

where N_{pos} and N_{pos} are the amount of positive and negative samples respectively, and η is a smooth factor. The smooth factor can prevent the weight of negative samples being too low when negative samples are much more than positive samples.

3.2 Word-Embedding-Based Segmentater

In WEB-CWS, we formalize the process of segmenting a sequence as a problem of hypotheses-based Viterbi decoding (Forney, 1973): given a sequence, generating segmentation hypotheses character-wise from the first to the last character, and then searching for the optimal path according to the predefined metric of probability.

3.2.1 Hypothesis Generation

Given a sentence consisting of n characters $S =< c_0 > c_1c_2...c_n < c_{n+1} >$ (c_0 and c_{n+1} are markers of the beginning/end of a sentence), we generate segmentation hypotheses character-wise from c_0 to c_{n+1}. At each time step t, a hypothesis h_t is defined as:

$$h_t = \begin{cases} SEG_t : [w_{0\{c_0\}} w_{1\{c_1...c_g\}} ... w_{m\{c_j...c_k\}}] \\ BUF_t : [c_{k+1}...c_t] \\ M_t = m + 1 \end{cases} \tag{6}$$

which includes a partial segmentation container SEG_t, a buffer container BUF_t, and the number of segmented words M_t. In h_t, characters $c_0c_1...c_k$ are segmented into words $w_0w_1...w_m$ stored in SEG_t; characters $c_{k+1}..c_t$ remain unsegmented and are stored in BUF_t. For the initial hypothesis h_0 and the final hypothesis h_{n+1}, the buffer container will be empty.

Given a character c_{t+1} and a hypothesis h_t, h_{t+1} can be generated in two ways, by either appending c_{t+1} to BUF_t ($t \neq n$), or first moving the sequence in BUF_t into SEG_t as a new word, and then appending c_{t+1} to BUF_t ($t \neq n$). In the former case:

$$h_{t+1} = \begin{cases} SEG_t : [w_{0\{c_0\}} ... w_{m\{c_j...c_k\}}] \\ BUF_t : [c_{k+1}...c_t c_{t+1}] \\ M_t = m + 1 \end{cases} \tag{7}$$

In the latter case:

$$h_{t+1} = \begin{cases} SEG_t = w_{0\{c_0\}} ... w_{m\{c_j...c_k\}} w_{m+1\{c_{k+1}...c_t\}} \\ BUF_t = c_{t+1} \\ M_t = m + 2 \end{cases} \tag{8}$$

Particularly, when generating the hypothesis for c_{n+1} (the end of sentence marker), the sequence in BUF_n has to be moved into SEG_n, and c_{n+1} also needs to be moved into SEG_n as a new word.

If a word w is not in the dictionary D, we cannot get its embedding. As a result, any hypothesis containing w in the segmentation container will be discarded. Moreover, to reduce search space, once the size of the sequence in a buffer container reaches a threshold m (i.e., the maximum word length), this sequence will be moved into the segmentation container when generating hypotheses at the next time step.

3.2.2 Probability Calculation

The log probability of a hypothesis h_t is defined as:

$$\log p(h_t) = \begin{cases} 0, & t = 0 \\ \frac{1}{M_t - 1} \log \prod_{i=1}^{M_t - 1} p(w_i | SEG_t, f), & t \neq 0 \end{cases} \tag{9}$$

where f is the window size (e.g., if $f = 2$, $p(w_i|SEG_t, f)$ will be decided by w_{i-1} and w_{i-2}).

In WEB-CWS, we use cosine similarity between embeddings of two words as the metric of probability. Given a hypothesis h_t, $p(w_i|SEG_t, f)$ is calculated as follows:

$$p(w_i|SEG_t, f) = \begin{cases} e^0, & i = 0 \\ e^{\frac{1}{min(f,i)} \sum\limits_{j=1}^{min(f,i)} \cos(v_{w_i}, v_{w_{i-j}})}, & i \neq 0 \end{cases} \tag{10}$$

where $\cos(v_{w_i}, v_{w_{i-j}})$ refers to the cosine similarity between embeddings of w_i and w_{i-j}.

Given a hypothesis h_t, the log probability of h_{t+1} can be dynamically computed as:

$$\begin{aligned} \log p(h_{t+1}) = & \frac{1}{M_{t+1} - 1}((M_t - 1) \log p(h_t) \\ & + \sum_{w_i \in \{SEG_{t+1} - SEG_t\}} \log p(w_i | SEG_{t+1}, f)) \end{aligned} \tag{11}$$

3.2.3 Dynamic Beam-Size and Maximum Word Length

Theoretically, a sequence of length n can have at most 2^{n-1} possible segmentations. By discarding hypotheses containing out-of-vocabulary (OOV) words and setting the maximum word length, the search space can be significantly reduced. The very limited search space makes dynamically deciding the beam-size and the maximum word length possible.

Given an initial beam-size k, at each time step t, the segmenter will only keep at most top k hypothesis sorted by log probabilities in a descending order. Some hypotheses will also be discarded due to OOV words and the maximum word length limit. As a result, it is sometimes possible for a sequence to have no hypothesis at all after some time steps. Once it happens, the segmenter will increase the beam-size by 10 and the maximum word length by 1, and then re-generate hypothesis from the beginning, till at least one hypothesis is generated at the final time step.

Dynamic beam-size and maximum word length ensure that for each sequence, at least one segmentation (the one given by the baseline segmenter) will be generated as the final segmentation result. This mechanism can guarantee the efficiency and reliability of the segmenter at the same time.

3.2.4 Similarity Score Look-up

To improve the decoding speed, we pre-calculate the cosine similarity of all word pairs co-occurring at least once in the automatically segmented corpus, and store them in a file (which only consists of millions of word pairs for a Chinese novel). In doing so, when decoding, for most word pairs, we only need to look up to this file for similarity scores, which can significantly improve the decoding speed. According to later experiments, this look-up strategy can cover about 92% of the similarity calculation needed for decoding.

4 Experiments

We conduct experiments on various datasets in different domains to thoroughly evaluate the performance of our model.

4.1 Experimental Setup

4.1.1 Datasets

We evaluate our model in terms of cross-domain CWS on five datasets, including three Chinese novel datasets (Qiu and Zhang, 2015): DL (*DouLuoDaLu*), FR (*FanRenXiuXianZhuan*) and ZX (*ZhuXian*), and two CWS datasets in special domains (Qiu et al., 2015): DM (dermatology) and PT (patent). We use the standard split for all datasets as they are published. Raw test data is also included for deriving word embeddings.

Statistics of these datasets are shown in Table 1. Since there are no gold segmentation of full novels for three Chinese novel datasets, their statistics are based on the segmentation given by the baseline segmenter.

Dataset	Sentence (K)		Token (K)		Character (K)	
	Full	Eval	Full	Eval	Full	Eval
DL	40	1	1,982	32	2,867	47
FR	148	1	5,004	17	7,126	25
ZX	59	1	2,131	21	3,006	31
DM	32	1	709	17	1,150	30
PT	17	1	556	34	903	57

Table 1: Statistics of full and evaluation datasets.

4.1.2 Pre-Processing

In some studies, pre-processing is applied in order to improve the performance of CWS models, including substituting consecutive digits and English letters, Chinese idioms and long words with unique symbols (Cai and Zhao, 2016; Cai et al., 2017; Chen et al., 2015). However, we do not deploy such techniques for fair comparison, focusing only on the possible improvements brought by word embeddings. The only pre-processing adopted in our model is to first split a sentence with a set of pre-defined delimiters: characters that are not Chinese characters, English letters or digits. Those fragments of a sentence are then fed into the segmenter, and a complete segmented sentence is returned by reassembling the segmented fragments and delimiters in the original order.

4.1.3 Hyperparameters

Hyperparameters used in our WEB-CWS model are explained and their values are displayed in Table 2. All hyperparameters are tuned on a small excerpt of ZX, which consists of 300 sentences (Qiu and Zhang, 2015). It is worth noting that, according to Mikolov et al. (2013), for each positive sample, the optimal number of negative samples drawn from a noise distribution is usually between 5 to 20. However, in our model, we find that, for each target word, drawing one negative sample from a noise distribution is good enough, which may be caused by the large amount of negative samples generated by context and in-word negative sampling. Also, Mikolov et al. (2013) report that the unigram distribution raised to the 3/4ths power is better than the uniform distribution for negative sampling. But in WEB-CWS, using the uniform distribution leads to better segmentation results.

H-param	Explanation	Value
ϵ	threshold for overall subsampling	10^{-5}
μ	threshold for multi-character word subsampling	0.5
P_n	noise distribution for general negative sampling	uniform
n	number of general negative samples per word	1
d	dimension of word embeddings	100
η	smoothing factor for class weights	0.2
f	window size	4
m	initial maximum word length	5
k	initial beam-size	10
e	number of epochs in Skip-gram training	1

Table 2: Hyperparameters used in WEB-CWS.

4.1.4 Evaluation

For consistency, all segmentation results are automatically calculated with the script provided in the SIGHAN Bakeoff (Emerson, 2005) and are reported as word F-measures.

4.2 Baseline Segmenter

Two state-of-the-art CWS models trained on a People's Daily corpus in 2000 January are tested. One is a joint word segmentation and POS-tagging model (Zhang and Clark, 2010), and the other is a word-based neural CWS model (Cai et al., 2017). When training both models, default settings are used, except that the maximum word length in Cai et al.'s model is set to 5, which is in line with the setting of WEB-CWS.

On the evaluation set of PKU (Emerson, 2005), both models yield comparable results, but on the evaluation set of DL, Zhang and Clark's model (F-measure = 0.905) performs better than Cai et al.'s model (F-measure = 0.849). It is very possible that Zhang and Clark's model can handle cross-domain CWS more effectively. As a result, we choose Zhang and Clark's model as the baseline segmenter for following experiments.

5 Results

Results in Table 3 show that our WEB-CWS model can obviously improve CWS on four datasets in special domains, including DL, FR, ZX and DM, with an increase of over 3.0% in F-measure. Those four datasets are all in domains (novel and dermatology) which are very different from that of the baseline segmenter (newspaper). This result suggests that WEB-CWS can effectively improve cross-domain CWS.

However, on another dataset in the special domain PT, the improvement is not significant. There are two possible reasons for this result. First, the size of PT is the smallest among all datasets, which may make the quality of word embeddings unsatisfactory. Second, the PT dataset contains a huge amount of decimal points (e.g., '3.14'), percentage signs (e.g., '28%'), hyphens (e.g., 'pMIV-Pnlp') and very long English strings (e.g., 'agctgagtcg'), which are all cases that cannot be handled by WEB-CWS without corresponding preprocessing techniques.

5.1 Comparison with State-of-the-Art Models

We also compare WEB-CWS with two state-of-the-art semi-supervised and unsupervised cross-domain CWS models by Qiu and Zhang (2015) and Liu and Zhang (2012), both of which use the same baseline model proposed by Zhang and Clark (2010) as used in our model. We adopt the method of combining character clustering and self-training in Liu and Zhang (2012) with datasets in our experiments. Results of the model in Qiu and Zhang (2015) are directly copied from the corresponding paper.

Results in Table 3 show that WEB-CWS outperforms these two state-of-the-art models with a large margin in terms of F-measure. Particularly, on the DM dataset, Liu and Zhang's model only achieves a relatively low F-score improvement rate (1.8%), which is likely to be caused by the large difference between the source and target domains. This result suggests that WEB-CWS is more robust to domain dissimilarity compared with self-training.

5.2 Run Time for Decoding

We test the run time for our decoder on a 3.5 GHz Intel Core i7 CPU. On all five test sets, the average decoding speed is 20.3 tokens per millisecond, when the initial beam-size is set to 10. In the work of Zhou et al. (2017), the decoding speed of their model is 14.7 tokens per millisecond for greedy segmentation. However, these results cannot be compared directly since they are produced on different machines. Our similarity look-up strategy is proved to be efficient in improving the decoding speed.

6 Analysis and Discussion

In order to assess the effect of negative sampling and subsampling methods, we conduct a series of

Dataset	Baseline (%)	WEB-CWS (%)	IR_WEB (%)	IR_Qiu&Zhang (%)	IR_Liu&Zhang (%)
DL	90.5	**93.5**	**+3.3**	+1.6	+2.1
FR	85.9	**89.6**	**+4.3**	+2.9	+2.5
ZX	86.8	**89.6**	**+3.2**	+2.2	+2.4
DM	77.9	**82.2**	**+5.5**	-	+1.8
PT	84.6	**85.1**	**+0.6**	-	+0.2

Table 3: F-measures of the baseline segmenter and WEB-CWS on datasets in special domains, and F-measure improvement rates (IR) of WEB-CWS, Qiu and Zhang (2015) and Liu and Zhang (2012).

Model	DL (%)	FR (%)	DM (%)
Baseline	90.5	85.9	77.9
WEB-basic	76.2	72.2	66.6
WEB + c_n	92.7	89.3	75.8
WEB + w_n	93.0	89.5	76.2
WEB + c_w_n	93.3	89.2	79.7
WEB + c_w_n + m_s	**93.5**	**89.6**	**82.2**

Table 4: F-measures of WEB-CWS with different subsampling and negative sampling methods.

Word	Meaning	Pre_base (%)	Pre_WEB (%)
点头	nod	0.0	**84.6**
兽武魂	**beast warrior spirit**	18.2	**100.0**
糖皮质激素	**glucocorticoid**	3.8	**76.9**
蛮胡子	**person name**	28.2	**97.4**
虚天鼎	**person name**	25.7	**94.3**
一对一	one on one	33.3	**100.0**
见于	to be seen in	34.5	**100.0**
鸡冠蛇	**cockscomb snake**	8.7	**73.9**
皮损	**skin lesions**	28.6	**92.9**
宁荣荣	**person name**	34.9	**98.8**

Table 5: Ten most improved words in terms of segmentation precision. Pre_base: segmentation precision by the baseline segmenter. Pre_WEB: segmentation precision by WEB-CWS.

ablation experiments. A detailed analysis is presented to understand in what way WEB-CWS can improve cross-domain CWS. All experiments and analyses in this section are carried out on three datasets with most significant improvements in F-measure: DL, FR and DM.

6.1 Ablation Experiments

In ablation experiments, we study the influence of two CWS-oriented negative sampling and multi-character words subsampling. Results in Table 4 show that WEB-CWS using word embeddings derived with the basic Skip-gram model ('*basic*') performs obviously worse than the baseline segmenter. When CWS-oriented negative sampling is applied alone, either context ('*c_n*') or in-word ('*w_n*') negative sampling, the performance of WEB-CWS is obviously better than or similar to that of the baseline segmenter. When both CWS-oriented negative sampling methods are applied together ('*c_w_n*'), WEB-CWS is ensured to obviously outperform the baseline segmenter. Also, when multi-character subsampling ('*m_s*') is applied, the performance of WEB-CWS can further improve a little.

6.2 Improvements in Noun Entity Segmentation

To see which words are incorrectly segmented by the baseline segmenter but correctly by WEB-CWS, all words occurring at least ten times in the three datasets are sorted in a descending order, by improvements in terms of segmentation precision. Table 5 displays the ten most improved words. As shown in Table 5, among the ten most improved words, seven words are domain-specific noun entities, including person names, disease names and chemical compound names. For some noun entities (e.g., *glucocorticoid*), even if the baseline segmenter can rarely segment them correctly, WEB-CWS can still find the correct segmentation in most cases. This result suggests that WEB-CWS is especially effective in segmenting domain-specific noun entities.

7 Conclusion

We have proposed WEB-CWS, a semi-supervised model that can be used to effectively improve cross-domain CWS. Our model only requires a baseline segmenter and a raw corpus in the target domain, deploying only word embeddings for CWS. WEB-CWS obviously improves the performance of the state-of-the-art baseline segmenter on four datasets in special domains, especially in segmenting domain-specific noun entities.

Abstract

Character-level models of tokens have been shown to be effective at dealing with within-token noise and out-of-vocabulary words. However, they often still rely on correct token boundaries. In this paper, we propose to eliminate the need for tokenizers with an end-to-end character-level semi-Markov conditional random field. It uses neural networks for its character and segment representations. We demonstrate its effectiveness in multilingual settings and when token boundaries are noisy: It matches state-of-the-art part-of-speech taggers for various languages and significantly outperforms them on a noisy English version of a benchmark dataset. Our code and the noisy dataset are publicly available at `http://cistern.cis.lmu.de/semiCRF`.

1 Introduction

Recently, character-based neural networks (NNs) gained popularity for different tasks, ranging from text classification (Zhang et al., 2015) and language modeling (Kim et al., 2016) to machine translation (Luong and Manning, 2016). Character-level models are attractive since they can effectively model morphological variants of words and build representations even for unknown words, suffering less from out-of-vocabulary problems (Pinter et al., 2017).

However, most character-level models still rely on tokenization and use characters only for creating more robust token representations (Santos and Zadrozny, 2014; Lample et al., 2016; Ma and Hovy, 2016; Plank et al., 2016). This leads to high performance on well-formatted text or text with misspellings (Yu et al., 2017; Sakaguchi et al., 2017) but ties the performance to the quality of the tokenizer. While humans are very robust to noise caused by insertion of spaces (e.g., “car nival”) or deletion of spaces (“deeplearning”), this can cause severe underperformance of machine learning models. Similar challenges arise for languages with difficult tokenization, such as Chinese or Vietnamese. For text with difficult or noisy tokenization, more robust models are needed.

In order to address this challenge, we propose a model that does not require any tokenization. It is based on semi-Markov conditional random fields (semi-CRFs) (Sarawagi and Cohen, 2005) which jointly learn to segment (tokenize) and label the input (e.g., characters). To represent the character segments, we compare different NN approaches.

In our experiments, we address part-of-speech (POS) tagging. However, our model is generally applicable to other sequence-tagging tasks as well since it does not require any task-specific hand-crafted features. Our model achieves state-of-the-art results on the Universal Dependencies dataset (Nivre et al., 2015). To demonstrate its effectiveness, we evaluate it not only on English but also on languages with inherently difficult tokenization, namely Chinese, Japanese and Vietnamese. We further analyze the robustness of our model against difficult tokenization by randomly corrupting the tokenization of the English dataset. Our model significantly outperforms state-of-the-art token-based models in this analysis.

Our contributions are: 1) We present a truly end-to-end character-level sequence tagger that does not rely on any tokenization and achieves state-of-the-art results across languages. 2) We show its robustness against noise caused by corrupted tokenization, further establishing the importance of character-level models as a promising research direction. 3) For future research, our code and the noisy version of the dataset are publicly available at `http://cistern.cis.lmu.de/semiCRF`.

2 Model

This section describes our model which is also depicted in Figure 1.

2.1 Character-based Input Representation

The input to our model is the raw character sequence. We convert each character to a one-hot representation. Out-of-vocabulary characters are represented with a zero vector. Our vocabulary does not include the space character since there is no part-of-speech label for it. Instead, our model represents space as two "space features" (lowest level in Figure 1): two binary dimensions indicate whether the previous or next character is a space. Then, a linear transformation is applied to the extended one-hot encoding to produce a character embedding. The character embeddings are fed into a bidirectonal LSTM (biLSTM) (Hochreiter and Schmidhuber, 1997) that computes context-aware representations. These representations form the input to the segment-level feature extractor.

2.2 Semi-Markov CRF

Our model partitions a sequence of characters $x = \{x_1, \dots, x_T\}$ of length T, into (token-like) segments $s = \{s_1, \dots, s_{|s|}\}$ with $s_j = \langle a_j, d_j, y_j \rangle$ where a_j is the starting position of the j^{th} segment, d_j is its length and y_j is its label. Thus, it assigns the same label y_j to the whole segment s_j. The sum of the lengths of the segments equals the number of non-space characters: $\sum_{j=1}^{|s|} d_j = T$.[1]

The semi-CRF defines the conditional distribution of the input segmentations as:

$$p(s|x) = \frac{1}{Z(x)} \exp\left(\sum_{j=1}^{|s|} F(s_j, x) + A(y_{j-1}, y_j)\right)$$

$$Z(x) = \sum_{s' \in S} \exp\left(\sum_{j=1}^{|s'|} F(s'_j, x) + A(y'_{j-1}, y'_j)\right)$$

where $F(s_j, x)$ is the score for segment s_j (including its label y_j), and $A(y_{t-1}, y_t)$ is the transition score of the labels of two adjacent segments. Thus, $p(s|x)$ jointly models the segmentation and label assignment. For the normalization term $Z(x)$, we sum over the set of all possible segmentations S.

The score $F(s_j, x)$ is computed as:

$$F(s_j, x) = \mathbf{w}_{y_j}^{\top} f(s_j, x) + b_{y_j}$$

where $W = (\mathbf{w}_1, \dots, \mathbf{w}_{|Y|})^{\top} \in \mathbb{R}^{|Y| \times D}$ and $b = (b_1, \dots, b_{|Y|})^{\top} \in \mathbb{R}^{|Y|}$ are trained parameters, $f(s_j, x) \in \mathbb{R}^D$ is the feature representation of the labeled segment s_j, $|Y|$ is the number of output classes and D is the length of the segment representation.

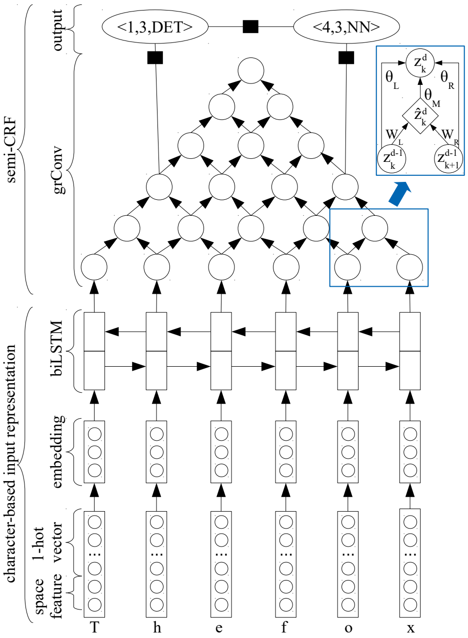

Figure 1: Overview of our model. Illustration of gating for grConv taken from (Zhuo et al., 2016).

For training and decoding, we use the semi-Markov analogies of the forward and Viterbi algorithm, respectively (Sarawagi and Cohen, 2005). In order to avoid numerical instability, all computations are performed in log-space.

2.2.1 Segment-level Features

Sarawagi and Cohen (2005) and Yang and Cardie (2012) compute segment-level features by handcrafted rules. Recent work learns the features automatically with NNs (Kong et al., 2015; Zhuo et al., 2016). This avoids the manual design of new features for new languages/tasks. We adopt ***Gated Recursive Convolutional Neural Networks* (grConv)** (Cho et al., 2014; Zhuo et al., 2016) since they allow to hierarchically combine features for segments. We argue that this is especially useful for compositionality in language. An example is the word "airport" which can be composed of the segments "air" and "port".

GrConv constructs features by recursively combining adjacent segment representations in a pyramid shape way (see Figure 1). The d^{th} level of the pyramid consists of all representations for segments of length d. The first level holds the char-

---

[1] For efficiency, we define a maximum segment length L: $d_j < L, 1 \leq j \leq |s|$. L is a hyperparameter. We choose it based on the observed segment lengths in the training set.

acter representations from our biLSTM. The representation $z_k^{(d)} \in \mathbb{R}^D$, stored in the k^{th} node of layer d, is computed as follows:

$$z_k^{(d)} = \theta_L \circ z_k^{(d-1)} + \theta_R \circ z_{k+1}^{(d-1)} + \theta_M \circ \hat{z_k}^{(d)}$$

$$\text{with } \hat{z_k}^{(d)} = g(W_L z_k^{(d-1)} + W_R z_{k+1}^{(d-1)} + b_w)$$

where $W_L, W_R \in \mathbb{R}^{D \times D}$ and $b_w \in \mathbb{R}^D$ are globally shared parameters, θ_L, θ_M and θ_R are gates, g is a non-linearity and $\circ$ denotes element-wise multiplication. The gates are illustrated in the blue box of Figure 1 and described in (Zhuo et al., 2016).

3 Experiments and Analysis

Our implementation is in PyTorch (Paszke et al., 2017). Hyperparameters are tuned on the development set. We use mini-batch gradient descent with a batch size of 20 and Adam (Kingma and Ba, 2014) as the optimizer. The learning rate is 1e-3, the coefficients for computing running averages of the gradient and its square are 0.9 and 0.999, respectively. A term of 1e-8 is added to the denominator for numerical stability. We use character embeddings of size 60 and three stacked biLSTM layers with 100 hidden units for each direction. For the semi-CRF, we set the maximum segment length to $L = 23$ as tokens of bigger length are rarely seen in the training sets. To avoid overfitting, we apply dropout with a probability of 0.25 on each layer including the input. For input dropout, we randomly replace a character embedding with a zero vector, similar to Gillick et al. (2016). This avoids overfitting to local character patterns. Moreover, we employ early stopping on the development set with a minimum of 20 training epochs. We run our experiments on a gpu which speeds up the training compared to multiple cpu cores considerably. We assume that it especially benefits from parallelizing the computation of each level of the grConv pyramid.

3.1 Multilingual Experiments on Clean Data

Data and Evaluation. To compare our model to state-of-the-art character-based POS taggers, we evaluate its accuracy on the English part of the Universal Dependencies (UD) v1.2 dataset (Nivre et al., 2015). For multilingual experiments, we use the English (EN), Chinese (ZH), Japanese (JA) and Vietnamese (VI) part of UD v2.0[2] (Nivre and Željko Agic, 2017), using the splits, training and evaluation rules from the CoNNL 2017 shared task (Zeman et al., 2017). In particular, we calculate joint tokenization and UPOS (universal POS) F_1 scores.

Model	$\vec{w}$	$\vec{c}$
MarMot	**94.36**	-
bilstm-aux	92.10	91.62
CNN Tagger	92.64	93.76
Our	-	**94.27**
Our without space feature	-	93.35
Our with SRNN	-	93.86

Table 1: POS tag accuracy on UD v1.2 (EN). '-' denotes that the model does not use this input.

Baselines for UD v1.2. We compare our model to two character-based models that are state of the art on UD v1.2: **bilstm-aux** (Plank et al., 2016) and **CNN Tagger** (Yu et al., 2017). We also compare to a state-of-the-art word-based CRF model **MarMot**[3] (Müller and Schütze, 2015).

Results on English (UD v1.2). Table 1 provides our results on UD v1.2, categorizing the models into token-level ($\vec{w}$) and character-only models ($\vec{c}$). While most pure character-level models cannot ensure consistent labels for each character of a token, our semi-CRF outputs correct segments in most cases (tokenization F_1 is 98.69%, see Table 4), and ensures a single label for all characters of a segment. Our model achieves the best results among all character-level models and comparable results to the word-level model MarMot.

In addition, we assess the impact of two components of our model: the space feature (see Section 2.1) and grConv (see Section 2.2.1). Table 1 shows that the performance of our model decreases when ablating the space feature, confirming that information about spaces plays a valuable role for English. To evaluate the effectiveness of grConv for segment representations, we replace it with a ***Segmental Recurrent Neural Network (SRNN)*** (Kong et al., 2015).[4] SRNN uses dynamic programming and biLSTMs to create segment representations. Its performance is slightly worse compared to grConv (last row of Table 1). We attribute

---

[2] UD v1.2 does not provide data for JA, VI, ZH.

[3] `http://cistern.cis.lmu.de/marmot/`

[4] In an initial experiment, we also replaced it with a simpler method that creates a segment representation by subtracting the character biLSTM hidden state of the segment start from the hidden state of the segment end. This is one of the segment-level features employed, for instance, by Ye and Ling (2018). However, this approach did not lead to promising results in our case. We assume that more sophisticated methods like grConv or SRNN are needed in this setup.

	UDPipe 1.2		Stanford		FBAML		TRL		IMS		Our	
	Tokens	POS	Tokens	POS	Tokens	POS	Tokens	POS	Tokens	POS	Tokens	POS
EN	**99.03**	93.50	98.67	**95.11**	98.98	94.09	94.31	82.41	98.67	93.29	98.79	93.45
JA	90.97	88.19	89.68	88.14	93.32	91.04	**98.59**	**98.45**	91.68	89.07	93.86	91.34
VI	84.26	75.29	82.47	75.28	83.80	75.84	85.41	74.53	86.67	**77.88**	**88.06**	77.67
ZH	89.55	83.47	88.91	85.26	**94.57**	**88.36**	83.64	71.31	92.81	86.33	93.82	88.15
Avg	90.95	85.11	89.93	85.95	92.67	87.33	90.49	81.68	92.46	86.64	**93.66**	**87.65**

Table 2: Tokenization and joint token-POS F_1 on UD v2.0. Best scores are in bold, second-best are underlined.

this to the different way of feature creation: While grConv hierarchically combines context-enhanced n-grams, SRNN constructs segments in a sequential order. The latter may be less suited for compositional segments like "airport".

Baselines for UD v2.0. We compare to the top performing models for EN, JA, VI, ZH from the CoNLL 2017 shared task: UDPipe 1.2 (Straka and Straková, 2017), Stanford (Dozat et al., 2017), FBAML (Qian and Liu, 2017), TRL (Kanayama et al., 2017), and IMS (Björkelund et al., 2017).

Multilingual Results (UD v2.0). Table 2 provides our results. While for each language another shared task system performs best, our system performs consistently well across languages (best or second-best except for EN), leading to the best average scores for both tokenization and POS tagging. Moreover, it matches the state of the art for Chinese (ZH) and Vietnamese (VI), two languages with very different characteristics in tokenization.

3.2 Analysis on Noisy Data

To further investigate the robustness of our model, we conduct experiments with different levels of corrupted tokenization in English. We argue that this could also give us insights into why it performs well on languages with difficult tokenization, e.g., on Chinese which omits spaces between tokens, or on Vietnamese which has spaces inside tokens, after each syllable. Note that we do not apply input dropout for these experiments, since the corrupt tokenization already acts as a regularizer.

Data. We are not aware of a POS tagging dataset with corrupted tokenization. Thus, we create one based on UD v1.2 (EN). For each token, we either delete the space after it with probability $P = p_d$ or insert a space between two characters with $P = p_i$: *"The fox chased the rabbit"* → *"The f ox cha sed therabbit"*. We vary p_d and p_i to construct three datasets with different noise levels (LOW, MID, HIGH, see Table 3). We note that there are more sophisticated ways of creating "errors" in text. An example is Kasewa et al. (2018) who generate grammatical errors. We leave the investigation of other methods for generating tokenization errors to future work.

level	p_d	# deletions	p_i	# insertions
LOW	0.1	15198	0.05	26497
MID	0.3	39361	0.11	40474
HIGH	0.6	65387	0.33	68209

Table 3: Noisy dataset statistics (three different noise levels).

Labeling. As mentioned before, we either delete the space after a token with probability p_d or insert a space between two of its characters with probability p_i. We assign the label from the original token to every sub-token created by space insertion. For space deletions, we randomly choose one of the two original labels for training and evaluate against the union of them. Figure 2 shows an example.

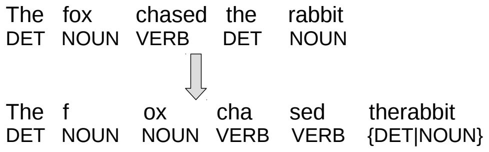

Figure 2: Example of label assignment.

Baseline. We compare our joint model to a traditional pipeline of tokenizer (UDpipe 1.0)[5] and token-level POS tagger (MarMot).[6] We re-train MarMot on the corrupted datasets.

Evaluation. We evaluate the models on the noisy datasets using two different metrics: (i) tokenization and joint token-POS F_1 as in Table 2, and (ii) a relaxed variant of POS tag accuracies. With the latter, we can assess the performance of MarMot without penalizing it for potential errors of UDpipe. For calculating the relaxed accuracy, we count the POS tag of a gold token as correct if MarMot predicts the tag for any subpart of it.

---

[6] In contrast to Table 1 where we use gold tokens for MarMot.

	UDpipe+MarMot			Our		
	F_1		acc	F_1		acc
Noise	Tokens	POS	POS	Tokens	POS	POS
CLEAN	98.48	92.75	93.48	**98.69**	**93.48**	**94.27**
LOW	70.90	65.56	83.73	**96.08**	**90.51**	**92.80**
MID	20.62	19.07	58.53	**95.28**	**89.80**	**92.54**
HIGH	20.47	18.05	56.96	**95.45**	**89.82**	**92.14**

Table 4: Tokenization F_1, joint token-POS F_1 and (relaxed) POS tag accuracies on noisy version of UD v1.2.

We provide more details on the relaxed evaluation (description, examples and implementation) in our code repository. Note that we apply the relaxed evaluation only to UDpipe+MarMot but not to our model. The output of our model is directly evaluated against the gold labels of the clean corpus.

Results. The performance of our model decreases only slightly when increasing the noise level while the performance of UDpipe+MarMot drops significantly (Table 4). This confirms that our model is robust against noise from tokenization. Note that most other character-based models would suffer from the same performance drop as MarMot since they rely on tokenized inputs.

Discussion. The results in Table 4 show that our model can reliably recover token boundaries, even in noisy scenarios. This also explains its strong performance across languages: It can handle different languages, independent of whether the language merges tokens without whitespaces (e.g., Chinese) or separates tokens with whitespaces into syllables (e.g., Vietnamese).

4 Related Work

Character-based POS Tagging. Most work uses characters only to build more robust token representations but still relies on external tokenizers (Santos and Zadrozny, 2014; Lample et al., 2016; Plank et al., 2016; Dozat et al., 2017; Liu et al., 2017). In contrast, our model jointly learns segmentation and POS tagging. Gillick et al. (2016) do not rely on tokenization either but in contrast to their greedy decoder, our model optimizes the whole output sequence and is able to revise local decisions (Lafferty et al., 2001). For processing characters, LSTMs (Lample et al., 2016; Plank et al., 2016; Dozat et al., 2017) or CNNs (Ma and Hovy, 2016; Yu et al., 2017) are used. Our model combines biLSTMs and grConv to model both the context of characters (LSTM) and the compositionality of language (grConv).

Joint Segmentation and POS Tagging. The top performing models of EN, JA, VI and ZH use a pipeline of tokenizer and word-based POS tagger but do not treat both tasks jointly (Björkelund et al., 2017; Dozat et al., 2017; Kanayama et al., 2017; Qian and Liu, 2017). Especially for Chinese, there is a lot of work on joint word segmentation and POS tagging, e.g., (Zhang and Clark, 2008; Sun, 2011; Hatori et al., 2012; Zheng et al., 2013; Kong et al., 2015; Cai and Zhao, 2016; Chen et al., 2017; Shao et al., 2017), of which some use CRFs to predict one POS tag per character. However, this is hard to transfer to languages like English and Vietnamese where single characters are less informative and tokens are much longer, resulting in a larger combinatory label space. Thus, we choose a semi-Markov formalization to directly model segments.

Semi-Markov CRFs for Sequence Tagging. Zhuo et al. (2016) and Ye and Ling (2018) apply semi-CRFs to word-level inputs for named entity recognition. In contrast, we model character-based POS tagging. Thus, the expected length of our character segments is considerably larger than the expected length of word-based segments for NER. Kong et al. (2015) build SRNNs that we use as a baseline. In contrast to their 0-order model, we train a 1-order semi-CRF to model dependencies between segment labels.

5 Conclusion

We presented an end-to-end model for character-based part-of-speech tagging that uses semi-Markov conditional random fields to jointly segment and label a sequence of characters. Input representations and segment representations are trained parameters learned in end-to-end training by the neural network part of the model. The model achieves state-of-the-art results on two benchmark datasets across several typologically diverse languages. By corrupting the tokenization of the dataset, we show the robustness of our model, explaining its good performance on languages with difficult tokenization.

Shrinking Japanese Morphological Analyzers With Neural Networks and Semi-supervised Learning

Arseny Tolmachev **Daisuke Kawahara** **Sadao Kurohashi**

Kyoto University, Graduate School of Informatics

Abstract

For languages without natural word boundaries, like Japanese and Chinese, word segmentation is a prerequisite for downstream analysis. For Japanese, segmentation is often done jointly with part of speech tagging, and this process is usually referred to as morphological analysis. Morphological analyzers are trained on data hand-annotated with segmentation boundaries and part of speech tags. A segmentation dictionary or character n-gram information is also provided as additional inputs to the model. Incorporating this extra information makes models large. Modern neural morphological analyzers can consume gigabytes of memory. We propose a compact alternative to these cumbersome approaches which do not rely on any externally provided n-gram or word representations. The model uses only unigram character embeddings, encodes them using either stacked bi-LSTM or a self-attention network, and independently infers both segmentation and part of speech information. The model is trained in an end-to-end and semi-supervised fashion, on labels produced by a state-of-the-art analyzer. We demonstrate that the proposed technique rivals performance of a previous dictionary-based state-of-the-art approach and can even surpass it when training with the combination of human-annotated and automatically-annotated data. Our model itself is significantly smaller than the dictionary-based one: it uses less than 15 megabytes of space.

1 Introduction

Languages with a continuous script, like Japanese and Chinese, do not have natural word boundaries in most cases. Natural language processing for such languages requires to perform some variation of word segmentation.

Although some NLP applications, like neural machine translation, started to use unsupervised segmentation methods (Kudo and Richardson, 2018), resulting segmentation often has decisions which are not natural to humans. Supervised segmentation based on a human-defined standard is essential for applications which are designed for interaction on a word-level granularity, for example, full-text search. Segmentation is commonly done jointly with part of speech (**POS**) tagging and usually referred to as Morphological Analysis.

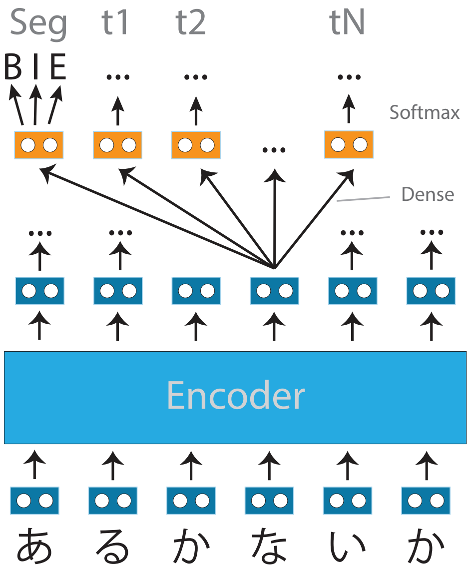

Figure 1: Proposed model. We encode character unigram embeddings into shared representations for each character. The shared representation is projected into a tag-specific representations from which we independently infer segmentation and per-character tags.

Modern Japanese Morphological Analyzers (**MA**) are very accurate, having a >99 segmentation tokenwise F1 score on news domain and a >98.5 F1 on web domain (Tolmachev et al., 2018). They often use segmentation dictionaries which define possible words. Also, their models are generally large and unwieldy, spanning hundreds of megabytes in case of traditional symbolic feature-based approaches. Neural models with word or n-

Proceedings of NAACL-HLT 2019, pages 2744–2755
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

gram embeddings are even larger, easily reaching gigabytes. This makes it difficult to deploy MA in space-constrained environments such as mobile applications and browsers.

It has been shown that simple or straightforward models can match or outperform complex models when using a large number of training data. For example, a straightforward backoff technique rivals a complicated smoothing technique for language models (Brants et al., 2007). Pretraining a bidirectional language model on a large dataset helps to solve a variety of NLP tasks (Devlin et al., 2018). Our approach is inspired by this line of work.

Contributions We propose a very straightforward fully-neural morphological analyzer which uses *only character unigrams* as its input[1]. Such an analyzer, when trained only on human-annotated *gold* data has low accuracy. However, when trained on a large amount of automatically tagged *silver* data, the analyzer rivals and even outperforms, albeit slightly, the bootstrapping analyzer. We conclude that there is no need for rich input representation. Neural networks learn the information to combine characters into words by themselves when given enough data.

Ignoring explicit dictionary information and rich input representations makes it possible to make analyzers that are highly accurate and very compact at the same time. We also perform ablation experiments which show that the encoder component of such an analyzer is more important than character embeddings.

2 Morphological Analysis Overview

Segmentation is a cornerstone requirement for processing languages with a continuous script, and thus it has been studied for a long time. Most current approaches use either rich feature representation, e.g. character n-grams or their embeddings, or a segmentation dictionary. There exist two main lines of approaches: pointwise and search-based. Pointwise approaches make a segmentation decision for each character, usually based on the information from its surroundings. Search-based approaches look for a maximum scored interpretation in some structure over the input sentence.

Most Japanese analyzers use segmentation dictionaries which define corpus segmentation standards. They usually have rich POS information attached and are human-curated. One focus of segmentation dictionaries is to be consistent: it should be possible to segment a sentence using the dictionary entries only in a single correct way. Such dictionaries are often maintained together with annotated corpora. On the other hand, Chinese-focused systems do not put much focus on dictionaries. Still, almost all aproaches use rich feature templates or additional resources such as pretrained character n-gram or word embeddings, which increase the model size.

Pointwise approaches make a segmentation decision independently for each position. They can be seen as a sequence tagging task. Such approaches are more popular for Chinese.

KyTea (Neubig et al., 2011) is an example of this approach in Japanese. It makes a binary decision for each character: whether to insert a boundary before it or not. It can be seen as sequence tagging with {B, I} tagset. POS tagging is done after inferring segmentation. The decisions are made by feature-based approaches, using characters, character n-grams, character type information, and dictionary information as features. KyTea can use word features obtained from a dictionary. It checks whether the character sequence before and after the current character forms a word from the dictionary. It also checks whether the current word is inside a word.

Neural networks were shown to be useful for Japanese in this paradigm as well (Kitagawa and Komachi, 2017). They use character embeddings, character type embeddings, character n-gram embeddings, and tricks to incorporate dictionary information into the model.

Many studies on Chinese adopt the pointwise approach. Often, the segmentation task is reformulated as sequence tagging (Xue, 2003) with {B, I, E, S} tagset. Peng et al. (2004) showed that CRFs help further in this task. This tactic was followed by many subsequent feature-based approaches (Tseng et al., 2005; Zhao et al., 2006; Zhang et al., 2013), using character n-gram, character type and word features.

Neural networks were applied to this paradigm as well. Zheng et al. (2013) used a feed-forward network on character and categorical features that were shown to be useful for computing a segmentation score from a fixed window. Qi et al. (2014) used a similar architecture. They predicted not only segmentation but POS tags and performed

---

[1] The source code is avaliable at `https://github.com/eiennohito/rakkyo`

named entity recognition as well. The character representation was pretrained on a language modeling task. Shao et al. (2017) used a bidirectional recurrent network with GRU cells followed by a CRF layer for joint segmentation and POS tagging. They used pretrained character n-gram embeddings together with sub-character level information extracted by CNNs as features. Using a dictionary with NN is also popular (Zhang et al., 2018b; Liu et al., 2018).

Search-based approaches induce a structure over a sentence and perform a search over it. A most frequently used structure is a lattice which contains all possible segmentation tokens. The search then finds the highest scoring path through the lattice. Another branch of search-based approaches splits decisions into transitions (starting a new token and appending a character to the token) and searches for the highest scoring chain of transitions. This also can be seen as dynamically constructing a lattice while performing the search in it at the same time.

Lattice-based approaches are popular for the Japanese language. Most of the time, the lattice is based on words which are present in a segmentation dictionary and a rule-based component for handling out-of-dictionary words. Usually, there are no machine-learning components in lattice creation, but the scoring can be machine-learning based. We believe that the availability of high quality consistent morphological analysis dictionaries is the reason for that. Still, the work of Kaji and Kitsuregawa (2013) is a counterexample of a lattice-based approach for Japanese which uses a machine-learning component for creating the lattice.

Traditional lattice-based approaches for Japanese use mostly POS tags or other hidden information accessible from the dictionary to score paths through the lattice. JUMAN (Kurohashi, 1994) is one of the first analyzers, which uses a hidden Markov model with manually-tuned weights for scoring. Lattice path scores are computed using connection weights for each pair of part of speech tags.

Probably the most known and used morphological analyzer for Japanese is MeCab (Kudo et al., 2004), where CRFs were used for learning the scoring. MeCab is very fast: it can analyze almost 50k sentences per second. It also achieves acceptable accuracy, and so the tool is very popular. The speed is realized by precomputing feature weights, but it takes a lot of space when the total number of features gets large. For example, the UniDic model for modern Japanese v2.3.0[2] takes 5.5GB because it uses many feature templates.

There were studies which tried to integrate NN into lattice-based approaches as well. Juman++ (Morita et al., 2015) uses dictionary-based lattice construction with the combination of two models for path scoring: the feature-based linear model using soft-confidence weighted learning (Wang et al., 2016) and a recurrent neural network (Mikolov, 2012). It significantly reduced the number of both segmentation and POS tagging errors. However, it was very slow, being able to analyze only about 15 sentences per second, hence the original version was impractical. The following improvement (Tolmachev et al., 2018) greatly increased analysis speed by doing aggressive beam trimming and performing heavyweight NN evaluation only after lightweight scoring by the linear model.

Direct lattice-based approaches are not very popular for Chinese, but some are lattice-based in spirit. A line of work by Zhang and Clark (2008, 2010) builds the lattice dynamically from partial words, searching paths with a perceptron-based scorer and customized beam search. The dictionary is built dynamically from the training data as frequent word-tag pairs which help the system to prune unlikely POS tags for word candidates.

One more variation on lattice-based approaches for Chinese is the work by Cai and Zhao (2016). In this work, a segmentation dictionary is used to construct a subnetwork, which combines character representations into word representations used for computing sentence-wise segmentation scores. This can be seen as explicitly learning dictionary information by a model. Resulting segmentation is still created from the start to the end by growing words one by one while performing beam search. The follow up (Cai et al., 2017) simplifies that model and shows that greedy search can be enough for estimating segmentation when using neural networks. Still, this line of work does not consider POS tagging.

Transition-based approaches treat input data (most frequently – characters) as input queue and store a current, possibly incomplete, token in a buffer. Models usually infer whether they should create a new token from a character in the input

---

[2] https://unidic.ninjal.ac.jp/

queue or append an input character to the already existing token. Neural models are often used in this paradigm (Ma and Hinrichs, 2015; Zhang et al., 2016; Yang et al., 2017; Ma et al., 2018; Zhang et al., 2018a). Almost all of them use both word and charcter n-gram embeddings. This paradigm was extended to do parsing jointly with MA (Hatori et al., 2012; Kurita et al., 2017).

Semi-supervised approaches to segmentation and POS tagging fall into several categories. The first one uses raw or automatically-annotated data to precompute feature representations and then uses these feature representations for supervised learning. For example, Sun and Xu (2011) and Wang et al. (2011) use data from automatically segmented texts as features. They precomute the features beforehand and train an analyzer afterwards. In addition to that, Zhang et al. (2013) use a variation of smoothing for handling automatic annotation errors. A lot of neural-based methods pretrain word and character n-gram embeddings. Yang et al. (2017) pretrain a part of the model on different data sources, including automatically segmented text, but the model itself is trained only on the gold data.

Another approach is to use heterogeneous data (annotated in incompatible annotation standards). In addition to corpus statistics from a raw corpus, Zhao and Kit (2008) exploit heterogeneous annotations. Li et al. (2015) use corpora with different annotation standards. They combine tags into “bundles” (e.g. [NN, n]) and infer them at the same time while paying attention to ambiguity. Chen et al. (2016) train a classifier that can annotate several standards jointly.

Finally, it is possible to use raw or automatically-annotated data directly. A study (Suzuki and Isozaki, 2008) is an example of a feature-based algorithm which uses raw data. Tri-training (Zhou and Li, 2005) is a generic way to use raw data. They propose to train on automatically analyzed examples where two of three diverse analyzers agree. Søgaard (2010) show that tri-training helps English POS-tagging with SVM and MaxEnt-based approaches. Zhou et al. (2017) use self-training and tri-training for Chinese word segmentation. They, however, also pretrain other features like word-context character embeddings, chracter unigrams and bigrams.

3 Proposed Approach

In order for MA to be practical, it should be not only accurate, but also fast and have relatively compact models. The speed of search-based approaches is dependent on how computationally heavy a weighting function is. Heavyweight models, like neural networks, require a large number of computations, and we think that it will be very difficult to create a practical search-based fully NN morphological analyzer with analysis speed comparable to traditional analyzers.

We do not want to use any explicit information about how to combine characters to form a word, like dictionaries, which takes space and is not trivial to incorporate into a character-based model. We also want our model to be fast, at least comparable with the speed of traditional analyzers. To this end, we follow a pointwise approach and force the neural network to learn the dictionary information from a corpus.

We use a straightforward architecture shown in Figure 1. We embed each character, and then apply an encoder, which produces an encoded representation for each character. Encoded character representations are independently transformed into tag representations. For each tag, the encoded representation is projected with a fully-connected layer with SeLU non-linearity (Klambauer et al., 2017). Finally, we multiply the tag representation by tag-specific embeddings and apply softmax non-linearity to get normalized tag probabilities.

Encoder Architectures We use two architectures for the encoder: a stacked bidirectional recurrent architecture with LSTM cells (Hochreiter and Schmidhuber (1997), **bi-LSTM**) and a Transofrmer-inspired mutihead self-attention network (Vaswani et al. (2017), **SAN**). We concatenate both directions of bi-LSTM outputs before passing them to the next layer without residual connections. We also apply layer normalization (Ba et al., 2016) to the concatenated outputs. We do not use dropout in encoders when using silver data for training.

Data Encoding Our model infers a tag for every input character. While this decision is natural for segmentation, POS tags are not usually tagged in this way.

For segmentation, we adopt {B, I, E} scheme. For POS tagging we broadcast tags to every character which is contained in a token. We use cor-

Figure 3: An example of partial sentence annotation

pora with the JUMAN-based segmentation standard (**Jumandic**), which has 4-layered POS tags: rough POS, fine POS, conjugation type and conjugation form. We treat each tag layer independently in our model, as shown in Figure 2.

We also consider a **partial annotation scheme**, where some tags are unknown. An example of partial sentence annotation is shown in Figure 3. Unknown tags are displayed by "?" symbols. We create partially annotated silver data by marking as unknown all tags which are ambiguous in a top-k analysis result. When computing the training loss, we treat unknown tags as padding: corresponding values are masked out of loss computation.

Loss Following Vaswani et al. (2017), we smooth softmax labels. They use the technique described by Szegedy et al. (2016), which uniformly distributes some small factor ϵ like 0.1 to incorrect labels. However, we do not induce a uniform smoothing. Instead, we want to prevent the model from being overconfident in its decisions without inducing uniformity. We slightly modify the cross-entropy loss as follows.

Remember that softmax probabilities are computed from unnormalized log-probabilities l_i as $q_i = e^{l_i}/Z$, where $Z = \sum_j e^{l_j}$. The cross-entropy loss will be $L = -\sum_i p_i \log q_i$, where p_i are gold probabilities. In our case the vector p is one-hot, meaning that $p_c = 1$ and other values are zero. This gives a sparse cross-entropy $L = -\log q_c = \log Z - l_c$, which is often implemented in deep learning frameworks. It has a minimum when $\log Z$ is equal to l_c, but it makes the model overconfident. Instead, we want to stop when $q_c = 1 - \epsilon$, or in other words $e^{l_c}/Z = 1 - \epsilon$. This gives us our modified loss:

$$L = \max(\log Z - l_c + \log(1 - \epsilon), 0).$$

It can be efficiently implemented using the sparse cross-entropy operation. In our experiments we use $\epsilon = 0.2$.

	Train		Test	
Corpus	Sents	Tokens	Sents	Tokens
KU	37k	930k	1783	46k
Leads	14k	217k	2195	36k

Table 1: Benchmark corpora sizes

Our final loss is a weighted sum of individual tag softmax losses. We use a weight coefficient of 10 for segmentation and 2 for the first POS tag layer.

4 Experiments

We conduct experiments on Japanese morphological analysis. For training we use two data sources. The first is usual human-annotated *gold* training data. The second is *silver* data from the results of automatic analysis. We use Juman++ V2 – the current state-of-the-art analyzer for the JUMAN segmentation standard as the bootstrap analyzer.

We use two gold corpora. The first is the Kyoto University Text Corpus (Kurohashi and Nagao (2003), referred to as **KU**), containing newspaper data. The second is the Kyoto University Web Document Leads Corpus (Hangyo et al. (2012), referred to as **Leads**) which consists of web documents. Corpus statistics are shown in Table 1. We denote models which use gold training data by **G**.

We take raw data to generate our silver annotated data from a crawled web corpus of 9.8B *unique* sentences. We sample 3B sentences randomly from it and analyze them using the Juman++ baseline model. From it we sample 500M sentences, which become our training silver data, prioritizing sentences which contain at least one not very frequent word. We prepare both top-scored (denoted as **T**) and non-ambigous in beam (denoted as **B**) variants of the silver data. Our silver data is in-domain for Leads and out-of-domain for KU.

Baselines We use four baselines: **JUMAN**, **MeCab**, **KyTea** and **Juman++** (V2). For MeCab,

Parameter	bi-LSTM	SAN
Char embedding size	128	128
Tag embedding size	32	32
# Layers	4	6
Hidden Size	128×2	32
# Heads	-	4
Projection Inner Dim	-	512
# Emedding Parameters	2.38M	2.38M
# Total Parameters	3.88M	3.59M

Table 2: Hyperparameters for neural models

KyTea and Juman++ we train a model using the same dictionary and merged training sections of KU and Leads, which is evaluated on each corpus independently.

Neural Models The hyper-parameters of the bi-LSTM-based model are displayed in Table 2. We use all unique characters present in our huge web corpus (18,581) as input. We select sizes of both neural models restricting the total number of parameters to be less than 4M. For optimization we use the Adam optimizer (Kingma and Ba, 2016) with hyperparameters and learning rate scheduling described by Vaswani et al. (2017). We train all models on Nvidia GPUs. On a single GeForce 1080Ti the bi-LSTM model can consume about 4,500 sentences per second and the SAN-based model about 6,500 sentences per second for training. We denote bi-LSTM-based models by **L** and SAN-based models by **S** in experimental results.

Treatment of Gold Data Existing methods are already highly accurate on this task, and it is difficult to perform hyperparameter and architecture selection reliably with a small development set. Because of that, we split our data in an unusual way. Generally, we use the silver data (B or T) as a train set, the human-annotated original training data (G) as a dev set and the original test set as a test set. Our hyperparameter selection decisions were based entirely on this setting. We do not perform additional hyperparameter search for a combination of silver and gold data for training.

The exception is cases when we use *only gold data* for training. For that, we cheat and optimize our hyperparameters, including dropout, which we use only for this setting, on test scores. Nontheless, the best scores on this setting are significantly lower than the worst baseline.

Table 3: Test F1 score comparison on benchmark corpora. Legend: bi-[L]STM, [S]AN, [G]old data, [T]op-only and [B]eam-non-ambigous silver data.

Experimental Results Results of our experiments are shown in Table 3. For each analyzer, we show six values. **Seg** is a tokenwise F1 measure on segmentation. **+P1** requires the 1st layer of POS tags (coarse-grained POS tags) also to match gold data. For the sake of simplicity, we use only POS tags co-located with "B" Seg tags for the evaluation. **+P2** is analogous for the 2nd layer of POS tags. For all results in this table, we train NN-based models for a single epoch, which means *the training procedure sees each silver sentence only once*. We use one gold example for ten silver examples for mixed-data settings, looping over the gold data until the silver data is extinguished.

Training neural models only on gold data quickly results in overfitting which can be seen in L:G and S:G results. These scores are significantly lower than that of our worst baseline: JUMAN.

Models trained on only non-ambiguous silver data (*:B) are comparable to the best baseline on Leads (in-domain), although they cannot reach the accuracy of Juman++ on KU. Using top-only silver data (*:T) further improves accuracy. Both of our models in this setting slightly outperform previous Leads SOTA and have more or less the same accuracy. On KU, the LSTM-based model seems to be slightly better than the SAN-based one. In the context of semi-supervised learning, tri-training emphasizes using data when there exists a disagreement between the analyzers. Instead, we throw

	Size, MB		
Analyzer	Dictionary	Model	Total
JUMAN	288	1	289
MeCab	312	8	320
KyTea:G	-	569	569
KyTea:TG	-	3218	3218
Juman++	157	288	434
bi-LSTM	1	14	15
SAN	1	13	14

Table 4: MA model sizes for Jumandic

away difficult cases for beam-based data, denoising it in a sense, but NN seem to handle that kind of noise relatively well.

Adding the gold data to the silver data (*:BG, *:TG) allows both models to improve their accuracy further. Results on Leads are comparable for both L:TG and S:TG and higher than the previous SOTA, giving segmentation error reduction of 8% in comparison to Juman++. On KU, the LSTM-based models seem to perform better without a significant difference on the TG and BG settings, while still underperforming the Juman++ baseline except +P2 case, where both models are stronger than Juman++.

Pre-training Scenario We also check the fine-tuning approach when we first learn the representations on a large corpus and then refine the model on a gold corpus. S:B→G(a-d) are four such runs of a SAN-based model with different hyperparameters. All four runs are initialized with the same S:B model and trained on the gold data only. We found it difficult to find good hyperparameters for fine-tuning. The models were prone to overfit very fast. Mixing gold and silver data resulted in stable training without hyperparameter search.

Model Sizes We compare the model sizes of analyzers in Table 4. In case of dictionary-based analyzers the dictionary takes most of the space. We count sizes of compiled models for all analyzers. KyTea, as another example of pointwise MA, uses string-based features and treats its features uniformly, hence dictionary size is not applicable to it. A **KyTea:TG** variant that uses additional 2M silver sentences takes almost 6x the space of the original model, reaching 3GB. When using neural networks, on the other hand, it is possible to control model sizes more easily. Moreover, our proposed models take significantly less space while having comparable accuracy.

Analyzer	KU	Leads
KyTea-D:G	98.45	97.04
KyTea-D:T	98.51	98.10
KyTea-D:TG	99.18	98.31
KyTea:G	99.13	97.98
KyTea:TG	99.33	98.42

Table 5: KyTea test Seg F1 comparison. -D models do not use the dictionary. T models use silver data (2M sentences, created like in the main experiment)

Dictionary-based analyzers store other information, like readings and lemma forms, in addition to token surface forms and POS, but removing that information would not make model sizes comparable with NN-based ones. For NN-based analyzers, we count a dictionary as 1 MB because they need a character-to-id mapping to work. However, the list of characters contains non-frequently used characters, some of which could be treated as UNKs without any accuracy loss. We also treat weights as 4-byte floating points, and so it would be possible to further decrease the NN model size, for example by using less precise storage formats.

5 Discussion

Dictionaries Dictionary information is usually added to character-based models either using a binary feature vector (e.g. a dictionary contains a trigram to the left of the decision point) or word embeddings. We believe that a dictionary can be replaced with a large training corpus which includes most of the entries from that dictionary. A neural model with only the unigram character input can solve word segmentation and POS tagging only if it builds some knowledge about the dictionary internally. Our main experimental results (Table 4) show that it seems to be the case and there is no need to model the dictionary explicitly.

Table 5 shows an effect of using dictionaries and silver data on KyTea, an instance of symbolic feature-based analyzer. Models tagged with **T** use additional 2M silver training data analyzed by Juman++. KyTea has better accuracy in settings when it uses the dictionary. The dictionary even helps in the setting with additional silver data. Unfortunately, the model size increases as well, limiting the amount of silver data we can use, and the accuracy cannot rival neural approaches.

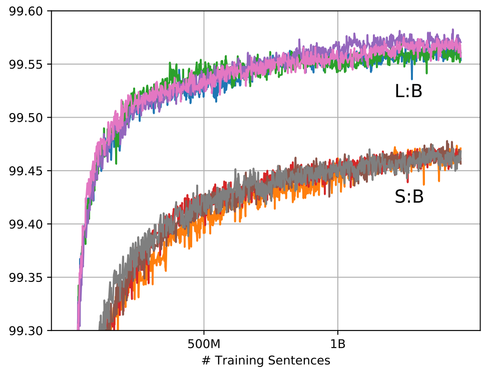

Figure 4: Dev Seg F1 curves for L:B and S:B

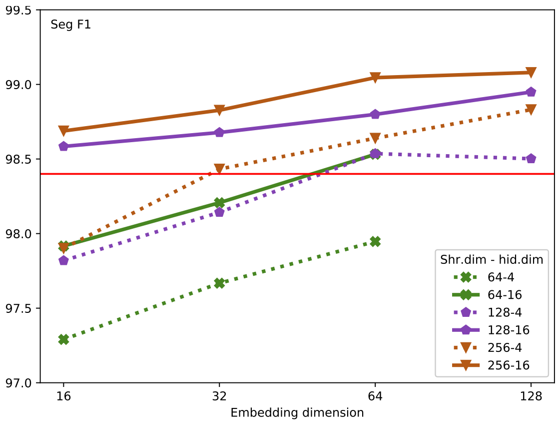

Figure 5: Effect of embedding size on Seg F1

How much data do we need? For our main experiments, we train all models for a single epoch on our silver dataset. Figure 4 shows KU train (our dev set) Seg F1 curves for L:B and S:B for three epochs. We ran each experiment four times with different random seeds. The learning curves become less sloppy when reaching 500M sentences but do not become flat there. The training does not seem to completely converge even after 3 epochs. We still use one full epoch (500M) for our main experiments. The curves are pretty noisy, but it seems that the model is robust with respect to initialization.

SAN Ablation Experiments The proposed MA achieves high accuracy while having very compact models. The inputs do not contain any information on how to combine characters into words and we assume that the model learns it from the data. To get the model size even smaller, we check which model parts contribute more to the resulting analysis accuracy, meaning that they contain the dictionary knowledge.

We perform ablation experiments on the SAN model by varying its hyperparameters and checking how it affects the accuracy of the resulting analyzer. The LSTM model could not converge in this setting. We used 2.5M of silver training data for these experiments.

Figure 5 shows the segmentation F1 score when varying input embedding, shared representation and SAN hidden dimension sizes. JUMAN score, as a lowest acceptable baseline, is shown in red. The embedding size seems to have a lower impact on accuracy than the shared representation and the SAN hidden dimension size. Namely, the (128-16) model with the embedding size of 16 has higher accuracy than the (128-4) model with the embedding size of 128. Accordingly, we believe that the encoder contributes much stronger to learning the dictionary than character embeddings.

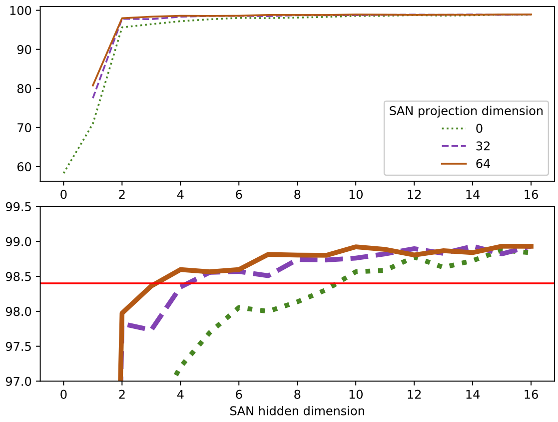

Figure 6: Effect of SAN hidden dimension on Seg F1

One more interesting observation is that the models are still better than JUMAN, while having much less parameters than our base model. We explore more extreme settings of the SAN hidden state, shown in Figure 6. We fix embedding and shared representation dimensions to 128 and vary the SAN hidden and projection dimensions. The lower subgraph is a scale-up version of top graph. The point at SAN hidden size equal to 0 means that we directly use unigram embeddings to predict segmentation without any encoder.

The SAN projection size is consistent with accuracy, especially on smaller SAN hidden sizes. An interesting observation here is that the SAN model seems to work even with hidden dimension of 2. When the hidden dimension size reaches 4, the extremely small model accuracy is higher than the JUMAN baseline. This shows that it is possible to create an extremely small MA with acceptable accuracy.

</table>

Table 6: n-grams with inconsistent POS tags which are also Juman++ errors

Label Uncertainty and Error Analysis Because our neural models infer all tags independently, they can be inconsistent, for example, a word can have different POS tags on different characters. We looked into frequent 3-grams where the central word has inconsistent tags (POS tags are not the same for all characters, or they do not form a correct 4-layered tag). Most of these trigrams occur in ambiguous situations.

We have picked several examples which are actually errors in Juman++ segmentation as well. They are shown in Table 6. In Japanese, words often have several orthographic forms. The most common variant is usage of hiragana (phonetic script) instead of kanji (ideographic characters). Verbs can have different possible endings, e.g. 曲がる and 曲る (magaru – to turn or bend) are two orthographic variants of a single verb. There are also colloquial variants; namely the verb 言う is usually read as いう (iu – to say), but can also be written as ゆう because the pronunciation is close. These phenomena are relatively common in web and user-generated texts, but corpus and segmentation dictionary coverage of them is not very good.

The first two examples contain alternative colloquial spellings of words こういう (ko:iu – such) and すごい (sugoi – awesome). In the first example the system incorrectly recognizes 曲|って (kyoku tte) as 曲って (magatte) – a conjugation of 曲る. The fourth example (a chanto asobitai/ac-chan to asobitai - ah! [I] want to play properly/[I] want to play with ac-chan <person name>) is actually ambiguous and can have two meanings. The second one is more probable though. The fact that frequent words with uncertain POS tags are Juman++ errors as well implies that insufficient gold data causes the uncertainty.

We also compare differences between Juman++ and our models to get an insight on general problems with proposed methods. Neural models make many errors in hiragana words. For example, both neural models make errors in the sentence 弱者|が|とうた|さ|れて (jyakusya ga to:ta sarete - weaklings lose to natural selection). LSTM makes a segmentation mistake (と|うたさ) and SAN does a POS tagging mistake, while Juman++ produces the correct answer. It knows that とうた is a special type of noun that is often followed by されて from POS tags. Hiragana-based spellings of most content words are somewhat rare in Japanese, and NN models do not have enough training data for these spellings. It could be possible to improve the situation by using data augmentation techniques. Another frequent problem is segmentation and tagging of proper nouns. We believe that this problem could be solved by data augmentation, but we leave this as future work.

6 Conclusion and Future Work

We presented a novel way to train small neural models for Japanese Morphological analysis by directly feeding the network a large number of silver training data. Our method achieves new SOTA on web domain when combining the silver data with gold one. This is an empirical evidence that there is no need for feature engineering for neural morphological analysis at all. A neural network can learn implicit dictionary information itself and it does not need to be large. We also show that training by mixing the data together works better than fine-tuning and is more stable.

Our work can be extended in the future in different ways. We will consider how to make the model to recognize new words, which is an important feature for a practical analyzer. Using tri-training also seems to be a natural extension for this work. It is easy to provide diverse models, required for tri-training, by using different types of encoder and varying network parameters. Furthermore, our tagging approach should be universal and work with other tasks like named entity recognition. A method to incorporate tags with a large number of possible values (like readings and lemmas) without introducing embeddings for them, hence keeping the models small, could also be a useful extension.

Abstract

This paper studies the performance of a neural self-attentive parser on transcribed speech. Speech presents parsing challenges that do not appear in written text, such as the lack of punctuation and the presence of speech disfluencies (including filled pauses, repetitions, corrections, etc.). Disfluencies are especially problematic for conventional syntactic parsers, which typically fail to find any EDITED disfluency nodes at all. This motivated the development of special disfluency detection systems, and special mechanisms added to parsers specifically to handle disfluencies. However, we show here that neural parsers can find EDITED disfluency nodes, and the best neural parsers find them with an accuracy surpassing that of specialized disfluency detection systems, thus making these specialized mechanisms unnecessary. This paper also investigates a modified loss function that puts more weight on EDITED nodes. It also describes tree-transformations that simplify the disfluency detection task by providing alternative encodings of disfluencies and syntactic information.

1 Introduction

While a great deal of effort has been expended on parsing written text, parsing speech (either transcribed or ASR output) has received less attention. Parsing speech is important because speech is the easiest and most natural means of communication, it is increasingly used as an input modality in human-computer interactions. Speech presents parsing challenges that do not appear in written text, such as the lack of punctuation and sentence boundaries, speech recognition errors and the presence of speech disfluencies (including filled pauses, repetitions, corrections, etc.) (Kahn et al., 2005). Of the major challenges associated with transcribed speech, we focus here on speech disfluencies, which are frequent in spontaneous speech.

Disfluencies include filled pauses (“um”, “uh”), parenthetical asides (”you know”, ”I mean”), interjections (“well”, ”like”) and partial words (“wou-”, “oper-”). One type of disfluency which is especially problematic for conventional syntactic parsers are speech repairs. Following the analysis of Shriberg (1994), a speech repair consists of three main parts; the *reparandum*, the *interregnum* and the *repair*. As illustrated in the following example, the reparandum *we don’t* is the part of the utterance that is replaced or repaired, the interregnum *uh I mean* (which consists of a filled pause *uh* and a discourse marker *I mean*) is an optional part of the disfluency, and the repair *a lot of states don’t* replaces the reparandum. The fluent version is obtained by removing the reparandum and the interregnum.

$$\overbrace{\textit{We don't}}^{\text{reparandum}}\ \overbrace{\textit{uh I mean}}^{\text{interregnum}}\ \overbrace{\textit{a lot of states don't}}^{\text{repair}}\ \textit{have capital punishment.} \qquad (1)$$

In the Switchboard treebank corpus (Mitchell et al., 1999) the reparanda, filled pauses and discourse markers are dominated by EDITED, INTJ and PRN nodes, respectively (see Figure 1). Of these disfluency nodes, EDITED nodes pose a major problem for conventional syntactic parsers, as the parsers typically fail to find any EDITED nodes at all. Conventional parsers mainly capture tree-structured dependencies between words, while the relation between reparandum and repair is quite different: the repair is often a “rough copy” of the reparandum, using the same or very similar words in roughly the same order (Charniak and Johnson, 2001; Johnson and Charniak, 2004). The “rough copy” dependencies are strong evidence of a disfluency, but conventional syntac-

Proceedings of NAACL-HLT 2019, pages 2756–2765
Minneapolis, Minnesota, June 2 - June 7, 2019.

tic parsers cannot capture them. Moreover, the reparandum and the repair do not form conventional syntactic phrases, as illustrated in Figure 1, which is an additional difficulty when integrating disfluency detection with syntactic parsing. This motivated the development of special disfluency detection systems which find and remove disfluent words from the input prior to parsing (Charniak and Johnson, 2001; Kahn et al., 2005; Lease and Johnson, 2006), and special mechanisms added to parsers specifically to handle disfluencies (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Yoshikawa et al., 2016; Tran et al., 2018).

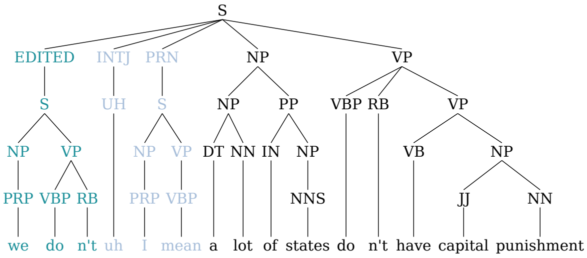

Figure 1: An example parse tree from the Switchboard corpus – *We don't uh I mean a lot of states don't have capital punishment,* where reparandum *We don't*, filled pause *uh* and discourse marker *I mean* are dominated by EDITED, INTJ and PRN nodes.

In this paper, we investigate the performance of a neural self-attentive constituency parser on speech transcripts. We show that an "off-the-shelf" self-attentive parser, unlike conventional parsers, can detect disfluent words with a performance which is competitive to or better than specialized disfluency detection systems. In summary, the main contributions of this paper are:

- We show that the self-attentive constituency parser sets a new state-of-the-art for syntactic parsing of transcribed speech,
- A neural constituency parser can detect EDITED words with an accuracy surpassing that of specialized disfluency detection models,
- We demonstrate that syntactic information helps the neural syntactic parsing detect disfluent words more accurately,
- Replacing the constituent-based representation of disfluencies with a word-based representation of disfluencies improves the detection of disfluent words,
- Modifying the training loss function to put more weight on EDITED nodes during training also improves disfluency detection.

2 Related Work

Speech recognition errors, unknown sentence boundaries and disfluencies are three major problems addressed by previous work on parsing speech. In this work, we focus on the problem of disfluency detection in parsing human-transcribed speech, where we assume that sentence boundaries are given and there are no word recognition errors. This section reviews approaches that add special mechanisms to parsers to handle disfluencies as well as specialized disfluency detection models.

2.1 Joint Parsing and Disfluency Detection

Many speech parsers adopt a transition-based dependency approach to (i) find the relationship between head words and words modifying the heads, and (ii) detect and remove disfluent words and their dependencies from the sentence. Transition-based parsers can be augmented with new parse actions to specifically handle disfluent words (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Yoshikawa et al., 2016; Wu et al., 2015). A classifier is trained to choose between the standard and the augmented parse actions at each time step. Using pattern-match features in the classifier significantly improves disfluency detection (Honnibal and Johnson, 2014). This reflects the fact that parsing based models use pattern-matching to capture the "rough copy" dependencies that are characteristic of speech disfluencies.

Speech parsing models usually use lexical features. One recent approach (Tran et al., 2018) integrates lexical and prosodic cues in an encoder-decoder constituency parser. Prosodic cues result in very small performance gain in both parsing and disfluency detection. Augmenting the parser with a location-aware attention mechanism is specially useful for detecting disfluencies (Tran et al., 2018).

In general, parsing models are poor at detecting disfluencies, mainly due to "rough copy" dependencies in disfluent sentences, which are difficult for conventional parsers to detect.

2.2 Specialized Disfluency Detection Models

Disfluency detection models often use a sequence tagging technique to assign a single label to each word of a sequence. Previous work shows that LSTMs and CNNs operating on words alone are poor at disfluency detection (Zayats et al., 2016; Wang et al., 2016; Jamshid Lou et al., 2018). The performance of state-of-the-art disfluency detection models depends heavily on hand-crafted pattern match features, which are specifically designed to find "rough copies". One recent paper (Jamshid Lou et al., 2018) augments a CNN model with a new kind of layer called an *auto-correlational layer* to capture "rough copy" dependencies. The model compares the input vectors of words within a window to find identical or similar words. The addition of the auto-correlational layer to a "vanilla" CNN significantly improves the performance over the baseline CNN model. The results are competitive to models using complex hand-crafted features or external information sources, indicating that the auto-correlation model learns "rough copies".

One recent paper (Wang et al., 2018) introduces a semi-supervised approach to disfluency detection. Their self-attentive model is the current state-of-the-art result in disfluency detection. The common factor in Wang et al. (2018) and the approach presented here is the self-attentive transformer architecture, which suggests that this architecture is capable of detecting disfluencies with very high accuracy. The work we present goes beyond the work of Wang et al. (2018) in also studying the impact of jointly predicting syntactic structure and disfluencies (so it can be understood as a kind of multi-task learning). We also investigate the impact of different ways of representing disfluency information in the context of a syntactic parsing task.

3 Neural Constituency Parser

We use the self-attentive constituency parser introduced by Kitaev and Klein (2018) and train it on the Switchboard corpus of transcribed speech (we describe the training and evaluation conditions in more detail in Section 4). The self-attentive parser achieves state-of-the-art performance on WSJ data, which is why we selected it as the best "off-the-shelf" parsing model. The constituency parser uses a self-attentive transformer (Vaswani et al., 2017) as an encoder and a chart-based parser (Stern et al., 2017) as a decoder, as reviewed in the following sections.

3.1 Self-Attentive Encoder

The encoder of a transformer is a stack of n identical layers, each consists of two stacked sublayers: a multi-head attention mechanism, and a point-wise fully connected network. The inputs to the encoder first flow through a self-attention sublayer, which helps the encoder attends to several words in the sentence as it encodes a specific word. Because the model lacks recurrent layers, this sublayer is the only mechanism which propagates information between positions in the sentence. The self-attention maps the input to three vectors called query, key and value and defines an attention function as mapping a query and a set of key-value pairs to an output vector. The output is computed as a weighted sum of the values, where the weight assigned to each value is computed by a compatibility function of the query with the corresponding key. Each self-attention sublayer has several attention heads, where each head has its own query, key and value weight matrices. The multi-head attention allows the model to jointly attend to information from several different positions. The outputs of the self-attention layer are fed to a feed-forward neural network, which is applied to each position independently. For further detail, see Vaswani et al. (2017).

We believe that the self-attention mechanism is especially useful for detecting disfluencies in a sentence. In pilot experiments we found that similar LSTM-based parsers, such as the AllenNLP parser (Gardner et al., 2018), were much worse at disfluency detection than the self-attentive parser. As shown in Figure 1, the "rough copy" similarity between the repair and the reparandum is a strong indicator of disfluency. "Rough copies" involve same or very similar words in roughly same word order; for example, in the Switchboard training data, over 60% of the words in the reparandum are exact copies of the words in the repair. Using the multi-head self-attention mechanism the model can presumably learn to focus on "rough copies" when detecting a reparandum.

3.2 Tree Score and Chart Parse Decoder

A chart-based parser scores a tree as a sum of potentials on its labeled constituent spans as follows:

$$s(T) = \sum_{(i,j,l)\in T} s(i,j,l) \qquad (2)$$

where $s(i, j, l)$ is a score of a constituent located between string positions i and j with label l. At test time, a modified CYK algorithm is used to find the highest scoring parse tree for a given sentence.

$$\hat{T} = \underset{T}{\operatorname{argmax}}\, s(T) \tag{3}$$

Given the gold tagged tree $T^\star$, we train the model by minimizing a hinge loss:

$$max\left(0, \max_{T \neq T^\star}[s(T) + \triangle(T, T^\star)] - s(T^\star)\right) \tag{4}$$

where $\triangle$ is the Hamming loss on labeled spans. For further detail, see Kitaev and Klein (2018) and Stern et al. (2017).

3.3 External Embedding and Edited Loss

Peters et al. (2018) have recently introduced a new approach for word representation called Embeddings from Language Models (ELMo) which has achieved state-of-the-art results in various NLP tasks. These embeddings are produced by a LSTM language model (LM) which inputs words and characters and generates a vector representation for each word of the sentence. The ELMo output is a concatenation of both the forward and backward LM hidden states. We found that using external ELMo embedding as the only lexical representation used by the model leads to the highest EDITED word f-score. Following Kitaev and Klein (2018), we use a trainable weight matrix to project the ELMo pretrained weights of 1024 dimension to a 512-dimensional content representation. We tried different combinations of input including predicted POS tags, character LSTM and word embeddings with ELMo, but the result was either worse or not significantly better than when using ELMo alone.

The sole change we made to the self-attentive parser was to modify the loss function, so it puts more weight onto EDITED nodes. We show below that this improves the model's ability to recover EDITED nodes. We modify the tree scoring in 2 as follows:

$$s(T) = \sum_{(i,j,l) \in T} w_l\, s(i, j, l) \tag{5}$$

where w_l depends on the label l. We only used two different values of w_l here, one for EDITED nodes and one for all other node labels. We treat these as hyperparameters, and tune them to maximize EDITED nodes f-score (this is $\mathrm{F(S_E)}$) in Section 4.1 below).

4 Experiments

We evaluate the self-attentive parser on the Penn Treebank-3 Switchboard corpus (Mitchell et al., 1999). Following Charniak and Johnson (2001), we split the Switchboard corpus into training, dev and test sets as follows: training data consists of the sw[23]∗.mrg files, dev data consists of the sw4[5-9]∗.mrg files and test data consists of the sw4[0-1]∗.mrg files. Except as explicitly noted below, we remove all partial words (words tagged XX and words ending in "-") and punctuation from data, as they are not available in realistic ASR applications (Johnson and Charniak, 2004).

4.1 Evaluation Metrics

We evaluate the self-attentive parser in terms of parsing accuracy and disfluency detection performance. We report *precision* (P), *recall* (R) and *f-score* (F) for both *constituent spans* (S) and *word positions* (W), treating each word position as labeled by all the constituents that contain that word. We also consider subsets of constituent spans and word positions; specifically: (i) $\mathrm{S_E}$, the set of constituent spans labeled EDITED, (ii) $\mathrm{W_E}$, the set of word positions dominated by one or more EDITED nodes, and (iii) $\mathrm{W_{EIP}}$, the set of word positions dominated by one or more EDITED, INTJ or PRN nodes.

We demonstrate the evaluation metrics with an example here. Consider the gold and predicted parse trees illustrated in Figure 2. The constituency trees are viewed as a set of labeled spans over the words of the sentence, where constituent spans are pairs of string positions. As explained earlier, we ignore punctuation and partial words when calculating evaluation scores. To calculate fscore for a span, i.e., F(S), the gold, predicted and correct labeled spans are counted. In this case, the number of predicted, gold and correctly predicted spans is 13, 14 and 12.

Since a parse tree with EDITED nodes identifies certain words as EDITED, we can evaluate how accurately a parser classifies words as EDITED (i.e. $\mathrm{F(W_E)}$). Continuing with the example in Figure 2, the number of predicted, gold and correctly predicted EDITED words is 1, 3 and 1.

Similarly, we can also measure how well the parser can identify all disfluency words, i.e., the words dominated by EDITED, INTJ or PRN nodes. Continuing with the example in Figure 2, the number of predicted, gold and correctly pre-

Figure 2: An example gold and predicted parse tree.

dicted EDITED, INTJ and PRN words is 4, 6, 4.

4.2 Model Training

We use randomized search (Bergstra and Bengio, 2012) to tune the optimization and architecture parameters of the model on the dev set. We optimize the model for its performance on parsing EDITED nodes F(S_E). The hyperparameters include dimensionality of the model, learning rate, edited loss weight, dropout, number of layers and heads as shown in Table 1. All other hyperparameters not mentioned here are the same as in Kitaev and Klein (2018).

Configuration	**Parser**
hidden label dim	340
model dim	2048
non-EDITED label weight	0.7
EDITED label weight	2
learning rate	0.0006
learning rate warmup steps	110
step decay factor	0.52
num heads	7
num layers	4
attention dropout	0.27
relu dropout	0.09
residual dropout	0.26
elmo dropout	0.57
tag embedding dropout	0.35
word embedding dropout	0.2

Table 1: Hyperparameter setting for the self-attentive constituency parser.

4.3 Edited Loss

Our best dev model (see Table 1) uses an edited loss that puts more weight on EDITED nodes and less weight on non-EDITED nodes. To explore the effect of edited loss, we retrained the best model with an equally weighted loss. The results in Table 2 indicate that differential weighting improves parsing EDITED nodes as well as EDITED word detection. It also rebalances the precision vs. recall trade-off and slightly increases overall parsing accuracy F(S).

	equal weight	**different weight**
P(S_E)	83.0	83.3
R(S_E)	91.6	91.4
F(S_E)	87.1	87.2
F(S)	92.8	93
F(W_E)	86.9	87.5

Table 2: Parsing precision P(S_E), recall R(S_E) and f-score F(S_E) of EDITED nodes, parsing f-score F(S) and EDITED word f-score F(W_E) on the Switchboard dev set for the equally and differentially weighted loss.

4.4 Modifying the Training Data

We investigate the effect of modifying the training data on the performance of the parser.

4.4.1 Simplified Tree Structures

We use different tree-transformations to explore the effect of different amounts of and encodings of disfluencies and syntactic information on the performance of the model.

- **Baseline:** Parse trees as they appear in the Switchboard corpus. A sample is shown in Figure 3.

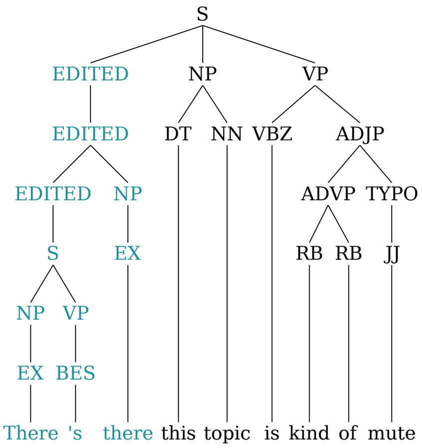

Figure 3: Baseline parse trees as they appear in the Switchboard corpus

- **Transformation PosDisfl:** Pushing disfluency nodes (i.e. EDITED, INTJ and PRN) down to POS tags, as shown in Figure 4.

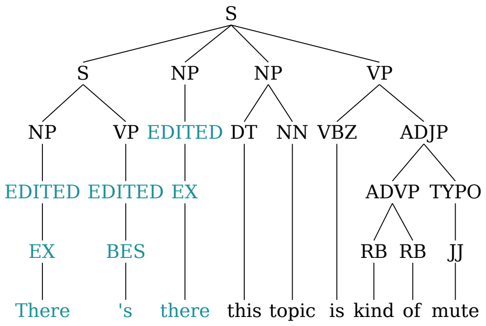

Figure 4: Transformation PosDisfl, where disfluency nodes are pushed down to POS tags.

- **Transformation NoSyntax:** Deleting all non-disfluency nodes, as shown in Figure 5.

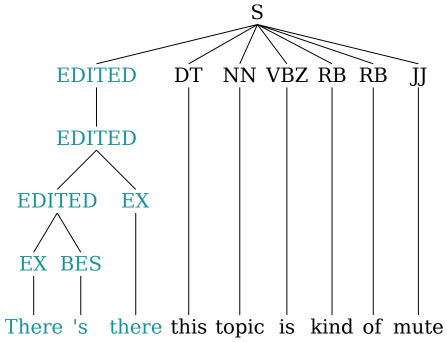

Figure 5: Transformation NoSyntax, where all non-disfluency nodes are deleted.

- **Transformation PosDisfl+NoSyntax:** Pushing disfluency nodes down to POS tags and deleting all non-disfluency nodes, as shown in Figure 6.

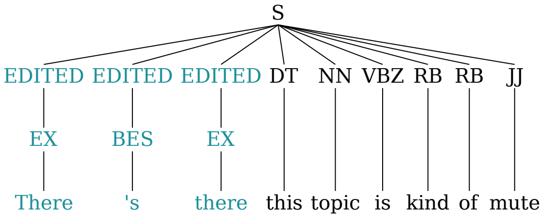

Figure 6: Transformation PosDisfl+NoSyntax, where disfluency nodes are pushed down to POS tags and all non-disfluency nodes are deleted.

- **Transformation TopDisfl:** Deleting all disfluency nodes but the top ones, as shown in Figure 7.

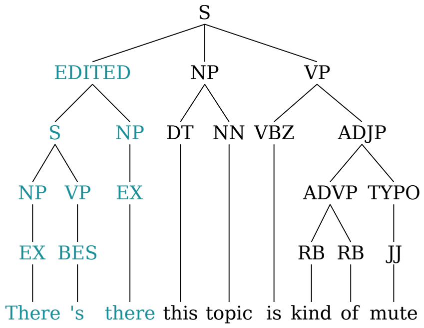

Figure 7: Transformation TopDisfl, where all disfluency nodes but the top ones are deleted.

- **Transformation TopDisfl+NoSyntax:** Deleting all nodes but the top-most disfluency nodes, as shown in Figure 8.

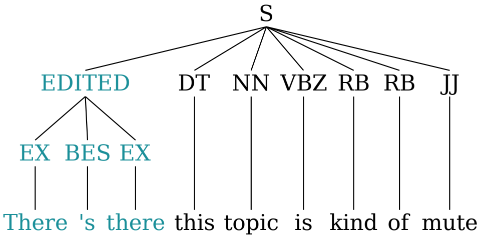

Figure 8: Transformation TopDisfl+NoSyntax, where all nodes but the top-most disfluency nodes are deleted.

We report the performance of the self-attentive parser in terms of EDITED word f-score and disfluency word f-score in Table 3. Since the transformations change the tree shapes, it is not meaningful to compare their parsing f-scores. As illustrated in Table 3, pushing disfluency nodes down to POS tags (i.e. *Transformation PosDisfl*) increases precision about 2%, resulting in 1% improvement in word f-score $F(W_E)$. It also improves $F(W_{EIP})$ by 0.4%. In general, the model can take advantage of the simplified encoding of disfluency nodes (see *Transformations PosDisfl* and *TopDisfl*). Moreover, deleting all but the top-most disfluency nodes as in *Transformation TopDisfl+NoSyntax* significantly drops precision (about 20%), resulting in more than 13% decrease in EDITED word f-score. It also hurts detecting all types of disfluency (more than 7% decrease in $F(W_{EIP})$). In general, removing syntactic structure dramatically degrades the performance of the model in terms of $F(W_E)$ and $F(W_{EIP})$, as shown in *Transformations NoSyntax*, *PosDisfl+NoSyntax* and *TopDisfl+NoSyntax*. This indicates that syntactic information is important for detecting disfluencies.

Setting	**$P(W_E)$**	**$R(W_E)$**	**$F(W_E)$**	**$F(W_{EIP})$**
Baseline	81.6	94.2	87.5	94.0
PosDisfl	83.7	94.2	**88.7**	**94.4**
NoSyntax	73.0	95.0	82.5	92.3
PosDisfl+NoSyntax	73.4	93.4	82.2	91.6
TopDisfl	81.9	94.3	87.7	93.8
TopDisfl+NoSyntax	61.3	93.1	74.0	86.7

Table 3: EDITED word precision $P(W_E)$, recall $R(W_E)$ and f-score $F(W_E)$ as well as EDITED, INTJ and PRN word f-score $F(W_{EIP})$ on the Switchboard dev set for different encodings of disfluency nodes in data. The best f-scores are shown in bold.

4.4.2 Punctuation and Partial words

As mentioned before, speech recognition models generally do not produce punctuation and partial words in their outputs. Thus, prior work has removed them from the data to make the evaluation more realistic. However, it is interesting to see what information partial words and punctuation convey about syntactic structure in general and disfluencies in particular, so we did an experiment to investigate the effect of including these in the training and test data. We use the best hyperparameter configuration on the Switchboard dev set and retrain the model on two versions of the data: (i) with partial words and (ii) with punctuation and partial words. As shown in Table 4, keeping punctuation and partial words in the training data increases EDITED word f-score by about 4%, indicating that punctuation and partial words greatly help disfluency detection. Punctuation leads to more gain in disfluency detection than partial words. Punctuation also improves the word f-score for all types of disfluencies by more than 1%.

Setting	**$F(W_E)$**	**$F(W_{EIP})$**
without punctuation & partial words	88.7	94.4
with partial words	89.7	94.4
with punctuations & partial words	92.2	95.5

Table 4: EDITED word $F(W_E)$ and EDITED, INTJ and PRN word f-score $F(W_{EIP})$ on the Switchboard dev set for three versions of the training data.

5 Results

We selected our best model based on the dev set results (including differentially weighted loss) and compared the results achieved for the *Tree Transformation PosDisfl* and *No Tree Transformation* on the test set with previous work. Although most previous work has used the Switchboard corpus, it is sometimes difficult to compare systems directly due to different scoring metrics and differences in experimental setup, such as the use of partial words, punctuation, prosodic cues and so on. Since some studies report their results using partial words and/or punctuation, we divide prior work according to the setting they used and report the results of the self-attentive parser on the test data for each setting.

Table 5 shows the test performance of the self-attentive constituency parser against previous parsing models of speech transcripts. The self-attentive parser outperforms all previous models in parsing accuracy. It has also better performance than Kahn et al. (2005) and Tran et al. (2018), who used acoustic/prosodic cues from speech waveform as well as the words in the transcript.

Parsing Model	**F(S)**
without partial words	
self-attentive parser (PDT)	92.4
self-attentive parser (NT)	**92.7**
partial words:	
Hale et al. (2006)	71.1
Kahn et al. (2005)	86.6
Tran et al. (2018)	88.5
self-attentive parser (NT)	92.3
self-attentive parser (PDT)	**92.6**

Table 5: Parse f-score F(S) for all constituent spans on the Switchboard test set with and without partial words. NT = No Transformation and PDT = PosDisfl Transformation.

We also compare the performance of the self-attentive parser with state-of-the-art disfluency detection methods in terms of EDITED word f-score. As shown in Table 6, the self-attentive parser (with *PosDisfl Transformation*) achieves a new state-of-the-art for detecting EDITED words. Its performance is competitive with specialized disfluency detection models that directly optimize for disfluency detection. Using partial words increases edited word f-score for *No Transformation* mode by 0.1% and for *PosDisfl Transformation* mode by 0.6%, which is not surprising as the presence of partial words is strongly correlated with the presence of a disfluency.

It is interesting to compare the self-attentive parser with the ACNN model presented in Jamshid Lou et al. (2018). They introduce a new ACNN layer which is able to learn the "rough copy" dependencies between words, for which previous models heavily relied on hand-crafted pattern-matching features. "Rough copies" are a strong indicator of disfluencies that can help the model detect reparanda (i.e. EDITED nodes). That the self-attentive parser is better than the ACNN model (Jamshid Lou et al., 2018) in detecting disfluencies may indicate that the self-attention mechanism can learn "rough copy" dependencies.

6 Conclusion and Future Work

This paper shows that using an "off-the-shelf" constituency parser achieves a new state-of-the-art in parsing transcribed speech. The self-attentive parser is effective in detecting disfluent words as it outperforms specialized disfluency detection models, suggesting that it is feasible to use standard neural architectures to perform disfluency detection as part of some other task, rather than requiring a separate disfluency detection pre-processing step. We also show that removing syntactic information hurts word f-score. That is, performing syntactic parsing and disfluency detection as a multi-task training objective yields higher disfluency detection accuracy than performing disfluency detection in isolation. Modifying encoding by indicating disfluencies at the word level leads to further improvements in disfluency detection.

In future work we hope to integrate syntactic parsing more closely with automatic speech recognition. A first step is to develop parsing models that parse ASR output, rather than speech transcripts. It may also be possible to more directly integrate an attention-based syntactic parser with a speech recogniser, perhaps trained in an end-to-end fashion.

Abstract

Conversational context information, higher-level knowledge that spans across sentences, can help to recognize a long conversation. However, existing speech recognition models are typically built at a sentence level, and thus it may not capture important conversational context information. The recent progress in end-to-end speech recognition enables integrating context with other available information (e.g., acoustic, linguistic resources) and directly recognizing words from speech. In this work, we present a direct acoustic-to-word, end-to-end speech recognition model capable of utilizing the conversational context to better process long conversations. We evaluate our proposed approach on the Switchboard conversational speech corpus and show that our system outperforms a standard end-to-end speech recognition system.

1 Introduction

Many real-world speech recognition applications, including teleconferencing, and AI assistants, require recognizing and understand long conversations. In a long conversation, there exists the tendency of semantically related words or phrases reoccur across sentences, or there exists topical coherence. Thus, such conversational context information, higher-level knowledge that spans across sentences, provides important information that can improve speech recognition. However, the long conversations typically split into short sentence-level audios to make building speech recognition models computationally feasible in current state-of-the-art recognition systems (Xiong et al., 2017; Saon et al., 2017).

Over the years, there have been many studies have attempted to inject a longer context information into language models. Based on a recurrent neural network (RNNs) language models (Mikolov et al., 2010), (Mikolov and Zweig, 2012; Wang and Cho, 2015; Ji et al., 2015; Liu and Lane, 2017; Xiong et al., 2018), proposed using a context vector that would encode the longer context information as an additional network input. However, all of these models have been developed on text data, and therefore, it must still be integrated with a conventional acoustic model which is built separately without a longer context information, for speech recognition on long conversations.

Recently, new approaches to speech recognition models integrate all available information (e.g. acoustic, linguistic resources) in a so-called end-to-end manner proposed in (Graves et al., 2006; Graves and Jaitly, 2014; Hannun et al., 2014; Miao et al., 2015; Bahdanau et al., 2014; Chorowski et al., 2014, 2015; Chan et al., 2015; Kim et al., 2017). In these approaches, a single neural network is trained to recognize graphemes or even words from speech directly. Especially, the model using semantically meaningful units, such as words or sub-word (Sennrich et al., 2015), rather than graphemes have been showing promising results (Audhkhasi et al., 2017b; Li et al., 2018; Soltau et al., 2016; Zenkel et al., 2017; Palaskar and Metze, 2018; Sanabria and Metze, 2018; Rao et al., 2017; Zeyer et al., 2018).

In this work, motivated by such property of the end-to-end speech recognition approaches, we propose to integrate conversational context information within a direct acoustic-to-word, end-to-end speech recognition to better process long conversations. Thus far, the research in speech recognition systems has focused on recognizing sentences and to the best of our knowledge, there have been no studies of word-based models incorporating conversational context information. There has been recent work attempted to use the conversational context information from the preceding graphemes (Kim and Metze, 2018), however, it is

Proceedings of NAACL-HLT 2019, pages 2766–2771
Minneapolis, Minnesota, June 2 - June 7, 2019.

limited to encode semantically meaningful context representation. Another recent work attempted to use a context information (Pundak et al., 2018), however, their method requires a list of phrases at inference (i.e. personalized contact list). We evaluate our proposed approach on the Switchboard conversational speech corpus (Godfrey and Holliman, 1993; Godfrey et al., 1992), and show that our model outperforms the sentence-level end-to-end speech recognition model.

2 Models

2.1 Acoustic-to-Words Models

We perform end-to-end speech recognition using a joint CTC/Attention-based approach (Kim et al., 2017; Watanabe et al., 2017). The neural network is trained by both CTC (Graves et al., 2006) and Attention-based sequence-to-sequence (seq2seq) objectives (Bahdanau et al., 2014) to combine the strength of the two. With CTC, it preserves left-right order between input and output and with attention-based seq2seq, it learns the language model jointly without relying on the conditional independence assumption.

As an output, we use word-level symbols which generated from the bite-pair encoding (BPE) algorithm (Sennrich et al., 2015). This method creates the target units based on the frequency of occurrence in training sets. Similar to (Zeyer et al., 2018; Palaskar and Metze, 2018; Sanabria and Metze, 2018), we use BPE-10k which contains roughly 10k units (9,838), including 7,119 words and 2719 sub-words.

2.2 Conversational Context Representation

In order to use conversational context information within the end-to-end speech recognition framework, we extend the decoder sub-network to predict the output additionally conditioning on conversational context. To do so, we encode the preceding sentence into a single vector, a conversational context vector, then inject to decoder network as an additional input at every output step.

Let we have K sentences in a conversation. For k-th sentence, s^k, we have T^k-length input acoustic feature ($\boldsymbol{x^k}$) and U^k-length output words. Our proposed decoder generates the probability distribution over words (y_u^k), conditioned on 1) high-level representation ($\boldsymbol{h^k}$) of input ($\boldsymbol{x^k}$) generated from encoder, and 2) all the words seen previously ($y_{1:u-1}^k$), and 3) previous decoder state (d_{u-1}^k) 4) additionally conditioning on conversational context vector (c^{k-1}), which represents the information of the preceding sentence ($k-1$):

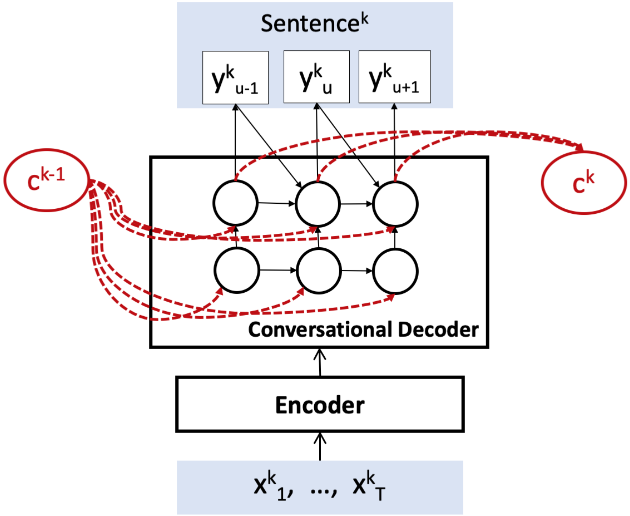

Figure 1: The architecture of our end-to-end speech recognition model with conversational context information. The c^{k-1} is the conversational context vector generated from the preceding $k-1$ sentence red curved dashed line represents the context information flow within the same conversation.

$$\boldsymbol{h^k} = Encoder(\boldsymbol{x^k}) \tag{1}$$

$$y_u^k \sim Decoder(\boldsymbol{h^k}, y_{1:u-1}^k, d_{u-1}^k, c^{k-1}) \tag{2}$$

We represent the context vector, c^{k-1}, from the preceding sentence in two different ways: (a) mean of word embedding, and (b) attentional word embedding. We first generate one-hot word vectors, and then we simply take the mean over word vectors to obtain a single vector in method (a), or we use attention mechanism over word vectors to obtain the weight over the words and then perform the weighted-sum. The parameter of the attention mechanism is optimized towards minimizing the conversation ID classification error similar to (Kim and Metze, 2018). The context vector is merged with a decoder state at every output step as follows:

$$\hat{d}_{u-1}^k = \tanh(W d_{u-1}^k + V c^{k-1} + b) \tag{3}$$

$$y_u^k \sim \text{softmax}(\text{LSTM}(\hat{d}_{u-1}^k, \boldsymbol{h_u^k}, y_{1:u-1}^k)) \tag{4}$$

where W, V, b are trainable parameters.

In order to learn and use the conversational-context during training and decoding, we serialize the sentences based on their onset times and their conversations rather than the random shuffling of data. We shuffle data at the conversation level and create mini-batches that contain only one sentence of each conversation.

3 Experiments

3.1 Datasets

We investigated the performance of the proposed model on the Switchboard LDC corpus (97S62) which has a 300 hours training set. We split the Switchboard data into two groups, then used 285 hours of data (192 thousand sentences) for model training and 5 hours of data (4 thousand sentences) for hyper-parameter tuning. The evaluation was carried out on the HUB5 Eval 2000 LDC corpora (LDC2002S09, LDC2002T43), which have 3.8 hours of data (4.4 thousand sentences), and we show separate results for the Callhome English (CH) and Switchboard (SWB) evaluation sets. We denote train_nodup, train_dev, SWB, and CH as our training, development, and two evaluation datasets for CH and SWB, respectively. There are 2,402 conversations in training sets and 20 conversations in CH, and 20 conversations in SWB.

We sampled all audio data at 16kHz, and extracted 80-dimensional log-mel filterbank coefficients with 3-dimensional pitch features, from 25 ms frames with a 10ms frame shift. We used 83-dimensional feature vectors to input to the network in total. We used 9,840 distinct labels: 9,838 word-level BPE units, start-of-speech/end-of-speech, and blank tokens. Note that no pronunciation lexicon was used in any of the experiments.

3.2 Training and decoding

We used joint CTC/Attention end-to-end speech recognition architecture (Kim et al., 2017; Watanabe et al., 2017) with ESPnet toolkit (Watanabe et al., 2018). We used a CNN-BLSTM encoder as suggested in (Zhang et al., 2017; Hori et al., 2017). We followed the same six-layer CNN architecture as the prior study, except we used one input channel instead of three since we did not use delta or delta delta features. Input speech features were downsampled to (1/4 x 1/4) along with the time-frequency axis. Then, the 6-layer BLSTM with 320 cells was followed by CNN. We used a location-based attention mechanism (Chorowski et al., 2015), where 10 centered convolution filters of width 100 were used to extract the convolutional features.

The decoder network of both our proposed models and the baseline models was a 2-layer LSTM with 300 cells. Our proposed models additionally require linear projection layer in order to encode the conversational context vector and merge with decoder states.

We also built an external RNN-based language model (RNNLM) on the same BPE-10k sets on the same Switchboard transcriptions. The RNNLM network architecture was a two-layer LSTM with 650 cells. This network was used only for decoding.

The AdaDelta algorithm (Zeiler, 2012) with gradient clipping (Pascanu et al., 2013) was used for optimization. We used $\lambda = 0.5$ for joint CTC/Attention training. We bootstrap the training our proposed conversational end-to-end models from the baseline end-to-end models. When we decode with RNNLM, we used joint decoder which combines the output label scores from the AttentionDecoder, CTC, and RNNLM by using shallow fusion (Hori et al., 2017):

$$\begin{aligned} \boldsymbol{y}* = \text{argmax}\{ & \log p_{att}(\boldsymbol{y}|\boldsymbol{x}) \\ & + \alpha \log p_{att}(\boldsymbol{y}|\boldsymbol{x}) \\ & + \beta \log p_{rnnlm}(\boldsymbol{y})\} \end{aligned} \tag{5}$$

The scaling factor of CTC, and RNNLM scores were $\alpha = 0.3$, and $\beta = 0.3$, respectively. We used a beam search algorithm similar to (Sutskever et al., 2014) with the beam size 10 to reduce the computation cost. We adjusted the score by adding a length penalty, since the model has a small bias for shorter utterances. The final score $s(\boldsymbol{y}|\boldsymbol{x})$ is normalized with a length penalty 0.5.

The models were implemented by using the PyTorch deep learning library (Paszke et al., 2017), and ESPnet toolkit (Kim et al., 2017; Watanabe et al., 2017, 2018).

4 Results

We evaluated both the end-to-end speech recognition model which was built on sentence-level data and our proposed end-to-end speech recognition model which leveraged conversational context information.

Table 1 shows the WER of our baseline, proposed models, and several other published results those were only trained on 300 hours Switchboard training data. As shown in Table 1, we obtained a performance gain over our baseline by using the

Proposed Conversational LM	o	64.30

conversational context information. Our proposed model *(a) mean* shows 4.1% and 2.4% relative improvement over our baseline on SWB and CH evaluation set, respectively. Our proposed model *(b) att* shows 3.5% and 1.7% relative improvement over our baseline on SWB and CH evaluation set, respectively. We also found that we can obtain further accuracy improvement by pre-training the decoder part only with transcription. With this pre-training technique, the *(b) att* shows 5.9% and 2.7% relative improvement. Unlike the previous work (Renduchintala et al., 2018), we did not use any additional encoder for the text data.

We also build the language model with or without the conversational context information. Table 2 shows the perplexity on a held-out set of our baseline LM and our conversational LM. We observed that incorporating the conversational context improves performance showing that 9.6% and 11.7% relative improvement on *SWBD only* and *SWBD + Fisher*. Note that the Fisher (LDC2004T19) parts (Cieri et al., 2004) of transcriptions is only used in these experiments.

We performed analyses in order to verify the conversational vector helps to improve recognition accuracy. We generate the context vector from an oracle preceding sentence and a random sentence, in addition to our predicted sentence. As described in Figure 2, the model using the oracle context performed best and the model using the random context was even worse than the baseline. Our model outperformed over the baseline and the model using the random context, we can conclude that the benefit from our proposed method is coming from the conversational context information.

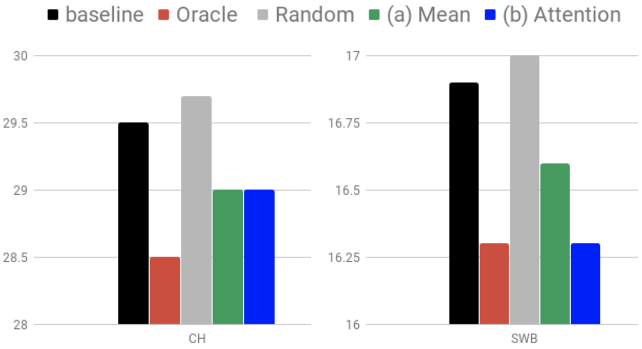

Figure 2: The architecture of our end-to-end speech recognition model with conversational context information. The c^{k-1} is the conversational context vector generated from the preceding $k-1$ sentence red curved line represents the context information flow within the same conversation.

5 Conclusion

We proposed an acoustic-to-word model capable of utilizing the conversational context to better process long conversations. A key aspect of our model is that the whole system can be trained with conversational context information in an end-to-end framework. Our model was shown to outperform previous end-to-end speech recognition models trained on isolated utterances by incorporating preceding conversational context representations.

A Dynamic Speaker Model for Conversational Interactions

Hao Cheng **Hao Fang** **Mari Ostendorf**
University of Washington
{chenghao,hfang,ostendorf}@uw.edu

Abstract

Individual differences in speakers are reflected in their language use as well as in their interests and opinions. Characterizing these differences can be useful in human-computer interaction, as well as analysis of human-human conversations. In this work, we introduce a neural model for learning a dynamically updated speaker embedding in a conversational context. Initial model training is unsupervised, using context-sensitive language generation as an objective, with the context being the conversation history. Further fine-tuning can leverage task-dependent supervised training. The learned neural representation of speakers is shown to be useful for content ranking in a socialbot and dialog act prediction in human-human conversations.[1]

1 Introduction

Representing language in context is key to improving natural language processing (NLP). There are a variety of useful contexts, including word history, related documents, author/speaker information, social context, knowledge graphs, visual or situational grounding, etc. This paper addresses the problem of modeling the speaker. Accounting for author/speaker variations has been shown to be useful in many NLP tasks, including language understanding (Hovy and Søgaard, 2015; Volkova et al., 2013), language generation (Mirkin et al., 2015; Li et al., 2016), human-computer dialog policy (Bowden et al., 2018), query completion (Jaech and Ostendorf, 2018; Shokouhi, 2013), comment recommendation (Agarwal et al., 2011) and more. In this work, we specifically focus on dialogs, including both human-computer (socialbot) and human-human conversations.

While many studies rely only on discrete metadata and/or demographic information, such information is not always available. Thus, it is of interest to learn about the speaker from the language directly, as it relates to the person's interests and speaking style. Motivated by the success of unsupervised contextualized representation learning for words and documents (Mikolov et al., 2013; Kiros et al., 2015; McCann et al., 2017; Peters et al., 2018; Devlin et al., 2019), our approach is to use unsupervised learning with a neural model of a speaker's dialog history. The model uses latent speaker mode vectors for representing a speaker turn as in (Cheng et al., 2017), which provides a framework for analysis of what the model learns about speaking style. Further, the model is structured to allow a dynamic update of the speaker vector at each turn in a dialog, in order to capture changes over time and improve the speaker representation with added data.

The speaker embeddings can be used as context in conversational language understanding tasks, e.g., as an additional input in dialog policy prediction in human-computer dialogs or in understanding dialog acts in human-human dialogs. In the supervised training of such tasks, the speaker model can be fine-tuned.

This work makes two primary contributions. First, we propose a neural model for learning dynamically updated speaker embeddings in conversational interactions. The model training is unsupervised, relying on only the speaker's conversation history rather than meta information (e.g., age, gender) or audio signals which may not be available in a privacy-sensitive situation. The model also has a learnable component for analyzing the latent modes of the speaker, which can be helpful for aligning the learned characteristics of a speaker with the human-interpretable factors. Second, we use the learned dynamic speaker embed-

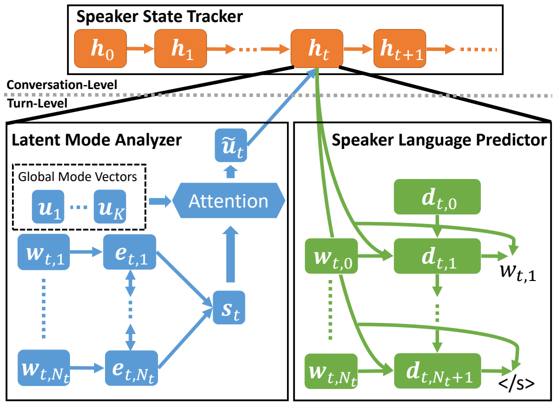

Figure 1: The dynamic speaker model. The speaker state tracker operates at the conversation level. The latent model analyzer and speaker language predictor operate at the turn level. The figure only shows processes in those two components for the turn t.

dings in two representative tasks in dialogs: predicting user topic decisions in socialbot dialogs, and classifying dialog acts in human-human dialogs. Empirical results show that using the dynamic speaker embeddings significantly outperforms the baselines in both tasks. In the public dialog act classification task, the proposed model achieves the state-of-the-art results.

2 Dynamic Speaker Model

In this section, we start with an overview of the proposed model for learning speaker embeddings that are dynamically refined over the course of a conversation. Details about individual components are described in subsequent subsections.

The model is based on two motivations. First, a speaker's utterances reflect intents, speaking style, etc. Thus, we may build speaker embeddings by analyzing latent modes that characterize utterances in terms of such characteristics, apart from topic-related interests a user might have. Second, the information about a speaker is accumulated as the conversation evolves, which allows us to gradually refine and update the speaker embeddings. The speaker embeddings can be directly used as features or fine-tuned based on the downstream tasks. We design the dynamic speaker model to focus on learning cues from the speaker's utterances, and leave the modeling of different speaker-addressee interactions for supervised downstream tasks.

The model consists of three components as illustrated in Fig. 1. First, a **latent mode analyzer** reads in an utterance and analyzes its latent modes. It processes the speaker's turns independently of each other and builds a local speaker mode vector for each turn. To accumulate speaker information as the conversation evolves, we build a **speaker state tracker** that maintains speaker states at individual turns. At each turn, it takes two input vectors to update the speaker state: 1) the local speaker mode vector for the current turn from the latent mode analyzer, and 2) the speaker state at the previous turn from the tracker itself. Finally, we employ a **speaker language predictor** to drive the learning of the latent model analyzer and the speaker state tracker. It reconstructs the utterance using the corresponding speaker state. Intuitively, the speaker language predictor models overall linguistic regularities itself and uses the speaker state to supply information related to speaker characteristics. For sequence modeling in all three components, we use the long short-term memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997). In our experiments, the three components are trained jointly.

2.1 Latent Mode Analyzer

At each turn t, the latent mode analyzer constructs a local speaker mode vector $\tilde{\mathbf{u}}_t \in \mathbb{R}^c$ that captures salient characteristics of the speaker's current utterance for use in the dynamic speaker model. First, the utterance word sequence $w_{t,1}, \cdots, w_{t,N_t}$ is mapped to an embedding sequence, where $w_{t,n}$ is represented with $\mathbf{w}_{t,n} \in \mathbb{R}^d$ according a lookup with dictionary $\mathbf{W} \in \mathbb{R}^{|\mathcal{V}|\times d}$ associated with vocabulary $\mathcal{V}$. Then, the latent mode analyzer goes through two stages to construct $\tilde{\mathbf{u}}_t$.

In the first stage, a bi-directional LSTM (Bi-LSTM), which consists of a forward LSTM and a backward LSTM, is used to encode the word embedding sequence into a fixed-size utterance summary vector $\mathbf{s}_t \in \mathbb{R}^{2m}$, where m is the dimension of the hidden layer in the forward and backward LSTMs. Formally, the forward LSTM computes its hidden states as $\mathbf{e}^F_{t,n} = g^F(\mathbf{w}_{t,n}, \mathbf{e}^F_{t,n-1}) \in \mathbb{R}^m$ for $n = 1, \ldots, N_t$, where $g^F(\cdot,\cdot)$ denotes the forward LSTM function. The backward LSTM computes its hidden states $\mathbf{e}^B_{t,n} \in \mathbb{R}^m$ similarly. The initial hidden states $\mathbf{e}^F_{t,0}$ and $\mathbf{e}^B_{t,N_t+1}$ are set to zeros. The summary vector $\mathbf{s}_t$ is the concatenation of the two final hidden states, $\mathbf{s}_t = [\mathbf{e}^F_{t,N_t}, \mathbf{e}^B_{t,1}]$.

In the second stage, the utterance summary vector $\mathbf{s}_t$ is compared with K global mode vectors

$\mathbf{u}_1, \dots, \mathbf{u}_K \in \mathbb{R}^c$ which are learned as part of the model. The association score $a_{t,k}$ between $\mathbf{s}_t$ and $\mathbf{u}_k$ is computed using the dot-product attention mechanism (Vaswani et al., 2017) as follows,

$$a_{t,k} = \frac{\exp(\langle \mathbf{P}\mathbf{s}_t, \mathbf{Q}\mathbf{u}_k \rangle)}{\sum_{k'=1}^{K} \exp(\langle \mathbf{P}\mathbf{s}_t, \mathbf{Q}\mathbf{u}_{k'} \rangle)}, \qquad (1)$$

where $\mathbf{P} \in \mathbb{R}^{c \times 2m}$ and $\mathbf{Q} \in \mathbb{R}^{c \times c}$ are learnable weights, and $\langle \cdot, \cdot \rangle$ indicates the dot-product of two vectors. The local speaker mode vector is then constructed as $\tilde{\mathbf{u}}_t = \sum_{k=1}^{K} a_{t,k} \mathbf{u}_k$.

2.2 Speaker State Tracker

The speaker state tracker provides a dynamic summary of speaker language features observed in the conversation history, using an LSTM to encode the sequence of local speaker mode vectors $\tilde{\mathbf{u}}_{t,1}, \cdots, \tilde{\mathbf{u}}_{t,N_t}$. At turn t, this LSTM updates its hidden state $\mathbf{h}_t \in \mathbb{R}^m$ using the local speaker mode vector $\tilde{\mathbf{u}}_t$ and its previous hidden state $\mathbf{h}_{t-1} \in \mathbb{R}^m$, i.e., $\mathbf{h}_t = g^S(\tilde{\mathbf{u}}_t, \mathbf{h}_{t-1})$, where $g^S(\cdot, \cdot)$ is the speaker LSTM function. The hidden state $\mathbf{h}_t$ provides the speaker state vector at turn t.

2.3 Speaker Language Predictor

The speaker language predictor is a conditional LSTM language model (LM) that reconstructs the word sequence in the current turn. Language modeling is a way to provide a training signal for unsupervised learning that models the conditional probability $\Pr(w_{t,n} | w_{t,<n})$, where $w_{t,<n}$ denotes all preceding words of $w_{t,n}$ in the turn t.

The speaker language predictor uses the same dictionary $\mathbf{W}$ for word embeddings as the latent mode analyzer to represent words at time t. The initial hidden state $\mathbf{d}_{t,0} \in \mathbb{R}^m$ of the LSTM is set to $\tanh(\mathbf{L}\mathbf{h}_t)$, where $\mathbf{L} \in \mathbb{R}^{m \times m}$ is a learnable matrix and $\tanh(\cdot)$ is the hyperbolic tangent function. Subsequent LSTM hidden states are computed as

$$\mathbf{d}_{t,n} = g^{LM}(r^I(\mathbf{w}_{t,n-1}, \mathbf{h}_t), \mathbf{d}_{t,n-1}),$$

for $n = 1, \dots, N_t + 1$, where $r^I(\mathbf{w}_{t,n-1}, \mathbf{h}_t) = \mathbf{R}_w^I \mathbf{w}_{t,n-1} + \mathbf{R}_h^I \mathbf{h}_t$ is a linear transformation with learned parameters $\mathbf{R}_w^I \in \mathbb{R}^{m \times d}$ and $\mathbf{R}_h^I \in \mathbb{R}^{m \times m}$, $g^{LM}(\cdot, \cdot)$ is a forward LSTM function, and $\mathbf{w}_{t,0}$ is the word embedding for the start-of-sentence token. By injecting the speaker state vector at every time step n in the turn t, the model is more likely to favor directly using the speaker state vector (vs. the word history) for predicting the speaker language. The conditional probability is then computed as

$$\Pr(w_{t,n} | w_{t,<n}) = \text{softmax}(\mathbf{V} r^O(\mathbf{h}_t, \mathbf{d}_{t,n})), \quad (2)$$

where $\mathbf{V} \in \mathbb{R}^{|\mathcal{V}| \times m}$ is the weight matrix, and $r^O(\mathbf{h}_t, \mathbf{d}_{t,n}) = \mathbf{R}_h^O \mathbf{h}_t + \mathbf{R}_d^O \mathbf{d}_{t,n}$ is another linear function with learnable parameters $\mathbf{R}_h^O, \mathbf{R}_d^O \in \mathbb{R}^{m \times m}$. The last word w_{t,N_t+1} is always the end-of-sentence token.

2.4 Model Training and Tuning

The training objective for a given conversation is the log-likelihood $\sum_t \sum_n \log \Pr(w_{t,n} | w_{t,<n})$, where the conditional probability is defined in (2). The Adam optimizer (Kingma and Ba, 2015) is used with a configuration of $\beta_1 = 0.9$ and $\beta_2 = 0.97$. The initial learning rate is set to 0.002. We halve the learning rate at each epoch once the development log-likelihood decreases, and terminate the training when it decreases for the second time. This validation protocol is used throughout the paper for training the proposed model.

In our experiments, the embedding dictionary $\mathbf{W}$ is initialized using pre-trained 300-dimensional word embeddings (Bojanowski et al., 2017) for words within the vocabulary of this resource. The remaining part of $\mathbf{W}$ and other model parameters are randomly initialized based on $\mathcal{N}(0, 0.01)$. The mode vector dimension c is set to 64. We tune the number of global mode vectors K from $\{16, 32\}$ and the hidden layer size m from $\{128, 160\}$. The final model is selected based on the log-likelihood on the development set.

3 User Topic Decision Prediction

We first study a prediction task that estimates whether the user engaged in a socialbot conversation would accept a suggested topic. Specifically, we use a corpus of human-socialbot conversations collected during the 2017 Alexa Prize competition (Ram et al., 2017) from the Sounding Board system (Fang et al., 2018; Fang, 2019). Due to privacy concerns, the socialbot does not have access to any identity information about users. Also, since each device may be used by multiple users, the device address is not a reliable indicator of the user ID. Therefore, the ability to profile the user through one conversational interaction is desirable for guiding the socialbot's dialog policy.

	train	dev	test
# conversations	19,076	6,321	6,465
# topic decisions	85,340	28,060	29,561

Table 1: Data statistics of the topic decision dataset.

3.1 Data

Each conversation begins with a greeting and ends when the user makes a stop command. The socialbot engages the user in the conversation using a wide range of content indexed by topics, where a topic corresponds to a noun or noun phrase that refers to a named entity (e.g., Google) or a concept (e.g., artificial intelligence). These topics are extracted using both constituency parsing results of the textual content and content meta-information. During the conversation, the socialbot sometimes negotiates the topic with the user using an explicit confirmation turn and records the user's binary decision (accept or reject) on the topic.

In socialbot conversations, a system turn is always followed by a user turn and vice versa. We tag system turns making explicit confirmation about a topic and attach the corresponding binary user decisions with them. To curate the dataset for the topic decision prediction task, we use a total of 31,862 conversations with more than 5 user turns. On average there are around 22 user turns per conversation. Not every system turn makes a topic suggestion, and the average number of topic decisions per conversation is 4.5. We randomly split the conversations into training, development, and test sets by $3/1/1$. The data statistics are shown in Table 1. In our experiments, we directly use the speech recognition output of user utterances. The vocabulary $\mathcal{V}$ consists of roughly 11K words that appear at least 5 times in the training set.

3.2 Topic Decision Classifier

We use a feed-forward neural network (FFNN) to make binary predictions (accept vs. reject) for individual topic suggestions. For each topic suggestion, the FFNN takes two inputs: 1) an embedding $\mathbf{x}_{t'}$ for the suggested topic at system turn t', and 2) a user embedding vector $\mathbf{z}_t$ at user turn t. Note the model does not have information about user turns after the system turn t' when making the prediction, i.e., the user turn t appears before the system turn t'.

The topic embedding $\mathbf{x}_{t'}$'s are looked up from the embedding dictionary learned by the FFNN. They are initialized by averaging the embeddings of their component words using the public pretrained 300-dimensional word embeddings (Bojanowski et al., 2017).

For the user embedding vector, we explore two settings that use different numbers of user turns as context. In both settings, topic decisions occurring in the first 5 user turns are not used for evaluations.

Static User Embeddings: Motivated by the findings that most user characteristics can be inferred from initial interactions (Ravichander and Black, 2018), we derive a static user embedding vector for a conversation using the first 5 user turns and apply it for predicting topic decisions afterwards.

Dynamic User Embeddings: Alternatively, we build a user embedding vector for user turn t using all previous user turns. Here, a topic decision for system turn t' is aligned with its preceding user turn t.

In our experiments, we compare different unsupervised models with our proposed dynamic speaker model. For both settings, all unsupervised models are pre-trained on *all* user turns in training conversations. They are fixed when training the FFNN classifier. The FFNN classifier is trained with the logistic loss using the Adam optimizer (Kingma and Ba, 2015). The training protocol is similar to that described in §2.4. We tune the hidden layer size from $\{64, 128\}$ and the number of hidden layers from $\{0, 1\}$. The model is selected based on the loss on the development set.

In addition, we use a user-agnostic **TopicPrior** baseline. It builds a probability lookup for each topic using its acceptance rate on the training set. We tune a universal probability threshold for all topics based on the development set accuracy.

In all experiments, three evaluation metrics are used: accuracy, area under the receiver operating characteristic curve (AUC), and normalized cross-entropy (N-CE). N-CE is computed as the relative cross-entropy reduction of the model over the TopicPrior baseline.

3.3 Experiments: Static User Embeddings

As described in §3.2, we use the first 5 user turns to derive the user embedding vector for a conversation. We compare our dynamic speaker model with three other unsupervised models.

DynamicSpeakerModel: For the proposed dynamic speaker model, we concatenate the speaker state vector $\mathbf{h}_t$ and the local speaker mode vector

Model	Acc	AUC	N-CE
TopicPrior	68.8	72.5	0
UtteranceLDA	68.8	73.1	12.6
UtteranceAE	68.8	73.4	12.8
TopicDecisionEncoder	68.9	73.8	13.4
DynamicSpeakerModel	**69.5**	**74.2**	**13.7**

Table 2: Test set results (in %) for topic decision predictions using *static* user embeddings.

$\tilde{\mathbf{u}}_t$ for each of the first 5 user turns. Then, we apply the max-pooling operation over the 5 concatenated vectors to summarize all the information. The resulting vector $\tilde{\mathbf{h}}$ is used as the user embedding vector.

UtteranceLDA: The latent Dirichlet allocation (LDA) model (Blei et al., 2003) is trained with 16 latent groups by treating all user utterances in a conversation as a document.[2] The trained LDA model builds a 16-dimensional probability vector as the user embedding vector by loading the first 5 user turns as a single document.

UtteranceAE: The utterance auto-encoder model is built upon the sequence auto-encoder (Dai and Le, 2015). We replace the original encoder by a BiLSTM that encodes the utterance at user turn t into a summary vector $\mathbf{s}_t$ in the same way as the first stage of the latent mode analyzer described in §2.1. The auto-encoder is trained on all user utterances in the training data, using the same training protocol described in §2.4. We set the hidden layer size to 128. The user embedding vector is constructed by applying the max-pooling operation over the summary vectors $\mathbf{s}_1, \dots, \mathbf{s}_5$ for the first 5 user turns.

TopicDecisionEncoder: This model encodes the topic decisions occurred in the first 5 user turns. The user embedding vector is the concatenation of two vectors. One is max-pooled from the topic embeddings for accepted topics, and the other for rejected topics, both include a dummy topic vector as default. The topic embeddings are composed by averaging the public pre-trained 300-dimensional embeddings (Bojanowski et al., 2017) for words in the topic.

Experiment results are summarized in Table 2. The TopicPrior is a very strong predictor, with an accuracy on par with other user embeddings. This indicates that the popularity-based approach is a good start for content ranking in socialbots when there is little user information. Nevertheless, we can still observe some improvement over the TopicPrior in terms of AUC and N-CE, which suggests using information from initial interactions reduces the uncertainty of predictions. The proposed dynamic speaker model performs the best among the compared models, reducing the cross-entropy by 13.7% over the TopicPrior baseline.

Model	Acc	AUC	N-CE
TopicDecisionLSTM	69.3	74.8	14.6
UtteranceAE + LSTM	69.9	75.4	15.3
DynamicSpeakerModel	**72.4**	**79.0**	**20.0***

Table 3: Test set results (in %) for topic decision predictions using *dynamic* user embeddings. *: The improvement of DynamicSpeakerModel over both TopicDecisionLSTM and UtteranceAE + LSTM is statistically significant based on both t-test and McNemar's test ($p < .001$).

3.4 Experiments: Dynamic User Embeddings

Here, we use all information accumulated before the system turn of suggesting the topic to build the corresponding user embedding vector. Since the UtteranceLDA is not as effective based on static embedding experiments, we only consider extending UtteranceAE and TopicDecisionEncoder models for comparison here.

DynamicSpeakerModel: The speaker state tracker in our model accumulates the user information as the conversation evolves. Thus, we directly concatenate the speaker state vector $\mathbf{h}_t$ and the local speaker mode vector $\tilde{\mathbf{u}}_t$ as the user embedding vector at user turn t. Other than using more turns, this is the same DynamicSpeakerModel configuration as in §3.3.

UtteranceAE+LSTM: This model uses an LSTM to encode the summary vector sequence derived from the same utterance auto-encoder used in §3.3. The LSTM hidden states are treated as user embedding vectors at individual user turns.

TopicDecisionLSTM: Similarly, an LSTM is used to encode the topic decision sequence. At each time step, the LSTM reads the concatenation of the topic embedding and the one-hot vector encoding the topic decision. We use the same topic embeddings as the TopicDecisionEncoder in §3.3. Since not every user turn is associated with a topic

---

[2] To allow the LDA model to take into account bi-grams, we replace the uni-gram token w_i with its bi-gram (w_i, w_{i+1}) concatenated as a single token if the bi-gram is among the top 500 frequent bi-grams.

decision, the time steps of this LSTM are aligned to a sequence of non-consecutive user turns. The LSTM hidden states are treated as user embedding vectors at corresponding user turns.

For UtteranceAE+LSTM and TopicDecisionLSTM, the hidden layer size of the LSTM is set to 128. While the utterance auto-encoder and topic embeddings are pre-trained, the LSTM components are jointly learned with the FFNN for composing dynamic user embeddings.

Experiment results are shown in Table 3. The DynamicSpeakerModel performs the best. Comparing to results in Table 2, all three unsupervised models outperform their static counterparts, which suggests the advantage of using dynamic context for predicting user topic decisions as conversation evolves.

Statistical significance tests of the difference in performance of two systems were conducted under both the t-test using the predicted probabilities and McNemar's test using the binary predictions. Under both tests, the predictions from the TopicDecisionLSTM and the DynamicSpeakerModel are highly signification ($p < .001$). Predictions from UtteranceAE + LSTM and DynamicSpeakerModel are also significantly different based on both tests ($p < .001$).

3.5 Qualitative Analysis

First, we manually inspect the predictions from the TopicDecisionLSTM and DynamicSpeakerModel used in §3.4 and the static baseline TopicPrior in §3.3. Compared with TopicPrior, we find that TopicDecisionLSTM is able to utilize the semantic relatedness between neighboring topics and corresponding user decisions. For example, "Elon Musk" (the CEO) is likely to be rejected if "Tesla" (the company) has been rejected earlier, though both are popular topics with high acceptance rates. In addition, it seems that the DynamicSpeakerModel is able to make use of user reactions. In the anecdotal example illustrated in Table 4, the user accepts the topic "Arnold Schwarzenegger" which is correctly predicted by both TopicDecisionLSTM and DynamicSpeakerModel, but only the DynamicSpeakerModel correctly predicts the rejection of "politics" later.

We then analyze what language features are learned by latent modes in our dynamic speaker model. For each mode, we extract top utterances sorted by their association scores as computed in (1). Examples from the most representative modes are provided in Appendix A. In brief, we find two separate modes related to positive and negative reactions; other modes correspond to classes of dialog acts, such as yes/no answers, topic requests and conversation-closing. Within topic request modes, some involve short topic phrases (e.g., "*holidays*") while others use complete requests (e.g. "*can we talk about cats*"). Along this line, some modes are associated with relatively terse users and others with talkative users. These findings indicate that our model cpatures various user characteristics that might be useful for predicting their interaction preferences.

Bot: Do you like the actor Arnold Schwarzenegger?
User: yeah before he got into politics
Bot: Super, would you like to know a fun fact about Arnold Schwarzenegger?
    - **TopicDecisionLSTM**: accept
    - **DynamicSpeakerModel**: accept
User: why not sure
...
Bot: I'm running out of things to say about him. Do you wanna hear some news about politics?
    - **TopicDecisionLSTM**: accept
    - **DynamicSpeakerModel**: reject
User: no

Table 4: A dialog snippet showing topic decision predictions from TopicDecisionLSTM and DynamicSpeakerModel. Topics are shown with underscores.

4 Dialog Act Classification

Dialog act analysis is widely used for conversations, which identifies the illocutionary force of a speaker's utterance following the speech act theory (Austin, 1975; Searle, 1969). In this section, we apply the proposed dynamic speaker model to the dialog act classification task.

4.1 Data

We use the Switchboard Dialog Act Corpus (SwDA), which has dialog act annotations on two-party human-human speech conversations (Jurafsky et al., 1997; Stolcke et al., 2000). In total, there are 1155 open-domain conversations with manual transcripts. Following recent work, we use 1115 conversations for training, 19 for testing, and the rest 21 for development.[3] The original fine-grained dialog act labels are mapped to 42

---

[3] The training and test split files are downloaded from `https://web.stanford.edu/~jurafsky/ws97/`.

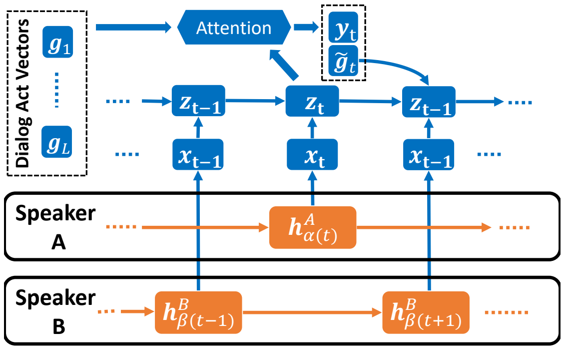

Figure 2: The attention-based LSTM tagging model for dialog act classification. The figure only shows the attention operation for turn t. The lower two boxes represent two speaker state trackers.

classes.[4] For this set of experiments, we use the golden segmentation and manual transcripts provided in the dataset.

Motivated by the recent success of unsupervised models (Peters et al., 2018; Devlin et al., 2019), we also study whether the dynamic speaker model can benefit from training on external unlabelled data. Thus, we use speech transcripts from 5850 conversations from the Fisher English Training Speech Part 1 Transcripts (Cieri et al., 2004), which (like Switchboard) consists of two-party human-to-human telephone conversations but without annotations for dialog acts.

4.2 Dialog Act Tagging Model

We use an attention-based LSTM tagging model for the dialog act classification. As shown in Fig. 2, the tagging LSTM is stacked on two speaker state trackers. Note the two trackers share the same parameters as well as the underlying latent mode analyzer and speaker language predictor. They generate speaker embeddings by tracking corresponding speakers separately.

Let $\alpha(t)$ and $\beta(t)$ denote the mappings from the global turn index t to the speaker-specific turn indices for speaker A and speaker B, respectively. The mapping returns a null value if the turn t is not associated with the corresponding speaker. The speaker state vectors are used as the input to the tagging LSTM for corresponding turns, i.e., $\mathbf{x}_t = I(\mathbf{h}^A_{\alpha(t)}, \mathbf{h}^B_{\beta(t)})$ where $I(\cdot,\cdot)$ is a switcher that chooses $\mathbf{h}^A_{\alpha(t)}$ or $\mathbf{h}^B_{\beta(t)}$ depending on whether $\alpha(t)$ and $\beta(t)$ return a non-null value.

The tagging LSTM also maintains a dictionary of L dialog act vectors $\mathbf{g}_1, \ldots, \mathbf{g}_L$. The dialog act probabilities $\mathbf{y}_t \in \mathbb{R}^L$ at turn t are computed using the dot-product attention mechanism, i.e., $\mathbf{y}_t = f(\mathbf{z}_t, [\mathbf{g}_1, \ldots, \mathbf{g}_L])$, where $f(\cdot,\cdot)$ is defined as in (1), and $\mathbf{z}_t$ is the hidden state vector of the LSTM.

The tagging LSTM computes hidden states as

$$\mathbf{z}_{t+1} = g^{DA}\left(r^{DA}(\tilde{\mathbf{g}}_t, \mathbf{x}_{t+1}), \mathbf{z}_t\right)$$

where $\tilde{\mathbf{g}}_t = \sum_{l=1}^{L} y_{t,l}\mathbf{g}_l$, $g^{DA}(\cdot,\cdot)$ is the LSTM function, and $r^{DA}(\cdot,\cdot)$ is a linear function with learnable parameters. In this way, both the history dialog act predictions and the utterance information are encoded in the hidden states.

The training objective of the tagging LSTM is the sum of the cross-entropy between the dialog act label and the probabilities $\mathbf{y}_t$ at each turn. The training configuration is the same as the topic decision classifier described in §3.2. We tune the size of hidden states $\mathbf{z}_t$ and dialog act embeddings $\mathbf{g}_l$ from $\{64, 128\}$ with arbitrary combinations, and vary the number of LSTM hidden layers from $\{1, 2\}$. The best model is selected according to the development set accuracy.

4.3 Experiment Results

In our experiments, we compare three settings for using the dynamic speaker model. In the **pre-train** setting, the dynamic speaker model is trained on the SwDA data without the dialog act labels. We then freeze the model when training the tagging LSTM. In contrast, in the **pretrain + fine-tune** setting, the dynamic speaker model is fine-tuned together with the tagging LSTM. Finally, in the **pre-train w/Fisher + fine-tune** setting, the dynamic speaker model is pre-trained on the combination of SwDA and Fisher datasets, and then fine-tuned together with the tagging LSTM on the SwDA dataset. For all three settings, we use the same vocabulary $\mathcal{V}$ of size 21K which combines all tokens from the SwDA training set and those appearing at least 5 time in the Fisher corpus.

We compare our results to best published results. In (Kalchbrenner and Blunsom, 2013), a convolutional neural network (CNN) is used to encode utterances. A recurrent neural network (RNN) is then applied on top of the CNN to encode both utterances and speaker label information for predicting the dialog acts. Ji et al. (2016) propose a discourse-aware RNN LM by treating

---

[4] Dialog act labels are mapped using scripts from `http://compprag.christopherpotts.net/swda.html`. Utterances labelled as "segment" are merged with corresponding previous utterance by the same speaker.

Model	Acc (%)
(Kalchbrenner and Blunsom, 2013)	73.9
(Tran et al., 2017a)	74.2
(Tran et al., 2017b)	74.5
(Tran et al., 2017c)	75.6
(Ji et al., 2016)	77.0
pre-train	75.6
pre-train + fine-tune	**77.2**
pre-train w/ Fisher + fine-tune	**78.6***

Table 5: Test set accuracy for SwDA dialog act classification. *: The improvement of pre-train w/ Fisher + fine-tune is statistically significant over pre-train + fine-tune based on McNemar's test ($p < .001$).

the dialog act as a conditional variable to the LM. Tran et al. (2017a,b,c) focus on building hierarchies of RNNs to model the dialog context using previous utterances or dialog act predictions. Results from (Lee and Dernoncourt, 2016) and (Liu et al., 2017) are not directly comparable due to different experiment settings.

Experiment results are summarized in Table 5. Our pre-train setting performs on par with previous state-of-the-art supervised models except (Ji et al., 2016). Fine-tuning significantly improves the performance and allows the model to achieve a similar accuracy as (Ji et al., 2016). The best result is achieved by pre-training the dynamic speaker model with both SwDA and Fisher datasets. The improvement of pre-train w/ Fisher + fine-tune is statistically significant over pre-train + fine-tune based on McNemar's test ($p < .001$). This illustrates the advantage of the unsupervised learning approach for the proposed model as it can exploit a large amount of unlabelled data.

4.4 Qualitative Analysis

We analyze the latent modes learned on SwDA using the same approach as in §3.5. Again, specific examples are included in Appendix A. Overall, there are several modes corresponding to coarse-grained dialog acts, such as statements, questions, agreement, backchannel and conversation-closing. Many modes characterize statements, probably due to their high relative frequency in the corpus. Among the statement modes, there are two distinct groups, one containing multiple filled pauses, such as *uh, you know, well*, and the other one with *because*-clauses. The fact that coarse-grained dialog act information is partly encoded in the modes may be helping with recognizing the dialog act.

In addition, we use the speaker gender information available in the SwDA data to determine whether the latent modes in the dynamic speaker model pick up gender-related language variation. Specific examples and statistics are included in Appendix B. The Cohen-d score (Cohen, 1988) is used to measure the strength of the difference between association score distributions of male vs. female utterances for individual modes. Based on the Cohen-d score, we identified two modes that have a strong association with male speakers, and two with female speakers. All have significantly different ($p < 0.001$) distributions of association scores for female vs. male speakers using Mann-Whitney U test. In the top associated utterances for the male modes, we find utterances with several filled pauses, which has been found to be indicative of male speakers in previous work on Switchboard (Boulis and Ostendorf, 2005). The female modes are mostly agreement, acknowledgement and backchannel, which aligns with a popular sociolinguistic theory that females are more responsive (Coates, 1998). Based on this, we conclude that some speaker gender language variations are indeed captured by the learned modes.

5 Related Work

As reviewed by Zukerman and Litman (2001), user modeling for conversational systems has a long history. The research can be tracked back to the GRUNDY system (Rich, 1979) which categorizes users in terms of hand-crafted sets of user properties for book recommendation. Other systems have focused on different aspects of users, e.g., the expertise level of the user in a specific domain (Chin, 1986; Sleeman, 1985; Paris, 1987; Hovy, 1987), the user's intent and plan (Allen and Perrault, 1980; Carberry, 1983; Litman, 1986; Moore and Paris, 1992), and the user's personality (Mairesse and Walker, 2006; DeVault et al., 2014; Fung et al., 2016; Fang et al., 2017). User modeling has also been employed for personalized topic suggestion in recent Alexa Prize socialbots, using a pre-defined mapping between personality types and topics (Fang et al., 2017), or a conditional random field sequence model with hand-crafted user and context features (Ahmadvand et al., 2018). Modeling speakers with continuous embeddings for neural conversation models is studied in (Li et al., 2016), where the model directly learns a dictionary of speaker embeddings. Our unsupervised dynamic speaker model differs from previous work in that we build speaker embeddings as a weighted combination of latent modes with weights computed based on the utterance. Thus, the model can construct embeddings for any new users and dynamically update the embeddings as the conversation evolves.

Speaker language variances have been analyzed by previous work and incorporated in NLP models. Preoţiuc-Pietro et al. (2016) and Johannsen et al. (2015) find that speaker-level language variance affects lexical choices and even syntactic structure based on psycholinguistic hypotheses. Speaker demographics are used to improve both low-level tasks such as part-of-speech tagging (Hovy and Søgaard, 2015) and high-level applications such as sentiment analysis (Volkova et al., 2013) and machine translation (Mirkin et al., 2015). Lynn et al. (2017) introduce a continuous adaptation method to include user age, gender, personality traits and language features for personalizing several supervised NLP models. Different from previous work, we study the use of speaker embeddings learned from utterances in an unsupervised fashion and analyze the possible interpretability of the latent modes.

6 Conclusion

In this paper, we address the problem of modeling speakers from their language using an unsupervised approach. A dynamic speaker model is proposed to learn speaker embeddings that are updated as the conversation evolves. The model achieves promising results on two representative tasks in dialogs: user topic decision prediction in human-socialbot conversations and dialog act classification in human-human conversations. In particular, we demonstrate that the model can benefit from unlabelled data in the dialog act classification task, where we achieve the state-of-the-art results. Finally, we carry out analysis on the learned latent modes on both tasks, and find cues that suggest the model captures speaker characteristics such as intent, speaking style, and gender. For future work, it could be interesting to explore guiding some latent modes with a few examples to pick up specific user features such as personality traits.

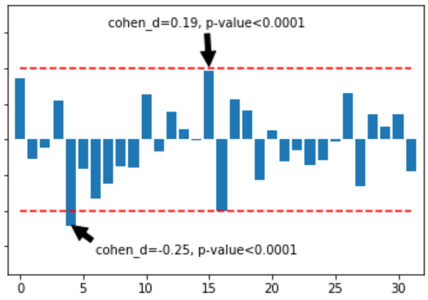
A Examples for Mode Analysis

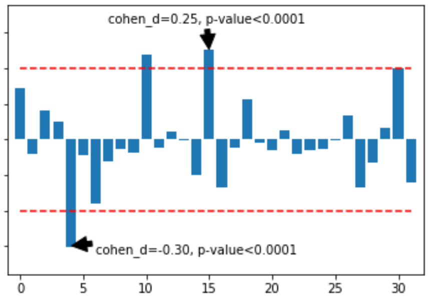
For each mode, we list top associated user utterances in Table 6 and Table 7 for the user topic decision corpus and SwDA corpus, respectively.

For modes learned in the user topic decision corpus, mode 4 seems to include positive reactions, while mode 2 involves slightly negative reactions. Modes 0 and 6 are mostly yes/no answers. Utterances associated with mode 3 are mostly conversation ending. Modes 9, 14, and 10 are mostly set topic commands, differing in style. Mode 10 is associated with complete requests (e.g., "*let's/can we talk about cats*)," while mode 9 and Mode 14 involve short topic phrases (e.g., "*holidays*"). Modes 8 and 11 capture talkative users, whereas modes 1 and 7 capture relatively terse users.

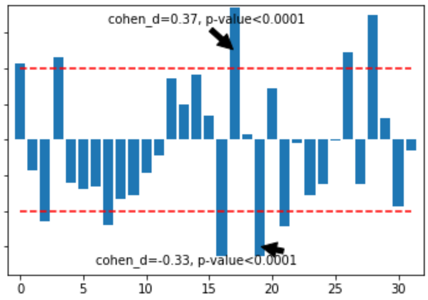
For latent modes learned in the SwDA corpus, there are several modes corresponding to coarse-grained dialog acts, such as statements (modes 2, 4, 6, 16, 19), questions (modes 8, 9), agreement (modes 12, 20), backchannel (modes 0, 28), and conversation-closing (mode 13). Among the statement modes, there are two distinct groups, one (modes 4, 6, 16, 19) containing multiple filled pauses, such as *uh, you know, well*, and the other one (mode 2) with *because*-clauses. The fact that coarse-grained dialog act information is partly encoded in the modes may be helping with recognizing the dialog act.



(a) all conversations



(b) same-gender conversations



(c) cross-gender conversations

Figure 3: Cohen-d scores for gender group tests. The x-axis is the mode index. The y-axis is the Cohen-d score, with a larger magnitude suggesting a large effect size, and a positive value for a more female-like mode. The red dash lines indicate the ±0.20 threshold.

B Speaker Gender Analysis

We use the speaker gender information from the SwDA data and analyze whether latent modes unsupervisedly learned in the dynamic speaker model could pick up some gender language variations. First, we gather the latent mode association scores for each of the 32 modes for all utterances as computed in (1). Then we carry out the group mean tests for individual modes to test the associate score distributions of male vs female utterances. The Cohen-d score is used to measure the strength of the difference (Cohen, 1988). We also compute the p-value using the Mann-Whitney U test. Previous work has observed larger gender language differences when the two speakers have the same gender (Boulis and Ostendorf, 2005). Thus, we carry out the group mean tests on the following three sets: 1) all conversations, 2) conversations involving only males or females, and 3) conversations involving both genders. The Cohen-d scores for overall, same-gender and cross-gender conversations are shown in Fig. 3. For each set, we identify the most female-like mode (with the most positive Cohen-d score) and the most male-like mode (with the most negative Cohen-d score). For female-like modes, modes 15 and 17 are identified in this way, whereas modes 4 and 19 are identified for male-like modes. By examining representative patterns in modes 15 and 17, they are mostly backchannel, acknowledgement, or agreement. For modes 4 and 19, filled pauses are prevalent.

Mode-0	• no no no no no no go back to my alexa . . . • no no no no let's stop talking now goodbye . . . • no let's chat let's chat about donald trump . . .

Fluent Translations from Disfluent Speech in End-to-End Speech Translation

Abstract

Spoken language translation applications for speech suffer due to conversational speech phenomena, particularly the presence of disfluencies. With the rise of end-to-end speech translation models, processing steps such as disfluency removal that were previously an intermediate step between speech recognition and machine translation need to be incorporated into model architectures. We use a sequence-to-sequence model to translate from noisy, disfluent speech to fluent text with disfluencies removed using the recently collected 'copy-edited' references for the Fisher Spanish-English dataset. We are able to directly generate fluent translations and introduce considerations about how to evaluate success on this task. This work provides a baseline for a new task, the translation of conversational speech with joint removal of disfluencies.

1 Introduction & Related Work

Spoken language translation (SLT) applications suffer due to conversational speech phenomena, particularly the presence of disfluencies. In conversational speech, speakers often use disfluencies such as filler words, repetitions, false starts, and corrections which do not naturally occur in text and may not be desired in translation outputs. Disfluency recognition and removal has previously been performed as an intermediate step between speech recognition (ASR) and machine translation (MT), to make disfluent ASR output better-matched to typically clean machine translation training data (Cho et al., 2013, 2014; Wang et al., 2010; Honal and Schultz, 2005; Zayats et al., 2016). With the rise of end-to-end sequence-to-sequence speech translation systems (Weiss et al., 2017; Bansal et al., 2018), disfluency removal can no longer be handled as an intermediate step between ASR and MT but needs to be incorporated into the model or handled as a post-processing step.

Generating fluent translations from disfluent speech may be desired for simultaneous SLT applications where removing disfluencies will improve the application's clarity and usability. To train end-to-end speech translation requires parallel speech and text translations. This introduces data considerations not previously relevant with chained ASR+MT models, as different datasets could be used to train ASR and MT components. Where aligned speech and translations exist, data is typically clean speech→clean text, as in news or TED talks, or disfluent speech→disfluent translations, as in Fisher or meeting data, where disfluencies were faithfully included in the references for completeness. While some corpora with labeled disfluencies exist (Cho et al., 2014; Burger et al., 2002), only subsets have been translated and/or released. Salesky et al. (2018) introduced a set of fluent references[1] for Fisher Spanish-English, enabling a new task: end-to-end training and evaluation against fluent references.

Previous work on disfluency removal has treated it as a sequence labeling task using word or span-level labels. However, in some cases, simply removing disfluencies from an utterance can create ill-formed output. Further, corpora can have different translation and annotation schemes: for example for Fisher Spanish-English, translated using Mechanical Turk, Salesky et al. (2018) found 268 unique filler words due to spelling and casing. Disfluencies can also be context-specific, such as false starts or corrections where a phrase may be 'disfluent' due to its surroundings. To remove disfluencies as a post-processing step would require a separate model trained with appropriate data and disfluency labels, and may lead to ill-formed output. By translating directly to fluent target data instead, we aim to handle these concerns implicitly. We present the first results translating directly from disfluent source speech to fluent target text.

2 Data

For our experiments, we use Fisher Spanish speech (Graff et al.) and with two sets of English translations (Salesky et al., 2018; Post et al., 2013). The speech dataset comprises telephone conversations between mostly native Spanish speakers recorded in realistic noise conditions. The original English translations were collected through crowdsourcing, as described in Post et al. (2013). Four references were collected for each of the development and test sets, and one for training. The training data consists of 819 conversations yielding ∼160 hours of speech and 150k utterances; the development and test sets are ∼4k utterances each. We use only the first of the two development sets (dev, not dev2).

This data is conversational and disfluent. The original translations faithfully maintain and translate phenomena in the Spanish transcripts such as filler words and hesitations, discourse markers (*you know*, *well*, *mm*), repetitions, corrections and false starts, among others. Salesky et al. (2018) introduced a new set of fluent reference translations collected on Mechanical Turk. They collected two references for each of the development and test sets, and one for the training set. Rather than labeling the disfluencies in the original target data, Turkers were asked to rewrite the utterance in a 'copy-edited' manner without disfluent phenomena. In some cases, simply removing disfluencies would created ill-formed structure in the resulting utterance. This scheme instead creates a sentence-level edit allowing for reordering and insertions as necessary to create fluent content, akin instead to monolingual translation or paraphrasing. Examples of source transcripts and original translations with the fluent counterparts are shown below in Table 1.

SRC	eh, eh, eh, um, yo pienso que es así
ORG	uh, uh, uh, um, i think it's like that

FLT	i am at the university of pennsylvania

Table 1: Disfluency examples in Spanish source (SRC), original (ORG) and fluent (FLT) English translations

3 Speech-to-Text Model

Initial work on the Fisher-Spanish dataset used HMM-GMM ASR models linked with phrase-based MT using lattices (Post et al., 2013; Kumar et al., 2014). More recently, it was shown in Weiss et al. (2017) and Bansal et al. (2018) that end-to-end SLT models perform competitively on this task. As in Bansal et al. (2018), we use a sequence-to-sequence architecture inspired by Weiss et al. but modified to train within available resources; specifically, all models may be trained in less than 5 days on one GPU. We build an encoder-decoder model with attention in `xnmt` (Neubig et al., 2018) with 512 hidden units throughout. We use a 3-layer BiLSTM encoder. We do not use the additional convolutional layers from Weiss et al. and Bansal et al. to reduce temporal resolution, but rather use network-in-network (NiN) projections from previous work in sequence-to-sequence ASR (Zhang et al., 2017; Sperber et al., 2018) to get the same total $4\times$ downsampling in time. This gives the benefit of added depth with fewer parameters. We closely follow the LSTM/NiN encoder used in Sperber et al. (2018) for ASR and use the same training procedure, detailed in Appendix A.

We extract 40-dimensional mel filterbank features with per-speaker mean and variance normalization with Kaldi (Povey et al., 2011). We did not see significant difference between 40, 40+deltas and 80-dimensional features in initial experiments, similar to Bansal et al. (2018), who chose 80-dim. Weiss et al. (2017) used 240-dim features comprising 80-dim filterbanks stacked with deltas and delta-deltas. We exclude utterances longer than 1500 frames to manage memory requirements.

Like Weiss et al. (2017), we translate to target characters as opposed to words (Bansal et al., 2018). We also use an MLP-based attention with 1 hidden layer with 128 units and 64-dimensional target embeddings, though we use only 1 decoder hidden layer as opposed to 3 or 4 in these works. We use input feeding (Luong et al., 2015). All models use the same preprocessing as previous work on this dataset: lowercasing and removing punctuation aside from apostrophes.

4 Experiments

4.1 Experimental Setup

We focus on the problem of translating directly from noisy speech to clean references without a separate disfluency removal step. We first demonstrate the efficacy of our models on the original disfluent Fisher Spanish-English task, comparing to the previously reported numbers on the SLT task (Weiss et al., 2017; Bansal et al., 2018). We then compare these results with models trained using the collected 'clean' target data with disfluencies removed. Finally, we look at the mismatched case where we train on disfluent data and evaluate on a cleaned test set; this is a more realistic scenario, as clean training data is difficult to collect, and we cannot expect to have it for each language and use case we encounter.

We evaluate using both BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014) to compare different aspects of model behavior on our two tasks.[2] BLEU assesses how well predicted translations match a set of reference translations using modified n-gram precision, weighted by a brevity penalty in place of recall to penalize short hypothesis translations without full coverage. The brevity penalty is computed as $e^{(1-r/c)}$, where r is the length of the reference and c the candidate translation. For our task of implicitly removing disfluencies during translation, our generated translations should contain much of the same content but with certain tokens removed, creating shorter translations. When scoring *fluent output* against the *original disfluent references*, then, differences in BLEU score will come from two sources: shorter n-gram matches, and the brevity penalty. METEOR, on the other hand, can be considered a more 'semantic' evaluation metric. It uses a harmonic mean of precision and recall, with greater weight given to recall. Further, while BLEU uses exact n-gram matches, METEOR also takes into account stem, synonym, and paraphrase matches. For our fluent task, we aim to maintain semantic meaning while removing disfluent tokens. Accordingly, when scored against the fluent target references, we hope to see similar METEOR scores between the disfluent models and fluent models. Both metrics are used for a holistic view of the problem: METEOR will indicate if meaning is maintained, but not assess disfluency removal, while BLEU changes will indicate whether disfluencies have been removed.

We provide both multi-reference and single-reference BLEU and METEOR scores: the original Fisher target data has four reference translations for the dev and test sets, which boosts scores considerably as hypothesis n-grams can match in any of the references. The fluent target data has two references, so the single reference scores better enable comparison between the two tasks.

4.2 Results & Discussion

Table 2 shows our results on the original disfluent data with comparisons to Weiss et al. (2017) and Bansal et al. (2018). All results are single task end-to-end speech translation models. Weiss et al.'s deeper model reaches a BLEU score of 47.3 on `test` after 2.5 weeks of training. Our model is more similar in depth to Bansal et al. (2018), having both made modifications to train on one GPU in < 5 days (see Section 3). While Bansal et al. use words on the target side to improve convergence time at a slight performance cost, we are able to use characters like Weiss et al. by having a still shallower architecture (2 fewer layers on both the encoder and decoder), giving us approximately the same training time per epoch they observe with words ($\sim$2 hours). We converge to a test BLEU of 33.7, 3-4 BLEU improved over Bansal et al. on dev and test. This demonstrates our model has reasonable performance on the original data, providing a strong baseline before turning to our targeted task of directly generating fluent translations.

	Weiss et al.		Bansal et al.		Ours	
Metric	**dev**	**test**	**dev**	**test**	**dev**	**test**
BLEU 4Ref	46.5	47.3	29.5	29.4	32.4	33.7
BLEU 1Ref	–	–	–	–	19.0	19.6
METEOR 4Ref	36.5	–	28.2	–	30.0	30.9
METEOR 1Ref	–	–	–	–	25.1	26.1

Table 2: Single task end-to-end speech translation using **original disfluent references** to train and evaluate. Comparing multi-reference scores using all four references (4Ref) vs average single reference score (1Ref).

Table 3 compares performance of speech translation models trained with the fluent target translations to models trained with the original disfluent translations, as scored on the fluent references. Comparing the disfluent and fluent models, we see that METEOR scores are almost the same while BLEU scores are lower with the disfluent model. This is as we would hope: with our fluent model, we want to generate translations that are semantically the same but with disfluencies removed. Therefore similar METEOR scores with similar

---

[2] BLEU scores are 4-gram word-level BLEU computed using `multi-bleu.pl` from the Moses toolkit (Koehn et al., 2007). METEOR is computed using the script from http://www.cs.cmu.edu/~alavie/METEOR/

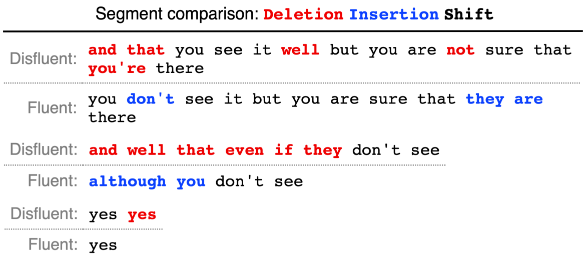
recall (52) on the fluent references are encouraging. For BLEU, however, the disfluencies generated by the disfluent model break up n-grams in the fluent references, thereby lowering scores.

Model	Metric	dev 1Ref	dev 2Ref	test 1Ref	test 2Ref
Disfluent	BLEU	13.0	16.2	13.5	17.0
Fluent	BLEU	14.6	18.1	14.6	18.1
Disfluent	METEOR	22.2	23.9	23.1	24.8
Fluent	METEOR	22.3	24.0	23.1	24.9

Table 3: End-to-end model performance evaluated with **new fluent references**. Comparing average single reference scores (1Ref) vs multi-reference scores using both generated references (2Ref).

Comparing single-reference scores with Table 2, we see that they are distinctly lower. This is to be expected with the shorter fluent references; a difference of a single token carries greater weight. Translating directly to the fluent references is a more challenging task. As shown in Table 1, the original English translations and Spanish speech are very one-to-one while the edited translations introduce deletions and reorderings. In learning to generate fluent translations, the model needs to learn to handle these more inconsistent behaviors.

Figure 1 shows a visual comparison between outputs generated by the two models. Using the fluent target data to train constrains the model output vocabulary, so filler words such as *'um', 'ah', 'mhm'* are not generated. We also see significant reductions in repetitions of both words and phrases from the model trained with fluent reference translations. Further, we also see instances where the fluent model generates a shorter paraphrase of a disfluent phrase, as in the 2nd example.



Segment comparison: **Deletion** **Insertion** **Shift**

Disfluent: **and** **that** you see it **well** but you are **not** sure that **you're** there

Fluent: you **don't** see it but you are sure that **they** **are** there

Disfluent: **and** **well** **that** **even** **if** **they** don't see

Fluent: **although** **you** don't see

Disfluent: yes **yes**

Fluent: yes

Figure 1: Comparison of example outputs generated by disfluent and fluent models, created with CharCut (Lardilleux and Lepage, 2017).

Disfluency removal for speech translation has traditionally been done as an intermediate step between ASR and MT to better-match additional clean corpora used for MT training; we do not compare to a pipeline approach here. However, to contextualize these results, we compare disfluency removal as a post-processing step after end-to-end speech translation with the original disfluent parallel data. Simply filtering filler words and repetitions from the disfluent model (Filter) outputs as a post-processing step, the dev scores improve slightly, but test stays the same or decreases. In some cases, treating disfluency removal as a filtering task can reduce the fluency of an utterance:

Model	dev 1Ref	dev 2Ref	test 1Ref	test 2Ref
Postproc. Filter	13.6	16.5	13.5	16.8
Postproc. MonoMT	14.4	17.8	14.4	18.0

Table 4: End-to-end disfluent model with different post-processing steps. Performance evaluated with **new fluent references**.

Disfluent	*mm well and from and the email is a scandal the spam.*
Fluent	*the email is a scandal it's spam.*

A filtering or tagging system may not capture all false starts or corrections, leading to lower fluency, and requires labeled spans. Treating the post-processing step as a monolingual translation task (MonoMT) rather than a filtering task allows for reordering and insertions, which we saw boost fluency. We trained a 4-layer BiLSTM encoder-decoder model to translate between the disfluent and fluent English references and applied this to the output of the end-to-end disfluent model. BLEU scores approach the results with the end-to-end fluent target model (Table 3), but we note, this requires the same resources as the direct task.

Showing the importance of fluent references for evaluation, Table 5 shows the performance of fluent models as evaluated on the original disfluent references. Disfluent target scores are the same as in Table 2, and have been copied for easy compar-

Model	Metric	dev 1Ref	dev 4Ref	test 1Ref	test 4Ref
Fluent	BLEU	16.6	29.8	17.0	30.4
Disfluent	BLEU	19.0	32.4	19.6	33.7
Fluent	METEOR	21.8	25.9	22.7	27.0
Disfluent	METEOR	25.1	30.0	26.1	30.9

Table 5: Performance evaluated with **original disfluent references**. Comparing average single reference scores (1Ref) vs multi-reference scores using all references (4Ref).

ison. As we would expect, here there is a greater difference in scores. The fluent references have fewer long n-gram matches with disfluencies removed, lowering BLEU. The fluent model's METEOR scores suffer more than BLEU due to the recall calculation; recall on the disfluent references is lower because the fluent model does not produce many of the disfluencies (indeed filler words are not in the vocabulary when trained with the fluent references). Recall is reduced by $\sim 14\%$ with the fluent model, reflecting the approximate distribution of disfluencies in the original data.

The differences in scores with these two metrics do not show the full picture. Outputs generated by the fluent model are on average 13% shorter and contain 1.5 fewer tokens per utterance than the disfluent model, which is significant with average utterance lengths of 10-11 tokens. When scoring the fluent output against the original disfluent references, the shorter length significantly contributes to the lower scores, with the BLEU brevity penalty calculated as 0.86 as opposed to 0.96-1.0 for all other conditions. Removing the length penalty from the BLEU score calculation, single-reference scores are boosted to 19.3 and 19.8 from 16.6 and 17.0 for dev and test, respectively (Table 5). This is a somewhat fairer comparison of the disfluent and fluent models, as we do not want the fluent output to match the disfluent sequence length, and the disfluent models are not penalized due to length. These BLEU scores are now very similar to those of the disfluent model on the disfluent references, though the outputs are very different (Figure 1). The changes here and the difference in trends between the two metrics with respect to the two types of references show that evaluating this task cannot be simply accomplished with one existing metric: depending on the combination of metric and references, it's possible to mask the difference between disfluent and fluent systems, unless you have word-level disfluency annotations, which are more difficult to obtain.

5 Conclusion

Machine translation applications for speech can suffer due to conversational speech phenomena, particularly the presence of disfluencies. Previous work to remove disfluencies in speech translation did so as a separate step between speech recognition and machine translation, which is not possible using end-to-end models. Using clean references for disfluent data collected by Salesky et al. (2018), we extend their text baseline to speech input and provide first results for direct generation of fluent text from noisy disfluent speech.

While fluent training data enables research on this task with end-to-end models, it is unlikely to have this resource for every corpus and domain and it is expensive to collect. In future work, we hope to reduce the dependence on fluent target data during training through decoder pretraining on external non-conversational corpora or multitask learning. Further, standard metrics alone do not tell the full story for this task; additional work on evaluation metrics may better demonstrate the differences between such systems.

A Appendix. LSTM/NiN Encoder and Training Procedure Details

A.1 Encoder Downsampling Procedure

Weiss et al. (2017) and Bansal et al. (2018) use two strided convolutional layers atop three bidirectional long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) layers to downsample input sequences in **time** by a total factor of 4. Weiss et al. (2017) additionally downsample **feature** dimensionality by a factor of 3 using a ConvLSTM layer between their convolutional and LSTM layers. This is in contrast to the pyramidal encoder (Chan et al., 2016) from sequence-to-sequence speech recognition, where pairs of consecutive layer outputs are concatenated before being fed to the next layer to halve the number of states between layers.

To downsample in time we instead use the LSTM/NiN model used in Sperber et al. (2018) and Zhang et al. (2017), which stacks blocks consisting of an LSTM, a network-in-network (NiN) projection, layer batch normalization and then a ReLU non-linearity. NiN denotes a simple linear projection applied at every timestep, performing downsampling by a factor of 2 by concatenating pairs of adjacent projection inputs. The LSTM/NiN blocks are extended by a final LSTM layer for a total of three BiLSTM layers with the same total downsampling of 4 as Weiss et al. (2017) and Bansal et al. (2018). These blocks give us the benefit of added depth with fewer parameters.

A.2 Training Procedure

We follow the training procedure from Sperber et al. (2018). The model uses variational recurrent dropout with probability 0.2 and target character dropout with probability 0.1 (Gal and Ghahramani, 2016). We apply label smoothing (Szegedy et al., 2016) and fix the target embedding norm to 1 (Nguyen and Chiang, 2018). For inference, we use a beam size of 15 and length normalization with exponent 1.5. We set the batch size dynamically depending on the input sequence length such that the average batch size was 36. We use Adam (Kingma and Ba, 2015) with initial learning rate of 0.0003, and decay by 0.5 when validation BLEU did not improve first over 10 epochs and after 5 epochs after the first decay. We do not use L2 weight decay or Gaussian noise, and use a single model replica. All models use the same preprocessing as previous work on this dataset: lowercasing and removing punctuation aside from apostrophes.

Relation Classification Using Segment-Level Attention-based CNN and Dependency-based RNN

Abstract

Recently, relation classification has gained much success by exploiting deep neural networks. In this paper, we propose a new model effectively combining Segment-level Attention-based Convolutional Neural Networks (SACNNs) and Dependency-based Recurrent Neural Networks (DepRNNs). While SACNNs allow the model to selectively focus on the important information segment from the raw sequence, DepRNNs help to handle the long-distance relations from the shortest dependency path of the related entities. Experiments on the SemEval-2010 Task 8 dataset show that our model is comparable to the state-of-the-art without using any external lexical features.

1 Introduction

Relation classification (RC) is a fundamental task in Natural Language Processing (NLP) that aims to identify semantic relations between pairs of marked entities in given sentences (instances). It has attracted much research effort as it plays a vital role in many NLP applications such as Information Extraction and Question Answering (Nguyen and Grishman, 2015). Traditional approaches (Kambhatla, 2004; Zhang et al., 2006) usually rely heavily on hand-crafted features and lexical resources, or elaborately designed kernels, which are time-consuming and challenging to adapt to novel domains. Recently, neural network (NN) models have dominated the work on RC since they can effectively learn meaningful hidden features without human intervention.

However, most previous NN models only exploit one of the following structures to represent relation instances: raw word sequences (Zhou et al., 2016; Wang et al., 2016) and dependency trees (Wen, 2017; Le et al., 2018). While raw sequences can provide all the information of relation instances, they also add noise to the models from redundant information. While dependency tree structures help the models focus on the concise information captured by the shortest dependency path (SDP) between two entities, they lose some supplementary context in the raw sequence. It is clear that the raw sequence and SDP highly complement each other. We, therefore, combine them to be more effective in determining the relation without losing any information.

While CNNs are able to learn short patterns (local features) (LeCun et al., 1995), RNNs have been effective in learning word sequence information (long-distance features) (Chung et al., 2014). In this paper, we present a new model combining both CNNs and RNNs, exploiting the information from both the raw sequence and the SDP.

Our contributions are summarized as follows:

(a) We combine Entity Tag Feature (ETF) (Qin et al., 2016) and Tree-based Position Feature (TPF) (Yang et al., 2016) to improve the semantic information between the marked entities in the raw input sentences.

(b) We propose Segment-Level Attention-based Convolutional Neural Networks (SACNNs) which automatically pay special attention to the important text segments from the raw sentence for RC.

(c) We build Dependency-based Recurrent Neural Networks (DepRNNs) on the SDP to gain long-distance features. Then, we combine the SACNN and the DepRNN to preserve the full relational information. Our proposed model achieves new state-of-the-art results on SemEval-2010 Task 8, compared with other complex models.

2 Related Work

RC plays a significant role in many NLP applications. Recent work usually present the task from a supervised perspective.

Proceedings of NAACL-HLT 2019, pages 2793–2798
Minneapolis, Minnesota, June 2 - June 7, 2019.

Traditional supervised approaches can be divided into feature-based methods and kernel methods. Feature-based methods focus on extracting and combining relevant features. Rink and Harabagiu (2010) leveraged useful features to achieve the best performance on SemEval-2010 Task 8. Meanwhile, kernel methods measure the structural similarity between two data samples, based on carefully designed kernels. Wang (2008) combined convolutional kernel and syntactic features to gain benefits for relation extraction.

Nowadays, deep neural networks are widely utilized in RC. Zeng et al. (2014) exploited a CNN to extract lexical and sentence features. Qin et al. (2016) used ETF to specify target entities in input sentences and fed them to a CNN. Vu et al. (2016) combined CNN and RNN to improve performance. Some recent work leveraged SDP for RC. Yang et al. (2016) proposed a position encoding CNN based on dependency parse trees, while Wen (2017) presented a model that learns representations from SDP, using both CNN and RNN.

3 Our Method

Given a sentence S with an annotated pair of entities ($e1$, $e2$), we aim to identify the semantic relation between them. Since the set of target relations is pre-defined, RC can be treated as a multi-class classification problem. In this section, we describe our model in detail for resolving this problem.

3.1 Input Representation

In Figure 1, Entity Tag Feature (ETF) is firstly used to annotate two entities in each raw sentence. Then, each word is represented by the concatenation of two parts: Word Embedding (WE) and Tree-based Position Features (TPFs). The representation sequence is then fed to the SACNN.

Entity Information. As the pairs of entities ($e1$, $e2$) are previously known, it is important to provide their information to the NNs. Following the work of Qin et al. (2016), we also use ETF which involves adding four tokens: $\langle e1S\rangle$, $\langle e1E\rangle$, $\langle e2S\rangle$ and $\langle e2E\rangle$ to each input sentence.

Word Embedding. Distributed representations of words in a vector space have helped learning algorithms to achieve better performance in NLP tasks (Mikolov et al., 2013). Following most previous work, we also use pre-trained word embeddings to initialize input word tokens in our model.

Tree-based Position Features. Yang et al. (2016) proposed TPFs for encoding relative distances of the current word to marked entities in dependency trees. The relative distance refers to the length of the SDP between the current word and the target entity. Then, each integer number is represented by a randomly initialized vector. Since TPFs help the neural network focus on crucial words and phrases in a sentence (Yang et al., 2016), we therefore utilize TPFs in our model. In Figure 1, TPF$_1$ and TPF$_2$ are relative distance features of each word to $e1$ and $e2$, respectively. For the four tokens: $\langle e1S\rangle$, $\langle e1E\rangle$, $\langle e2S\rangle$ and $\langle e2E\rangle$, which do not belong to the dependency tree, we simply pad zero vectors for their TPFs.

SDP. For the input of the DepRNN, we merely use the SDP between two marked entities from the original sentence as in Figure 1. Each normal word in the SDP is represented by a vector from pre-trained word embeddings. Meanwhile, following Le et al. (2018), we also consider dependency relations between words in the SDP and represent each dependency relation d_i as a vector D_i that is the concatenation of two vectors as follows:

$$D_i = Dtyp_i \oplus Ddir_i,$$

where *Dtyp* is the undirected dependency vector (*i.e.,* nmod), and *Ddir* is the orientation of the dependency vector (*i.e.,* left-to-right or vice versa). Both *Dtyp* and *Ddir* are initialized randomly.

3.2 Framework

The architecture of our model is illustrated in Figure 1. The example sentence with two entities $e1$ (*play*) and $e2$ (*religion*) is labeled by the directional relation "*Message-Topic(e1;e2)*". While the raw sequence is passed to the SACNN, the SDP between $e1$ and $e2$ is used in the DepRNN.

Segment Attention-based CNN. In the SACNN, each raw sentence is divided into three segments according to two entities: the left segment, the middle segment, and the right segment. The repetitions of $e1$ and $e2$ in these segments help the semantic meaning of each segment to be more clear. Intuitively, the middle segment is often more important to reflect the semantic relation. Qin et al. (2016) only used the middle segment with a CNN for RC, while Vu et al. (2016) proposed an extended middle context to pay special attention to the middle part.

Although the middle segment is more significant than two remaining segments in many cases,

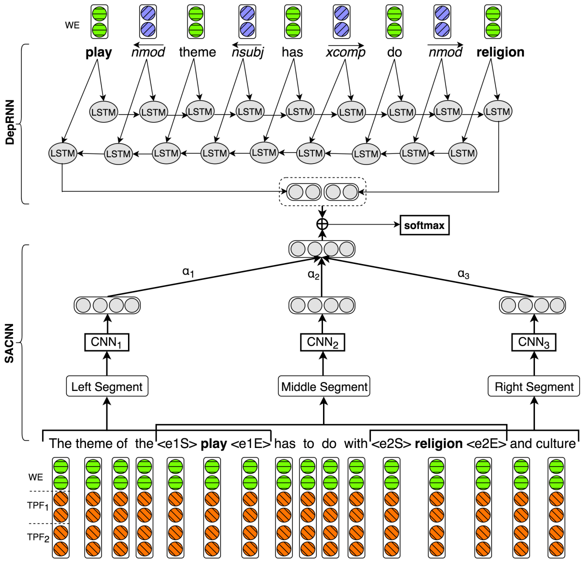

Figure 1: Our model for relation classification.

it is not always true for all. For example, in the sentence "*All other* $\langle e1S \rangle$ ***blood*** $\langle e1E \rangle$ $\langle e2S \rangle$ ***products*** $\langle e2E \rangle$ *are derived from whole blood.*" with the relation label "*Entity-Origin(e2;e1)*", the right segment is more important to reflect the relation type. Besides, the left and right segments might also provide the necessary information to RC. We therefore proceed three segments independently through three separate CNNs, which allow the model to automatically identify segments containing important information. Each CNN includes one convolutional layer and one max-pooling layer.

Let M be a matrix consisting of output vectors of three CNNs: $M = [m_1, m_2, m_3]$, where m_i is the output of CNN_i. The final representation r_1 of the raw sentence generated by SACNN is formed by a weighted sum of output vectors in M:

$$z_i = tanh(m_i),$$

$$\alpha_i = \frac{exp(w^T z_i + b)}{\sum_{i=1}^{3} exp(w^T z_i + b)},$$

$$r_1 = \sum_{i=1}^{3} \alpha_i m_i,$$

where w is a weight vector, w^T is its transformation, and b is a bias parameter.

Dependency-based RNN. While SACNN can learn local features, it cannot handle long-distance dependency between two entities. This disadvantage causes difficulty in correctly assigning subject and object roles of two entities when capturing the directional relation. Meanwhile, RNN could tackle the problem of long-distance pattern learning (Zhang and Wang, 2015). Besides, the SDP naturally offers the relative positions of subjects and objects through the path directions (Xu et al., 2015). We, therefore, exploit SDP based on RNN to gain the information in the directional relation.

An shown in Figure 1, we use Bidirectional Long Short-Term Memory (BLSTM) on the SDP between two entities. Due to its ability to capture long term memory, the BLSTM accumulates increasingly richer information as it goes through the SDP from both two forward and backward directions (Palangi et al., 2016). When it reaches the last two words, the last two hidden states are expected to provide the full semantic meaning of the whole SDP. Additionally, since the length of the SDP is often not so long, we concatenate two output vectors of the last two hidden states as the final representation r_2 of the SDP by DepRNN.

Combination of SACNN and DepRNN. Finally, we combine both SACNN and DepRNN models to exploit fully their own distinct advantages. While SACNN can focus on important segments and gain local features, DepRNN helps to handle long-distance dependency between two entities based on the SDP as well as provide subject and object roles of two entities for the directional relation. Therefore, the final representation r of the relation instance is concatenated by two output vectors (r_1 , r_2) of SACNN and DepRNN, which is then fed to a softmax classifier.

4 Experiments

4.1 Datasets and Settings

We evaluate our model on the SemEval2010 Task 8 which contains $8,000$ training sentences and $2,717$ test sentences, with 19 relations (9 directed relations and an undirected *Other* class). Therefore, the relation classification task is treated as a multi-class classification problem. Following previous work, the official macro-averaged F1-score, which excludes the *Other* relation, is used for evaluation.

We randomly held out 10% of the training set for validation. The Stanford Parser is also used to convert sentences to dependency trees.

For word embeddings, we use the 300-dimensional embeddings of Komninos and Manandhar (2016). In this work, we do not focus on comparing the effectiveness of the different pre-

Table 4: Comparison of different classification models. DT, PF stand for Dependency Tree, Position Feature. The *italic* features are external lexical features used.

trained embedding sets. The above pre-trained embedding set is selected since it embeds dependency context to provide valuable syntactic information. Four tokens: $\langle e1S \rangle$, $\langle e1E \rangle$, $\langle e2S \rangle$, $\langle e2E \rangle$ and out-of-vocabulary words are initialized by sampling from a uniform distribution (Kim, 2014). TPF is 15-dimensional and initialized randomly. Thus, the representation of each word has a dimensionality of 330 in the raw sentence.

Hyper-parameters in our model are as follows: 100 filters for each window size [3, 4, 5] and ReLU as the activation function for each CNN in SACNN. In DepRNN, the dimension of each token is 300, the $tanh$ activation function is applied to the last two hidden states, the dimension of each hidden state vector is 150. Other parameters include: L2 regularization with a weight of 10^{-4}, a mini-batch size of 64, a dropout rate at the final layer p = 0.5 before a softmax classifier.

4.2 Results and Analysis

Impact of SACNN and DepRNN. We consider the performance of each model by feeding separately their output vector to a softmax classifier.

In Table 1, we see the effect of different features to SACNN's performance. Combining ETF and TPF significantly enhances the $F1$ score by 0.6%. It proves that ETF and TPF complement each other to more fully provide information about the marked entities and important words to SACNN.

We also examine the segment-level attention mechanism of SACNN. In Table 2, with the same input features (WE, ETF, TPF), the segment-level attention mechanism makes a great contribution by increasing the $F1$ score by 1%.

To check the effect of combining SACNN and DepRNN, in Table 3, we compare the performance of each model to our combined model. First, the SACNN's performance is superior to the DepRNN. One possible reason is that while SACNN selectively focuses on the important segments as well as gains local features from the raw sentences, DepRNN based on the SDP, which is short in the SemEval2010 Task 8, can only provide effectively the entities role. Then, by combining SACNN and DepRNN, our model can exploit the fully necessary information and achieve the best performance.

Comparisons with the State of the Art. We compare our model to some recent work on RC in Table 4. Most previous work exploited some external lexical features (WordNet, NER) and combine NNs to improve the performance (Yang et al., 2016; Wang et al., 2017). Wang et al. (2017) and Wen (2017) proposed complex structures for integrating the CNN and the LSTM, and achieved an $F1$ of 84.7% and 85.1% respectively. Zhang et al. (2018) combined CNN and BLSTM, and reached an $F1$ of 83.7% using only WE, PF features.

Without using any external lexical resources, our model achieves an $F1$ of 85.8%, showing that combining SACNN and DepRNN is very effective, since SACNN helps to selectively focus on the important segments and gains local features, DepRNN provides the role information of subject and object of two entities in addressing the relation directionality. Comparing with some recent work, our model obtains a notable performance.

5 Conclusion

This work presents a new model that combines the SACNN and the DepRNN for RC. Combining ETF and TPF provides entity and semantic information of the input sentences to the model effectively. We also propose the SACNN which automatically focus on the essential segments and gains local features. Besides, the DepRNN helps to exploit long-distance dependency between two entities and their roles. Finally, combining the SACNN and the DepRNN brings the best performance since they highly complement each other. Our model achieved a notable performance on the SemEval2010 Task 8 without using any external lexical resources.

Abstract

Document-level event factuality identification is an important subtask in event factuality and is crucial for discourse understanding in Natural Language Processing (NLP). Previous studies mainly suffer from the scarcity of suitable corpus and effective methods. To solve these two issues, we first construct a corpus annotated with both document- and sentence-level event factuality information on both English and Chinese texts. Then we present an LSTM neural network based on adversarial training with both intra- and inter-sequence attentions to identify document-level event factuality. Experimental results show that our neural network model can outperform various baselines on the constructed corpus.

1 Introduction

Document-level event factuality identification is the task of deciding the commitment of relevant sources towards the factual nature of an event, and to determine whether an event is a fact, a possibility, or an impossible situation from the view of document. Identifying document-level factuality of events requires comprehensive understanding of documents. As illustrated in Figure 1 where events are in ***bold***, the event "*reach*" (including its other forms) have various factuality values in different sentences. For example, in paragraph 2, "*reach*" is impossible/CT- according to the negative word "*denied*", while in paragraph 3, "*reach*" is possible/PS+ due to the speculative word "*may*". The main contents of this document is "*Mexico denied that they will reach an agreement with the U.S. on the new trade deal*", and the document-level factuality of the event "*reach*" is CT-.

> *According to Politico.com, it is said the United States will* ***reach*****(CT+)** *an agreement with Mexico on the new trade deal that will replace North American Free Trade Agreement (NAFTA) before December, 2017.*
>
> *However, Mexican Economy Minister Ildefonso Guajardo denied that they plan to* ***reach*****(CT-)** *any agreement with the U.S. on the trade deal talks.*
>
> *"We are not going to sacrifice the quality of an agreement because of pressure of time. We will keep engaged." he said. Just two days ago, Guajardo said the two sides may* ***reach*****(PS+)** *an agreement within hours.*
>
> *The government has not been informed that any agreement will be* ***reached*****(CT-)** *yet, said another two Mexican officials.*
>
> *During the past few weeks, the U.S. has been negotiating with Mexico on the new trade deal and has achieved much progress. Thus, some media speculate that they will possibly* ***reach*****(PS+)** *an agreement. But now it seems that the negotiations will continue before they can get a good deal.*
>
> (Time: November, 2017)
> (Document-level factuality of the event "*reach*" is **CT-**.)

Figure 1: An example document with both sentence- and document-level event factuality.

Document-level event factuality identification is fundamental for document-level NLP applications, such as machine reading comprehension, which aims to have machines read a text passage and then answer questions about the text. According to the document in Figure 1, the answer of the following question should be "*No*", which is consistent with the document-level factuality of the event "*reach*" (CT-):

Q*: Does the U.S. reach an agreement with Mexico on the new trade deal before December 2017?*

A*: No.*

Previous studies mostly reported on sentence-level event factuality identification tasks. On one hand, due to the scarcity of document-level event factuality corpus, these studies only considered the corpora annotated with sentence-level event factuality information, such as ACE 2005[1], LU (Diab et al., 2009), FactBank (Saurí and Pustejovsky, 2009), and UDS-IH2 (Rudinger et al., 2018).

On the other hand, previous studies only con-

Minneapolis, Minnesota, June 2 - June 7, 2019.

sidered information within sentences, using rules (Saurí, 2008; Saurí and Pustejovsky, 2012), machine learning models (de Marneffe et al., 2012; Werner et al., 2015; Baly et al., 2018), and combinations of them (Qian et al., 2015; Stanovsky et al., 2017) for modeling. Neural network models have also recently been used for the sentence-level event factuality identification (He et al., 2017; Rudinger et al., 2018; Qian et al., 2018). According to Figure 1, document-level event factuality can not be deduced from each sentence-level factuality separately, but depends on the comprehensive semantic information of sentences. However, no suitable model for document-level task has been proposed yet.

To solve the issues above, this paper focuses on **document-level** event factuality identification. Our contributions can be summarized as follows.

1) We construct a document-level event factuality corpus, i.e. DLEF, on both English and Chinese texts. To our best knowledge, this is the first document-level event factuality corpus. The statistics on the corpora and the experimental results show that our corpus can sufficiently reflect linguistic characteristics of news texts, and provide adequate support on resource for research.

2) We propose an LSTM neural network with both intra- and inter-sequence attentions to identify document-level event factuality, and consider dependency paths from speculative and negative cues to the event and sentences containing the event as features. Due to the diversity of various contents of the texts in DLEF corpus, we employ Adversarial Training to improve the robustness of our model. Experimental results show that our model is superior to various baselines. The corpus and code of this paper will be released at `https://github.com/qz011/dlef`.

2 Corpus Annotation

This section introduces our **D**ocument-**L**evel **E**vent **F**actuality (DLEF) corpus, including the source, detailed guidelines for both document- and sentence-level event factuality, and the main statistics of the corpus.

2.1 Source

News texts contain sufficient speculative and negative information that is significant for event factuality identification, and usually focus on one event with a specific topic. Moreover, FactBank (Saurí and Pustejovsky, 2009), the sentence-level event factuality corpus, is also based on news texts.

	+	-	u
CT	CT+	CT-	CTu
PS	PS+	PS-	(NA)
U	(NA)	(NA)	Uu

Table 1: Event factuality values.

Therefore, we choose news texts in both English and Chinese to construct our corpus. The English corpus consists of 1727 documents from January 2017 to January 2018, among which 1506 documents are from China Daily[2], and 221 documents are from Sina Bilingual News[3]. The Chinese corpus consists of 4649 documents from Sina News[4]. These news documents cover various topics, e.g., politics, economy, culture, military, and society, which can reflect the heterogeneity of language in news texts.

2.2 Factuality Values

Saurí (2008) employed modality and polarity to describe event factuality values. Modality conveys the certainty degree of events, such as *certain* (CT), *probable* (PR), and *possible* (PS), while polarity expresses whether the event happened, including *positive*(+) and *negative*(-).

We use the factuality values in Table 1 according to Saurí (2008). Both PR and PS are speculative values and share similar certainty degrees in our corpus, and are merged into PS . U/u means *underspecified*. PSu and U+/- are not applicable (NA) and are not considered. Although CTu is applicable, neither document-level nor sentence-level event can be annotated as CTu in our corpus.

2.3 Annotation Guidelines

We adopt the definition of events proposed by TimeML (Pustejovsky et al., 2003) and consider the events that can be critical for computing the factuality. To ensure that the task is meaningful, we focus on the events that have various types of sentence-level factuality values. If there is more than one suitable event in a document, we annotate them separately.

First, the annotation of document-level event factuality is based on the definition, i.e., determining the factuality of an event from the view of

---

[3] http://roll.edu.sina.com.cn/english/syxw/index.shtml

[4] http://news.sina.com.cn

the document requires to understand the semantic of the document, including various sentence-level event factuality.

Second, sentence-level event factuality is essential for document-level task, which makes sense when document- and sentence-level factuality of events have different values. Therefore, we annotate the sentence-level event factuality as follows:

CT- events are negated by negative cues. For example, the events "*enter*" and "*merger*" are governed by negative cues "*impossible*" and "*denied*" in sentence S1 and S2, respectively.

(S1) *He said that the loss made it impossible for them to **enter** the semifinals.*

(S2) *Sinopec responded to National Business Daily, and denied the rumors of a **merger** with PetroChina.*

PS+ events (e.g. "*improve*" and "*fallen*") are governed by speculative cues (e.g., "*impossible*" and "*denied*"), just as illustrated in sentence S4 and S5.

(S4) *We think that further investigation may help to **improve** the treatment of people with similar infections.*

(S5) *The missing parts may have **fallen** during the flight of the plane.*

PS- events are governed by both speculative and negative cues. Different from CT-, PS- means incompletely negation. For example, the PS- event "*noticed*" is governed by the speculative cue "*probably*" and the negative cue "*not*" in sentence S6, and "*fall*" is modified by the cues "*may*" and "*not*" in sentence S7.

(S6) *The bus driver had probably not **noticed** the truck early enough.*

(S7) *Oil prices may not **fall** sharply due to the strong global demand.*

Uu events can appear in questions (e.g., "*considering*" in sentence S8) and in the intensional contexts with underspecified semantics (e.g., "*raises*" in sentence S9):

(S8) *Is France **considering** to leave EU?*

(S9) *The US dollar's declination can not be reversed even if the Federal Reserve **raises** rates three times.*

CT+ events are factual and do not meet the above conditions.

2.4 Statistics

The task is trivial if most documents have only one type of sentence-level factuality value, and in this case, document-level factuality probably shares the same value. To understand the usefulness of document-level event factuality identification and DLEF corpus, we launched the statistics of documents with n different types of sentence-level event factuality values shown in Table 2. From the table we can find that for English corpus there are 41.94% CT- and 66.06% PS+ documents with different sentence-level event factuality values, but these CT+ documents only cover 11.13%. While for Chinese corpus, these CT- and PS+ documents cover 63.41% and 62.15%, but these CT+ documents only make up 14.23%.

Corpus	**Docs**	***n*=1**	***n*=2**	***n*⩾3**
English	CT-	162	97	20
	PS+	93	157	24
	PS-	2	6	4
	Uu	5	6	1
	CT+	1022	119	9
	Total	1284	385	58
Chinese	CT-	491	612	239
	PS+	321	425	102
	PS-	9	11	16
	Uu	8	5	7
	CT+	2061	290	52
	Total	2890	1343	416

Table 2: Statistics of the documents in DLEF corpus with *n* types of sentence-level event factuality values.

Table 2 indicates that sentence-level factuality usually agrees with document-level factuality in CT+ documents, making them straightforward to be identified. However, in those non-CT+ documents with non-factual document-level values, sentence-level factuality is likely to have different values from documents, making them more difficult to be identified. In general, English and Chinese corpus have 25.64% and 37.84% documents with different sentence-level event factuality values, indicating this corpus is suitable for the document-level event factuality identification.

Table 3 shows the statistics of the DLEF corpus. CT+ document-level events are in the majority, because information reported by news texts is usually real.

Kappa (Cohen, 1960) is employed to measure the inter-annotator agreement of annotating document- and sentence-level event factuality between the two independent annotators who annotate the entire corpus, just as shown in Table 4. These two annotators are postgraduate stu-

dents who major in NLP. In addition, the Kappa of events on English and Chinese corpus are 0.83 and 0.85, respectively. All the Kappa values are larger than 0.75, proving the effectiveness and meaningfulness of our DLEF corpus.

3 Adversarial Neural Network for Document-Level Event Factuality Identification

This section describes the LSTM neural network for document-level event factuality identification in detail. As shown in Figure 2, to extract feature representations of events from the view of documents, we consider both intra- and inter-sequence attention for dependency paths and sentences. In addition, due to the diversity of contents of documents in DLEF corpus, we consider adversarial training to ensure the robustness of our model.

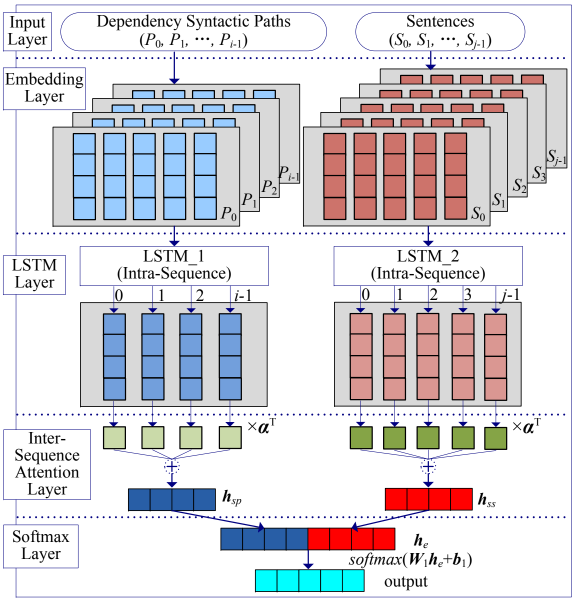

Figure 2: Neural network architecture for document-level event factuality identification.

3.1 Input Features

For our task, we use the specified events that have been annotated, and utilize the Chinese cues in CNeUn corpus (Zou et al., 2015) and the English cues in BioScope corpus (Vincze et al., 2008) that also considers multi-word cues, e.g., *rule out*. We do not use any annotated sentence-level event factuality. For one event, we consider all the sentences containing it, and mainly employ the following two features in our model:

1) **Syntactic Features**: Previous studies (Saurí and Pustejovsky, 2012; de Marneffe et al., 2012) have proved the effectiveness of dependency trees on event factuality identification tasks. Hence, we employ the dependency paths from speculative or negative cues to the event as syntactic features.

2) **Semantic Features**: We use the sentences containing the event as semantic features.

In addition, we also consider the above features in contexts of each sentence containing the event as the input, and set the windows size as 3, i.e., one sentence before and after the current one. If adjacent sentences contain speculative or negative cues, the dependency path is the concatenation of the path from the cue to the root and the path from the root to the event (Quirk and Poon, 2017).

3.2 LSTM with Two Attention Layers

A dependency path or sentence can be represented as $\boldsymbol{X}_0$ according to the embedding table. We employ LSTM with hidden units n_h to model the sequences from both directions to produce the forward hidden sequence $\overrightarrow{\boldsymbol{H}}$, the backward hidden sequence $\overrightarrow{\boldsymbol{H}}$, and the output sequence $\boldsymbol{H} = \overrightarrow{\boldsymbol{H}} + \overleftarrow{\boldsymbol{H}}$. We adopt the attention mechanism to capture the most important information from $\boldsymbol{H}$, and obtain the output $\boldsymbol{h}$:

$$\boldsymbol{H}_m = \tanh(\boldsymbol{H}) \tag{1}$$

$$\boldsymbol{\alpha} = \mathrm{softmax}(\boldsymbol{v}^T \boldsymbol{H}) \tag{2}$$

$$\boldsymbol{h} = \tanh(\boldsymbol{H}\boldsymbol{\alpha}^T) \tag{3}$$

where $\boldsymbol{v} \in \mathbb{R}^{n_h}$ is the parameter. One event can have k sequences $\boldsymbol{X}_0, \boldsymbol{X}_1, \ldots, \boldsymbol{X}_{k-1}$, whose representation is $\boldsymbol{H}_s = \boldsymbol{h}_0, \boldsymbol{h}_1, \ldots, \boldsymbol{h}_{k-1}$ according to the above equations, where $\boldsymbol{H}_s \in \mathbb{R}^{k \times n_h}$. To extract the feature representation $\boldsymbol{h}_s \in \mathbb{R}^{n_h}$ from the k sequences, we utilize an inter-sequence attention mechanism that is computed as:

$$\boldsymbol{H}_{ms} = \tanh(\boldsymbol{H}_s) \tag{4}$$

$$\boldsymbol{\alpha}_s = \mathrm{softmax}(\boldsymbol{v}_s^T \boldsymbol{H}_{ms}) \tag{5}$$

$$\boldsymbol{h}_s = \tanh(\boldsymbol{H}_s \boldsymbol{\alpha}_s^T) \tag{6}$$

where $\boldsymbol{v}_s \in \mathbb{R}^{n_h}$ is the parameter. Suppose that an event has i dependency paths $\boldsymbol{P}_0, \boldsymbol{P}_1, \ldots, \boldsymbol{P}_{i-1}$, and appears in j sentences $\boldsymbol{S}_0, \boldsymbol{S}_1, \ldots, \boldsymbol{S}_{j-1}$. Considering that dependency paths and sentences contain syntactic and semantic information, respectively, we employ two LSTM neural networks defined above to learn vector representations $\boldsymbol{h}_{sp}$ and $\boldsymbol{h}_{ss}$ of dependency paths and sentences, and concatenate them into the feature representation of the event $\boldsymbol{h}_e$:

$$\boldsymbol{h}_e = \boldsymbol{h}_{sp} \oplus \boldsymbol{h}_{ss} \tag{7}$$

where $\oplus$ is the concatenation operator. Finally, $\boldsymbol{h}_e$ is fed into the softmax layer to compute the probability of the factuality values of the event:

$$\boldsymbol{o} = \mathrm{softmax}(\boldsymbol{W}_1 \boldsymbol{h}_e + \boldsymbol{b}_1) \tag{8}$$

where $\boldsymbol{W}_1 \in \mathbb{R}^{c \times \dim(\boldsymbol{h}_e)}$ and $\boldsymbol{b}_1 \in \mathbb{R}^c$ are parameters, and $c = 5$ is the number of categories of factuality values (CT+, CT-, PS+, PS-, Uu). The objective function of the proposed neural network is designed as:

$$L_D(\theta) = -\frac{1}{m} \sum_{i=0}^{m-1} \log p(y_j^{(i)} | x^{(i)}, \theta) \tag{9}$$

where $y^{(i)}$ is the golden label of the instance $x^{(i)}$ and $p(y_j^{(i)} | x^{(i)})$ is the probability, m is the number of instances, and θ is the parameter set to learn. This model with **TWO** attention layers is denoted as **Att_2** in the next section.

3.3 Adversarial Training

As described in Section 2, documents in DLEF corpus cover various topics. To improve the robustness of our model, we consider Adversarial Training. Similar to previous work (Miyato et al., 2016; Wu et al., 2017), we add a small adversarial perturbation $\boldsymbol{e}_{adv}$ to word embeddings, and employ the following objective function:

$$L_{adv}(\boldsymbol{X}|\theta) = L(\boldsymbol{X} + \boldsymbol{e}_{adv}|\theta) \tag{10}$$

$$\boldsymbol{e}_{adv} = \underset{\|\boldsymbol{e}\| \leqslant \epsilon}{\arg\max}\, L(\boldsymbol{X} + \boldsymbol{e}|\hat{\theta}) \tag{11}$$

where $\hat{\theta}$ is a fixed copy value of the current θ and $\boldsymbol{X}$ is the input. Due to the intractable nature in the computation of Eq. (11), Goodfellow et al. (2014) proposed Eq. (12) to linear $L(\boldsymbol{X}|\theta)$ near $\boldsymbol{X}$ to approximate Eq. (11):

$$\boldsymbol{e}_{adv} = \epsilon \boldsymbol{g} / \|\boldsymbol{g}\| \tag{12}$$

$$\boldsymbol{g} = \nabla_{\boldsymbol{T}} L(\boldsymbol{X}|\hat{\theta}) \tag{13}$$

where $\boldsymbol{T}$ is the embedding table.

4 Experiments

We introduce the experimental settings and the baselines, finally presenting the experimental results and analysis in detail.

4.1 Experimental Settings

The PS- and Uu documents only cover 1.39% and 1.20% in our English and Chinese corpus, respectively. Therefore, we mainly focus on the performance of CT+, CT-, and PS+.

For fair comparison, we perform 10-fold cross-validation on English and Chinese corpora, respectively. In addition to Precision, Recall, and F1-measure for each category of factuality value, we consider macro- and micro-averaging to obtain the overall performance of all the categories of factuality values. The hidden units of LSTM are set as $n_h = 50$. We initialize word embeddings via Word2Vec (Mikolov et al., 2013), setting the dimensions as $d_0 = 100$, and fine-tuning them during training. SGD with momentum is applied to optimize our models.

Att_2 and **Att_2+AT** are the models proposed in Section 3 that consider the contexts, i.e., one sentence before and after the current sentence containing the event as the input. Compared to Att_2, Att_2+AT considers Adversarial Training (AT, the same below). We also consider the following baselines for the comparison with our models:

MaxEntVote is a maximum entropy model that only considers the view of *AUTHOR* (de Marneffe et al., 2012). We use maximum entropy model to identify sentence-level event factuality, and consider voting mechanism, i.e., choose the value committed by the most sentences as the document-level factuality value. We also consider other machine learning models, e.g. Lee et al. (2015), but obtain lower micro-/macro-averaged F1 on English (59.38/33.36) and Chinese corpus (53.91/43.20).

SentVote identifies sentence-level event factuality, and does not consider inter-sequence attention in the model proposed in Section 3. Similar to MaxEntVote model, voting mechanism is used to identify document-level event factuality in this SentVote model.

MP_2 considers Max-Pooling instead of attention compared with Att_2.

Att_1 considers only intra-sequence attention, but not the inter-sequence attention. For an event, we concatenate its i dependency paths and j sentences into one path and one sentence as the input, respectively.

4.2 Results and Analysis

4.2.1 Architecture of Neural Networks

Table 5 presents the performances of our models and baselines. MaxEntVote gives relatively lower results than other models, especially on CT- and PS+. SentVote models are better than MaxEntVote, but still obtain lower results than Att_2, which can prove that inter-sequence attention is more useful than voting. Max-pooling only selects the most active information for each dimension of features, While attention takes into account all the features and assigns weights for them according their degrees of importance. Hence, Att_2 gets better results than MP_L2. Att_1 only considers the intra-sequence attention and obtains lower results than Att_2, which proves the effectiveness of inter-sequence attention. Att_2 and Att_2+AT achieve better results than other baselines. Compared to Att_2, Att_2+AT considers the adversarial perturbation and training that can alleviate overfitting. Therefore, Att_2+AT is superior to Att_2, which can prove the effectiveness of adversarial training.

On both English and Chinese corpora, the performance of CT+ is better than those of PS+ and CT-. On one hand, it is easier to identify CT+ documents due to their majority. On the other hand, most news texts hardly contain bogus and false contents. Therefore, in most CT+ documents, sentence-level factuality values are consistent with the document-level value, just as in S10. However, in PS+ and CT- documents with non-CT+ document-level values, sentence-level factuality values have different viewpoints with the corresponding document, varying among CT-, PS+, and CT+, making the task more difficult, e.g., S11.

(S10) *India successfully* ***tested***(CT+) *a supersonic missile, capable of destroying an incoming ballistic missile at low altitude. ...... The* ***test***(CT+) *was carried out from a test range in Odisha , official sources said.*

(S11) *Argentine navy said it had not* ***contacted***(CT-) *the SAN Juan submarine. ... ... Some media previously said the navy may have received signals from the submarine and* ***contacted***(PS+) *it.*

4.2.2 Input of Neural Networks

For Att_2+AT, we also investigate the effects of contexts of the sentences containing events as the input on the performance. The results is given in Table 6, which shows that contexts can improve the performance more significantly on the Chinese corpus than the English corpus. We find that in the Chinese corpus these sentences are commonly in the same paragraph and have a strong semantic coherence. Therefore, information in adjacent sentences can contribute to the identification of the document-level factuality of the events in the current sentences.

Sentences S12 and S13 are adjacent sentences in one paragraph. The document-level factuality value of the event "*provided*" in S12 is CT-. However, the sentence-level value of "*provided*" is PS+. If we consider S13, the negative cue "*denied*" can lead to the correct document-level factuality value of "*provided*". While in the English corpus, similar sentences are much fewer, because paragraphs in most English news texts only contain one or two sentences, and sentences in different paragraphs share less semantic correlation

Corpus	Systems	CT-	PS+	CT+	Micro-A	Macro-A

	w/o Dpath (Only Sent)	-10.31	-7.23	-7.80	-8.49	-8.44
	w/o Sent (Only Dpath)	-17.53	-11.02	-14.79	-15.19	-14.44

Table 6: F1-measures of Att_2+AT with different input features.

than those in the same paragraph. Hence, performance improvement is less when considering adjacent sentences in the English corpus.

(S12) 外界质疑在竞标过程中，墨西哥政府为相关企业**提供**了“有利位置”。(*It is doubted that the Mexican government* ***provided*** *“vantage points” for the enterprises involved during the bidding process.*)

(S13) 墨西哥外交部在7日对此予以回应，否认了这种说法。(*The Mexican Foreign Ministry responded and denied the rumor on 7th.*)

If we consider more adjacent sentences, e.g., two sentences before and after the current sentence, however, the results will be a bit lower. The micro-/macro-averaged F1 on English and Chinese corpus are 81.20/75.65 and 82.57/80.91, respectively. We think the reason is that some sentences are far away from the current sentence and have little effect on the current event, and considering more contexts may also lead to overfitting.

Moreover, we explore the effects of considering only dependency path (Dpath) and only sentence (Sent) in Table 6. Att_2+AT achieves the best results when considering both paths and sentences as input, proving that both of them are effective features for our model. Att_2+AT obtains higher performance with only sentences than only paths as input, meaning that Att_2+AT is mainly beneficial from sentences that can offer semantic information. Error analysis shows that documents with incorrect identified values contains sentences with more speculative or negative cues:

(S14) *When asked if it might be* ***arson****, authorities said that no fire raiser has been found now, but the possibility of artificial arson should not been ruled out.*

S14 contains speculative cues “*if*”, “*might*”, “*possibility*” and negative cues “*no*”, “*not*”, “*ruled out*”. It is difficult to identify whether the events are governed by the cues when only considering the dependency paths and ignoring the semantic information offered by sentences. S14 can demonstrate the importance of semantic features.

4.2.3 Documents with Different Sentence-Level Event Factuality Values

As mentioned in Section 2.4, the document-level task becomes trivial if most documents have only one category of sentence-level factuality value that

Corpus	*n*	CT-	PS+	CT+	Micro-A	Macro-A
English	n=1	**85.63**	64.46	**94.91**	**91.36**	**81.67**
	$n\geqslant 2$	58.33	**65.79**	56.01	60.91	60.04
Chinese	n=1	**84.45**	**76.73**	**93.44**	**89.85**	**84.87**
	$n\geqslant 2$	82.68	69.91	58.51	73.22	70.37

Table 7: F1-measures of Att_2+AT on the documents with *n* types of sentence-level factuality values.

Corpus	Level	CT-	PS+	CT+	Micro-A	Macro-A
English	Sentence	72.05	59.68	91.14	85.96	74.29
	Document (with Joint Opt)	75.46	**62.80**	88.65	82.89	75.64
	Document (w/o Joint Opt)	**76.87**	62.14	**89.84**	**83.56**	**76.28**
Chinese	Sentence	74.20	68.88	87.73	81.98	76.94
	Document (with Joint Opt)	83.30	73.74	87.40	83.83	81.48
	Document (w/o Joint Opt)	**83.35**	**74.06**	**87.52**	**84.03**	**81.64**

Table 8: F1-measures of Att_2+AT with joint optimization.

is the same as document-level value. Table 7 shows the performance of Att_2+AT on the documents with n different types of sentence-level factuality values. The micro- and macro-averaged F1 of $n\geqslant 2$ are lower than those of n=1, indicating that the factuality of documents that have different types of sentence-level factuality are more difficult to identify due to the interference from sentence-level values.

We notice that in the Chinese corpus, the performance of CT- is much higher than that of PS+ and CT+ when $n\geqslant 2$. According to the analysis on the Chinese corpus, we find that most CT- documents are usually used to deny the rumors, i.e., those sentence-level events whose factuality values are not CT-. Therefore, the sentence-level CT- events are often in the topic sentences of the documents and dominate among sentences, which can contribute to the better results of document-level CT- events in Chinese corpus.

4.2.4 Joint Optimization Model

Because document-level event factuality is related with sentence-level factuality information, we also consider the joint optimization model for them. For sentence-level task, we use the LSTM neural network in Section 3 and only consider the current sentence, i.e., do not consider information in adjacent sentences and the inter-sequence attention layer. The objective of document- and sentence-level task are denoted as $L_D(\theta)$ and $L_S(\theta)$, and the objective of our joint optimization model is:

$$L_J(\theta) = \varepsilon L_D(\theta) + (1-\varepsilon) L_S(\theta) \qquad (14)$$

where ε=0.6 is the trade-off. The performance of both sentence-level and document-level event factuality identification is shown in Table 8. The micro-/macro-averaged F1 of joint optimization model on English and Chinese corpus are 82.89/75.64 and 83.83/81.48, respectively. Although document-level event factuality is based on the factuality information in sentences, sentence-level factuality value of an event only depends on the current sentence, and is likely to have a different value compared to the current document-level factuality. Therefore, the joint model can not improve the performance of document-level task.

5 Related Work

Researchers have studied document-level tasks in many NLP applications, e.g., sentiment analysis (Xu et al., 2016; Dou, 2017), named entity recognition (Luo et al., 2018), and machine translation (Born et al., 2017). But related studies on event factuality are limited to the sentence-level task. Diab et al. (2009) and Prabhakaran et al. (2010) presented studies of belief annotation and tagging, and classified predicate events into Committed Belief (CB), Non-CB or Not Applicable using a supervised framework. For factuality assessment, Lee et al. (2015) employed dependency features, while Stanovsky et al. (2017) considered deep linguistic information, such as modality classes, syntactic re-ordering with PropS tree annotation structure (Lotan et al., 2013). Baly et al. (2018) considered a set of features and predicted the factuality of reporting and bias of news media.

Saurí (2008) and Saurí and Pustejovsky (2012) proposed a rule-based model to identify event factuality on FactBank. de Marneffe et al. (2012) used a machine learning model and Qian et al. (2015) utilized a two-step framework combining machine learning and rule-based approaches on FactBank. In addition to FactBank, Prabhakaran et al. (2015) proposed a ongoing framework for a larger corpus based on LU, and Cao et al. (2013) constructed a Chinese corpus annotated with event factuality based on ACE 2005. However, no previous work annotated a document-level corpus. We construct DLEF corpus with document-level event factuality for the first time.

Some studies focused on document-level event identification task. Choubey et al. (2018) designed a rule-based classifier to identify central events according to event coreference relations. Liu et al. (2018) utilized a kernel-based neural model that captured semantic relations between discourse units for event salience identification. However, they did not consider the document-level event factuality. To our best knowledge, this paper is the first work on document-level event factuality identification task.

Previous studies (He et al., 2017; Rudinger et al., 2018; Qian et al., 2018) have tried neural network models on sentence-level factuality identification. Recent research has shown that neural networks with multi-level attention can extract meaningful information from heterogeneous input and improve the performance of NLP tasks, e.g., discourse relation (Liu and Li, 2016), relation classification (Wang et al., 2016), and question answering (Yu et al., 2017). Moreover, to improve the robustness of neural networks, related studies considered adversarial perturbation and training on text classification (Miyato et al., 2016) and relation extraction (Wu et al., 2017). This paper is in line in proposing an adversarial neural network with both intra- and inter-sequence attention.

6 Conclusion

We investigated document-level event factuality identification task by constructing a corpus annotated with document- and sentence-level event factuality based on both English and Chinese texts. To identify document-level event factuality, we proposed an LSTM neural network with both intra- and inter-sequence attention, and consider adversarial training to improve the robustness. Experimental results showed that document-level event identification on our DLEF corpus is useful, and our adversarial training model outperforms several baselines. To our knowledge, this is the first paper for the document-level event factuality identification.

In the future work, we will consider to detect events and their sentence-level and document-level factuality with a joint framework, and we will also continue to expand the scale of our DLEF corpus.

Abstract

This paper presents a neural relation extraction method to deal with the noisy training data generated by distant supervision. Previous studies mainly focus on sentence-level de-noising by designing neural networks with intra-bag attentions. In this paper, both intra-bag and inter-bag attentions are considered in order to deal with the noise at sentence-level and bag-level respectively. First, relation-aware bag representations are calculated by weighting sentence embeddings using intra-bag attentions. Here, each possible relation is utilized as the query for attention calculation instead of only using the target relation in conventional methods. Furthermore, the representation of a group of bags in the training set which share the same relation label is calculated by weighting bag representations using a similarity-based inter-bag attention module. Finally, a bag group is utilized as a training sample when building our relation extractor. Experimental results on the New York Times dataset demonstrate the effectiveness of our proposed intra-bag and inter-bag attention modules. Our method also achieves better relation extraction accuracy than state-of-the-art methods on this dataset[1].

1 Introduction

Relation Extraction is a fundamental task in natural language processing (NLP), which aims to extract semantic relations between entities. For example, sentence "[*Barack Obama*]$_{e1}$ was born in [*Hawaii*]$_{e2}$" expresses the relation *BornIn* between entity pair **Barack Obama** and **Hawaii**.

Conventional relation extraction methods, such as (Zelenko et al., 2002; Culotta and Sorensen, 2004; Mooney and Bunescu, 2006), adopted supervised training and suffered from the lack of large-scale manually labeled data. To address this issue, the distant supervision method (Mintz et al., 2009) was proposed, which generated the data for training relation extraction models automatically. The distant supervision assumption says that if two entities participate in a relation, **all** sentences that mention these two entities express that relation. It is inevitable that there exists noise in the data labeled by distant supervision. For example, the precision of aligning the relations in Freebase to the New York Times corpus was only about 70% (Riedel et al., 2010).

bag	sentence	correct?
B1	S1. **Barack Obamna** was born in **the United States**.	**Yes**
	S2. **Barack Obamna** was the 44th president of **the United States**	**No**
B2	S3. **Kyle Busch** , a **Las Vegas** resident who ran second to Johnson last year, finished third, followed by Kasey Kahne, Jeff Gordon and mark martin .	**No**
	S4. Hendrick drivers finished in three of the top four spots at **Las Vegas** , including **Kyle Busch** in second and ...	**No**

Table 1: Examples of sentences with relation *place_of_birth* annotated by distant supervision, where "Yes" and "No" indicate whether or not each sentence actually expresses this relation.

Thus, the relation extraction method proposed in (Riedel et al., 2010) argued that the distant supervision assumption was too strong and relaxed it to *expressed-at-least-once* assumption. This assumption says that if two entities participate in a relation, **at least one sentence** that mentions these two entities might express that relation. An example is shown by sentences S1 and S2 in Table 1. This relation extraction method first divided the training data given by distant supervision into bags where each bag was a set of sentences containing the same entity pair. Then, bag representations were derived by weighting sentences within

Proceedings of NAACL-HLT 2019, pages 2810–2819
Minneapolis, Minnesota, June 2 - June 7, 2019.

each bag. It was expected that the weights of the sentences with incorrect labels were reduced and the bag representations were calculated mainly using the sentences with correct labels. Finally, bags were utilized as the samples for training relation extraction models instead of sentences.

In recent years, many relation extraction methods using neural networks with attention mechanism (Lin et al., 2016; Ji et al., 2017; Jat et al., 2018) have been proposed to alleviate the influence of noisy training data under the *expressed-at-least-once* assumption. However, these methods still have two deficiencies. First, only the target relation of each bag is used to calculate the attention weights for deriving bag representations from sentence embeddings at training stage. Here we argue that the bag representations should be calculated in a relation-aware way. For example, the bag B1 in Table 1 contains two sentences S1 and S2. When this bag is classified to relation *BornIn*, the sentence S1 should have higher weight than S2, but when classified to relation *PresidentOf*, the weight of S2 should be higher. Second, the *expressed-at-least-once* assumption ignores the **noisy bag problem** which means that all sentences in one bag are incorrectly labeled. An example is shown by bag B2 in Table 1.

In order to deal with these two deficiencies of previous methods, this paper proposes a neural network with multi-level attentions for distant supervision relation extraction. At the instance/sentence-level, i.e., intra-bag level, all possible relations are employed as queries to calculate the relation-aware bag representations instead of only using the target relation of each bag. To address the noisy bag problem, a bag group is adopted as a training sample instead of a single bag. Here, a bag group is composed of bags in the training set which share the same relation label. The representation of a bag group is calculated by weighting bag representations using a similarity-based inter-bag attention module.

The contributions of this paper are threefold. First, an improved intra-bag attention mechanism is proposed to derive relation-aware bag representations for relation extraction. Second, an inter-bag attention module is introduced to deal with the noisy bag problem which is ignored by the expressed-at-least-once assumption. Third, our methods achieve better extraction accuracy than state-of-the-art models on the widely used New York Times (NYT) dataset (Riedel et al., 2010).

2 Related Work

Some previous work (Zelenko et al., 2002; Mooney and Bunescu, 2006) treated relation extraction as a supervised learning task and designed hand-crafted features to train kernel-based models. Due to the lack of large-scale manually labeled data for supervised training, the distant supervision approach (Mintz et al., 2009) was proposed, which aligned raw texts toward knowledge bases automatically to generate relation labels for entity pairs. However, this approach suffered from the issue of noisy labels. Therefore, some subsequent studies (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012) considered distant supervision relation extraction as a multi-instance learning problem, which extracted relation from a bag of sentences instead of a single sentence.

With the development of deep learning techniques (LeCun et al., 2015), many neural-network-based models have been developed for distant supervision relation extraction. Zeng et al. (2015) proposed piecewise convolutional neural networks (PCNNs) to model sentence representations and chose the most reliable sentence as the bag representation. Lin et al. (2016) employed PCNNs as sentence encoders and proposed an intra-bag attention mechanism to compute the bag representation via a weighted sum of all sentence representations in the bag. Ji et al. (2017) adopted a similar attention strategy and combined entity descriptions to calculate the weights. Liu et al. (2017) proposed a soft-label method to reduce the influence of noisy instances. All these methods represented a bag with a weighted sum of sentence embeddings, and calculated the probability of the bag being classified into each relation using the same bag representation at training stage. In our proposed method, intra-bag attentions are computed in a relation-aware way, which means that different bag representations are utilized to calculate the probabilities for different relation types. Besides, these existing methods focused on intra-bag attentions and ignored the noisy bag problem.

Some data filtering strategies for robust distant supervision relation extraction have also been proposed. Feng et al. (2018) and Qin et al. (2018b) both employed reinforcement learning to train instance selector and to filter out the samples with wrong labels. Their rewards were calcu-

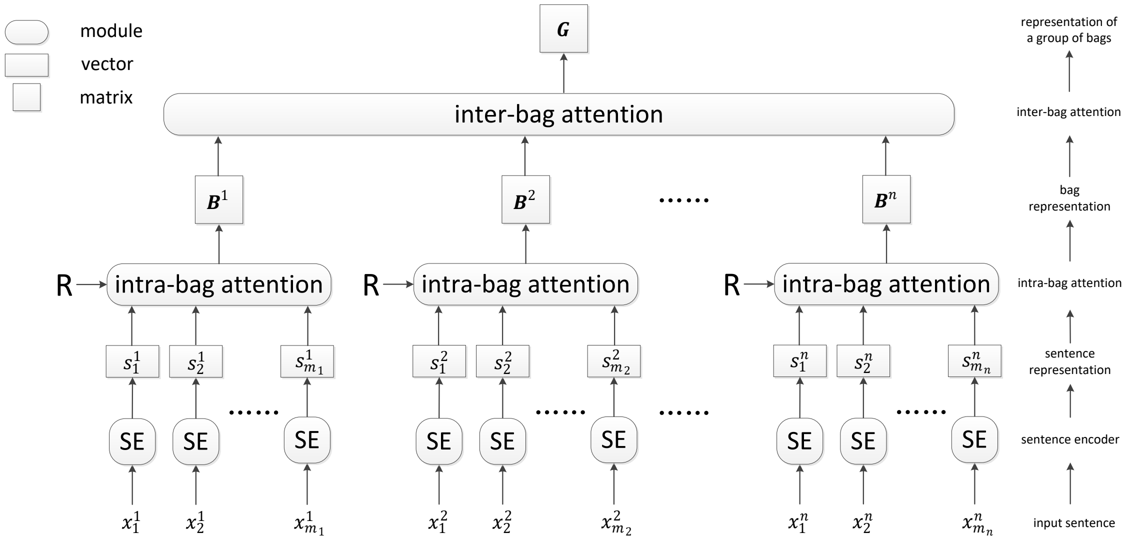

Figure 1: The framework of our proposed neural network with intra-bag and inter-bag attentions for relation extraction.

lated from the prediction probabilities and the performance change of the relation classifier respectively. Qin et al. (2018a) designed an adversarial learning process to build a sentence-level generator via policy-gradient-based reinforcement learning. These methods were proposed to filter out the noisy data at sentence-level and also failed to deal with the noisy bag problem explicitly.

3 Methodology

In this section, we introduce a neural network with intra-bag and inter-bag attentions for distant supervision relation extraction. Let $g = \{b^1, b^2, ..., b^n\}$ denote a group of bags which have the same relation label given by distant supervision, and n is the number of bags within this group. Let $b^i = \{x_1^i, x_2^i, ..., x_{m_i}^i\}$ denote all sentences in bag b^i, and m_i is the number of sentences in bag b^i. Let $x_j^i = \{w_{j1}^i, w_{j2}^i, ..., w_{jl_{ij}}^i\}$ denote the j-th sentence in the i-th bag and l_{ij} is its length (i.e., number of words). The framework of our model is shown in Fig. 1, which has three main modules.

- **Sentence Encoder** Given a sentence x_j^i and the positions of two entities within this sentence, CNNs or PCNNs (Zeng et al., 2015) are adopted to derive the sentence representation $\mathbf{s}_j^i$.
- **Intra-Bag Attention** Given the sentence representations of all sentences within a bag b^i and a relation embedding matrix $\mathbf{R}$, attention weight vectors $\boldsymbol{\alpha}_k^i$ and bag representations $\mathbf{b}_k^i$ are calculated for all relations, where k is the relation index.
- **Inter-Bag Attention** Given the representations of all bags with the group g, a weight matrix $\boldsymbol{\beta}$ is further calculated via similarity-based attention mechanism to obtain the representation of the bag group.

More details of these three modules will be introduced in the following subsections.

3.1 Sentence Encoder

3.1.1 Word Representation

Each word w_{jk}^i within the sentence x_j^i is first mapped into a d_w-dimensional word embedding. To describe the position information of two entities, the position features (PFs) proposed in (Zeng et al., 2014) are also adopted in our work. For each word, the PFs describe the relative distances between current word and the two entities and are further mapped into two vectors $\mathbf{p}_{jk}^i$ and $\mathbf{q}_{jk}^i$ of d_p dimensions. Finally, these three vectors are concatenated to get the word representation $\mathbf{w}_{jk}^i = [\mathbf{e}_{jk}^i; \mathbf{p}_{jk}^i; \mathbf{q}_{jk}^i]$ of $d_w + 2d_p$ dimensions.

3.1.2 Piecewise CNN

For sentence x_j^i, the matrix of word representations $\mathbf{W}_j^i \in \mathbb{R}^{l_{ij} \times (d_w+2d_p)}$ is first input into a CNN with d_c filters. Then, piecewise max pooling (Zeng et al., 2015) is employed to extract features from the three segments of CNN outputs, and the segment boundaries are determined by the positions of the two entities. Finally, the sentence representation $\mathbf{s}^i_j \in \mathbb{R}^{3d_c}$ can be obtained.

3.2 Intra-Bag Attention

Let $\mathbf{S}^i \in \mathbb{R}^{m_i \times 3d_c}$ represent the representations of all sentences within bag b^i, and $\mathbf{R} \in \mathbb{R}^{h \times 3d_c}$ denote a relation embedding matrix where h is the number of relations.

Different from conventional methods (Lin et al., 2016; Ji et al., 2017) where a unified bag representation was derived for relation classification, our method calculates bag representations $\mathbf{b}^i_k$ for bag b^i on the condition of all possible relations as

$$\mathbf{b}^i_k = \sum_{j=1}^{m_i} \alpha^i_{kj} \mathbf{s}^i_j, \tag{1}$$

where $k \in \{1, 2, ..., h\}$ is the relation index and α^i_{kj} is the attention weight between the k-th relation and the j-th sentence in bag b^i. α^i_{kj} can be further defined as

$$\alpha^i_{kj} = \frac{exp(e^i_{kj})}{\sum_{j'=1}^{m_i} exp(e^i_{kj'})}, \tag{2}$$

where e^i_{kj} is the matching degree between the k-th relation query and the j-th sentence in bag b^i. In our implementation, a simple dot product between vectors is adopted to calculate the matching degree as

$$e^i_{kj} = \mathbf{r}_k \mathbf{s}^{i\top}_j, \tag{3}$$

where $\mathbf{r}_k$ is the k-th row of the relation embedding matrix $\mathbf{R}$[2].

Finally, the representations of bag b^i compose the matrix $\mathbf{B}^i \in \mathbb{R}^{h \times 3d_c}$ in Fig. 1, where each row corresponds to a possible relation type of this bag.

3.3 Inter-Bag Attention

In order to deal with the noisy bag problem, a similarity-based inter-bag attention module is designed to reduce the weights of noisy bags dynamically. Intuitively, if two bags b^{i_1} and b^{i_2} are both labeled as relation k, their representations $\mathbf{b}^{i_1}_k$ and $\mathbf{b}^{i_2}_k$ should be close to each other. Given a group of bags with the same relation label, we assign higher weights to those bags which are close to other bags in this group. As a result, the representation of bag group g can be formulated as

$$\mathbf{g}_k = \sum_{i=1}^{n} \beta_{ik} \mathbf{b}^i_k, \tag{4}$$

where $\mathbf{g}_k$ is the k-th row of the matrix $\mathbf{G} \in \mathbb{R}^{h \times 3d_c}$ in Fig. 1, k is the relation index and β_{ik} composes the attention weight matrix $\boldsymbol{\beta} \in \mathbb{R}^{n \times h}$. Each β_{ik} is defined as

$$\beta_{ik} = \frac{exp(\gamma_{ik})}{\sum_{i=1}^{n} exp(\gamma_{ik})}, \tag{5}$$

where γ_{ik} describes the confidence of labeling bag b^i with the k-th relation.

Inspired by the self-attention algorithm (Vaswani et al., 2017) which calculates the attention weights for a group of vectors using the vectors themselves, we calculate the weights of bags according to their own representations. Mathematically, γ_{ik} is defined as

$$\gamma_{ik} = \sum_{i'=1,...,n, i' \neq i} \text{similarity}(\mathbf{b}^i_k, \mathbf{b}^{i'}_k), \tag{6}$$

where the function *similarity* is a simple dot product in our implementation as

$$\text{similarity}(\mathbf{b}^i_k, \mathbf{b}^{i'}_k) = \mathbf{b}^i_k \mathbf{b}^{i'\top}_k. \tag{7}$$

And also, in order to prevent the influence of vector length, all bag representations $\mathbf{b}^i_k$ are normalized to unit length as $\overline{\mathbf{b}^i_k} = \mathbf{b}^i_k / ||\mathbf{b}^i_k||_2$ before calculating Eq.(4)-(7).

Then, the score o_k of classifying bag group g into relation k is calculated via $\mathbf{g}_k$ and relation embedding $\mathbf{r}_k$ as

$$o_k = \mathbf{r}_k \mathbf{g}^\top_k + d_k, \tag{8}$$

where d_k is a bias term. Finally, a softmax function is employed to obtain the probability that the bag group g is classified into the k-th relation as

$$p(k|g) = \frac{exp(o_k)}{\sum_{k'=1}^{h} exp(o_{k'})}. \tag{9}$$

It should be noticed that the same relation embedding matrix $\mathbf{R}$ is used for calculating Eq.(3) and Eq.(8). Similar to Lin et al. (2016), the dropout strategy (Srivastava et al., 2014) is applied to bag representation $\mathbf{B}^i$ to prevent overfitting.

---

[2] We also tried $\mathbf{r}_k \mathbf{A} \mathbf{s}^{i\top}_j$, where $\mathbf{A}$ was a diagonal matrix, in experiments and achieved similar performance.

3.4 Implementation Details

3.4.1 Data Packing

First of all, all sentences in the training set that contain the same two entities are accumulated into one bag. Then, we tie up every n bags that share the same relation label into a group. It should be noticed that a bag group is one training sample in our method. Therefore, the model can also be trained in mini-batch mode by packing multiple bag groups into one batch.

3.4.2 Objective Function and Optimization

In our implementation, the objective function is defined as

$$\mathrm{J}(\theta) = -\sum_{(g,k)\in T} \mathrm{logp}(k|g;\theta) \qquad (10)$$

where T is the set of all training samples and θ is the set of model parameters, including word embedding matrix, position feature embedding matrix, CNN weight matrix and relation embedding matrix. The model parameters are estimated by minimizing the objective function J(θ) through mini-batch stochastic gradient descent (SGD).

3.4.3 Training and Test

As introduced above, at the training phase of our proposed method, n bags which have the same relation label are accumulated into one bag group and the weighted sum of bag representations is calculated to obtain the representation $\mathbf{G}$ of the bag group. Due to the fact that the label of each bag is unknown at test stage, each single bag is treated as a bag group (i.e., n=1) when processing the test set.

And also, similar to (Qin et al., 2018b), we only apply inter-bag attentions to positive samples, i.e., the bags whose relation label is not NA ($NoRelation$). The reason is that the representations of the bags that express no relations are always diverse and it's difficult to calculate suitable weights for them.

3.4.4 Pre-training Strategy

In our implementation, a pre-training strategy is adopted. We first train the model with only intra-bag attentions until convergence. Then, the inter-bag attention module is added and the model parameters are further updated until convergence again. Preliminary experimental results showed that this strategy can lead to better model performance than considering inter-bag attentions from the very beginning.

Component	Parameter	Value
word embedding	dimension	50
position feature	max relative distance	±30
	dimension	5
CNN	window size	3
	filter number	230
dropout	dropout rate	0.5
optimization	strategy	SGD
	learning rate	0.1
	batch size N_p	50
	batch size N_t	10
	group size n	5
	gradient clip	5.0

Table 2: Hyper-parameters of the models built in our experiments.

4 Experiment

4.1 Dataset and Evaluation Metrics

The New York Times (NYT) dataset was adopted in our experiments. This dataset was first released by (Riedel et al., 2010) and has been widely used by previous research on distant supervision relation extraction (Liu et al., 2017; Jat et al., 2018; Qin et al., 2018a,b). This dataset was generated by aligning Freebase with the New York Times (NYT) corpus automatically. There were 52 actual relations and a special relation NA which indicated there was no relation between two entities.

Following previous studies (Mintz et al., 2009; Liu et al., 2017), we evaluated our models on the held-out test set of the NYT dataset. Precision-recall (PR) curves, area under curve (AUC) values and Precision@N (P@N) values (Lin et al., 2016) were adopted as evaluation metrics in our experiments. All of the numerical results given by our experiments were the mean values of 10 repetitive trainings, and the PR curves were randomly selected from the repetitions because there was no significant visual difference among them.

4.2 Training Details and Hyperparameters

All of the hyperparameters used in our experiments are listed in Table 2. Most of them followed the hyperparameter settings in (Lin et al., 2016). The 50-dimensional word embeddings released by (Lin et al., 2016)[3] were also adopted for initialization. The vocabulary contained the words which appeared more than 100 times in the NYT corpus.

---

4	CNN+ATT_RA+BAG_ATT	0.407 ± 0.004
5	PCNN+ATT_BL	0.388 ± 0.004
6	PCNN+ATT_BL+BAG_ATT	0.403 ± 0.002
7	PCNN+ATT_RA	0.403 ± 0.003
8	PCNN+ATT_RA+BAG_ATT	$\mathbf{0.422 \pm 0.004}$

Table 3: AUC values of different models.

Two different batch sizes N_p and N_t were used for pre-training and training respectively. In our experiments, a grid search is employed using training set to determine the optimal values of n, N_p and N_t among $n \in \{3, 4, ..., 10\}$, $N_p \in \{10, 20, 50, 100, 200\}$ and $N_t \in \{5, 10, 20, 50\}$. Note that increasing the bag group size n may boost the effect of inter-bag attentions but lead to less training samples. The effects of inter-bag attentions would be lost when n=1. For optimization, we employed mini-batch SGD with the initial learning rate of 0.1. The learning rate was decayed to one tenth every 100,000 steps. The pre-trained model with only intra-bag attentions converged within 300,000 steps in our experiments. Thus, the initial learning rate for training the model with inter-bag attentions was set as 0.001.

4.3 Overall performance

Eight models were implemented for comparison. The names of these models are listed in Table 3, where *CNN* and *PCNN* denote using CNNs or piecewise CNNs in sentence encoders respectively, *ATT_BL* means the baseline intra-bag attention method proposed by (Lin et al., 2016), *ATT_RA* means our proposed relation-aware intra-bag attention method, and *BAG_ATT* means our proposed inter-bag attention method. At the training stage of the *ATT_BL* method, the relation query vector for attention weight calculation was fixed as the embedding vector associated with the distant supervision label for each bag. At the test stage, all relation query vectors were applied to calculate the posterior probabilities of relations respectively and the relation with the highest probability was chosen as the classification result (Lin et al., 2016). The means and standard deviations of the AUC values given by the whole PR curves of these models are shown in Table 3 for a quantitative comparison. Following (Lin et al., 2016), we also plotted the PR curves of these models in Fig. 2 and 3 with recall smaller than 0.5 for a visualized comparison.

From Table 3, Fig. 2 and Fig. 3, we have the following observations. (1) Similar to the results of previous work (Zeng et al., 2015), PCNNs worked better than CNNs as sentence encoders. (2) When using either CNN or PCNN sentence encoders, *ATT_RA* outperformed *ATT_BL*. It can be attributed to that the *ATT_BL* method only considered the target relation when deriving bag representations at training time, while the *ATT_RA* method calculated intra-bag attention weights using all relation embeddings as queries, which improved the flexibility of bag representations. (3) For both sentence encoders and both intra-bag attention methods, the models with *BAG_ATT* always achieved better performances than the ones without *BAG_ATT*. This result verified the effectiveness of our proposed inter-bag attention

# of Test Sentences	**one**				**two**				**all**

method for distant supervision relation extraction. (4) The best AUC performance was achieved by combining PCNN sentence encoders with the intra-bag and inter-bag attentions proposed in this paper.

4.4 Comparison with previous work

4.4.1 PR curves

The PR curves of several models in previous work and our best model *PCNN+ATT_RA+BAG_ATT* are compared in Fig. 4, where Mintz (Mintz et al., 2009), MultiR (Hoffmann et al., 2011) and MIMLRE (Surdeanu et al., 2012) are conventional feature-based methods, and (Lin et al., 2016) and (Liu et al., 2017) are PCNN-based ones[4]. For a fair comparison with (Lin et al., 2016) and (Liu et al., 2017), we also plotted the curves with only the top 2000 points. We can see that our model achieved better PR performance than all the other models.

model	**CNN**	**PCNN**
ATT_BL†	0.219	0.253
ATT_BL+RL	0.229	0.261
ATT_BL+DSGAN	0.226	0.264
ATT_BL‡	0.242	0.271
ATT_RA	0.254	0.297
ATT_BL+BAG_ATT	0.253	0.285
ATT_RA+BAG_ATT	**0.262**	**0.311**

Table 5: AUC values of previous work and our models, where *ATT_BL+DSGAN* and *ATT_BL+RL* are two models proposed in (Qin et al., 2018a) and (Qin et al., 2018b) respectively, † indicates the baseline result reported in (Qin et al., 2018a,b) and ‡ indicates the baseline result given by our implementation.

4.4.2 AUC values

ATT_BL+DSGAN (Qin et al., 2018a) and *ATT_BL+RL* (Qin et al., 2018b) are two recent studies on distant supervision relation extraction with reinforcement learning for data filtering, which reported the AUC values of PR curves composed by the top 2000 points. Table 5 compares the AUC values reported in these two papers and the results of our proposed models. We can see that introducing the proposed *ATT_RA* and *BAG_ATT* methods to baseline models achieved larger improvement than using the methods proposed in (Qin et al., 2018a,b).

4.5 Effects of Intra-Bag Attentions

Following (Lin et al., 2016), we evaluated our models on the entity pairs with more than one training sentence. One, two and all sentences for each test entity pair were randomly selected to construct three new test sets. The P@100, P@200, P@300 values and their means given by our proposed models on these three test sets are reported in Table 4 together with the best results of (Lin et al., 2016) and (Liu et al., 2017). Here, P@N

$\geq$ **5**	0.256 ± 0.043

Table 7: The distributions of inter-bag attention weights for the bags with different number of sentences.

means the precision of the relation classification results with the top N highest probabilities in the test set.

We can see our proposed methods achieved higher P@N values than previous work. Furthermore, no matter whether *PCNN* or *BAG_ATT* were adopted, the *ATT_RA* method outperformed the *ATT_BL* method on the test set with only one sentence for each entity pair. Note that the decoding procedures of *ATT_BL* and *ATT_RA* were equivalent when there was only one sentence in a bag. Therefore, the improvements from *ATT_BL* to *ATT_RA* can be attributed to that *ATT_RA* calculated intra-bag attention weights in a relation-aware way at the training stage.

4.6 Distributions of Inter-Bag Attention Weights

We divided the training set into 5 parts according to the number of sentences in each bag. For each bag, the inter-bag attention weights given by the *PCNN+ATT_RA+BAG_ATT* model were recorded. Then, the mean and standard deviation of inter-bag attention weights for each part of the training set were calculated and are shown in Table 7. From this table, we can see that the bag with smaller number of training sentences were usually assigned with lower inter-bag attention weights. This result was consistent with the finding in (Qin et al., 2018b) that the entity pairs with fewer training sentences were more likely to have incorrect relation labels.

4.7 Case Study

A test set example of relation */location/location/contains* is shown in Table 6. The bag group contained 3 bags, which consisted of 2, 1, and 2 sentences respectively. We calculated the intra-bag and inter-bag attentions for this bag group using our *PCNN+ATT_RA+BAG_ATT* model and the weights of the target relation are also shown in Table 6.

In this example, the second bag was a noisy bag because the only sentence in this bag didn't express the relation */location/location/contains* between the two entities **Naugatuck** and **Connecticut**. In conventional methods, these three bags were treated equally for model training. After introducing inter-bag attention mechanism, the weight of this noisy bag was reduced significantly as shown in the last column of Table 6.

5 Conclusion

In this paper, we have proposed a neural network with intra-bag and inter-bag attentions to cope with the noisy sentence and noisy bag problems in distant supervision relation extraction. First, relation-aware bag representations are calculated by a weighted sum of sentence embeddings where the noisy sentences are expected to have smaller weights. Further, an inter-bag attention module is designed to deal with the noisy bag problem by calculating the bag-level attention weights dynamically during model training. Experimental results on New York Times dataset show that our models achieved significant and consistent improvements compared with the models using only conventional intra-bag attentions. To deal with the multi-label problem of relation extraction and to integrate external knowledge into our model will be the tasks of our future work.

Abstract

Extreme Multi-label classification (XML) is an important yet challenging machine learning task, that assigns to each instance its most relevant candidate labels from an extremely large label collection, where the numbers of labels, features and instances could be thousands or millions. XML is more and more on demand in the Internet industries, accompanied with the increasing business scale / scope and data accumulation. The extremely large label collections yield challenges such as computational complexity, inter-label dependency and noisy labeling. Many methods have been proposed to tackle these challenges, based on different mathematical formulations. In this paper, we propose a deep learning XML method, with a word-vector-based self-attention, followed by a ranking-based AutoEncoder architecture. The proposed method has three major advantages: 1) the autoencoder simultaneously considers the inter-label dependencies and the feature-label dependencies, by projecting labels and features onto a common embedding space; 2) the ranking loss not only improves the training efficiency and accuracy but also can be extended to handle noisy labeled data; 3) the efficient attention mechanism improves feature representation by highlighting feature importance. Experimental results on benchmark datasets show the proposed method is competitive to state-of-the-art methods.

1 Introduction and Related Work

In multi-label classification (Tsoumakas and Katakis, 2007; Zhang and Zhou, 2014), one assigns multiple labels to each instance. Multi-label classification has many real-word applications: for example, a movie may be associated with multiple genres, a web page may contain several topics, and an image can be tagged with a few objects. In these classification tasks, labels often exhibit complex dependencies: for example, *Documentary* and *Sci-Fi* are usually mutually exclusive movie genres, while *Horror* and *Thriller* are typically highly correlated. Predicting labels independently fails to capture these dependencies and suffers suboptimal performance (Tsoumakas and Katakis, 2007; Ghamrawi and McCallum, 2005; Li et al., 2016). Several methods that capture label dependencies have been proposed, including Conditional Random Fields (CRF) (Lafferty et al., 2001; Ghamrawi and McCallum, 2005), Classifier Chains (CC) (Read et al., 2011; Dembczynski et al., 2010), Conditional Bernoulli Mixtures (CBM) (Li et al., 2016), and Canonical Correlated AutoEncoder (C2AE) (Yeh et al., 2017). However, these methods typically only work well on small-to-medium scale datasets.

Extreme multi-label classification (XML) is a multi-label classification task in which the number of instances, features and labels are very large, often on the order of thousands to millions (Zubiaga, 2012; Bhatia et al., 2015). It has numerous real-world applications such as merchandise tagging and text categorization. Although the label vocabulary is large, typically each instance only matches a few labels. The scale of the classification task, the inter-dependent labels, and label sparsity all pose significant challenges for accurate and efficient classification.

Many methods have been proposed for extreme multi-label classification. We group them into different categories and describe representative methods in each category.

Independent Classification: A popular method is to divide the multi-label classification problem into multiple binary classification prob-

Proceedings of NAACL-HLT 2019, pages 2820–2830
Minneapolis, Minnesota, June 2 - June 7, 2019.

lems (Tsoumakas and Katakis, 2007; Hariharan et al., 2012; Babbar and Schölkopf, 2017; Yen et al., 2016, 2017). A typical implementation is to treat labels independently and train one-vs-all classifiers for each of the labels. These independent classifiers can be trained in parallel and thus are computationally efficient in practice. Ignoring the inter-label dependency also enables efficient optimization algorithm, which further reduces computational cost. However, ignoring label dependency inherently limits prediction accuracy. A competitive method in this category is called PD-Sparse (Yen et al., 2016), with a variant of the Block-Coordinate Frank-Wolfe training algorithm that exploits data sparsity and achieves complexity sub-linear in the number of primal and dual variables. PD-Sparse (Yen et al., 2016) shows better performance with less training and prediction time than 1-vs-all Logistic Regression or SVM on extreme multi-label datasets.

Tree Based Classifiers: Following the success of tree-based algorithms in binary classification problems, people also proposed tree-based algorithms for multi-label classification (Agrawal et al., 2013; Weston et al., 2013; Prabhu and Varma, 2014), which achieve promising prediction accuracy. Similar to decision trees, these methods make classification decisions in each branch split. Different from decision trees, each split evaluates all features, instead of one, to make a decision. Also, each decision is for a subset of labels rather than one label. Finally, via ensembling and parallel implementation, trees can boost their prediction accuracy with practically affordable computational cost. Among these tree based classifiers, FastXML (Prabhu and Varma, 2014) further optimizes an nDCG-based ranking loss function and achieves significantly higher accuracy than other peer methods.

Embedding: A major difficulty of extreme multi-label classification is the large number of labels. When labels are inter-dependent, one can attempt to find a lower dimensional latent label space from which one can fully reconstruct the original label space. Over the past decade, many methods were proposed to find this latent label space. In early work, methods were proposed to linearly project the original label space into a lower-dimension space and reconstruct predictions from that space (Tai and Lin, 2012; Balasubramanian and Lebanon, 2012). However, there are two assumptions: (1) the label dependency is linear and (2) the label matrix is low-rank, which do not always hold, as reflected by the low prediction accuracy of these methods. To overcome the limitation of the linear assumption, different methods were proposed using non-linear embeddings, including kernels, sub-sampling (Yu et al., 2014), feature-aware (Lin et al., 2014; Yeh et al., 2017) and pairwise distance preservation (Bhatia et al., 2015). Among these methods, SLEEC (Bhatia et al., 2015) stands out for less training time and higher accuracies. SLEEC introduces a method for learning a small ensemble of local pairwise distance preserving embeddings which allows it to avoid the low-rank and linear-dependency assumption.

Deep Learning: Deep learning has not been well studied for XML, although it has achieved great successes in binary and multi-class classification problems (Lin et al., 2017; Kim, 2014).

FastText (Grave et al., 2017) reconstructs a document representation by averaging the embedding of the words in the document, followed by a softmax transformation. It is a simple but very effective and accurate multi-class text classifier, as demonstrated in both sentiment analysis and multi-class classification (Grave et al., 2017). However, FastText may not be directly applicable for more complicated problems, like XML.

BoW-CNN (Johnson and Zhang, 2014) learns powerful embedding of small text regions by applying CNN to high-dimensional text data. The embedding of all regions are sent to one or multiple convolutional layers, a pooling layer and the output layer at the end.

XML-CNN (Liu et al., 2017) achieves computational efficiency by training a deep neural network with a hidden bottleneck layer much smaller than the output layer. However, this method has a few drawbacks. First, it is trained using the binary cross entropy loss. This loss tends to be sensitive to label noise, which is frequently observed in extreme multi-label data. Since the label vocabulary is large, it is quite common for human annotator to miss relevant tags. When the classifier's prediction (which might be correct) disagrees with the annotation, the cross entropy loss can potentially assign an unbounded penalty to the classifier during training procedure. The second issue is that because labels are trained independently as separate binary classification tasks, their prediction probabilities/scores may not be directly comparable. This is problematic because in many applications the requirement is to rank all labels according to their relevance, as opposed to making an independent binary decision on each label. The third defect is that XML-CNN requires raw documents as input since it adopts the CNN structure on top of sentences (Kim, 2014); this is problematic when datasets are given in other formats such as bag-of-words for text.

C2AE (Yeh et al., 2017) uses a ranking loss as the training objective. But the ranking loss employed there needs to compare all (positive label, negative label) pairs, and therefore does not scale well to extreme data. Furthermore, C2AE only takes the bag-of-words representation (one-hot encoding) as the input, which makes it harder to learn powerful representations from extreme multi-label dataset.

Our Contribution In this paper, we propose a new deep learning method to address extreme multi-label classification. Our contributions are as follows:

- Motivated by the recent success of attention techniques, we propose an efficient attention mechanism that can learn rich representations from any type of input features, including but not limited to bag-of-words, raw documents and images.
- Inspired by C2AE, our proposed model projects both features and labels onto common latent spaces wherein correlations between features and labels are exploited. By decoding this latent space into the original label space in the prediction stage, the dependencies between labels are implicitly captured.
- We propose a margin-based ranking loss that is simultaneously more effective for extreme settings and more tolerant towards noisy labeling.

2 The Proposed Method (Rank-AE)

In this section, we introduce the data format in XML, and the proposed networks, including the marginal-based ranking loss and attentions.

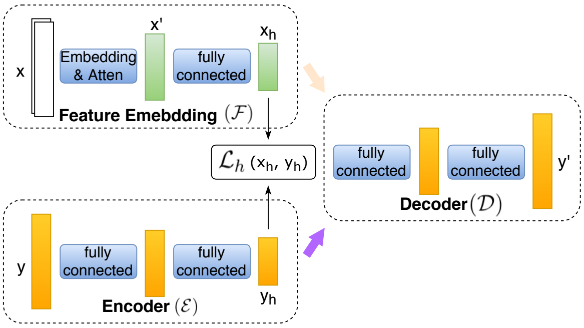

Figure 1: Ranking-based AutoEncoder for XML.

2.1 Data Format

In XML, we are given a set of label candidates $\mathcal{Y} = \{1, 2, \ldots, L\}$. The dataset D consists of features and labels: $D = \{(x_i, y_i)\}_{i=1}^N$, wherein N is number of data, and each instance $x \in \mathbb{R}^V$ (V is the feature dimension) matches a label subset $y \subseteq \mathcal{Y}$, which can be written as a binary vector $y = \{0, 1\}^L$, with each bit y_l representing the presence or absence of label l. Given such dataset, our goal is to build a classifier c: $\mathbb{R}^V \rightarrow \{0, 1\}^L$, mapping an instance to a subset of labels with arbitrary size.

2.2 Auto-Encoder Network

Inspired by the C2AE (Yeh et al., 2017), we propose a Ranking-based Auto-Encoder (**Rank-AE**), as depicted in Figure 1. Similar to C2AE, Rank-AE includes three mapping functions to be trained: a mapping from input features x to feature embeddings x_h, denoted as $\mathcal{F}(x)$, where h is the embedding size; an encoder from output labels y to label embeddings y_h as $\mathcal{E}(y)$; a decoder from label embeddings y_h to output labels y', written as $\mathcal{D}(y_h)$. The proposed model is built on two assumptions: first, each instance can be represented from two different aspects, features x and labels y, so there exists a common latent space between x and y; second, labels can be reproduced by an autoencoder. Based on these two assumptions, we design the object function as below:

$$\mathcal{L}(D) = \min_{\mathcal{F},\mathcal{E},\mathcal{D}} \mathcal{L}_h(x_h, y_h) + \lambda \mathcal{L}_{ae}(y, y') \quad (1)$$

wherein loss $\mathcal{L}_h(x_h, y_h)$ aims to find the common latent space for input x and output y and $\mathcal{L}_{ae}(y, y')$ enforces the output to be reproducible. λ is a hyper-parameter to balance these two losses. During the training, the model learns a joint network including $\mathcal{F}, \mathcal{E}$ and $\mathcal{D}$ to minimize the empirical loss Eq (1).

During inference, a given input $\hat{x}$ will be first transformed into a vector in latent space $\hat{x}_h = \mathcal{F}(\hat{x})$, which will then be fed into the label decoder to compute the predictions $\hat{y} = \mathcal{D}(\hat{x}_h)$. It is worth mentioning that although the label encoder $\mathcal{E}$ is ignored during the prediction, it is able to exploit cross-label dependency during the label embedding stage (Yeh et al., 2017). Recent work (Kurata et al., 2016; Baker and Korhonen, 2017) also show that using co-occurring labels information to initialize the neural network can further improve accuracy in multi-label classification.

2.3 $\mathcal{L}_h$ and $\mathcal{L}_{ae}$ Loss Functions

Learning Common Embedding ($\mathcal{L}_h$). Minimizing the common hidden space loss $\mathcal{L}_h$ has been proposed based on different considerations (Zhang and Schneider, 2011; Yeh et al., 2017; Shen et al., 2018), ranging from canonical correlation analysis to alignment of two spaces with a perspective of cross-view. Since the hidden space is usually small and requires less computational cost, we simply employ the mean squared loss for $\mathcal{L}_h$.

Reconstructing Output ($\mathcal{L}_{ae}$). Unlike $\mathcal{L}_h$ with small space, $\mathcal{L}_{ae}$ loss usually involves a large number of labels. Moreover, $\mathcal{L}_{ae}$ also directly affects the classification performance significantly since different loss functions lead to their own properties (Hajiabadi et al., 2017). Accordingly, solving such problems with large scale and desirable properties presents open challenges in three aspects: 1) how to improve time efficiency, 2) how to produce comparable labels scores and 3) how to deal with noise labels. Unfortunately, most of the related deep learning methods only target one or two aspects. C2AE attempts to minimize the number of misclassified pairs between relevant and irrelevant labels, as a result its computational complexity is quadratic with number of labels in the worst case; also it fails to scale well on large number of input features or labels due to its inefficient implementation[1]. XML-CNN (Liu et al., 2017) achieves computational efficiency by training a deep neural network with hidden layers much smaller than the output layer with binary cross-entropy loss (BCE), which has linear complexity in number of labels. Despite this, BCE loss could neither capture label dependencies nor produce directly comparable label scores, since each label is treated independently. Moreover, BCE loss tends to be sensitive to label noise, which is frequently observed in XML data (Reed et al., 2014; Ghosh et al., 2017).

To void the aforementioned issues, we propose a marginal-based ranking loss in AutoEncoder:

$$\mathcal{L}_{ae}(y, y') = \mathcal{L}_P(y, y') + \mathcal{L}_N(y, y') \tag{2}$$

$$\mathcal{L}_P(y, y') = \sum_{n \in N(y)} \max_{p \in P(y)} (m + y'_n - y'_p)_+ \tag{3}$$

$$\mathcal{L}_N(y, y') = \sum_{p \in P(y)} \max_{n \in N(y)} (m + y'_n - y'_p)_+ \tag{4}$$

wherein $N(y)$ is the set of negative label indexes, $P(y)$ is the complement of $N(y)$, and margin $m \in [0, 1]$ is a hyper-parameter for controlling the minimal distance between positive and negative labels. The loss consists of two parts: 1) $\mathcal{L}_P$ targets to raise the minimal score from positive labels over all negative labels at least by m; 2) $\mathcal{L}_N$ aims to penalize the most violated negative label under all positive labels by m. The proposed loss has the following attractive properties: 1) having linear complexity in number of labels $\mathcal{O}(L)$; 2) capturing the relative rankings between positive and negative labels; 3) tolerating the noisy labels with a tunable hyper-parameter m. To explain the last property, assume y'_n and y'_p are the predicted probabilities bounded in $[0, 1]$, then on one extreme case with noise-free labels and $m = 1$, all positive labels are raised to probability 1, while negatives are penalized to 0; on the other extreme case with all random labels, e.g. from i.i.d. Bernoulli distribution, setting $m = 0$ indicates that the annotated labels are completely random noises.

2.4 Dual Attention

Extracting rich feature representations in XML is helpful for predicting more complicated labels structures, but on the other hand, requires an efficient and feasible method. A recent work (CBAM) (Woo et al., 2018) proposes a block attention module, with a Channel-Attention and a Spatial Attention for images tasks only, wherein Channel-Attention emphasizes information from channels, e.g. RBG, and Spatial-Attention pays attention to partial areas in an image. By sequentially applying channel and spatial attentions, CBAM is shown to be effective in images classification and object detection. We take advantage of the attentions in CBAM and apply it on textual data.

---

[1] `https://github.com/dhruvramani/C2AE-Multilabel-Classification`

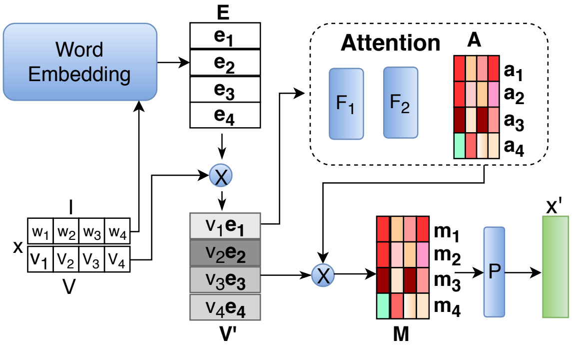

Figure 2: Dual-Attention in Feature Embedding.

In our proposed attention module, it also consists of spatial-wise and channel-wise attentions. First, we force spatial-wise attention to attend on a list of important words in a way that simply multiply word embeddings by term-frequency or tf-idf (whichever is provided in the feature matrix). It is worth noting that spatial-wise module does not involve any parameters, but it efficiently captures the importance of words with numerical statistics, like tf-idf. We demonstrate spatial-wise attention on the left side of Figure 2, where the input $x = (I, V)$ contains bag-of-words vector $I = (w_1, w_2, \ldots, w_n)^T \in \mathbb{R}^n$ and tf-idf vector $V = (v_1, v_2, \ldots, v_n)^T \in \mathbb{R}^n$. Bag-of-words I are fed into an embedding layer $\mathbf{E} = (\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n)^T \in \mathbb{R}^{n\times C}$ to get the word embeddings, where $\mathbf{e}_j \in \mathbb{R}^C$ is word embedding vector of w_j. Then we multiply word embeddings by V to obtain weighted word embeddings: $\mathbf{V}' = (v_1\mathbf{e}_1, v_2\mathbf{e}_2, \ldots, v_n\mathbf{e}_n)^T \in \mathbb{R}^{n\times C}$.

The channel attention is designed to emphasize the significant aspects by assigning different weights on bits in a word embedding. For example, in the word embedding of "apple", some of the bits may reflect fruit, while others may indicate the company name. To achieve this, we adopt the excitation network from the SENet (Hu et al., 2017) with a slight increase in model complexity. The excitation network includes two fully connected layers with a non-linearity activation function in between, see the top-right part in Figure 2:

$$\mathbf{A}^T = \sigma\left(F_2\delta(F_1\mathbf{V}'^T)\right) = (\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_n) \quad (5)$$

wherein $\mathbf{A} \in \mathbb{R}^{n\times C}$, δ and σ refer to the two activation functions, *ReLU* and *Sigmoid*, $F_1 \in \mathbb{R}^{\frac{C}{r}\times C}$ and $F_2 \in \mathbb{R}^{C\times\frac{C}{r}}$ are the two fully connected layers, with word embedding size C and reduction ratio r. After obtaining the attention matrix $\mathbf{A}$, we can apply those attentions to the weighted word embeddings to get a re-scaled word embedding matrix $\mathbf{M}$: $\mathbf{M} = \mathbf{V}' \circ \mathbf{A} = (\mathbf{m}_1, \mathbf{m}_2, \ldots, \mathbf{m}_n)^T \in \mathbb{R}^{n\times C}$, which is computed via the element-wise product. The obtained attention matrix $\mathbf{A}$ introduces dynamics conditioned on the input weighted word embeddings and further boosts feature discriminability. The last step is to feed the re-scaled embedding matrix into an average pooling to obtain the feature embedding $x' \in \mathbb{R}^C$. With the proposed spatial-wise and channel-wise attentions, Rank-AE can learn rich feature representations in an efficient way.

Dataset	train	test	label	feature	cardinality	inst/L

Table 1: Dataset Characteristics: train, test, label and feature are the numbers of training, testing, labels and features respectively; cardinality is the average number of label per instance; inst/L is the average number of instances per label. * indicates only feature matrix is provided and no raw document.

3 Experiments & Analysis

3.1 Dataset & Experiment Setup

Dataset. Our experiments are conducted on six extreme multi-label datasets and their characteristics are shown in Table 1, among which IMDb is crawled from online movie database[2] and the rest five datasets are downloaded from the extreme classification repository[3]. For datasets from the repository, we adopt the provided train/test split, and for IMDb we randomly choose 20% of the data as test set and the rest of 80% as training set. For all datasets, we reserve another 20% of training data as validation for tuning hyper-parameters. After tuning, all models are trained on the entire training set.

Among these datasets, three of them are only provided with BoW feature matrix: Delicious, Mediamill (dense feature matrix extracted from image data) and RCV, which are only feasible for the non-deep learning methods (SLEEC, FastXML, PDSparse) and Rank-AE. We provide

---

[2] `https://www.imdb.com/`

[3] `http://manikvarma.org/downloads/XC/XMLRepository.html`

both feature matrix and raw documents for IMDb, EURLex and Wiki10, which are feasible for both deep learning and non-deep learning methods. For those data with both formats, we remove the words from the raw documents that do not have corresponding BoW features so that the vocabulary size is the same for both deep and non-deep learning methods.

Evaluation Metrics. To evaluate the performances of each model, we adopt the metrics that have been widely used in XML: Precision at top k ($P@k$), and the Normalized Discounted Cummulated Gains at top k ($n@k$) (Bhatia et al., 2015; Prabhu and Varma, 2014; Yen et al., 2016; Liu et al., 2017). $P@k$ is a measure based on the fraction of correct predictions in the top k predicted scoring labels and $n@k$ is a normalized metric for Discounted Cumulative Gain:

$$P@k = \frac{1}{k} \sum_{l \in rank_k(\hat{y})} y_l \tag{6}$$

$$DCG@k = \sum_{l \in rank_k(\hat{y})} \frac{y_l}{log(l+1)} \tag{7}$$

$$nDCG@k = \frac{DCG@K}{\sum_{l=1}^{\min(k,|y|)} \frac{1}{\log(l+1)}} \tag{8}$$

wherein the $rank_k$ returns k largest indices of the prediction $\hat{y}$ in a descending order, and $|y|$ is the number of positive labels in ground truth. In the results, we report the average $P@k$ and $n@k$ on testing set with $k = 1, 3, 5$ respectively.

Hyper-parameters. In Rank-AE, we use the fixed neural network architecture, with two fully connected layers in both **Encoder** and **Decoder**, and one fully connected layer following **Embedding & Atten** network in **Feature Embedding**. We also fix most of the hyper-parameters, including hidden dimension h (100 for small number of labels data and 200 for large ones), word embedding size $C = 100$, and reduction ratio $r = 4$. The remaining hyper-parameters, such as balance λ between $\mathcal{L}_h$ and $\mathcal{L}_{ae}$, margin m in $\mathcal{L}_{ae}$, and others (decay, learning rate) in the optimization algorithms, are tuned on validation set. In addition, if the vocabulary for BoW is available, e.g. IMDb and Wiki10, the **Word Embedding** component is initialized by Glove[4], a pre-trained word embeddings of 100 dimensions; if it is not, e.g. Mediamill, Delicious and RCV, a random initialization is employed.

For the existing methods with the same train/test split, we take the scores from the original papers for SLEEC, FastXML and PD-Sparse directly. For the new datasets and splits, the hyper-parameters are tuned on the validation set for all methods, as suggested in their papers.

3.2 Comparisons with Related Methods

We evaluate the proposed Rank-AE with other six state-of-the-art methods, SLEEC, FastXML, PD-Sparse, FastText, Bow-CNN and XML-CNN, which are the leading methods among their categories. Among them, FastText, Bow-CNN and XML-CNN only take raw documents, which are not available for Delicious, Mediamill and RCV datasets. For Rank-AE, we adopt the raw text as the input for IMDb, and feature matrix for the rest.

The performances evaluated on $P@k$ and $n@k$ with $k = 1, 3, 5$ are summarized in Table 2 (a) and (b) separately. As reported, Rank-AE reaches the best performances on two datasets (IMDb and EURLex) out of 6 datasets, while SLEEC achieves the best performances on Mediamill and Wiki10, and FastXML performs the best on Delicious and RCV. In general, SLEEC and FastXML are very competitive to each other in non-deep learning methods, but PD-Sparse performs worse. Rank-AE always performs better than PD-Sparse with at least 1% increase, up to almost 20% improvement on Delicious data. When compared with FastXML, Rank-AE outperforms on 4 datasets with 1% to 10% growth, but underperforms on Delicious and RCV with 1% decrease. SLEEC, as the best non-deep learning method in our experiments, performs almost identical to Rank-AE, but on IMDb data, it performs $7\% \sim 15\%$ less than non-deep methods, and even worse than Rank-AE.

Comparing Rank-AE with deep learning methods, we narrow down to three datasets with available raw documents: IMDb, EURLex and Wiki10. As shown in Table 2, FastText and Bow-CNN, not planned for XML but for multi-class, perform much worse than XML-CNN and Rank-AE as expected. On the other hand, XML-CNN achieves close performance to Rank-AE: with similar performance on IMDb dataset, but lower scores on EURLex and Wiki10 with 2% drop in $P@k$ and $n@k$. In spite of this, Rank-AE, trained on feature matrix for EURLex and Wiki10, surprisingly performs better than XML-CNN on raw data.

In the comparisons, there is no such method that

could perform the best on all datasets. We discover that each dataset has its own intrinsic properties, such as diversity of labels, number of features, average number of relevant labels per instance and average number of training instances per label, see Table 1. All those properties will affect training procedure, for example, how much flexibility a model should be in order to explain labels well by the given training data. Because those factors are always changing from data to data, they also influence the performances on different models. In order to have a reasonable comparisons, we report the average ranking score for each method. To compute the average ranks, we first rank the methods based on their performance in each row in Table 2, then average them through all rows, and report the final ranking scores in the last row of each table. The average ranking scores show that Rank-AE is the best model with ranking scores 1.78 in $P@k$ and 1.89 in $n@k$.

3.3 Comparisons with Noise Labels

As mentioned previously, noisy labels in XML are a quite common issue in the real-world applications (Yeh et al., 2017; Ghosh et al., 2017), but our proposed marginal ranking loss naturally mitigates this problem. Since IMDb is a real-world dataset with relatively clean labels, we conduct the noise experiments on it. In the experiments, we control the noise labels in two different ways: 1) missing labels: changing each positive label from $y_l = 1$ to $y_l = 0$ with certain rate, 2) both

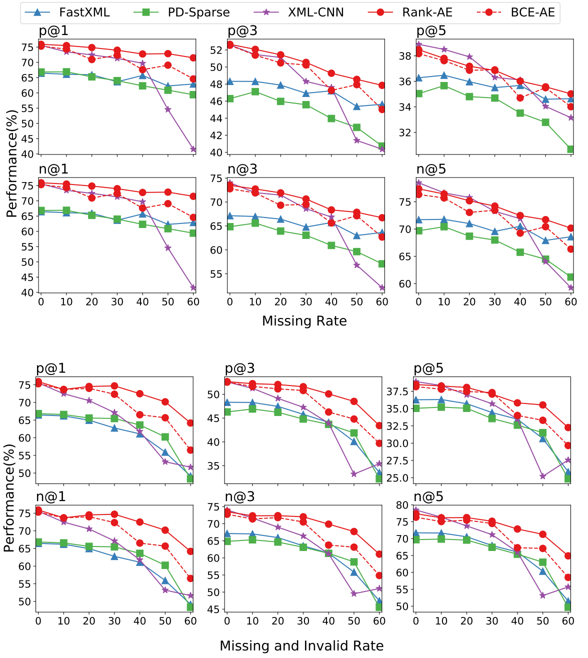

Figure 3: Comparisons on noisy labelling IMDb data.

missing and invalid labels: flipping either from positive to negative or from negative to positive with a noise rate. The noise rates are varied from 0% to 60% on 80% of the training set, and the rest of 20% is noise-free validation set for model selection. We select five algorithms: FastXML, PD-Sparse, XML-CNN, Rank-AE and BCE-AE, wherein BCE-AE is our proposed method but using binary cross-entropy loss in $\mathcal{L}_{ae}(y, y')$. Comparing BCE-AE with Rank-AE can be used to verify whether the robustness to label noise is due to the use of marginal ranking loss.

The performances are reported on the same clean test set, shown in Figure 3. Rank-AE consistently outperforms other four approaches and has the best robustness tolerating noise labels. Besides, FastXML and PD-Sparse are more tolerant to missing noises than XML-CNN, which may due to XML-CNN has greater capacity and thus more prone to over-fitting the noise. Furthermore, when comparing Rank-AE with BCE-AE, both of which share the same structure but have different loss functions, the proposed marginal-based ranking loss seems to be robuster than binary cross-entropy loss.

3.4 More Analysis in Rank-AE

Ablation Study. The effectiveness and robustness of Rank-AE have been demonstrated in the previous section. However, it is not clear to us yet that if the effectiveness benefits from the proposed components, such as attention mechanism and marginal ranking loss. To further understand the impacts from these two factors, we conduct a controlling experiment with three different settings: 1) removing the Attention component $\mathcal{A}$ in Figure 2 from Rank-AE, in which case $\mathbf{V}'$ is directly passed to the average pooling to obtain x', called **No attn**; or 2) examining the performances by replacing the marginal ranking loss ($\mathcal{L}_{ae}$) with a binary cross entropy loss, named **No loss**; or 3) keeping the original **Rank-AE** without any change. In Figure 4, $P@k$ is reported on the six datasets for the ablation experiment, because $n@k$ is similar to $P@k$, thus eliminated here. The comparisons results show that Rank-AE without any change works better than the other two on all datasets consistently, especially on Wiki10. First, channel-attention extracts richer information from the word embeddings by introducing the channel weights. Thus, it is more suitable when classification tasks become more complicated and a word more likely represents multiple aspects. Second, Rank-AE gains some advantage of tolerating noise labels with marginal ranking loss comparing to BCE loss. We could even further infer that IMDb and RCV may have relatively less noise labels since the performance does not benefit much from the marginal ranking loss.

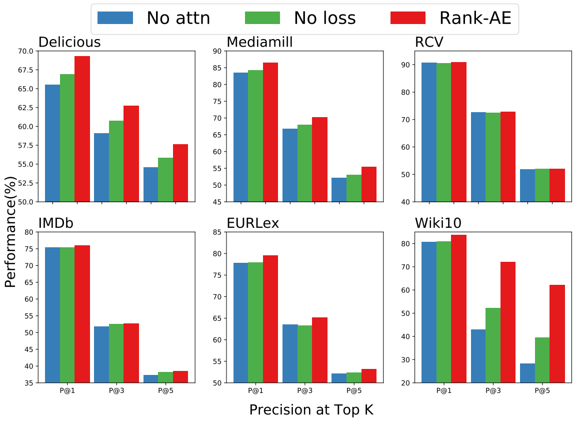

Figure 4: Precision at top k comparisons: No attn (/) is no attention Rank-AE; No loss (+) is using binary cross entropy lose instead of marginal ranking loss; Rank-AE (x) is our proposed model.

Channel-Attention Visualization. Our channel-attention is implemented by an excitation network, which is adopted from SENet (Hu et al., 2017) and only applied to images before. To demonstrate its effectiveness and feasibility on textual data, we

Figure 5: Visualization for Attention in Rank-AE. The labels are movie genres split by underline, and the input is a movie story line.

employ the visualization tool (Lin et al., 2017) to highlight important words based on the attention output. Specifically, we run our method on IMDb dataset, wherein each instance is a movie story associated with relevant genres as labels. Instead of extracting $\mathbf{V}'$ matrix using the proposed spatial-wise attention, we obtain a fixed size embeddings from a bidirectional LSTM on variable length of sentence, fed to our channel-attention network. Through the channel-attention network, we can observe the attention matrix $\mathbf{A}$ for each input document. By summing up the attention weights of each word embedding vector, we can visualize the overall attention for that word with the visualization tool[5]. We randomly select three movies from IMDb testing set (See Figure 5). By looking at the highlighted regions, we can see that the proposed channel-attention is able to focus more on the words that are highly related to the topics.

4 Conclusion

In this paper, we propose a marginal ranking loss, which not only predicts comparable labels scores between labels, more suitable for ranking metrics, but also consistently performs better on noisy labeling data, with both missing and invalid labels. In addition, the dual-attention component allows Rank-AE to learn more powerful feature representations efficiently. By integrating those components, Rank-AE usually achieves the best or the second best on six benchmark XML datasets comparing with other outstanding methods in state-of-the-art.

Abstract

This paper provides a new way to improve the efficiency of the REINFORCE training process. We apply it to the task of instance selection in distant supervision. Modeling the instance selection in one bag as a sequential decision process, a reinforcement learning agent is trained to determine whether an instance is valuable or not and construct a new bag with less noisy instances. However unbiased methods, such as REINFORCE, could usually take much time to train. This paper adopts posterior regularization (PR) to integrate some domain-specific rules in instance selection using REINFORCE. As the experiment results show, this method remarkably improves the performance of the relation classifier trained on cleaned distant supervision dataset as well as the efficiency of the REINFORCE training.

1 Introduction

Relation extraction is a fundamental work in natural language processing. Detecting and classifying the relation between entity pairs from the unstructured document, it can support many other tasks such as question answering.

While relation extraction requires lots of labeled data and make methods labor intensive, (Mintz et al., 2009) proposes distant supervision (DS), a widely used automatic annotating way. In distant supervision, knowledge base (KB) , such as Freebase, is aligned with nature documents. In this way, the sentences which contain an entity pair in KB all express the exact relation that the entity pair has in KB. We usually call the set of instances that contain the same entity pair a bag. In this way, the training instances can be divided into N bags $\mathbf{B} = \{B^1, B^2, ..., B^N\}$. Each bag B^k are corresponding to an unique entity pair $E^k = (e^k_1, e^k_2)$ and contains a sequence of instances $\{x^k_1, x^k_2, ..., x^k_{|B^k|}\}$. However, distant supervision may suffer a wrong label problem. In other words, the instances in one bag may not actually have the relation.

To resolve the wrong label problem, just like Fig.2 shows, (Feng et al., 2018) model the instance selection task in one bag B^k as a sequential decision process and train an agent $\pi(a|s, \theta_\pi)$ denoting the probability $P_\pi(A_t = a, |S_t = s, \theta_t = \theta_\pi)$ that action a is taken at time t given that the agent is in state s with parameter vector θ_π by REINFORCE algorithm (Sutton and Barto, 1998). The action a can only be 0 or 1 indicating whether an instance x^k_i is truly expressing the relation and whether it should be selected and added to the new bag $\overline{B^k}$. The state s is determined by the entity pair corresponding to the bag, the candidate instance to be selected and the instances that have already been selected. Accomplishing this task, the agent gets a new bag $\overline{B^k}$ at the terminal of the trajectory with less wrong labeled instances. With the newly constructed dataset $\overline{\mathbf{B}} = \{\overline{B^1}, \overline{B^2}, ..., \overline{B^N}\}$ with less wrong labeling instances, we can train bag level relation predicting models with better performance. Meanwhile, the relation predicting model gives reward to the instance selection agent. Therefore, the agent and the relation classifier can be trained jointly.

However, REINFORCE is a Monte Carlo algorithm and need stochastic gradient method to optimize. It is unbiased and has good convergence properties but also may be of high variance and slow to train (Sutton and Barto, 1998).

Therefore, we train a REINFORCE based agent by integrating some other domain-specific rules to accelerate the training process and guide the agent to explore more effectively and learn a better policy. Here we use a rule pattern as the Fig.1 shows (**?**). The instances that return true (match

the pattern and label in any one of the rules) are denoted as x_{MI} and we adopt posterior regularization method (Ganchev, 2010) to regularize the posterior distribution of $\pi(a|s, \theta_\pi)$ on x_{MI}. In this way, we can construct a rule-based agent π_r. π_r tends to regard the instances in x_{MI} valuable and select them without wasting time in trial-and-error exploring. The number of such rules is 134 altogether and can match nearly four percents of instances in the training data.

Our contributions include:

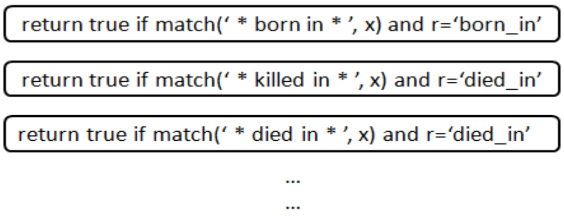
- We propose PR REINFORCE by integrating domain-specific rules to improve the performance of the original REINFORCE.
- We apply the PR REINFORCE to the instance selection task for DS dataset to alleviate the wrong label problem in DS.

2 Related Work

Among the previous studies in relation extraction, most of them are supervised methods that need a large amount of annotated data (Bach and Badaskar, 2007). Distant supervision is proposed to alleviate this problem by aligning plain text with Freebase. However, distant supervision inevitably suffers from the wrong label problem.

Some previous research has been done in handling noisy data in distant supervision. An expressed-at-least-once assumption is employed in (Mintz et al., 2009): if two entities participated in a relation, at least one instance in the bag might express that relation. Many follow-up studies adopt this assumption and choose a most credible instance to represent the bag. (Lin et al., 2016; Ji et al., 2017) employs the attention mechanism to put different attention weight on each sentence in one bag and assume each sentence is related to the relation but have a different correlation.

Another key issue for relation extraction is how to model the instance and extract features, (Zeng et al., 2014, 2015; Zhou et al., 2016) adopts deep neural network including CNN and RNN, these methods perform better than conventional feature-based methods.



```
return true if match(' * born in * ', x) and r='born_in'
return true if match(' * killed in * ', x) and r='died_in'
return true if match(' * died in * ', x) and r='died_in'
...
...
```

Figure 1: Rule Pattern Examples

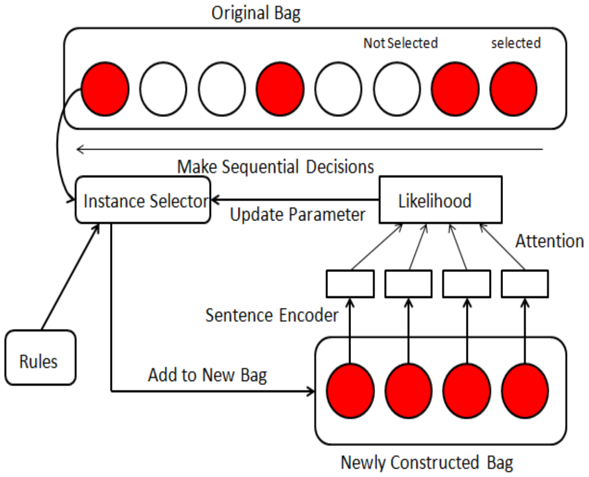


Figure 2: Overall Framework

Reinforcement learning has been widely used in data selection and natural language processing. (Feng et al., 2018) adopts REINFORCE in instance selection for distant supervision which is the basis of our work.

Posterior regularization (Ganchev, 2010) is a framework to handle the problem that a variety of tasks and domains require the creation of large problem-specific annotated data. This framework incorporates external problem-specific information and put a constraint on the posterior of the model. In this paper, we propose a rule-based REINFORCE based on this framework.

3 Methodology

In this section, we focus on the model details. Besides the interacting process of the relation classifier and the instance selector, we will introduce how to model the state, action, reward of the agent and how we add rules for the agent in training process.

3.1 Basic Relation Classifier

We need a pretrained basic relation classifier to define the reward and state. In this paper, we adopt the BGRU with attention bag level relation classifier f_b (Zhou et al., 2016). With $\mathbf{o}$ denoting the output of f_b corresponding to the scores associated to each relation, the conditional probability can be written as follows:

$$P_{f_b}(r|B^k, \theta_b) = \frac{exp(o_r)}{\sum_{k=1}^{n_r} exp(o_k)} \quad (1)$$

where r is relation type, n_r is the number of relation types, θ_b is the parameter vector of the basic relation classifier f_b and B^k denotes the input bag of the classifier.

In the basic classifier, the sentence representation is calculated by the sentence encoder network BGRU, the BGRU takes the instance x_i^k as input and output the sentence representation BGRU(x_i^k). And then the sentence level(ATT) attention will take $\{BGRU(x_1^k), BGRU(x_2^k), ..., BGRU(x_{|B^k|}^k)\}$ as input and output **o** which is the final output of f_b corresponding to the scores associated to each relation.

3.2 Original REINFORCE

Original REINFORCE agent training process is quite similar to (Feng et al., 2018). The instance selection process for one bag is completed in one trajectory. Agent $\pi(a|s, \theta_\pi)$ is trained as an instance selector.

The key of the model is how to represent the state in every step and the reward at the terminal of the trajectory. We use the pretrained f_b to address this key problem. The reward defined by the basic relation classifier is as follows:

$$R = \log P_{f_b}(r^k|\overline{B^k}, \theta_b) \quad (2)$$

In which r^k denotes the corresponding relation of B^k.

The state s mainly contained three parts: the representation of the candidate instance, the representation of the relation and the representation of the instances that have been selected.

The representation of the candidate instance are also defined by the basic relation classifier f_b. At time step t, we use BGRU(x_t^k) to represent the candidate instance x_t^k and the same for the selected instances. As for the embedding of relation, we use the entity embedding method introduced in TransE model (Bordes et al., 2013) which is trained on the Freebase triples that have been mentioned in the training and testing dataset, and the relation embedding re_k will be computed by the difference of the entity embedding element-wise.

The policy π with parameter $\theta_\pi = \{W, b\}$ is defined as follows:

$$P_\pi(A_t|S_t, \theta_\pi) = softmax(WS_t + b) \quad (3)$$

With the model above, the parameter vector can be updated according to REINFORCE algorithm (Sutton and Barto, 1998).

3.3 Posterior Regularized REINFORCE

REINFORCE uses the complete return, which includes all future rewards up until the end of the trajectory. In this sense, all updates are made after the trajectory is completed (Sutton and Barto, 1998). These stochastic properties could make the training slow. Fortunately, we have some domain-specific rules that could help to train the agent and adopt posterior regularization framework to integrate these rules. The goal of this framework is to restrict the posterior of π. It can guide the agent towards desired behavior instead of wasting too much time in meaninglessly exploring.

Since we assume that the domain-specific rules have high credibility, we designed a rule-based policy agent π_r to emphasize their influences on π. The posterior constrains for π is that the policy posterior for x_{MI} is expected to be 1 which indicates that agent should select the x_{MI}. This expectation can be written as follows:

$$E_{P_\pi}[\mathbf{l}(A_t = 1)] = 1 \quad (4)$$

where **l** here is the indicator function. In order to transfer the rules into a new policy π_r, the KL divergence between the posterior of π and π_r should be minimized, this can be formally defined as

$$minKL(P_\pi(A_t|S_t, \theta_\pi)||P_{\pi_r}(A_t|S_t, \theta_\pi)) \quad (5)$$

Optimizing the constrained convex problem defined by Eq.(4) and Eq.(5), we get a new policy π_r:

$$P_{\pi_r}(A_t|S_t, \theta_\pi) = \frac{P_\pi(A_t|S_t, \theta_\pi)exp(\mathbf{l}(A_t = 1) - 1)}{Z} \quad (6)$$

where Z is a normalization term.

$$Z = \sum_{A_t=0}^{1} P_{\pi_r}(A_t|X, \theta_\pi)exp(\mathbf{l}(A_t = 1) - 1)$$

Algorithm 1 formally define the overall framework of the rule-based data selection process.

4 Experiment

Our experiment is designed to demonstrate that our proposed methodologies can train an instance selector more efficiently.

    end
    $\theta'_\pi = \tau\theta_\pi + (1-\tau)\theta'_\pi$;
    Update the classifier $f_b$;
end
```

Algorithm 1: PR REINFORCE

We tuned our model using three-fold cross validation on the training set. For the parameters of the instance selector, we set the dimension of entity embedding as 50, the learning rate as 0.01. The delay coefficient τ is 0.005. For the parameters of the relation classifier, we follow the settings that are described in (Zhou et al., 2016).

The comparison is done in rule-based reinforcement learning method, original reinforcement learning and method with no reinforcement learning which is the basic relation classifier trained on original DS dataset. We use the last as the baseline.

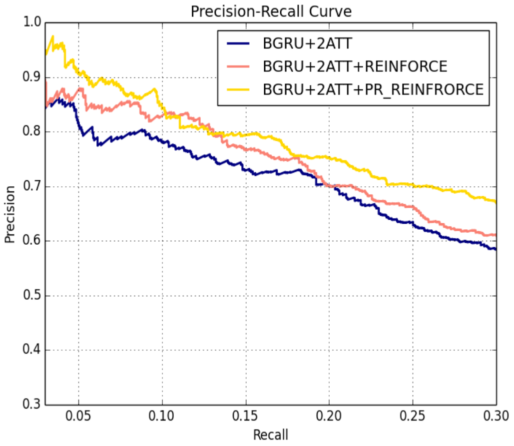

Figure 3: Precision/Recall Curves

4.1 Dataset

A widely used DS dataset, which is developed by (Riedel et al., 2010), is used as the original dataset to be selected. The dataset is generated by aligning Freebase with New York Times corpus.

4.2 Metric and Performance Comparison

We compare the data selection model performance by the final performance of the basic model trained on newly constructed dataset selected by different models. We use the precision/recall curves as the main metric. Fig.3 presents this comparison. PR REINFORCE constructs cleaned DS dataset with less noisy data compared with the original REINFORCE so that the BGRU+2ATT classifier can reach better performance.

5 Conclusions

In this paper, we develop a posterior regularized REINFORCE methodology to alleviate the wrong label problem in distant supervision. Our model makes full use of the hand-crafted domain-specific rules in the trial and error search during the training process of REINFORCE method for DS dataset selection. The experiment results show that PR REINFORCE outperforms the original REINFORCE. Moreover, PR REINFORCE greatly improves the efficiency of the REINFORCE training.

Scalable Collapsed Inference for High-Dimensional Topic Models

Rashidul Islam and **James Foulds**

University of Maryland, Baltimore County
{islam.rashidul,jfoulds}@umbc.edu

Abstract

The bigger the corpus, the more topics it can potentially support. To truly make full use of massive text corpora, a topic model inference algorithm must therefore scale efficiently in 1) documents and 2) topics, while 3) achieving accurate inference. Previous methods have achieved two out of three of these criteria simultaneously, but never all three at once. In this paper, we develop an online inference algorithm for topic models which leverages *stochasticity* to scale well in the number of documents, *sparsity* to scale well in the number of topics, and which operates in the *collapsed representation* of the topic model for improved accuracy and run-time performance. We use a Monte Carlo inner loop in the online setting to approximate the collapsed variational Bayes updates in a sparse and efficient way, which we accomplish via the Metropolis-Hastings Walker method. We showcase our algorithm on LDA and the recently proposed mixed membership skip-gram topic model. Our method requires only amortized $O(k_d)$ computation per word token instead of $O(K)$ operations, where the number of topics occurring for a particular document $k_d \ll$ the total number of topics in the corpus K, to converge to a high-quality solution.

1 Introduction

Topic models are powerful tools for analyzing today's massive, constantly expanding digital text information by representing high-dimensional data in a low-dimensional subspace. We can recover the main themes of a corpus by using topic models such as latent Dirichlet allocation (LDA) to organize, understand, search, and explore the documents (Blei et al., 2003).

Traditional LDA inference techniques such as variational Bayes and collapsed Gibbs sampling do not readily scale to corpora containing millions of documents. To scale up inference, the main approaches are distributed algorithms (Newman et al., 2008) and stochastic algorithms (Hoffman et al., 2010, 2013). Stochastic algorithms, such as stochastic variational inference (SVI), operate in an online fashion, and hence do not need to see all of the documents before updating the topics, so they can be applied to corpora of any size, without expensive distributed hardware (Hoffman et al., 2010). The "collapsed" representation of topic models is also frequently important, as it leads to faster convergence, efficient updates, and lower variance in estimation (Griffiths and Steyvers, 2004). The stochastic collapsed variational Bayesian inference (SCVB0) algorithm, proposed by (Foulds et al., 2013), combines the benefits of stochastic and collapsed inference.

Larger corpora typically support more topics, which brings the additional efficiency challenge of training a larger model (Mimno et al., 2012). This challenge has been addressed by exploiting sparsity to perform updates in time sublinear in the number of topics. A sparse variant of the SVI algorithm for LDA, SSVI, proposed by (Mimno et al., 2012), is scalable to large numbers of topics, but does not fully exploit the collapsed representation of LDA, which is important for faster convergence and improved inference accuracy, due to a better variational bound (Teh et al., 2007). The Metropolis Hastings Walker (MHW) method (Li et al., 2014) scales well in the number of topics, and uses a collapsed inference algorithm, but it operates in the batch setting, so it is not scalable to large corpora. LightLDA (Yuan et al., 2015)

Proceedings of NAACL-HLT 2019, pages 2836–2845
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

is a distributed approach to the MHW method which adopts a data-and-model-parallel strategy to maximize memory and CPU efficiency. However, it is not an online approach, and furthermore requires multiple expensive computer clusters to converge faster. Tensor methods are another approach to speeding up topic models (Anandkumar et al., 2014; Arora et al., 2012), which theoretically guarantee the recovery of the true parameters by overcoming the problem of local optima. These techniques use the method of moments instead of maximum likelihood estimation or Bayesian inference, which leads to lower data efficiency, and sometimes unreliable performance.

In this work, we propose a highly efficient and scalable inference algorithm for topic models. We develop an online algorithm which leverages *stochasticity* to scale well in the number of documents, *sparsity* to scale well in the number of topics, and which operates in the *collapsed* representation of topic models. We thereby combine the individual benefits of SVI, SSVI, SCVB0, and MHW into a single algorithm. Our approach is to develop a sparse version of SCVB0. Inspired by SSVI, we use a Monte Carlo inner loop to approximate the SCVB0 variational distribution updates in a sparse and efficient way, which we accomplish via MHW method. To show the generality of our algorithm, we explore the benefits of our inference method for LDA and another recently proposed topic model, MMSGTM, with experiments on both small and large-scale datasets.

2 Background

To build the foundation for our proposed method, in this section we provide the necessary background on LDA and MMSGTM topic models and their associated inference algorithms. This is followed by a description of the MHW sampler for reducing topic model sampling complexity.

2.1 Latent Dirichlet Allocation and SCVB0

Probabilistic topic models such as LDA (Blei et al., 2003) use latent variables to encode co-occurrence patterns between words in text corpora and other bag-of-words represented data. In LDA, we assume that the D documents in a corpus are each from mixture distributions of K individual topics ϕ_k, $k \in \{1, ..., K\}$, each of which are discrete distributions over words. For a document j of length N_j, the local (document-level) variables θ_j are a distribution over topics drawn from a Dirichlet prior with parameters α_k and for each token, global variables (corpus-level) ϕ_k are drawn from a Dirichlet prior with parameters β_w. Due to conjugacy, we can marginalize out topics $\boldsymbol{\Theta}$ and distributions over topics $\boldsymbol{\Phi}$, and perform inference only on the topic assignments $\boldsymbol{Z}$ in the collapsed representation of LDA (Griffiths and Steyvers, 2004). For scalable and accurate inference, Foulds et al. (2013) proposed a stochastic collapsed variational inference algorithm, SCVB0. The SCVB0 approach computes a variational discrete distribution γ_{ij} over the K topic assignment probabilities for each word i in each document j, but does not maintain the γ variables that increase the memory requirement of original batch CVB0 algorithm (Asuncion et al., 2009). SCVB0 iteratively updates each γ_{ij} using

$$\gamma_{ijk} :\propto \frac{N^{\Phi}_{w_{ij}k} + \beta_{w_{ij}}}{N^{Z}_{k} + \sum_w \beta_w}(N^{\Theta}_{jk} + \alpha_k) \qquad (1)$$

for each topic k, with j^{th} document's i^{th} word w_{ij}. The $\boldsymbol{N^Z}$, $\boldsymbol{N^\Theta}$, and $\boldsymbol{N^\Phi}$ are referred to as CVB0 statistics, where $\boldsymbol{N^Z}$ is the vector of expected number of words assigned to each topic, each entry j, k of matrix $\boldsymbol{N^\Theta}$, and each entry w, k of matrix $\boldsymbol{N^\Phi}$ are the expected number of times document j, and word w are assigned to topic k, respectively, across the corpus. To do stochastic updates of these variables, one sequence of step-sizes ρ^Φ for $\boldsymbol{N^\Phi}$ and $\boldsymbol{N^Z}$ and another sequence ρ^Θ for $\boldsymbol{N^\Theta}$ are maintained. The update of $\boldsymbol{N^\Theta_j}$ for every token i of document j with an online average of the current value and its expected value is

$$\boldsymbol{N^\Theta_j} := (1 - \rho^\Theta_t)\boldsymbol{N^\Theta_j} + \rho^\Theta_t C_j \gamma_{ij} \qquad (2)$$

where C_j is the document length. In practice, it is too expensive to update $\boldsymbol{N^\Phi}$ after every token. This leads to the use of minibatch updates with the average of the M per-token estimates of the form $\boldsymbol{Y_{ij}}$, which is a $W \times K$ matrix with the w_{ij}th row being γ_{ij} and with zeros in the other entries:

$$\boldsymbol{N^\Phi} := (1 - \rho^\Phi_t)\boldsymbol{N^\Phi} + \rho^\Phi_t \hat{\boldsymbol{N}}^{\boldsymbol{\Phi}} \qquad (3)$$

$$\boldsymbol{N^Z} := (1 - \rho^\Phi_t)\boldsymbol{N^Z} + \rho^\Phi_t \hat{\boldsymbol{N}}^{\boldsymbol{Z}}\ , \qquad (4)$$

where $\hat{\boldsymbol{N}}^{\boldsymbol{\Phi}} = \frac{C}{|M|}\sum_{ij\in M}\boldsymbol{Y_{ij}}$, $\hat{\boldsymbol{N}}^{\boldsymbol{Z}} = \frac{C}{|M|}\sum_{ij\in M}\gamma_{ij}$, and C is the number of words in the corpus. The SCVB0 algorithm outperforms stochastic VB (Hoffman et al., 2010) on large corpora by converging faster and often to a better solution (Foulds et al., 2013). However, the SCVB0 algorithm does not leverage sparsity, and hence requires $O(K)$ operations per word token.

2.2 MMSG Topic Model

To show the generality of our approach to topic models other than LDA, we will also apply our method to a recent model called the Mixed Membership Skip-gram Topic Model (MMSGTM) (Foulds, 2018), which combines ideas from topic models and word embeddings (cf. also (Das et al., 2015; Liu et al., 2015)). MMSGTM's generative model for words and their surrounding context is:

- For each word w_i in the corpus
  - Sample a topic $z_i \sim$ Discrete(θ_{w_i})
  - For each word $w_c \in context(i)$
    - Sample a context word $w_c \sim$ Discrete(ϕ_{z_i}) .

The inferred model can then be used to train embeddings for topics and words, although we do not consider this here. The MMSGTM admits a collapsed Gibbs sampler (CGS) which efficiently resolves the cluster assignments. With Dirichlet priors on the parameters, the CGS update is

$$p(z_i = k|.) :\propto (N^{(\Phi)-i}_{w_i k} + \alpha_k) \times \prod_{c=1}^{|context(i)|} \frac{N^{(\Phi)-i}_{w_c k} + \beta_{w_c} + N^{(i,c)}_{w_c}}{N^{(Z)-i}_{k} + \sum_w \beta_w + c - 1}\,, \quad (5)$$

where α and β are parameter vectors for Dirichlet priors over the topic and word distributions, $\boldsymbol{N^{\Phi}_{w_i}}$ and $\boldsymbol{N^{\Phi}_{w_c}}$ are input and output word-topic counts (excluding the current word), N^Z is the total topic counts in output word-topic counts, and $N^{(i,c)}_{w_c}$ is the number of occurrences of word w_c before the c^{th} word in the i^{th} context. MMSGTM exploits the MHW algorithm, which scales sub-linearly in K, but not in the number of training documents.

2.3 Metropolis-Hastings-Walker Sampler

The MHW method (Li et al., 2014), which is a key component of our approach, uses a data structure called an alias table which allows sampling from a discrete distribution in amortized $O(1)$ time. Assuming initial probabilities $p_0, p_1, ..., p_{l-1}$ of a distribution over l outcomes and average of probabilities $a = \frac{1}{l}$, the alias table A can be formed as follows (Marsaglia et al., 2004):

- Initialize: for i from 0 to $l - 1$
  - $A_{alias}[i] = i$ and $A_{prob} = (i + 1)a$
- Do the following steps $n - 1$ times
  - Find smallest p_i and largest p_j
  - Set $A_{alias}[i] = j$ and $A_{prob} = i \times a + p_i$
  - $p_j := p_j - (a - p_i)$ and $p_i := a$.

Then, to sample from p using the alias table:

- Roll l-sided fair die to choose element i of A
- If $Rand(1) < A_{prob}[i]$ return i, else return $A_{alias}[i]$.

Li et al. (2014) cache alias table samples, avoiding the need to store the table. Once the supply of samples is exhausted they compute a new alias table. They draw samples from the Gibbs sampling update, analogous to γ_{ij} in Equation 1, in amortized $O(k_d)$ time by decomposing the update into

$$p(z_{ij} = k|.) \propto N^{\Theta}_{jk}\frac{N^{\Phi}_{w_{ij}k} + \beta_{w_{ij}}}{N^{Z}_{k} + \sum_w \beta_w} + \alpha_k \frac{N^{\Phi}_{w_{ij}k} + \beta_{w_{ij}}}{N^{Z}_{k} + \sum_w \beta_w} \quad (6)$$

where the first term, sparse in k_d, admits sampling in $O(k_d)$ time, and the second term is dense but slow changing. A Metropolis-Hastings (M-H) update is used to correct for approximating the CGS update with a proposal distribution $q(k)$ based on the stale alias samples. Foulds et al. (2018) propose to apply simulated annealing to optimize instead of sample, and which improves mixing for the MMSGTM. This is achieved by raising the model part of the M-H acceptance ratio for a new sample $z_i^{(new)} \sim q(k)$ to the power of $\frac{1}{T_j}$ at iteration j:

$$p(accept\ z_i^{(new)}|.) = \quad (7)$$
$$min(1, (\frac{p(z_i^{(new)})}{p(z_i^{(old)})})^{\frac{1}{T_j}} \frac{q(z_i^{(old)})}{q(z_i^{(new)})})\,.$$

3 Sparse Stochastic CVB0

In this section, we introduce our approach, a sparse version of SCVB0, which combines the individual benefits of the SVI, SSVI, SCVB0 and MHW algorithms, to scale well not only in the

end for
```

number of documents but also in the number of topics, while gaining the benefits of collapsed inference. We refer to our method as the sparse stochastic collapsed variational Bayesian inference (SparseSCVB0) algorithm.

In SparseSCVB0, we obtain sparsity by substituting sparse Monte Carlo approximations $\gamma_{ij}^{(pseudo)}$ for the original SCVB0 variational distributions γ_{ij}. The justification for this procedure, also used by (Mimno et al., 2012), is that the expected value of an average over one-hot samples from a distribution is equal to that distribution:

$$E_{s_i \sim p(\mathbf{s})}\Big[\frac{\sum_{i=1}^S \delta_k(s_i)}{S}\Big] = \frac{1}{S}\sum_{i=1}^S E_{s_i \sim p(\mathbf{s})}\Big[\delta_k(s_i)\Big]$$

$$= \frac{1}{S}\sum_{i=1}^S \sum_{k'} \delta_k(s_i = k')p(s_i = k') = p(s = k)\,.$$

Thus, the overall procedure is still a valid stochastic optimization algorithm. We approximate the inner loop sampler in time sublinear in K, constructing $\gamma^{(pseudo)}$ by generating S samples from γ_{ij} using the MHW method. To describe the general form of our algorithm, we introduce SparseSCVB0 statistics: local (e.g. document-level) expected counts $\boldsymbol{N^L}$, global (corpus-level) expected counts $\boldsymbol{N^G}$, and total expected topic counts $\boldsymbol{N^Z}$. We approximate local sufficient statistics $\boldsymbol{N^L}$ for each token i in document j via:

$$N_{jk}^L \approx C_j E_{\gamma_{ij}^{(pseudo)}}\Big[\frac{\sum_{s \in S}\delta_{z_{ij}^s = k}}{S}\Big]\,.$$

Since $\gamma^{(pseudo)}$ is sparse, we can efficiently update these statistics using only its non-zero entries. This approach allows us to learn high-dimensional topic models efficiently on very large corpora. Before updating global parameters in a similar fashion, it may also be beneficial to perform a small number of burn-in passes to learn the local parameters $\boldsymbol{N^L}$ (Foulds et al., 2013). For large-scale datasets (e.g. Wikipedia), SparseSCVB0 operates in a "mini-epoch" approach where we process a large subset of the corpus (e.g. $5,000$ documents) several (e.g. 3) times, before discarding and processing the next subset, and so on. This allows a "warm start" of $\boldsymbol{N^L}$ in repeating iterations, with a small memory overhead. Pseudo-code of SparseSCVB0 for a mini-epoch is provided in Algorithm 1, which we discuss more in the next two sections, including model-specific aspects.

4 SparseSCVB0 for LDA

To deploy SparseSCVB0 for LDA, we use the M-H proposal distribution from (Li et al., 2014) which involves drawing samples exactly from document-specific sparse terms or approximately using cached samples from the alias table:

$$q(k) := \frac{P_L}{P_L + Q_G} p_L(k) + \frac{Q_G}{P_L + Q_G} q_G(k) \quad (8)$$

where $p_L(k)$ and $q_G(k)$ represent the sparse and dense part, respectively from Equation 6 and $P_L = \sum_k p_L(k)$, $Q_G = \sum_k q_G(k)$. When $\frac{P_L}{P_L+Q_G} > RandUnif(1)$, we sample from the sparse part in $O(k_d)$ time depending on only the non-zero entries of $\boldsymbol{N_j^L}$ (analogous to $\boldsymbol{N_j^\Theta}$), as $\boldsymbol{N_j^L}$ is sparse in the LDA setting. Otherwise, we sample from the dense part in amortized $O(1)$ time using the alias method. Unfortunately, due to the stochastic update, any entry of $\boldsymbol{N_j^L}$ never becomes exactly zero, however it may maintain a very small value. To address this, we apply a sparsification heuristic, where we threshold $\boldsymbol{N_j^L}$ after burn-in passes for each document iteration. We parameterize the threshold as $\tau \rho^L_{t_{C_j}} C_j$; where C_j is the length of the j document, $\rho^L_{t_{C_j}}$ is the step size for the last token of this document, and constant $0 < \tau \leq 1$ controls the sparsity. In our preliminary experiments, we found that, somewhat counter-intuitively, the Monte Carlo and sparsification approximations actually improve convergence in early iterations. We believe that this is because they help SCVB0 escape the initial high-entropy regime, during which convergence of variational algorithms is poor (Salakhutdinov et al., 2003). This property makes the benefit of annealing insignificant, so we do not use simulated annealing for LDA inference, fixing $T_j = 1$.

An additional optimization of SparseSCVB0 for LDA inference can be performed by "clumping" (Teh et al., 2007; Foulds et al., 2013), where one update of the local parameters is performed for each distinct word type in each document. This is performed by fixing the variational distribution, and scaling the update by number of copies of the distinct word type in the document. If we observe the distinct word type w_{aj}, which occurs m_{aj} times in document j, the update is

$$\begin{aligned}\boldsymbol{N_j^L} &:= (1 - \rho_t^L)^{m_{aj}} \boldsymbol{N_j^L} \\ &\quad + (1 - (1 - \rho_t^L)^{m_{aj}}) C_j \gamma_{aj}^{(pseudo)} \,.\end{aligned} \quad (9)$$

5 SparseSCVB0 for MMSGTM

The main contribution of our approach for the MMSGTM algorithm is to scale this algorithm in number of documents with online inference, as MMSGTM already scales sublinearly in K using MHW. Foulds et al. (2018) use an MHW proposal which approximates the CGS update, interpreted as a product of experts (Hinton, 2002) in which each word in the context is an "expert" which weighs in multiplicatively on the update, with a mixture of experts. In the proposal, they draw a

context word w_c uniformly from the context of the current word, $w_c \sim Uniform(|context(w_i)|)$, and then sample a word based on the chosen context word's contribution to the update:

$$q(k) :\propto \frac{N^G_{w_c k} + \beta_{w_c}}{N^Z_k + \sum_w \beta_w} \qquad (10)$$

where $\boldsymbol{N^G_{w_c}}$ is analogous to the output context word-topic counts $\boldsymbol{N^\Phi_{w_c}}$ of original MMSGTM model. The proposal samples via the alias method in amortized $O(1)$ time, instead of $O(k_d)$ time, since it does not involve the sparse term. We use this proposal to approximate the CVB0 update for the model, which is a deterministic version of Equation 5, neglecting to exclude the current assignment of z_i. We update $\boldsymbol{N^G_{w_i}}$ (analogous to $\boldsymbol{N^\Phi_{w_c}}$) for each current word w_i locally, but update $\boldsymbol{N^G_{w_c}}$ and $\boldsymbol{N^z}$ via minibatch counts $\boldsymbol{\hat{N}^G_{w_c}}$ and $\boldsymbol{\hat{N}^Z}$, respectively, for each context word w_c of current word w_i. Unlike for LDA, C_j in the local updates represents the total number of input word j in the corpus. As we draw multiple output words from each topic assignment, the effective temperature of the MMSGTM model is much lower than for standard LDA which may cause problems with mixing and leads it to get stuck in the initial regime. Following Foulds et al. (2018), we perform simulated annealing which varies the M-H acceptance ratio to improve mixing. We parameterize the temperature schedule as $T_j = T_0 + \lambda\kappa^{\frac{\mu j}{D}}$, where T_0 is the target final temperature, $\kappa \leq 1$, constant μ controls the amount of temperature reduction after each document iteration j and λ controls the initial temperature.

6 Experiments

In this section we study the performance of our SparseSCVB0 [1] algorithm, on small as well as large corpora to validate the proposed method for topic models such as LDA and MMSGTM, and to compare with other state-of-the-art algorithms.

6.1 Experimental Environment and Datasets

We compared SparseSCVB0 to SCVB0 and SVI. For a fair comparison, we implemented all of them in the fast high-level language Julia V0.6.2 (Bezanson et al., 2017). We conducted all experiments on a computer with 64GB memory and an Intel Xeon E5-2623 V4 processor with 2.60 GHz clock rate, 8×256KB L2 Cache and 10MB L3 Cache. As we only use one single thread for sampling across all experiments, only one CPU core is active throughout the experiment with only 256KB available L2 Cache.[2]

We used *NIPS*, *Reuters-150*, *PubMed Central*, and *Wikipedia* as representative very small, small, medium, and large-scale datasets, respectively. The *NIPS* corpus has 1740 scientific articles from years 1987-1999 with 2.3M tokens, due to Sam Roweis. The newswire corpus *Reuters-150* contains $15,500$ articles with dictionary size of $8,350$ words. *PubMed Central* has $320M$ tokens across $165,000$ scientific articles and a vocabulary size of around $38,500$ words. The *Wikipedia* corpus contained 4.6 million articles from the online

[1] Code implementing SparseSCVB0 can be found at `https://github.com/dr97531/SparseSCVB0`.

[2] Since SSVI relies on multiple complex implementation details, we were unable to develop a fair implementation, nor were we able to obtain soure code for a previous implementation. We expect that its accuracy would be similar to SVI, with a speed-up at or below that bestowed by a MHW-based inner loop. (Mimno et al., 2012) apply it with only 200 topics for most of their experiments, and at most 1000 topics.

encyclopedia. We used the dictionary of $7,700$ words which was extracted by Hoffman et al. (Hoffman et al., 2013). There were 811M tokens in the corpus.

6.2 Performance for LDA

We implement SparseSCVB0, original SCVB0 and SVI algorithms using the clumping optimization (Teh et al., 2007) technique. In all LDA experiments, each algorithm was trained using mini-batches of size 20 for the NIPS corpus and 100 for other corpora. For PubMed and Wikipedia, we chose mini-epoch subsets of size $5,000$ documents and processed for 5 passes. We used a step-size schedule of $\frac{scale}{(\eta+t)^{\kappa}}$ as in original SCVB0 for global parameters, where t is the document iteration with $scale = 100.0$, $\eta = 1000.0$ and $\kappa = 0.9$. For document-level parameters, we used the $scale = 1.0$, $\eta = 10.0$ and $\kappa = 0.9$, with t referring here to the word iteration of the current document. In case of PubMed corpus, we found out that original SCVB0 and SVI tend to stuck in the initial regime for document-level step-size parameter $\eta = 1.0$ which we later fixed by setting $\eta = 10.0$, while SparseSCVB0 didn't suffer from this problem due to the extra randomness from the sparse sampled updates. Finally, we choose hyper-parameters $\alpha = 0.1$ and $\beta = 0.01$ and burn-in pass of 5 for each document in all LDA experiments. For SparseSCVB0, we used sample size $S = 5$ to approximate $\gamma^{(pseudo)}$ and $\tau = 1/K$ for the sparsification heuristic on local parameters.

To study the acceleration benefits of our approach, we evaluated the runtime performance per

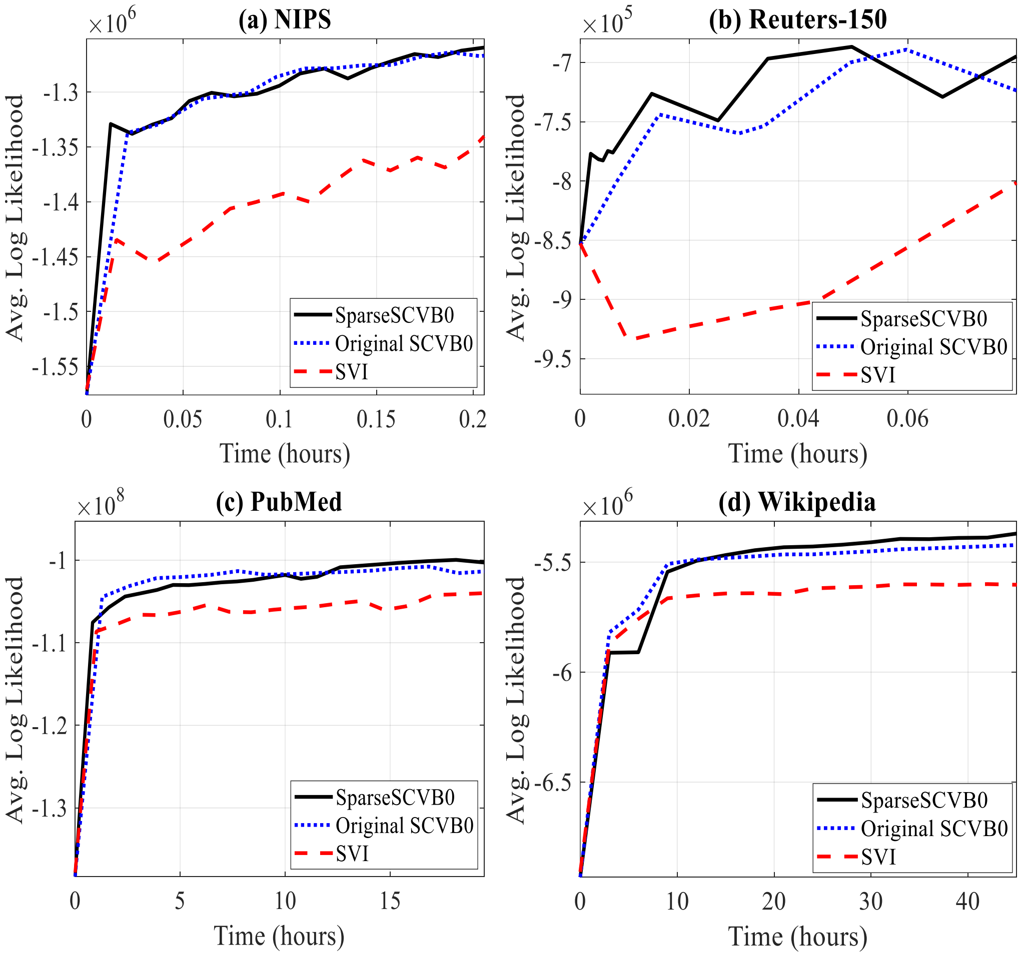

Figure 3: Comparison of average log-likelihood *vs*. Time for LDA on (a) NIPS, (b) PubMed, and (c) Wikipedia.

iteration on the number topics and the number of iterations. In Figure 1(a), SparseSCVB0 is compared to original SCVB0 in terms of the average runtime per document iteration as a function of the number topics. We see that original SCVB0 requires average linear runtime due to $O(K)$ operations to compute collapsed variational distribution, while the average runtime for SparseSCVB0 grows sublinearly in K, due to $O(k_d)$ operations instead of $O(K)$ operations. SparseSCVB0 starts with approximately $O(K)$ operations in its initial stage of iterations, but it starts getting a benefit from sparsification heuristic after burning in, as shown in Figure 1(b) for $K = 10,000$.

To evaluate the performance in terms of learned topic quality, we start by comparing all of the algorithms in qualitative experiments (see Table 1, Table 2, and Table 3) where we show randomly selected example topics, while all the models were trained on the NIPS, PubMed, and Wikipedia corpus for $K = 500$, $K = 1,000$, and $1,000$, respectively. To get a quantitative insight we evaluated the topics using the per topic coherence metric, which measures the semantic quality of a topic based on the W most probable words for the topics (Mimno et al., 2011), thereby approximating the user viewing experience. In Figure 2, we see that SparseSCVB0 generates better quality topics with higher coherence scores than the other two models for $K = 1000$ with $W = 10$ after running all the models on each corpus for the same amount of time. The coherence performance of SparseSCVB0 increases substantially in the case of the large-scale corpus (Figure 2(c)), since it gets the opportunity to use its runtime advantage and process more documents than the other algorithms.

To investigate model convergence, we measured the held-out log-probability versus wall-clock time for all the algorithms. For each experiment we held-out a set of documents (150 documents for NIPS, 3500 documents for Reuters, and 1000 documents for all other corpora) as test data

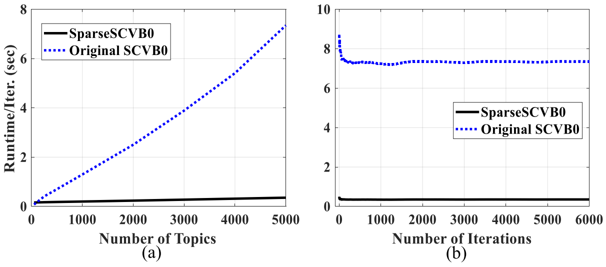

Figure 4: Comparison of runtime per iteration for MMSGTM in terms of: (a) number of topics K and (b) number of iterations when $K = 5,000$. SparseSCVB0 runs in amortized $O(1)$ time, while original SCVB0 is linear in K.

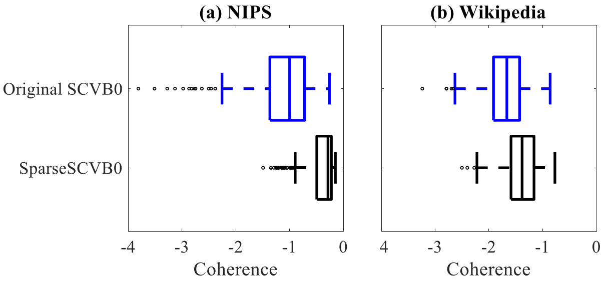

Figure 5: Per-topic coherence for MMSGTM, $K = 500$, on (a) NIPS and (b) Wikipedia. SparseSCVB0 has higher coherence scores for both the small and large corpora.

and trained the model on the rest of the corpus. Then, we split each test document in half, estimated local parameters on first half and finally computed the log-likelihood of the remaining half of the document. Figure 3 shows the comparison of average log-likelihood versus wall-clock time for all four corpora. In terms of log-likelihood, SparseSCVB0 provides an approximately similar result to original SCVB0 for the small corpus, but it converged to a better solution than others in the case of large corpora like Wikipedia (see Figure 3(c)), likely due to its processing a larger number of documents.

SparseSCVB0 enables the large-scale computation needed to learn high-dimensional topic models that could not feasibly be trained using previous methods due to their runtime complexity in the number of documents and/or topics. We show randomly selected topics from the LDA model with $K = 10,000$ in Table 5. This big topic model was trained for 36 hours using SparseSCVB0 on Wikipedia. We performed a dense initialization, running original SCVB0 for the first 5 hours, which was found to help avoid local optima.

6.3 Performance for MMSGTM

We also conducted experiments to evaluate the performance of SparseSCVB0 for MMSGTM and compare with original SCVB0. In all MMSGTM experiments, we kept the same step size schedule for global parameters as $scale = 1.0$, $\eta = 5.0$ and $\kappa = 0.9$, but for local parameter updates we maintain a separate step-size schedule of $\frac{scale}{(\eta+t)^\kappa}$ for each input word, with t referring to the number of times we processed this input word, while η and κ values remained the same. For simulated annealing of SparseSCVB0, we used $T_0 = 0.00001$, $\kappa = 0.9$, $\mu = 5$ and $\lambda = |context|$ with a $context$ size of 5. We kept the same number of document burn-in passes as we did for the LDA experiments.

In Figure 4, we show the runtime improvement of SparseSCVB0 over original SCVB0 for MMSGTM in a similar experiment to the one for LDA. For MMSGTM, SparseSCVB0 substantially outperforms original SCVB0 by processing each document in amortized $O(1)$ time. We provide qualitative results in the case of MMSGTM model by showing several top words in the top 2 topics for an input word using original SCVB0 and SparseSCVB0 in Table 4 for $K = 500$. As for LDA, SparseSCVB0 allows us to generate topics with higher coherence scores compared to the original SCVB0 after running for the same amount of time (Figure 5) on both small and large corpora.

7 Conclusions

This paper introduced SparseSCVB0, a sparse version of the SCVB0 inference algorithm which performs fast, scalable high-dimensional topic model inference. SparseSCVB0 leverages stochasticity to scale well in both the corpus size and in the number of topics. It operates in the collapsed representation of topic models which leads to fast convergence while providing an improved variational bound. We show that SparseSCVB0 reduces the operational complexity for the variational Bayes update of online topic models from $O(K)$ to $O(k_d)$ time for LDA and amortized $O(1)$ time for MMSGTM. We evaluated and compared the performance of our approach with state-of-the-art models such as original SCVB0 and SVI to demonstrate that SparseSCVB0 converges much more efficiently, while maintaining high quality topics with a better per-topic coherence score.

Abstract

In this paper, we present a novel integrated approach for keyphrase generation (KG). Unlike previous works which are purely extractive or generative, we first propose a new multi-task learning framework that jointly learns an extractive model and a generative model. Besides extracting keyphrases, the output of the extractive model is also employed to rectify the copy probability distribution of the generative model, such that the generative model can better identify important contents from the given document. Moreover, we retrieve similar documents with the given document from training data and use their associated keyphrases as external knowledge for the generative model to produce more accurate keyphrases. For further exploiting the power of extraction and retrieval, we propose a neural-based merging module to combine and re-rank the predicted keyphrases from the enhanced generative model, the extractive model, and the retrieved keyphrases. Experiments on the five KG benchmarks demonstrate that our integrated approach outperforms the state-of-the-art methods.

1 Introduction

Keyphrases are short text pieces that can quickly express the key ideas of a given document. The keyphrase generation task aims at automatically generating a set of keyphrases given a document. As shown in the upper part of Figure 1, the input is a document and the output is a set of keyphrases. Due to the concise and precise expression, keyphrases are beneficial to extensive downstream applications such as text summarization (Zhang et al., 2004; Wang and Cardie, 2013), sentiment analysis (Wilson et al., 2005; Berend, 2011), and document clustering (Hulth and Megyesi, 2006; Hammouda et al., 2005).

Figure 1: An example of keyphrase generation and retrieval. The present keyphrases are bold.

Existing methods on keyphrase generation can be divided into two categories: *extractive* and *generative*. Extractive methods (Medelyan et al., 2009; Mihalcea and Tarau, 2004; Zhang et al., 2016; Luan et al., 2017) identify present keyphrases that appear in the source text like "parameter control" in Figure 1. Although extractive methods are simple to implement, they cannot predict absent keyphrases which are not in the document like "optimization" in Figure 1. Generative methods (Meng et al., 2017; Chen et al., 2018a; Ye and Wang, 2018; Yuan et al., 2018) adopt the well-known encoder-decoder generative model (Luong et al., 2015; Bahdanau et al., 2014) with copy mechanism (Gu et al., 2016; See et al., 2017) to produce keyphrases. In a generative model, the decoder generates keyphrases word by word through either selecting from a predefined vocabulary according to a language model or copying from the source text according to the copy probability distribution computed by a copy mechanism. Thus, these generative methods are capable of generating both present and absent keyphrases.

From a high-level perspective, extractive methods directly locate essential phrases in the docu-

Proceedings of NAACL-HLT 2019, pages 2846–2856
Minneapolis, Minnesota, June 2 - June 7, 2019.

ment while generative models try to understand the document first and then produce keyphrases. To the best of our knowledge, these two kinds of methods have been developing independently without any combinations among them.

However, when human annotators are asked to assign keyphrases to a document, they usually first obtain a global sense about which parts of the document are important and then write down the keyphrases word by word based on a more detailed understanding. To achieve such a goal, we propose a multi-task learning framework to take advantage of both extractive and generative models. For keyphrase extraction, we adopt a neural sequence labeling model to output the likelihood of each word in the source text to be a keyphrase word (or the importance score of each word). These importance scores are then employed to rectify the copy probability distribution of the generative model. Since the extractive model is explicitly trained to identify keyphrases from the source text, its importance scores can help the copy mechanism to identify important source text words more accurately. Different from the copy probability distribution which is dynamic at each generation step, these importance scores are static. Therefore, they can provide a global sense about which parts of the document are important. In addition, these scores are also utilized to extract present keyphrases which will be exploited by the merging module.

Moreover, human annotators can also incorporate relevant external knowledge like the keyphrases of similar documents that they read before to assign more appropriate keyphrases. Correspondingly, to incorporate external knowledge, we propose a *retriever* to retrieve similar documents of the given document from training data. For instance, as shown in Figure 1, we retrieve a document from the **KP20k** training dataset that has the highest similarity with the upper document. The retrieved document is assigned with almost the same keyphrases as the upper document. Therefore, keyphrases from similar documents (i.e., retrieved keyphrases) can give useful knowledge to guide the generation of keyphrases for the given document. More concretely, we encode the retrieved keyphrases as vector representations and use them as an external memory for the decoder of the generative model in our multi-task learning framework. Besides providing external knowledge, the retrieved keyphrases themselves are regarded as a kind of keyphrase prediction and can be utilized by the merging module.

Finally, to imitate the integrated keyphrase assignment process of humans more comprehensively, we further exploit the extractive model and the retrieved keyphrases by proposing a merging module. This merging module collects and re-ranks the predictions from our aforementioned components. First, keyphrase candidates are collected from three different sources: (1) keyphrases generated by the enhanced generative model; (2) keyphrases extracted by the extractive model; and (3) the retrieved keyphrases. Then, we design a neural-based merging algorithm to merge and re-rank all the keyphrase candidates, and consequently return the top-ranked candidates as our final keyphrases.

We extensively evaluate the performance of our proposed approach on five popular benchmarks. Experimental results demonstrate the effectiveness of the extractive model and the retrieved keyphrases in our multi-task learning framework. Furthermore, after introducing the merging module, our integrated approach consistently outperforms all the baselines and becomes the new state-of-the-art approach for keyphrase generation.

In summary, our main contributions include: (1) a new multi-task learning framework that leverages an extractive model and external knowledge to improve keyphrase generation; (2) a novel neural-based merging module that combines the predicted keyphrases from extractive, generative, and retrieval methods to further improve the performance; and (3) the new state-of-the-art performance on five real-world benchmarks.

2 Related Work

2.1 Automatic Keyphrase Extraction

Keyphrase extraction focuses on predicting the keyphrases that are present in the source text. Existing methods can mainly be categorized into two-step extraction approaches and sequence labeling models. Two-step extraction approaches first identify a set of candidate phrases from the document using different heuristics, such as the phrases that match specific part-of-speech (POS) tags (Liu et al., 2011; Wang et al., 2016; Le et al., 2016). Then, they learn a score for each candidate and select the top-ranked candidates as predicted keyphrases. The scores can be learned by either supervised methods with hand-crafted textual features (Medelyan et al., 2009; Witten et al., 1999; Nguyen and Kan, 2007; Frank et al., 1999; Hulth, 2003) or unsupervised graph ranking methods (Mihalcea and Tarau, 2004; Grineva et al., 2009; Wan and Xiao, 2008). Sequence labeling models are built on a recurrent neural network to sequentially go through a source text and learn the likelihood of each word in the source text to be a keyphrase word (Zhang et al., 2016; Luan et al., 2017; Gollapalli et al., 2017). In contrast to these extractive methods, our approach can generate both absent and present keyphrases.

2.2 Automatic Keyphrase Generation

Keyphrase generation aims at predicting both present and absent keyphrases for a source text. Meng et al. (2017) proposed CopyRNN, which is built on the attentional encoder-decoder model (Bahdanau et al., 2014) with copy mechanism (Gu et al., 2016) to generate keyphrases. CorrRNN (Chen et al., 2018a), an extension of CopyRNN, was proposed to model the correlations among keyphrases. This model utilizes hidden states and attention vectors of previously generated keyphrases to avoid generating repetitive keyphrases. The title information of the source text was explicitly exploited by Ye and Wang (2018) and Chen et al. (2018b) to further improve the performance. Ye and Wang (2018) first considered a semi-supervised setting for keyphrase generation. In contrast, inspired by Hsu et al. (2018) and Cao et al. (2018), we enhance existing generative methods by adopting an extractive model to assist the copy mechanism and exploiting external knowledge from retrieved keyphrases to help the generation. Furthermore, we also design a merging module to combine the predictions from different components.

3 Our Methodology

As shown in Figure 2, our integrated framework consists of a retriever, two encoders, an extractor, a decoder, and a merging module. Given a document $\mathbf{x}$, the retriever returns the keyphrases $\mathbf{r}$ retrieved from the training corpus. In addition to acting as keyphrase candidates, these retrieved keyphrases are also exploited to provide external guidance for the decoder. Then keyphrase extraction and generation are jointly conducted by the extractor and the decoder through sharing an encoder. Besides extracting keyphrase candidates, the importance scores of the source text words, β, predicted by the extractor are also employed to rescale the original copy probability distribution of the decoder. Thus, they can help the copy mechanism to detect important words more accurately. Finally, the merging module merges the candidates from three different sources (i.e., the retrieved, extracted, and generated candidates) and output the final predictions.

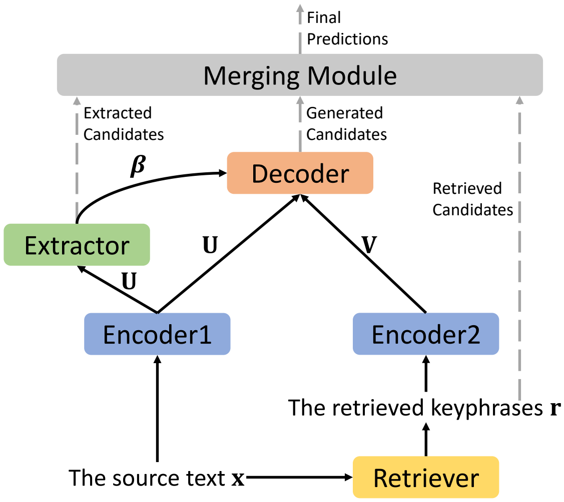

Figure 2: Our integrated framework. The “Encoder1” and the “Extractor” compose our extractive model. Our generative model mainly includes the “Encoder1”, the “Encoder2”, and the “Decoder”.

3.1 Retriever

Given a document $\mathbf{x}$, the retriever module retrieves top K (document, keyphrases) pairs from the training corpus. The retrieval is based on the Jaccard similarities of the non-stop-word sets between $\mathbf{x}$ and the corpus documents. After that, the keyphrases of the top K pairs are returned and used in the later modules in two ways. First, these retrieved keyphrases are regarded as the keyphrase candidates of $\mathbf{x}$ and directly fed into the final merging module. In addition, these keyphrases are concatenated together as a guidance input $\mathbf{r}$ for the decoder to provide useful external knowledge for the generation process. A separator token is inserted among keyphrases when concatenating them together.

3.2 Joint Extraction and Generation

We propose a multi-task learning framework which simultaneously learns to extract keyphrases from the source text and generate keyphrases word by word with external knowledge. Before describing in detail, we first define the tasks of the extraction and the generation.

3.2.1 Problem Definition

The inputs of the multi-task learning framework are the source text $\mathbf{x}$ and the concatenated retrieved keyphrases $\mathbf{r}$. Both $\mathbf{x}$ and $\mathbf{r}$ are a sequence of tokens (i.e., $\mathbf{x} = [x_1, ..., x_{L_\mathbf{x}}]$, $\mathbf{r} = [r_1, ..., r_{L_\mathbf{r}}]$), where $L_\mathbf{x}$ and $L_\mathbf{r}$ are the length of $\mathbf{x}$ and $\mathbf{r}$ respectively. The output of the extractor is a sequence of importance scores $\boldsymbol{\beta} = [\beta_1, ..., \beta_{L_\mathbf{x}}]$, where β_i is the probability of the i-th source word of being a keyphrase word. The output of the generator is a set of keyphrases $\mathcal{Y} = \{\mathbf{y}^i\}_{i=1,..,N}$, where N is the keyphrase number of $\mathbf{x}$ and $\mathbf{y}^i = [y_1^i, ..., y_{L_{\mathbf{y}^i}}^i]$ is a token sequence with length $L_{\mathbf{y}^i}$.

To fit the encoder-decoder framework, N tuples $\{(\mathbf{x}, \mathbf{r}, \boldsymbol{\beta}^*, (\mathbf{y}^i)^*)\}_{i=1,...,N}$ are split during training, where $\boldsymbol{\beta}^*$ and $(\mathbf{y}^i)^*$ are the gold binary importance scores and one of the gold keyphrases of $\mathbf{x}$ correspondingly. For simplicity, we adopt $(\mathbf{x}, \mathbf{r}, \boldsymbol{\beta}^*, \mathbf{y}^*)$ to represent such a tuple.

3.2.2 Encoders

Two encoders are employed in our multi-task learning framework. One is for the source text encoding (i.e., "Encoder1" in Figure 2) and the other is for retrieved keyphrases encoding (i.e., "Encoder2" in Figure 2). Both of them employ a bidirectional GRU (Cho et al., 2014) layer to obtain a context-aware representation of each word:

$$\mathbf{u}_i = \text{BiGRU}_1(\mathbf{x}_i, \overrightarrow{\mathbf{u}}_{i-1}, \overleftarrow{\mathbf{u}}_{i+1}), \quad (1)$$

$$\mathbf{v}_j = \text{BiGRU}_2(\mathbf{r}_j, \overrightarrow{\mathbf{v}}_{j-1}, \overleftarrow{\mathbf{v}}_{j+1}), \quad (2)$$

where $i = 1, 2, ..., L_\mathbf{x}$ and $j = 1, 2, ..., L_\mathbf{r}$. $\mathbf{x}_i$ and $\mathbf{r}_j$ are the d_e-dimensional embedding vectors of the i-th source text word x_i and j-th retrieved keyphrases word r_j respectively. $\mathbf{u}_i = [\overrightarrow{\mathbf{u}}_i; \overleftarrow{\mathbf{u}}_i] \in \mathbb{R}^d$ and $\mathbf{v}_j = [\overrightarrow{\mathbf{v}}_j; \overleftarrow{\mathbf{v}}_j] \in \mathbb{R}^d$ are regarded as the corresponding context-aware representations, where d is the hidden size of the biderectional GRU layer. Finally, we obtain the internal memory bank $\mathbf{U} = [\mathbf{u}_1, ..., \mathbf{u}_{L_\mathbf{x}}]$ for later extraction and generation, and the external memory bank $\mathbf{V} = [\mathbf{v}_1, ..., \mathbf{v}_{L_\mathbf{r}}]$ for later generation.

3.2.3 Extractor

Based on the internal memory bank, we use the following sequence identifier as our extractor to identify whether the word is a keyphrase word in the source text. We denote the importance score $P(\beta_j = 1 | \mathbf{u}_j, \mathbf{s}_j, \mathbf{d})$ as β_j for simplicity:

$$\begin{aligned}\beta_j = \text{sigmoid}(&\mathbf{W}_c \mathbf{u}_j + \mathbf{u}_j^T \mathbf{W}_s \mathbf{d} \\ &- \mathbf{u}_j^T \mathbf{W}_n \text{tanh}(\mathbf{s}_j) + b),\end{aligned} \quad (3)$$

where $\mathbf{d} = \text{tanh}(\mathbf{W}_d[\overrightarrow{\mathbf{u}}_{L_\mathbf{x}}; \overleftarrow{\mathbf{u}}_1] + \mathbf{b})$ is the global document representation and $\mathbf{s}_j = \sum_{i=1}^{j-1} \mathbf{u}_i \beta_i$ is current summary representation. $\mathbf{W}_c, \mathbf{W}_s$, and $\mathbf{W}_n$ are the content, salience and novelty weights respectively. Although this extractor is inspired by Nallapati et al. (2017), our extractor identifies important words instead of sentences within the source text.

3.2.4 Decoder

In addition to the internal memory bank $[\mathbf{u}_1, ..., \mathbf{u}_{L_\mathbf{x}}]$, our decoder employs the external memory bank $[\mathbf{v}_1, ..., \mathbf{v}_{L_\mathbf{r}}]$ to provide external guidance for the generation process. We exploit a decoder equipped with attention and copy mechanisms (Luong et al., 2015; See et al., 2017) to generate keyphrases. This decoder mainly consists of a forward GRU layer:

$$\mathbf{h}_t = \overrightarrow{\text{GRU}}([\mathbf{e}_{t-1}; \tilde{\mathbf{h}}_{t-1}], \mathbf{h}_{t-1}), \quad (4)$$

$$\mathbf{c}_t^{in} = \text{attn}(\mathbf{h}_t, [\mathbf{u}_1, ..., \mathbf{u}_{L_\mathbf{x}}], \mathbf{W}_{in}), \quad (5)$$

$$\mathbf{c}_t^{ex} = \text{attn}(\mathbf{h}_t, [\mathbf{v}_1, ..., \mathbf{v}_{L_\mathbf{r}}], \mathbf{W}_{ex}), \quad (6)$$

$$\tilde{\mathbf{h}}_t = \text{tanh}(\mathbf{W}_1[\mathbf{c}_t^{in}; \mathbf{c}_t^{ex}]; \mathbf{h}_t), \quad (7)$$

where $\mathbf{e}_{t-1}$ is the embedding vector of the $(t-1)$-th predicted word. The "attn" operation in Eq. (5) is defined as $\mathbf{c}_t^{in} = \sum_{i=1}^{L_\mathbf{x}} \alpha_{t,i}^{in} \mathbf{u}_i$, where $\alpha_{t,i}^{in} = \exp(s_{t,i}) / \sum_{j=1}^{L_\mathbf{x}} \exp(s_{t,j})$ and $s_{t,i} = (\mathbf{h}_t)^T \mathbf{W}_{in} \mathbf{u}_i$. Similarly, we can obtain the external aggregated vector $\mathbf{c}_t^{ex}$.

Then, the final predicted probability distribution at the current time step is:

$$P(y_t) = (1 - g_t) P_v(y_t) + g_t P_c(y_t), \quad (8)$$

where $g_t = \sigma(\mathbf{w}_g^T \tilde{\mathbf{h}}_t + b_g) \in \mathbb{R}$ is the soft switch between generating from the predefined vocabulary V and copying from X that are all words appearing in the source text. $P_v(y_t) = \text{softmax}(\mathbf{W}_2 \tilde{\mathbf{h}}_t + \mathbf{b}_v) \in \mathbb{R}^{|V|}$ is the generating probability distribution over V and $P_c(y_t) = \sum_{i:x_i = y_t} \alpha_{t,i}^c \in \mathbb{R}^{|X|}$ is the copying probability distribution over X. Previous work either directly uses the internal attention scores as the copy probabilities (i.e., $\alpha_{t,i}^c = \alpha_{t,i}^{in}$) or employs extra neural network layers to calculate new copy scores. But we employ the rescaled internal attention scores α_t^{in} by the importance scores $[\beta_1, ..., \beta_{L_{\mathbf{x}}}]$ from the extractor as the final copy probabilities:

$$\alpha_{t,i}^c = \frac{\alpha_{t,i}^{in} * \beta_i}{\sum_{j=1}^{L_{\mathbf{x}}} \alpha_{t,j}^{in} * \beta_j}. \tag{9}$$

The purpose of this rescaling is to provide extra guidance that which words within the source text are important and thus should obtain more attention when copying.

3.2.5 Joint Training

Finally, the summation of the following extraction loss and generation loss is used to train the whole joint framework in an end-to-end way.

Extraction Loss. We choose the source text words appearing in the assigned keyphrases as the gold important words and use the weighted cross-entropy loss for the extraction training i.e., $\mathcal{L}_e = -\frac{1}{L_{\mathbf{x}}} \sum_{j=1}^{L_{\mathbf{x}}} w\beta_j^* \log\beta_j + (1-\beta_j^*)\log(1-\beta_j)$, where $\beta_j^* \in \{0, 1\}$ is the ground-truth label for the j-th word and w is the loss weight for the positive training samples.

Generation Loss. The negative log likelihood loss is utilized for the generation training i.e., $\mathcal{L}_g = -\sum_{t=1}^{L_{\mathbf{y}^*}} \log P(y_t^*|\mathbf{y}_{t-1}, \mathbf{x}, \mathbf{r})$, where $\mathbf{y}_t = [y_1, ..., y_{t-1}]$ is the previously predicted word sequence, $L_{\mathbf{y}^*}$ is the length of target keyphrase $\mathbf{y}^*$, and y_t^* is the t-th target word in $\mathbf{y}^*$.

3.3 Merging Module

In this module, the retrieved, extracted and generated keyphrases are collected and then merged to produce the final keyphrase predictions.

3.3.1 Keyphrase Candidate Collection

Retrieved Candidate Collection. The retrieved keyphrases from the retriever are regarded as the retrieved candidates. Each retrieved candidate (rk) obtains a retrieval score (rs) that is the Jaccard similarity between the corresponding document and $\mathbf{x}$. The duplicates with lower retrieval scores are removed. Finally, we get $N_{\mathbf{rk}}$ retrieved keyphrase candidates $\mathbf{rk} = [rk_1, \ldots, rk_{N_{\mathbf{rk}}}]$ and their retrieval scores $\mathbf{rs} = [rs_1, \ldots, rs_{N_{\mathbf{rk}}}]$.

Extracted Candidate Collection. The extracted keyphrase candidates are from the extractor. We select the word x_j as a keyword if its importance score β_j is larger or equal than a threshold ϵ (i.e., $\beta_j \geq \epsilon$). The adjacent keywords compound a keyphrase candidate. If no other adjacent keywords, the keyword itself becomes a single-word keyphrase candidate. Each extracted keyphrase candidate (ek) is accompanied by an extraction score (es) that is the mean of the importance scores of the words within this candidate. Similarly, duplicates with lower extraction scores are removed. Consequently, we obtain $N_{\mathbf{ek}}$ extracted keyphrase candidates $\mathbf{ek} = [ek_1, \ldots, ek_{N_{\mathbf{ek}}}]$ and the corresponding extraction scores $\mathbf{es} = [es_1, \ldots, es_{N_{\mathbf{ek}}}]$.

Generated Candidate Collection. The generated keyphrase candidates directly come from the beam search process of the decoder. Each generated phrase is a keyphrase candidate. The beam search score of the generated candidate (gk) represents its generation score (gs). Duplicates with lower generation scores are removed. Then, we get $N_{\mathbf{gk}}$ generated candidates $\mathbf{gk} = [gk_1, \ldots, gk_{N_{\mathbf{gk}}}]$ and their generation scores $\mathbf{gs} = [gs_1, \ldots, gs_{N_{\mathbf{gk}}}]$.

3.3.2 Merging

In addition to the original importance scores (i.e., $\mathbf{rs}, \mathbf{es}, \mathbf{gs}$), we also employ an auxiliary *scorer* to assign an auxiliary importance score to each keyphrase candidate. Given a document-candidate pair ($\mathbf{x}$, candidate), the scorer should output the probability that the candidate is one of the keyphrases of $\mathbf{x}$. That means the scorer should determine the relationship between the given document $\mathbf{x}$ and the candidate, which is similar to a natural language inference (NLI) problem. Therefore, we adapt the most popular NLI model (Parikh et al., 2016) as our scorer. Different from typical natural language inference which is a multi-class classification problem, we use a binary classification setting to train the scorer. Besides, we learn the word embeddings and use two bi-directional GRU to obtain the input representations. The positive samples are the ground-truth keyphrases. The negative samples come from either the phrases in the document or the retrieved candidates. Notably, the ground-truth keyphrases are filtered when selecting negative samples. Consequently, a cross-entropy loss is utilized to train the scorer. Finally, the trained scorer is used to help the merging process as shown in Algorithm 1. The $\frac{u_{\mathbf{gs}}}{u_{\mathbf{rs}}}$ and $\frac{u_{\mathbf{gs}}}{u_{\mathbf{es}}}$ factors are used to enforce the average of $\mathbf{rs}$ and $\mathbf{es}$ to be the same with the average of $\mathbf{gs}$ and thus these three scores become comparable.

Algorithm 1 Merging Algorithm

```
Require: The retrieved, extracted and generated candidates $\mathbf{rk}, \mathbf{ek}, \mathbf{gk}$. The retrieval, extraction and generation scores $\mathbf{rs}, \mathbf{es}, \mathbf{gs}$; The average of each kind of score: $u_{\mathbf{rs}}, u_{\mathbf{es}}, u_{\mathbf{gs}}$; The trained $scorer$; The document $\mathbf{x}$.
Adjust $\mathbf{gs}$: $gs_i = gs_i \times scorer(\mathbf{x}, gk_i)$ where $i = 1, \ldots, N_{\mathbf{gk}}$.
Adjust $\mathbf{rs}$: $rs_i = rs_i \times \frac{u_{\mathbf{gs}}}{u_{\mathbf{rs}}} \times scorer(\mathbf{x}, rk_i)$ where $i = 1, \ldots, N_{\mathbf{rk}}$.
Adjust $\mathbf{es}$: $es_i = es_i \times \frac{u_{\mathbf{gs}}}{u_{\mathbf{es}}} \times scorer(\mathbf{x}, ek_i)$ where $i = 1, \ldots, N_{\mathbf{ek}}$.
Merge $\mathbf{rk}, \mathbf{ek}, \mathbf{gk}$: the final importance score of a candidate is the summation of its adjusted retrieval, extraction and generation scores. If not in $\mathbf{rk}$, $\mathbf{ek}$ or $\mathbf{gk}$, the corresponding scores are set to 0.
Sort all the candidates based on the final importance scores and then output the final predictions.
```

4 Experiment Settings

4.1 Datasets

Similar to Meng et al. (2017), we use **KP20k** dataset (Meng et al., 2017) to train our models. The released dataset contains 530,809 articles for training, 20,000 for validation, and the other 20,000 for testing. However, there exist duplicates in the **KP20k** training dataset with itself, the **KP20k** validation dataset, the **KP20k** testing dataset, and other four popular testing datasets (i.e., **Inspec** (Hulth, 2003), **Krapivin** (Krapivin et al., 2009), **NUS** (Nguyen and Kan, 2007), and **SemEval** (Kim et al., 2010)). After removing these duplicates, we maintain 509,818 articles in the training dataset. As for testing, following Meng et al. (2017), we employ five popular testing datasets from scientific publications as our testbeds for the baselines and our methods, which include **Inspec**, **Krapivin**, **NUS**, **SemEval**, and **KP20k**.

4.2 Baseline Models and Evaluation Metrics

For a comprehensive evaluation, we compare our methods with the traditional extractive baselines and the state-of-the-art generative methods. The extractive baselines include two unsupervised methods (i.e., TF-IDF and TextRank (Mihalcea and Tarau, 2004)) and one supervised method Maui (Medelyan et al., 2009). The generative baselines consist of CopyRNN (Meng et al., 2017) and CorrRNN (Chen et al., 2018a). We also conduct several ablation studies as follows:

- **KG-KE.** The joint extraction and generation model without using the retrieved keyphrases and merging process.
- **KG-KR.** The encoder-decoder generative model with retrieved keyphrases as external knowledge, but without combining with the extractive model and using the merging process.
- **KG-KE-KR.** The joint extraction and generation model with the retrieved keyphrases without using the merging process.

All the above ablation models directly use the generated candidates as the final predictions. We denote our final integrated method which combines all the proposed modules as **KG-KE-KR-M**.

Similar to CopyRNN and CorrRNN, we adopt macro-averaged *recall* (R) and *F-measure* (F_1) as our evaluation metrics. In addition, we also apply Porter Stemmer before determining whether two keyphrases are identical. Duplications are removed after stemming.

4.3 Implementation Details

We apply similar preprocessing procedures with Meng et al. (2017) including lowercasing, tokenizing and replacing digits with $\langle digit \rangle$ symbol. The title and the abstract of each article are concatenated as the source text input. We use the **KP20k** training dataset as the retrieval corpus. The implementations of our models are based on the OpenNMT system (Klein et al., 2017). The encoders, the decoder, and the scorer have the same vocabulary V with 50,000 tokens. The multi-task learning model and the scorer are trained separately.

The embedding dimension d_e and the hidden size d are set to 100 and 300 respectively. The initial state of the decoder GRU cell (i.e., $\mathbf{h}_0$) is set to $[\overrightarrow{\mathbf{u}}_{L_{\mathbf{x}}}; \overleftarrow{\mathbf{u}}_1]$. The other GRU cells are set to zero. The retrieval number K is set to 3 after evaluating the retrieved keyphrases on the evaluation dataset. When concatenating the retrieved keyphrases together as an external knowledge input, we use ';' as the separator among them. During training, all the trainable parameters including the embeddings are randomly initialized with uniform distribution in [-0.1, 0.1]. We engage Adam (Kingma and Ba, 2014) as the optimizer with positive extraction loss weight w=9.0, batch size=64, dropout rate=0.1, max gradient norm=1.0, initial learning rate=0.001. The training is early stopped when the validation perplexity stops dropping for several continuous evaluations. While testing, the beam search depth, and beam size are set as 6 and 200

correspondingly. The extraction threshold ϵ is set to 0.7 after evaluating the extracted keyphrases on the evaluation dataset. Notably, the stemmer is not applied to the gold keyphrases of **SemEval** testing dataset since they have already been stemmed. We do not remove any single-word predictions for **KP20k** but only keep one single-word prediction for other testing datasets. The averaged results of three different random seed are reported[1].

5 Results and Analysis

5.1 Total Keyphrase Prediction

Unlike the previous works which only separately analyze the present and absent keyphrase prediction ability, we also compare the whole keyphrase prediction ability regardless of the presence or absence of keyphrases, which is more reasonable in real applications. We show the F_1 scores at the top 5 and 10 predictions on Table 1.

This table displays our KG-KE-KR-M method consistently outperforms the state-of-the-art models CopyRNN and CorrRNN demonstrating the effectiveness of our method. Moreover, we also observe that the KG-KE model exceeds CopyRNN and CorrRNN on most datasets, which indicates the strength of our combination with the extractive model. Besides, we also see the KG-KR model perform comparably or better than the baselines, suggesting the effective guidance ability of the retrieved keyphrases. In addition, after combining these two ideas, the KG-KE-KR model surpasses both or one of KG-KE and KG-KR on all datasets, which shows the effectiveness of the combination with extraction model and the retrieved keyphrases again. Finally, the performance gap between KG-KE-KR and KG-KE-KR-M implies the power of our merging module. For mean average precision (MAP) metric which considers prediction orders, we obtain similar conclusions as shown in Table 2.

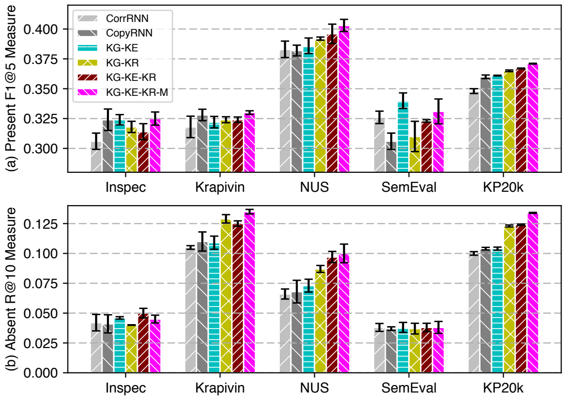

Figure 3: The present and absent keyphrase prediction performance of all neural-based methods.

5.2 Present and Absent Keyphrase Prediction

In this section, we analyze the performance of present and absent keyphrase prediction. Only

$\mathbf{rk}$, no merging	0.093±0.000	0.121±0.000	0.107±0.000

Table 3: Ablation study of the candidate sources of Algorithm 1 on Krapivin dataset. "no merging" means we do not use the merging algorithm.

Scoring Method	Total F_1@10	Present F_1@5	Absent R@10
Combined	**0.250±0.002**	**0.330±0.002**	**0.172±0.002**
Only $\mathbf{gs}, \mathbf{es}, \mathbf{rs}$	0.248±0.003	0.325±0.003	0.166±0.003
Only *scorer*	0.210±0.005	0.291±0.006	0.106±0.005

Table 4: Ablation study of the scoring method of Algorithm 1 on Krapivin dataset. "Only $\mathbf{gs}, \mathbf{es}, \mathbf{rs}$" means we do not use the *scorer*. "Only *scorer*" represents we directly use the scores predicted by the *scorer* as the final importance scores.

the present (absent) predictions and gold present (absent) keyphrases are preserved for the corresponding evaluation. We use F_1@5 metric for present predictions and R@10 for absent predictions. Since the neural-based baselines are the state-of-the-art models, we focus on the comparison with them in this section. The results are depicted on Figure 3.

The main observations are similar to the conclusions of total keyphrase prediction. Besides, we also note that after incorporating retrieved keyphrases, KG-KR model achieves substantial improvement gains over baselines on absent keyphrase prediction on **Krapivin**, **NUS**, and **KP20k**. These results demonstrate that the retrieved keyphrases indeed help the model to understand the main topics of the given document since generating absent keyphrase is an abstractive process and requires more powerful text understanding abilities. We notice that the KG-KE-KR-M method does not outperform the KG-KE-KR model on absent keyphrase prediction on **Inspec** dataset. One potential reason is that the merging module only merges two sources for absent keyphrases (i.e., the generated and retrieved keyphrases) instead of three sources like the present keyphrases do. Hence, the improvement for the absent keyphrases from the merging module is less stable than that for the present keyphrases. Moreover, we find that after combining with the extraction model, the KG-KE model achieves a huge improvement gain over CopyRNN on present keyphrase prediction on **SemEval** dataset, which manifests such a combination can improve the keyphrase extraction ability of the generative model.

5.3 Ablation Study on Merging Module

We also conduct in-depth ablation studies on our merging module. The objectives of these ablation studies are to (1) evaluate the effects of different candidate sources (i.e., what kinds of candidates are merged), and (2) analyze the effects of different final importance score calculating methods.

Concerning candidate sources, we show the ablation study results on Table 3. When comparing "$\mathbf{gk}$" with "$\mathbf{gk}$, no merging", we can see that the merging algorithm improves the performance of total and present keyphrase predictions, but it degrades the performance of absent keyphrase prediction. These results indicate the trained *scorer* performs better on scoring present keyphrases than scoring absent keyphrases. One possible reason is that scoring absent keyphrases requires a stronger text understanding ability than scoring present keyphrases. However, as shown in the row of "$\mathbf{gk}, \mathbf{rk}$" on Table3, this problem can be solved by incorporating the retrieved keyphrases which provide external information to this module. Besides absent keyphrase prediction, it is observed that the retrieved keyphrases can also benefit the present keyphrase prediction. For the extracted keyphrases, as shown in the "$\mathbf{gk}, \mathbf{ek}$" row, they only improve the present keyphrase prediction ability and do not affect absent keyphrases as we anticipated.

Regarding the scoring method, we further explore the effects of not using or only using the *scorer* in Algorithm 1. We show the results on Table 4. From this table, we note that after removing the *scorer* (i.e., "Only $\mathbf{gs}, \mathbf{es}, \mathbf{rs}$"), both present and absent keyphrase prediction performance become worse, which demonstrates the effectiveness of the combination with the *scorer*. Moreover, if we totally ignore the previously obtained retrieval, extraction and generation scores, and only use the *scorer* to predict the final keyphrase importance score (i.e., "Only *scorer*"), we find the performance decreases dramatically, which indicates the indispensability of the previously obtained retrieval, extraction, and generation scores.

Approximating minimum power covers of ***intersecting families*** and directed edge connectivity problems . Given a (directed) graph with costs on the edges , the power of a node is the maximum cost of an edge leaving it , and the power of the graph is the sum of the powers of its nodes . . . We consider problems that seek to find a min power spanning subgraph G of g that satisfies a prescribed ***edge connectivity*** property . . . Figure 4: A keyphrase prediction example of CopyRNN, KG-KE-KR, and KG-KE-KR-M. "Retrieved" is the retrieved keyphrases. The extracted keyphrases by the extractor of KG-KE-KR are underlined in the source text. Top 10 present and absent predictions are compared and some incorrect predictions are omitted for simplicity. The correct predictions are bold and italic.

5.4 Case Study

To illustrate the advantages of our proposed methods, we show an example of the present and absent keyphrase predictions in Figure 4. For fairness, we only compare with CopyRNN since our models are based on its implementation. From the results of the present keyphrase prediction, we find the extractor of the KG-KE-KR model successfully extracts all the present keyphrases from the source text, which shows the power of the extractor. With the help of the copy probability rescaling from the extractor, the KG-KE-KR model correctly predicts the keyphrase "intersecting families" which is not successfully predicted by CopyRNN and retrieved by the retriever. Moreover, by merging the extracted keyphrases into the final predictions, the KG-KE-KR-M model assigns a higher rank to this keyphrase (i.e., from 7 to 6). As for absent keyphrase prediction, we note that KG-KE-KR successfully predicts the keyphrase "wireless networks" while CopyRNN fails. Since the retriever successfully retrieves this absent keyphrase, it shows that the retrieved keyphrases can provide effective external guidance for the generation process. Furthermore, the KG-KE-KR-M method assigns a higher rank to this keyphrase after merging the retrieved keyphrases into the final predictions (i.e., from 6 to 5). The overall results demonstrate the effectiveness of our proposed methods.

6 Conclusion and Future Work

In this paper, we propose a novel integrated approach for keyphrase generation. First, an end-to-end multi-task learning framework is introduced, which not only combines the keyphrase extraction and generation but also leverages the retrieved keyphrases from similar documents to guide the generation process. Furthermore, we introduce a neural-based merging algorithm to merge the candidates from three different components. Comprehensive empirical studies demonstrate the effectiveness of our approach. One interesting future work is to incorporate the similar documents themselves into keyphrase generation.

Abstract

Text analytics is a useful tool for studying malware behavior and tracking emerging threats. The task of automated malware attribute identification based on cybersecurity texts is very challenging due to a large number of malware attribute labels and a small number of training instances. In this paper, we propose a novel feature learning method to leverage diverse knowledge sources such as small amount of human annotations, unlabeled text and specifications about malware attribute labels. Our evaluation has demonstrated the effectiveness of our method over the state-of-the-art malware attribute prediction systems.

1 Introduction

Securing computer systems has become a necessity for both organizations and individuals, as many cyber attacks result in devastating consequences. An outbreak of the WannaCry ransomware in 2017 affected more than 200,000 computers across 150 countries, with total damages ranging from hundreds of millions to billions of dollars (Berr, 2017). Detection of malware often relies on an understanding of the characteristics of malware behavior. To establish a standard for unambiguously characterizing malware, MAEC (Malware Attribute Enumeration and Characterization), a community-based project organized by MITRE, has specified a set of standard malware attributes (Kirillov et al., 2011). Based on MAEC, the actions of a malware can be categorized by four attributes: *ActionName*, *Capability*, *StrategicObjectives* and *TacticalObjectives*. *ActionName* specifies the actions taken by a malware. For example, "delete file" is a malware action that deletes existing files from affected systems. *Capability* defines the general capabilities of a malware. For example, "anti-removal" is a malware capability that prevents itself from being removed from a system. *StrategicObjectives* and *TacticalObjectives* are subcategories of *Capability* to capture more details. For example, a malware can have a *StrategicObjective* of "staging data for exfiltration" and a *TacticalObjective* of "moving data to a staging server". In total, MAEC specified 211 *ActionNames*, 20 *Capabilities*, 65 *StrategicObjectives*, and 148 *TacticalObjectives*.

The goal of this research is to automatically assign malware attribute labels based on cybersecurity texts. The task is challenging. The system needs to assign a large number of labels (444 in total). However, it is difficult to obtain sufficient training examples for each label since malware attribute labeling requires extensive cybersecurity knowledge and only domain experts can do this reliably. Given a large number of possible labels and a small number of training examples, typical supervised text classification techniques do not work well. In this work, we focus on incorporating additional knowledge sources to improve feature learning. The main contributions of this work include

1. Develop a novel ***malware attribute prediction system*** with the state of the art performance to automatically characterize malware behavior based on cybersecurity text.

2. Propose a novel ***Word Annotation Embedding (WAE) algorithm*** to encode diverse information from heterogeneous knowledge sources such as human annotations, raw texts and MAEC specifications.

Proceedings of NAACL-HLT 2019, pages 2857–2861
Minneapolis, Minnesota, June 2 - June 7, 2019.

3. Since WAE generates embeddings for both words and malware attribute labels, we construct ***high-quality predicting features*** based on both types of embeddings.

2 Related Work

Cybersecurity researchers have recently recognized the benefits of leveraging information extracted from security documents. Most prior work utilizing NLP for cybersecurity has focused on privacy policy analysis and Android security (Peng et al., 2012; Pandita et al., 2013; Qu et al., 2014; Slavin et al., 2016; Zhu and Dumitras, 2016). These systems aim to map written policies and the actual permission requests from Android applications and assess the risk level of these applications.

Lim et al. (2017) represents the first major effort to apply NLP techniques for general text-based malware behavior analysis. It processes reports by cybersecurity companies (e.g., FireEye, IBM X-Force, Symantec and Trend Micro) on malware or campaigns associated with Advanced Persistent Threat (APT) groups (Blanda and Westcott, 2018) and assign attributes to identified malware actions. They use word unigrams as predicting features. SVM and Naive Bayes are used to build classifiers for attribute label prediction.

To extend this effort, SemEval organized a shared task (called SecureNLP) on semantic analysis for cybersecurity texts. It adopted the same dataset and task definitions as (Lim et al., 2017). There are four subtasks in SemEval SecureNLP: (1) identifying sentences containing malware actions from APT reports; (2) identifying "Malware Action", "Subject of Action", "Object of Action" and "Modifier of Action"in the identified sentences; (3) identifying four relations,"Subject-Action", "Action-Object", "Modifier-Action" and "Action-Modifier" in identified sentences; (4) assigning attribute labels to each identified action based on the MAEC specification. Figure 1 shows an annotated example for these tasks. This paper describes our approach to solve subtask 4. The input to our system includes all the sentences identified in subtask 1 with additional labels for the entities identified in subtask 2. Each training and testing instance used in SemEval SecureNLP only contains a single malware action.

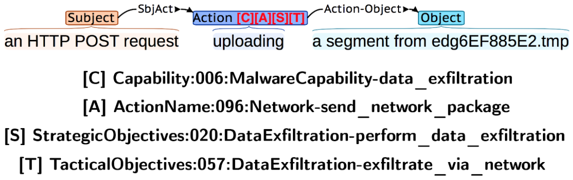

Figure 1: Annotated sentence fragment for SemEval shared task.

3 System Overview

Figure 2 shows the high-level system architecture. First, we augment all the raw APT reports with annotations to encode the knowledge from both the training data and MAEC. This allows us to design a unified representation for both types of knowledge. The annotated texts are then used by WAE to simultaneously learn embeddings for both words and malware attribute labels. The learned word and attribute label embeddings are then used to construct high qualify prediction features. Finally, we employ supervised machine learning to predict malware attribute labels. We build four classifiers, one for each malware attribute. Each classifier performs n+1-way classification, where n is the number of possible labels for each attribute and 1 is for 'no value' when the value of an attribute is not conveyed in the text.

4 Annotation Generation

To annotate text with additional information, the first step is to map each attribute label to a set of keywords based on both MAEC and the human annotations in the training data.

Identify Keywords from MAEC: Figure 3 shows a snippet of the MAEC specification. Each malware attribute label in MAEC includes a description and a few keywords. The malware action 004 in Figure 3 has a name 'emulate driver', a description 'specify the defined action of emulating an existing driver on a system' and two keywords: 'driver' and 'emulate'. Since the keywords carry the most essential information about a malware at-

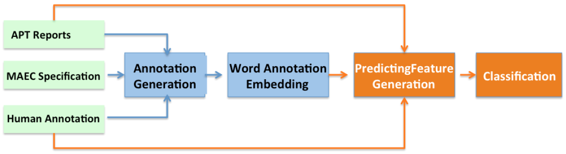

Figure 2: System Architecture

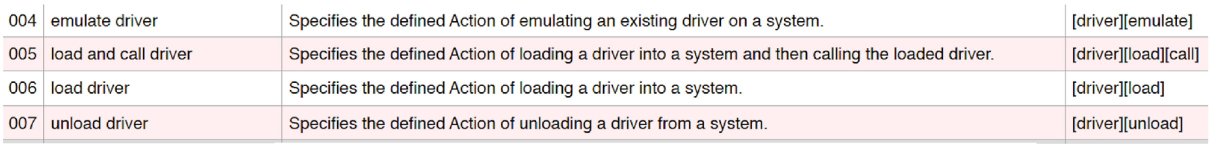

004	emulate driver	Specifies the defined Action of emulating an existing driver on a system.	[driver][emulate]
005	load and call driver	Specifies the defined Action of loading a driver into a system and then calling the loaded driver.	[driver][load][call]
006	load driver	Specifies the defined Action of loading a driver into a system.	[driver][load]
007	unload driver	Specifies the defined Action of unloading a driver from a system.	[driver][unload]

Figure 3: A Snippet of the MAEC Specification

tribute label, we link each label with these keywords (e.g., ActionName004: ‘driver’, ‘emulate’).
Identify Keywords from Training Data: Since a malware attribute label in the training data is at the sentence level, to extract keywords for each attribute label, we extract all the sentences associated with the same label and consider them one document. To select the most relevant keywords, we only keep those conveying “Malware Action”, “Subject of Action”, or “Object of Action” (which were identified in subtask 2).
Keywords Ranking: For the same attribute label, we merge the keywords from MAEC and those from the training data to form a single document. We then use TF-IDF scores to select the most informative keywords to differentiate these labels. In our experiments, we use the top 25 keywords based on their TF-IDF scores.
Text Annotation Generation Finally, for all the APT documents, we annotate the text with malware attribute labels. Specifically, for any word in the APT documents, if it is a keyword associated with K different labels, we annotate the word with K attribute labels.

5 Word Annotation Embedding (WAE)

Similar to word embedding (Mikolov et al., 2013), we want to learn features that capture the semantic relations between words. In addition, to facilitate attribute classification, we want to capture the semantic relations between words and their labels. Specifically, we want the words and their attribute labels to be close to each other in the embedding space and the embeddings of different labels to be far away from each other.

To achieve the goals, we developed a novel Word Annotation Embedding method. As shown in Figure 4, the target word is used to predict not only its context words but also its labels. To further strengthen their relations, the labels of the target word are also used to predict the target word. Specifically, given a sequence of T words (W_1,..,W_t,...,W_T) and their annotations (($A_{1,1}$,...,A_{1,M_1}),...,($A_{T,1}$,...,A_{T,M_T})), the objective of the WAE model is to maximize the average log probability shown in Equation 1, where C is the size of the context window, W_t is the target word, W_{t+j} is a context word, M_t is number of annotations W_t has and $A_{t,k}$ is the k-th annotation of W_t.

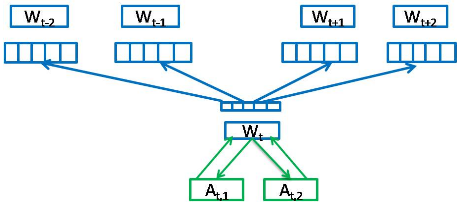

Figure 4: Architecture of WAE Model

$$\frac{1}{T}\sum_{t=1}^{T}\Big(\sum_{-C\leq j\leq C, j\neq 0}\log P(W_{t+j}|W_t) + \sum_{0\leq k\leq M_t}(\log P(A_{t,k}|W_t)+\log P(W_t|A_{t,k}))\Big) \qquad (1)$$

Label-aware Negative Sampling: Negative sampling (Mikolov et al., 2013) was introduced as an approximation method in word2vec to improve the efficiency of model training. Previously, negative samples were selected either randomly or based on popularity. The method, however, is insensitive to class labels. Here, we propose a new annotation-aware negative sampling method to (1) keep different annotations apart in the embedding space and (2) to keep words associated with different labels apart, in addition to bringing words and their associated labels closer to each other via positive samples. To achieve this, WAE randomly selects (1) a word as a negative sample if it does not share the same annotations as the target word; (2) an attribute label as a negative sample if it is not the same as the labels of the target word.

6 Feature Generation and Classification

We construct six sets of features to train the classifiers.
(S1) WAE_W*+Sim:* Assume the average word embeddings for a given data instance generated by WAE is WE_{wae}, and the malware attribute label

Models	**ActionName**	**Capability**	**StratObj**	**TactObj**
(B1) (Lim et al., 2017)	0.33	0.41	0.27	0.22
(B2) Word2vec	0.40	0.57	0.41	0.36
(B3) Word2vec+Cap	NA	NA	0.41	0.39
(S1) WAE_W+Sim	0.44	0.61	0.43	0.41
(S2) $w.WAE_W$+Sim	**0.46**	0.62	0.44	0.43
(S3) WAE_W+WAE_L+Sim	0.45	**0.63**	0.46	0.43
(S4) $w.WAE_W$+WAE_L+Sim	0.45	**0.63**	0.45	0.43
(s5) WAE_W+WAE_L+Sim+Cap	NA	NA	**0.47**	**0.45**
(S6) $w.WAE_W$+WAE_L+Sim+Cap	NA	NA	**0.47**	**0.45**
$\Delta 1$: over (Lim et al., 2017)	↑**39%** ($p < 0.05$)	↑**54%** ($p < 0.05$)	↑**74%**($p < 0.05$)	↑**105%** ($p < 0.05$)
$\Delta 2$: over word2vec	↑**15%** ($p < 0.05$)	↑**11%**($p < 0.05$)	↑**15%**($p < 0.05$)	↑**25%**($p < 0.05$)
$\Delta 3$: over word2vec+Cap	NA	NA	↑**15%** ($p < 0.05$)	↑**15%**($p < 0.05$)

Table 1: Evaluation Results. B1-B3 are the three baselines. S1-S6 are our models with six different sets of predicting features. Δ1-Δ3 are the improvements of our best models over the three baselines.

embedding learned by WAE is $LabelE_i$ for each label i. For each $LabelE_i$, we compute SIM_i, which is the cosine similarity between WE_{wae} and $LabelE_i$. WAE_W+*Sim* is the concatenation of WE_{wae} and all the SIM_i. For example, to predict *ActionName*, the model will include 100 word embedding features learned by WAE plus 211 similarity features, one for each *ActionNames*.

(S2) $w.WAE_W$*+Sim:* This feature set is similar to WAE_W+*Sim* except when computing WE_{wae}, we assign twice as much weight for a word with a label as one without a label. The intuition is words with labels are important keywords based on either MAEC or the training data.

(S3) WAE_W+WAE_L*+Sim:* It is similar to WAE_W+*Sim* except we also include the average embeddings of attribute labels associated with the instance.

(S4) $w.WAE_W$+WAE_L*+Sim:* This is the weighted version of (S3).

(S5) WAE_W+WAE_L*+Sim+Cap:* Since the label of *StrategicObjective* and *TacticalObjective* depends on the label of *Capability*, we added the *capability* label in the feature set. We use a 1-hot vector with 20 elements to encode a *Capability* label. We use the ground truth and the predicted label of *Capability* during training and testing respectively.

(S6) $w.WAE_W$+WAE_L*+Sim+Cap:* This is the weighted version of (S5)

7 Experiments

7.1 Dataset

The dataset used in the experiments was provided as a part of the SemEval shared task. It contains 456 APT reports (Blanda and Westcott, 2018), 39 of them were annotated by humans. Among them, 2975 sentences contain malware actions, which are the data instances used in this study. The annotated data are very sparse. Out of the 444 attribute labels, 190 labels do not appear in the labeled data. For the remaining 254 attribute labels, 92 labels occur less than five times, and 50 labels occur only once. In our experiments, we used the raw text in all the APT reports to train WAE. There are 16423 unique tokens and a total of 2544645 tokens in the dataset. We trained both word2vec and WAE with context window size 5 and 100 dimension vectors. The 39 annotated documents were divided into a training set (23 documents), a validation set (8 documents) and a test set (8 documents). Only the training dataset was used to generate annotations for WAE.

7.2 Evaluation Results

For classification, we tried both SVM and neural network-based models such as multilayer perceptron. After experimenting with different model parameters, we found that the best SVM model with a linear kernel performed slightly better than the best neural network models. We speculate that this might be because SVM is less likely to overfit when the training data are sparse. Table 1 shows the average F-scores over 5 runs by the SVM models on the test data. We compare our models with three baseline systems: (B1) (Lim et al., 2017), (B2) word2vec and (B3) word2vec + cap. Among them, (B1) represents the best published results on the same dataset. (B2) and (B3) are all the comparable models with embeddings learned by word2vec.

As shown in Table 1, all our models outperformed all the baseline systems. The improvement over the word2vec model is 15%, 11%, 15% and 25% respectively, and, the improvement over (Lim et al., 2017), a previous state of the art, is 39%, 54%, 74% and 105% respectively. The improvement over $Word2vec + Cap$ is 15% and 15% respectively for *StrategicObjective* and *TechnicalObjective*. We also conducted t-tests to verify the significance of the improvements. The t-test results confirmed that our models significantly outperformed the baseline models with $p<0.05$. Moreover, the value of ”Capability” seems to help the prediction of *StrategicObjective* and *TechnicalObjective*.

8 Conclusion

In this paper, we present a novel method to predict malware attribute labels from cybersecurity text. Given a large number of attribute labels and limited training data, we propose a new feature learning method to incorporate knowledge from diverse knowledge sources such as raw text, MAEC specifications and human annotations. We tested our system using the SemEval shared task data and our evaluation demonstrates that the features learned by our models are much more effective than an existing state of the art as well as embedding features learned by word2vec. Our investigation has highlighted the importance of incorporating diverse knowledge sources in complex classification tasks when human annotations are sparse.

Abstract

Recently, distant supervision has gained great success on Fine-grained Entity Typing (FET). Despite its efficiency in reducing manual labeling efforts, it also brings the challenge of dealing with false entity type labels, as distant supervision assigns labels in a context-agnostic manner. Existing works alleviated this issue with partial-label loss, but usually suffer from confirmation bias, which means the classifier fit a pseudo data distribution given by itself. In this work, we propose to regularize distantly supervised models with Compact Latent Space Clustering (CLSC) to bypass this problem and effectively utilize noisy data yet. Our proposed method first dynamically constructs a similarity graph of different entity mentions; infer the labels of noisy instances via label propagation. Based on the inferred labels, mention embeddings are updated accordingly to encourage entity mentions with close semantics to form a compact cluster in the embedding space, thus leading to better classification performance. Extensive experiments on standard benchmarks show that our CLSC model consistently outperforms state-of-the-art distantly supervised entity typing systems by a significant margin.

1 Introduction

Recent years have seen a surge of interests in fine-grained entity typing **(FET)** as it serves as an important cornerstone of several nature language processing tasks including relation extraction (Mintz et al., 2009), entity linking (Raiman and Raiman, 2018), and knowledge base completion (Dong et al., 2014). To reduce manual efforts in labelling training data, distant supervision (Mintz et al., 2009) has been widely adopted by recent FET systems. With the help of an external knowledge base (KB), an entity mention is first linked to an existing entity in KB, and then labeled with all possible types of the KB entity as supervision. However, despite its efficiency, distant supervision also brings the challenge of **out-of-context noise**, as it assigns labels in a context agnostic manner. Early works usually ignore such noise in supervision (Ling and Weld, 2012; Shimaoka et al., 2016), which dampens the performance of distantly supervised models.

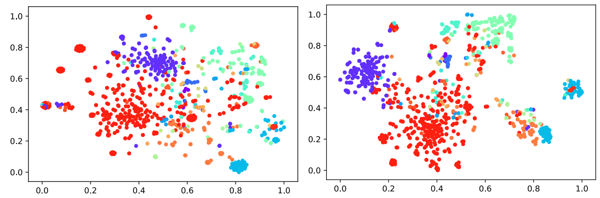

Figure 1: T-SNE visualization of the mention embeddings generated by NFETC (left) and CLSC (right) on the BBN dataset. Our model (CLSC) clearly groups mentions of the same type into a compact cluster.

Towards overcoming out-of-context noise, two lines of work have been proposed to distantly supervised FET. The first kind of work try to filter out noisy labels using heuristic rules (Gillick et al., 2014). However, such heuristic pruning significantly reduces the amount of training data, and thus cannot make full use of distantly annotated data. In contrast, the other thread of works try to incorporate such imperfect annotation by partial-label loss (**PLL**). The basic assumption is that, *for a noisy mention, the maximum score associated with its candidate types should be greater than the scores associated with any other non-candidate types* (Ren et al., 2016a; Abhishek et al., 2017; Xu and Barbosa, 2018). Despite their success, **PLL**-based models still suffer from ***Confirmation Bias*** by taking its own prediction as optimization objective in the next step. Specifically, given an entity mention, if the typing system selected a wrong

Minneapolis, Minnesota, June 2 - June 7, 2019.

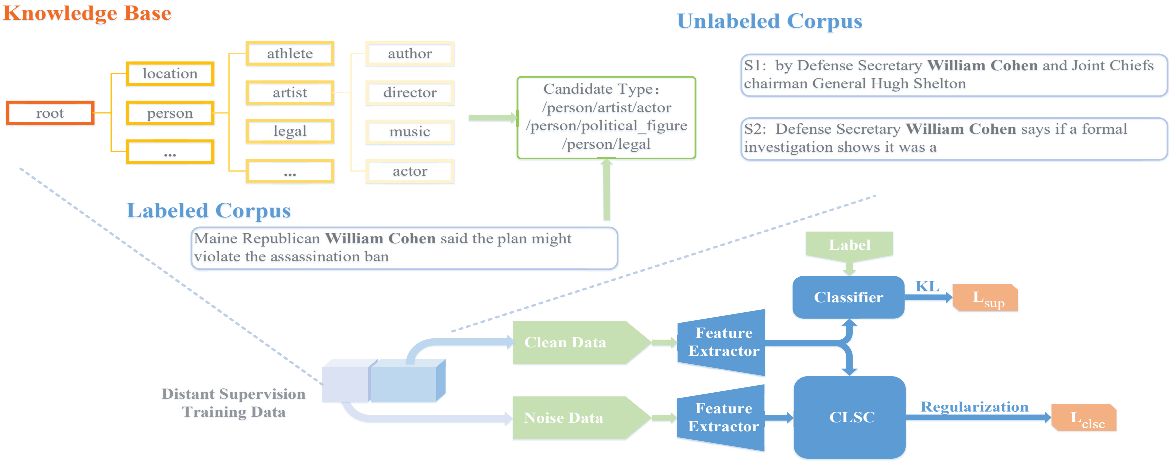

Figure 2: The overall framework of CLSC. We calculate classification loss only on clean data, while regularize the feature extractor with CLSC using both clean and noisy data.

type with the maximum score among all candidates, it will try to further maximize the score of the wrong type in following optimization epoches (in order to minimize **PLL**), thus amplifying the confirmation bias. Such bias starts from the early stage of training, when the typing model is still very suboptimal, and can accumulate in training process. Related discussion can be also found in the setting of semi-supervised learning (Lee et al., 2006; Laine and Aila, 2017; Tarvainen and Valpola, 2017).

In this paper, we propose a new method for distantly supervised fine-grained entity typing. Enlightened by (Kamnitsas et al., 2018), we propose to effectively utilize imperfect annotation as model regularization via **C**ompact **L**atent **S**pace **C**lustering (**CLSC**). More specifically, our model encourages the feature extractor to group mentions of the same type as a compact cluster (dense region) in the representation space, which leads to better classification performance. For training data with noisy labels, instead of generating pseudo supervision by the typing model itself, we dynamically construct a similarity-weighted graph between clean and noisy mentions, and apply label propagation on the graph to help the formation of compact clusters. Figure 1 demonstrates the effectiveness of our method in clustering mentions of different types into dense regions. In contrast to **PLL**-based models, we do not force the model to fit pseudo supervision generated by itself, but only use noisy data as part of regularization for our feature extractor layer, thus avoiding bias accumulation.

Extensive experiments on standard benchmarks show that our method consistently outperforms state-of-the-art models. Further study reveals that, the advantage of our model over the competitors gets even more significant as the portion of noisy data rises.

2 Problem Definition

Fine-grained entity typing takes a corpus and an external knowledge base (KB) with a type hierarchy $\mathcal{Y}$ as input. Given an entity mention (i.e., a sequence of token spans representing an entity) in the corpus, our task is to uncover its corresponding type-path in $\mathcal{Y}$ based on the context.

By applying distant supervision, each mention is first linked to an existing entity in KB, and then labeled with all its possible types. Formally, a labeled corpus can be represented as triples $\mathcal{D} = \{(m_i, c_i, \mathcal{Y}_i)\}_{i=1}^{n}$, where m_i is the i-th mention, c_i is the context of m_i, $\mathcal{Y}_i$ is the set of candidate types of m_i. Note that types in $\mathcal{Y}_i$ can form one or more type paths. In addition, we denote all terminal (leaf) types of each type path in $\mathcal{Y}_i$ as the target type set $\mathcal{Y}_i^t$ (*e.g.*, for $\mathcal{Y}_i = \{artist, teacher, person\}$, $\mathcal{Y}_i^t = \{artist, teacher\}$). This setting is also adopted by (Xu and Barbosa, 2018).

As each entity in KB can have several type paths, *out-of-context* noise may exist when $\mathcal{Y}_i$ contains type paths that are irrelevant to m_i in context c_i. In this work, we argue triples where $\mathcal{Y}_i$ contains only one type path (i.e., $|\mathcal{Y}_i^t| = 1$) as **clean data**. Other triples are treated as **noisy data**, where $\mathcal{Y}_i$ contains both the true type path and irrel-

Figure 3: The architecture of feature extractor $z((m_i, c_i); \theta_z)$

evant type paths. Noisy data usually takes a considerable portion of the entire dataset. The major challenge for distantly supervised typing systems is to incorporate both clean and noisy data to train high-quality type classifiers.

3 The Proposed Approach

Overview. The basic assumptions of our idea are: (1) all mentions belong to the same type should be close to each other in the representation space because they should have similar context, (2) similar contexts lead to the same type. For clean data, we compact the representation space of the same type to comply (1). For noisy data, given assumption (2), we infer the their type distributions via label propagation and candidate types constrain.

Figure 2 shows the overall framework of the proposed method. Clean data is used to train classifier and feature extractor end-to-endly, while noisy data is only used in CLSC regularization. Formally, given a batch of samples $\{(m_i, c_i, \mathcal{Y}_i^t)\}_{i=1}^B$, we first convert each sample (m_i, c_i) into a real-valued vector z_i via a feature extractor $z((m_i, c_i); \theta_z)$ parameterized by θ_z. Then a type classifier $g(z_i; \theta_g)$ parameterized by θ_g gives the posterior $P(y|z_i; \theta_g)$. By incorporating CLSC regularization in the objective function, we encourage the feature extractor z to group mentions of the same type into a compact cluster, which facilitates classification as is shown in Figure 1. Noisy data enhances the formation of compact clusters with the help of label propagation.

3.1 Feature Extractor

Figure 3 illustrates our feature extractor. For fair comparison, we adopt the same feature extraction pipeline as used in (Xu and Barbosa, 2018). The feature extractor is composed of an embedding layer and two encoders which encode mentions and contexts respectively.

Embedding Layer: The output of this layer is a concatenation of word embedding and word position embedding. We use the popular 300-dimensional word embedding supplied by (Pennington et al., 2014) to capture the semantic information and random initialized position embedding (Zeng et al., 2014) to acquire information about the relation between words and the mentions.

Formally, Given a word embedding matrix W_{word} of shape $d_w \times |V|$, where V is the vocabulary and d_w is the size of word embedding, each column of W_{word} represents a specific word w in V. We map each word w_j in (m_i, c_i) to a word embedding $\mathbf{w_j^d} \in R^{d_w}$. Analogously, we get the word position embedding $\mathbf{w}_j^p \in R^{d_p}$ of each word according to the relative distance between the word and the mention, we only use a fixed length context here. The final embedding of the j-th word is $\mathbf{w_j^E} = [\mathbf{w_j^d}, \mathbf{w_j^P}]$.

Mention Encoder: To capture lexical level information of mentions, an averaging mention encoder and a LSTM mention encoder (Hochreiter and Schmidhuber, 1997) is applied to encode mentions. Given $m_i = (w_s, w_{s+1}, \cdots, w_e)$, the averaging mention representation $r_{a_i} \in R^{d_w}$ is :

$$r_{a_i} = \frac{1}{e-s+1} \sum_{j=s}^{e} \mathbf{w_j^d} \tag{1}$$

By applying a LSTM over an extended mention $(w_{s-1}, w_s, w_{s+1}, \cdots, w_e, w_{e+1})$, we get a sequence $(h_{s-1}, h_s, h_{s+1}, \cdots, h_e, h_{e+1})$. We use h_{e+1} as LSTM mention representation $r_{l_i} \in R^{d_l}$. The final mention representation is $r_{m_i} = [r_{a_i}, r_{l_i}] \in R^{d_w+d_l}$.

Context Encoder: A bidirectional LSTM with d_l hidden units is employed to encode embedding sequence $(\mathbf{w^E_{s-W}}, \mathbf{w^E_{s-W+1}}, \cdots, \mathbf{w^E_{e+W}})$:

$$\begin{aligned}\overrightarrow{h_j} &= LSTM(\overrightarrow{h_{j-1}}, \mathbf{w^E_{j-1}}) \\ \overleftarrow{h_j} &= LSTM(\overleftarrow{h_{j-1}}, \mathbf{w^E_{j-1}}) \\ h_j &= [\overrightarrow{h_j} \oplus \overleftarrow{h_j}]\end{aligned} \tag{2}$$

where $\oplus$ denotes element-wise plus. Then, the word-level attention mechanism computes a score $\beta_{i,j}$ over different word j in the context c_i to get the final context representation r_{c_i}:

$$\begin{aligned}\alpha_j &= w^T tanh(h_j) \\ \beta_{i,j} &= \frac{exp(\alpha_j)}{\sum_k exp(\alpha_k)} \\ r_{c_i} &= \sum_j \beta_{i,j} h_{i,j}\end{aligned} \tag{3}$$

We use $r_i = [r_{m_i}, r_{c_i}] \in R^{d_z} = R^{d_w+d_l+d_l}$ as the feature representation of (m_i, c_i) and use a Neural Networks q over r_i to get the feature vector z_i. q has n layers with h_n hidden units and use ReLu activation.

3.2 Compact Latent Space Clustering for Distant Supervision

The overview of CLSC regularization is exhibited in Figure 4, which includes three steps: dynamic graph construction (Figure 4c), label propagation (Figure 4d, e) and Markov chains (Figure 4g). The idea of compact clustering for semi-supervised learning is first proposed by (Kamnitsas et al., 2018). The basic idea is to encourage mentions of the same type to be clustered into a dense region in the embedding space. We introduce more details of CLSC for distantly supervised FET in following sections.

Dynamic Graph Construction: We start by creating a fully connected graph G over the batch of samples $\mathbf{Z} = \{z_i\}_{i=1}^{B}$, as shown in Figure 4c[1]. Each node of G is a feature representation z_i, while the distance between nodes is defined by a scaled dot-product distance function (Vaswani et al., 2017):

$$\begin{aligned}A_{ij} &= exp(\frac{z_i^T z_j}{\sqrt{d_z}}), \forall z_i, z_j \in \mathbf{Z} \\ A &= exp(\frac{Z^T Z}{\sqrt{d_z}})\end{aligned} \tag{4}$$

Each entry A_{ij} measures the similarity between z_i and z_j, $A \in R^{B \times B}$ can be viewed as the weighted adjacency matrix of G.

Label Propagation: The end goal of CLSC is to cluster mentions of the same type to a dense region. For mentions which have more than one labeled types, we apply label propagation (**LP**) on G to estimate their type distribution. Formally, we denote $\mathbf{\Phi} \in R^{B \times K}$ as the label propagation posterior of a training batch.

The original label propagation proposed by (Zhu and Ghahramani, 2002) uses a transition matrix H to model the probability of a node i propagating its type posterior $\phi_i = P(y_i|x_i) \in R^K$ to the other nodes. Each entry of the transition matrix $H \in R^{B \times B}$ is defined as:

$$H_{ij} = A_{ij} / \sum_b A_{ib} \tag{5}$$

The original label propagation algorithm is defined as:

1. Propagate the label by transition matrix H, $\mathbf{\Phi}^{(t+1)} = H\mathbf{\Phi}^{(t)}$
2. Clamp the labeled data to their true labels. Repeat from step 1 until $\mathbf{\Phi}$ converges

In this work $\Phi^{(0)}$ is randomly initialized[2]. Unlike unlabeled data in semi-supervised learning, distantly labeled mentions in FET have a limited set of candidate types. Based on this observation, We assume that (m_i, c_i) can only transmit and receive probability of types in $\mathcal{Y}_i^t$ no matter it is noisy data or clean data. Formally, define a $B \times K$ indicator matrix $M \in R^{B \times K}$, where $M_{ij} = 1$ if type j in $\mathcal{Y}_i^t$ otherwise 0, where B is the batch size and K

---

[1] $\mathbf{Z} = \{z_i\}_{i=1}^{B}$ is a small subsample of the entire data, we didn't observe significant performance gain when the batch size increases.

[2] We also explored other initialization (e.g. uniform initialization), but found no essential performance difference between different initialization setups.

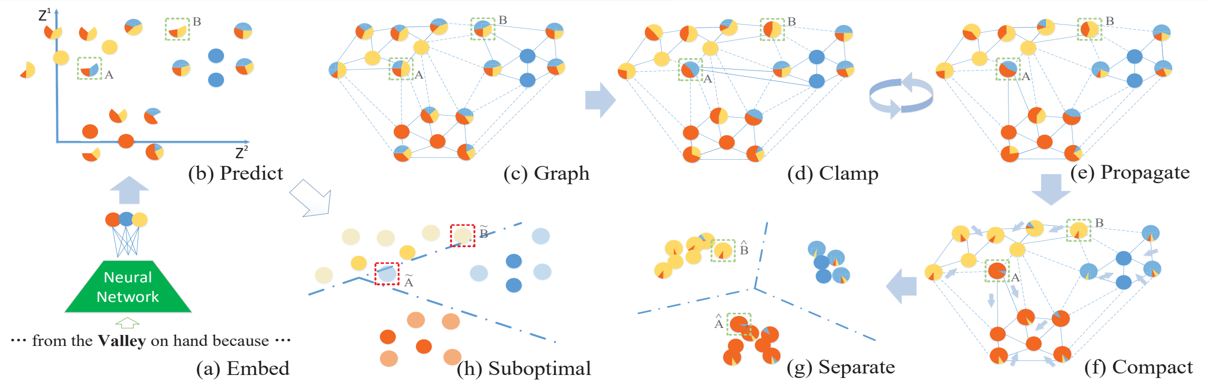

Figure 4: A demonstration of the CLSC process. (a) represents the feature extraction step; (b)→(h) shows the traditional type classification process (each color represents one candidate type), where suboptimal classifiers make predictions for each mention and misclassifies A into the Blue type; (c)→(d)→(e)→(f)→(g) demonstrates the process of CLSC as described in Section 3. Through label propagation and compact clustering, our model is able to group mentions of the same type into a dense region and leaves clear separation boundaries in sparse regions.

is the number of types. Our clamping step relies on M as is shown in Figure 4d:

$$\Phi_{ij}^{(t+1)} \leftarrow \Phi_{ij}^{(t+1)} M_{ij} / \sum_{k} \Phi_{ik}^{(t+1)} M_{ik} \tag{6}$$

For convenience, we iterate through these two steps S_{lp} times, S_{lp} is a hyperparameter.

Compact Clustering: The **LP** posterior $\mathbf{\Phi} = \mathbf{\Phi}^{(S_{lp}+1)}$ is used to judge the label agreement between samples. In the desired optimal state, transition probabilities between samples should be uniform inside the same class, while be zero between different classes. Based on this assumption, the desirable transition matrix $T \in R^{B\times B}$ is defined as:

$$T_{ij} = \sum_{k=1}^{K} \Phi_{ik} \frac{\Phi_{jk}}{m_k}, m_k = \sum_{b=1}^{B} \Phi_{bk} \tag{7}$$

m_k is a normalization term for class k. Transition matrix H derived from $z((m_i, c_i); \theta_z)$ should be in keeping with T. Thus we minimize the cross entropy between T and H:

$$\mathcal{L}_{1-step} = -\frac{1}{B^2} \sum_{i=1}^{B} \sum_{j=1}^{B} T_{ij} log(H_{ij}) \tag{8}$$

For instance, if T_{ij} is close to 1, H_{ij} needs to be bigger, which results in the growth of A_{ij} and finally optimize θ_z (Eq.4). The loss $\mathcal{L}_{1-step}$ has largely described the regularization we use in $z((m_i, c_i); \theta_z)$ for compression clustering.

In order to keep the structure of existing clusters, (Kamnitsas et al., 2018) proposed an extension of $\mathcal{L}_{1-step}$ to the case of **Markov chains** with multiple transitions between samples, which should remain within a single class. The extension maximizes probability of paths that only traverse among samples belong to one class. Define $E \in R_{B\times B}$ as:

$$E = \mathbf{\Phi}^T \mathbf{\Phi} \tag{9}$$

E_{ij} measures the label similarities between z_i and z_j, which is used to mask the transition between different clusters. The extension is given by:

$$\begin{aligned} H^{(1)} &= H \\ H^{(s)} &= (H \odot E)^{(s-1)} H \\ &= (H \odot E) H^{(s-1)}, \end{aligned} \tag{10}$$

where $\odot$ is Hadamard Product, and $H_{ij}^{(s)}$ is the probability of a Markov process to transit from node i to node j after $s-1$ steps within the same class. The extended loss function models paths of different length s between samples on the graph:

$$\mathcal{L}_{clsc} = -\frac{1}{S_m} \frac{1}{B^2} \sum_{s=1}^{S_m} \sum_{i=1}^{B} \sum_{j=1}^{B} T_{ij} log(H_{ij}^{(s)}). \tag{11}$$

For $S_m = 1$, $\mathcal{L}_{clsc} = \mathcal{L}_{1-step}$. By minimizing the cross entropy between T and $H^{(s)}$ (Eq.11), $\mathcal{L}_{clsc}$ compact paths of different length between samples within the same class. Here, S_m is a hyper-parameter to control the maximum length of Markov chain. $\mathcal{L}_{clsc}$ is added to the final objective function as regularization to encourage compact cluttering.

3.3 Overall Objective

Given the representation of a mention, the type posterior is given by a standard softmax classifier parameterized by θ_g:

$$P(\hat{y}_i|z_i;\theta_g) = softmax(W_c z_i + b_c), \tag{12}$$

where $W_c \in R^{K \times d_z}$ is a parameter matrix, $b \in R^K$ is the bias vector, where K is the number of types. The predicted type is then given by $\hat{t}_i = argmax_{y_i} P(\hat{y}_i|z_i;\theta_g)$.

Our loss function consists of two parts. $\mathcal{L}_{sup}$ is supervision loss defined by KL divergence:

$$L_{sup} = -\frac{1}{B_c}\sum_{i=1}^{B_c}\sum_{k=1}^{K} y_{ik} log(P(y_i|z_i;\theta_g))_k \tag{13}$$

Here B_c is the number of clean data in a training batch, K is the number of target types. The regularization term is given by $\mathcal{L}_{clsc}$. Hence, the overall loss function is:

$$\mathcal{L}_{final} = \mathcal{L}_{sup} + \lambda_{clsc} \times \mathcal{L}_{clsc} \tag{14}$$

λ_{clsc} is a hyper parameter to control the influence of CLSC.

4 Experiments

4.1 Dataset

We evaluate our method on two standard benchmarks: OntoNotes and BBN:

- **OntoNotes:** The OntoNotes dataset is composed of sentences from the Newswire part of OntoNotes corpus (Weischedel et al., 2013). (Gillick et al., 2014) annotated the training part with the aid of DBpedia spotlight (Daiber et al., 2013), while the test data is manually annotated.
- **BBN:** The BBN dataset is composed of sentences from Wall Street Journal articles and is manually annotated by (Weischedel and Brunstein, 2005). (Ren et al., 2016a) regenerated the training corpus via distant supervision.

In this work we use the preprocessed datasets provided by (Abhishek et al., 2017; Xu and Barbosa, 2018). Table 2 shows detailed statistics of the datasets.

4.2 Compared Methods

We compare the proposed method with several state-of-the-art FET systems[3]:

- **Attentive** (Shimaoka et al., 2016) uses an attention based feature extractor and doesn't distinguish clean from noisy data;
- **AFET** (Ren et al., 2016a) trains label embedding with partial label loss;
- **AAA** (Abhishek et al., 2017) learns joint representation of mentions and type labels;
- **PLE+HYENA/FIGER** (Ren et al., 2016b) proposes heterogeneous partial-label embedding for label noise reduction to boost typing systems. We compare two PLE models with HYENA (Yogatama et al., 2015) and FIGER (Ling and Weld, 2012) as the base typing system respectively;
- **NFETC** (Xu and Barbosa, 2018) trains neural fine-grained typing system with hierarchy-aware loss. We compare the performance of the NFETC model with two different loss functions: partial-label loss and **PLL**+hierarchical loss. We denote the two variants as $\mathbf{NFETC}$ and $\mathbf{NFETC}_{hier}$ respectively;
- **NFETC-CLSC** is the proposed model in this work. We use the NFETC model as our base model, based on which we apply Compact Latent Space Clustering Regularization as described in Section 3.2; Similarly, we report results produced by using both KL-divergense-based loss (**NFETC-CLSC**) and **KL**+hierarchical loss ($\mathbf{NFETC\text{-}CLSC}_{hier}$).

4.3 Evaluation Settings

For evaluation metrics, we adopt strict accuracy, loose macro, and loose micro F-scores widely used in the FET task (Ling and Weld, 2012). To fine tuning the hyper-parameters, we randomly sampled 10% of the test set as a development set for both datasets. With the fine-tuned hyper-parameter as mentioned in 4.4, we run the model five times and report the average strict accuracy, macro F1 and micro F1 on the test set.

---

[3] The baselines result are reported on (Abhishek et al., 2017; Xu and Barbosa, 2018) in addition to performance of NFETC on BBN, we search the hyper parameters for it. (Xu and Barbosa, 2018) didn't report the results on BBN

Method		**OntoNotes**			**BBN**		
		Strict Acc.	**Macro F1**	**Micro F1**	**Strict Acc.**	**Macro F1**	**Micro F1**
AFET (Ren et al., 2016a)		55.3	71.2	64.6	68.3	74.4	74.7

4.4 Hyper Parameters

We search the hyper parameter of Ontonotes and BBN respectively via Hyperopt proposed by (Bergstra et al., 2013). Hyper parameters are shown in **Appendix A**. We optimize the model via Adam Optimizer. The full hyper parameters includes the learning rate lr, the dimension d_p of word position embedding, the dimension d_l of the mention encoder's output (equal to the dimension of the context encoder's ourput), the input dropout keep probability p_i and output dropout keep probability p_o for LSTM layers (in context encoder and LSTM mention encoder), the L2 regularization parameter λ, the factor of hierarchical loss normalization α ($\alpha > 0$ means use the normalization), BN (whether using Batch normalization), the max step S_{lp} of the label propagation, the max length S_m of Markov chain, the influence parameter λ_{clsc} of CLSC, the batch size B, the number n of hidden layers in q and the number h_n of hidden units of the hidden layers. We implement all models using Tensorflow[4].

4.5 Performance comparison and analysis

Table 1 shows performance comparison between the proposed CLSC model and state-of-the-art FET systems. On both benchmarks, the CLSC model achieves the best performance in all three metrics. When focusing on the comparison between **NFETC** and CLSC, we have following observation:

- Compact Latent Space Clustering shows its effectiveness on both clean data and noisy data. By applying CLSC regularization on the basic **NFETC** model, we observe consistent and significant performance boost;
- Hierarchical-aware loss shows significant advantage on the OntoNotes dataset, while showing insignificant performance boost on the BBN dataset. This is due to different distribution of labels on the test set. The proportion of terminal types of the test set is 69% for the BBN dataset, while is only 33% on the OntoNotes dataset. Thus, applying hierarchical-aware loss on the BBN dataset brings little improvement;
- Both algorithms are able to utilize noisy data to improve performance, so we would like to further study their performance in different noisy scenarios in following discussions.

---

[4] The code for experiments is available at https://github.com/herbertchen1/NFETC-CLSC

4.6 How robust are the methods to the proportion of noisy data?

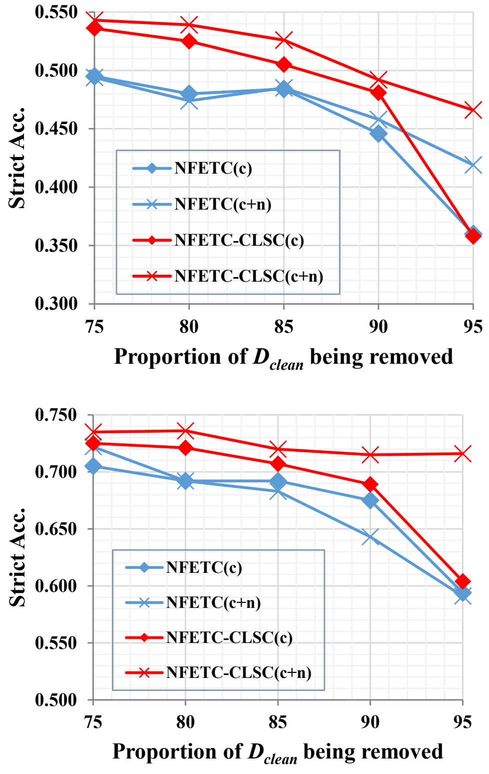

Figure 5: Performance comparison between NFETC-CLSC and NFETC by removing 75%-95% clean data.

By principle, with sufficient amount of clean training data, most typing systems can achieve satisfying performance. To further study the robustness of the methods to label noise, we compare their performance with the presence of $25\%, 20\%, 15\%, 10\%$ and 5% clean training data and all noisy training data. Figure 5 shows the performance curves as the proportion of clean data drops. As it reveals, the CLSC model consistently wins in the comparison. The advantage is especially clear on the BBN dataset, which offers less amount of training data. Note that, with only 27.9% of training data (when only leaving 5% clean data) on the BBN dataset, the CLSC model yield a comparable result with the **NFETC** model trained on full data. This comparison clearly shows the superiority of our approach in the effectiveness of utilizing noisy data.

4.7 Ablation: Do Markov Chains improve typing performance?

Table 3 shows the performance of CLSC with one-step transition ($\mathcal{L}_{1-step}$) and with Markov Chains ($\mathcal{L}_{clsc}$) as described in Section 3.2. Results show that the use of Markov Chains does bring improvement to the overall performance, which is consistent with the model intuition.

5 Related Work

Named entity Recognition (NER) has been excavated for a long time (Collins and Singer, 1999; Manning et al., 2014), which classifies coarse-grained types (e.g. person, location). Recently, (Nagesh and Surdeanu, 2018a,b) applied ladder network (Rasmus et al., 2015) to coarse-grained entity classification in a semi-supervised learning fashion. (Ling and Weld, 2012) proposed Fine-Grained Entity Recognition (FET). They used distant supervision to get training corpus for FET. Embedding techniques was applied to learn feature representations since (Yogatama et al., 2015; Dong et al., 2015). (Shimaoka et al., 2016) introduced attention mechanism for FET to capture informative words. (Xin et al., 2018a) used the TransE entity embeddings (Bordes et al., 2013) as the query vector of attention.
Early works ignore the out-of-context noise, (Gillick et al., 2014) proposed context dependent FET and use three heuristics to clean the noisy labels with the side effect of losing training data. To utilize noisy data, (Ren et al., 2016a) distinguished the loss function of noisy data from clean data via partial label loss (**PLL**). (Abhishek et al., 2017; Xu and Barbosa, 2018) proposed variants of **PLL**, which still suffer from confirmation bias. (Xu and Barbosa, 2018) proposed hierarchical loss to handle over-specific noise. On top of **AFET**, (Ren et al., 2016b) proposed a method **PLE** to reduce the label noise, which lead to a great success in FET. Because label noise reduction is separated from the learning of FET, there might be error propagation problem. Recently, (Xin et al., 2018b) proposed utilizing a pretrained language model measures the compatibility between context and type names, and use it to repel the interference of noisy labels. However, the compatibility got by language model may not be right and type information is defined by corpus and annotation guidelines rather than type names as is mentioned in (Azad et al., 2018). In addition, there are some work about entity-level typing which aim to figure out the types of entities in KB (Yaghoobzadeh and Schütze, 2015; Jin et al., 2018).

6 Conclusion

In this paper, we propose a new method for distantly supervised fine-grained entity typing, which leverages imperfect annotations as model regularization via Compact Latent Space Clustering (CLSC). Experiments on two standard benchmarks demonstrate that our method consistently outperforms state-of-the-art models. Further study reveals our method is more robust than the former state-of-the-art approach as the portion of noisy data rises. The proposed method is general for other tasks with imperfect annotation. As a part of future investigation, we plan to apply the approach to other distantly supervised tasks, such as relation extraction.

Abstract

When constructing models that learn from noisy labels produced by multiple annotators, it is important to accurately estimate the reliability of annotators. Annotators may provide labels of inconsistent quality due to their varying expertise and reliability in a domain. Previous studies have mostly focused on estimating each annotator's overall reliability on the entire annotation task. However, in practice, the reliability of an annotator may depend on each specific instance. Only a limited number of studies have investigated modelling per-instance reliability and these only considered binary labels. In this paper, we propose an unsupervised model which can handle both binary and multi-class labels. It can automatically estimate the per-instance reliability of each annotator and the correct label for each instance. We specify our model as a probabilistic model which incorporates neural networks to model the dependency between latent variables and instances. For evaluation, the proposed method is applied to both synthetic and real data, including two labelling tasks: text classification and textual entailment. Experimental results demonstrate our novel method can not only accurately estimate the reliability of annotators across different instances, but also achieve superior performance in predicting the correct labels and detecting the least reliable annotators compared to state-of-the-art baselines.[1]

1 Introduction

In many natural language processing (NLP) applications, the performance of supervised machine learning models depends on the quality of the corpus used to train the model. Traditionally, labels are collected from multiple annotators/experts who are assumed to provide reliable labels. However, in reality, these experts may have varying levels of expertise depending on the domains, and thus may disagree on labelling in certain cases (Aroyo and Welty, 2013). A rapid and cost-effective alternative is to obtain labels through crowdsourcing (Snow et al., 2008; Poesio et al., 2013, 2017). In crowdsourcing, each instance is presented to multiple expert or non-expert annotators for labelling. However, labels collected in this manner could be noisy, since some annotators could produce a significant number of incorrect labels. This may be due to differing levels of expertise, lack of financial incentive and interest (Poesio et al., 2017), as well as the tedious and repetitive nature of the annotation task (Raykar et al., 2010; Bonald and Combes, 2017).

Thus, in order to ensure the accuracy of the labelling and the quality of the corpus, it is crucial to estimate the reliability of the annotators automatically without human intervention.

Previous studies have mostly focused on evaluating the annotators' overall reliability (Gurevych and Kim, 2013; Sheshadri and Lease, 2013; Poesio et al., 2017). Measuring the reliability on a per-instance basis is however useful as we may expect certain annotators to have more expertise in one domain than another, and as a consequence certain annotation decisions will be more difficult than others. This resolves a potential issue of models that only assign an overall reliability to each annotator, where such a model would determine an annotator with expertise in a single domain to be unreliable for the model, even though the annotations are reliable within the annotator's domain of expertise.

Estimating per-instance reliability is also helpful for unreliable annotator detection and task allocation in crowdsourcing, where the cost of labelling data is reduced using proactive learn-

Minneapolis, Minnesota, June 2 - June 7, 2019.

ing strategies for pairing instances with the most cost-effective annotators (Donmez and Carbonell, 2008; Li et al., 2017). Although reliability estimation has been studied for a long time, only a limited number of studies have examined how to model the reliability of each annotator on a per-instance basis. Additionally, these in turn have only considered binary labels (Yan et al., 2010, 2014; Wang and Bi, 2017), and cannot be extended to multi-class classification in a straightforward manner.

In order to handle both binary and multi-class labels, our approach extends one of the most popular probabilistic models for label aggregation, proposed by Hovy et al. (2013). One challenge of extending the model is the definition of the label and reliability probability distributions on a per-instance basis. Our approach introduces a classifier which predicts the correct label of an instance, and a reliability estimator, providing the probability that an annotator will label a given instance correctly. The approach allows us to simultaneously estimate the per-instance reliability of the annotators and the correct labels, allowing the two processes to inform each other. Another challenge is to select appropriate training methods to learn a model with high and stable performance. We investigate training our model using the EM algorithm and cross entropy. For evaluation, we apply our method to six datasets including both synthetic and real-world datasets (see Section 4.1). In addition, we also investigate the effect on the performance when using different text representation methods and text classification models (see Section 4.2).

Our contributions are as follows: firstly, we propose a novel probabilistic model for the simultaneous estimation of per-instance annotator reliability and the correct labels for natural language labelling tasks. Secondly, our work is the first to propose a model for modelling per-instance reliability for both binary and multi-class classification tasks. Thirdly, we show experimentally how our method can be applied to different domains and tasks by evaluating it on both synthetic and real-world datasets. We demonstrate that our method is able to capture the reliability of each annotator on a per-instance basis, and that this in turn helps improve the performance when predicting the underlying label for each instance and detecting the least reliable annotators.

2 Related Work

2.1 Modelling Annotator Reliability

Probabilistic graphical models have been widely used for inferring the overall reliability of annotators in the absence of ground truth labels. Approaches include modelling a single overall reliability score for each annotator (Whitehill et al., 2009; Welinder et al., 2010; Karger et al., 2011; Liu et al., 2012; Demartini et al., 2012; Hovy et al., 2013; Rodrigues et al., 2014; Li et al., 2014a,b), estimating the reliability of each annotator on a per-category basis (Dawid and Skene, 1979; Zhou et al., 2012; Kim and Ghahramani, 2012; Zhang et al., 2014), and estimating the sensitivity and specificity for each annotator in binary classification tasks (Raykar et al., 2010).

Fewer attempts have been made to model the per-instance reliability of annotators, focusing mainly on medical image classification. One approach is that by Yan et al. (2010; 2014) who use logistic regression to predict the per-instance reliability of annotators. Wang and Bi (2017) used a modified support vector machine (SVM; Cortes and Vapnik 1995) loss, modelling the per-instance reliability as the distance from the given instance to a separation boundary.

2.2 True Label Prediction in Crowdsourcing

True label prediction in crowdsourcing is the aggregation of labels produced by different annotators to infer the correct label of each instance. Majority voting assigns to each instance the most commonly occurring label among the annotators, which can result in a high agreement between the predicted label and the ground truth for some NLP tasks (Snow et al., 2008). Dawid and Skene (1979), Whitehill et al. (2009), Raykar et al. (2010), Welinder et al. (2010), Liu et al. (2012), Zhou et al. (2012), Kim and Ghahramani (2012), Hovy et al. (2013), Yan et al. (2010; 2014), Li et al. (2014b) and Zhang et al. (2014) investigated binary or multi-class label prediction using probabilistic graphical models. Karger et al. (2011), Wang and Bi (2017), and Bonald and Combes (2017) formalised the label prediction as an optimisation problem. Rodrigues et al. (2014) and Nguyen et al. (2017) investigated how to aggregate sequence labels using probabilistic graphical models.

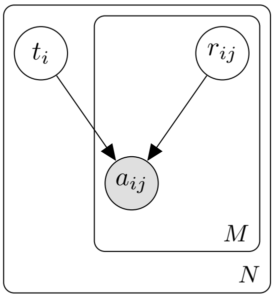

Figure 1: Graphical model.

```
for $i = 1$ to $N$
    $t_i \sim \text{Categorical}(f_t(\mathbf{x}_i))$
    for $j = 1$ to $M$
        $r_{ij} \sim \text{Bernoulli}(f_r(\mathbf{x}_i, j))$
        $a_{ij} \sim \begin{cases} \text{Uniform}(T) & r_{ij} = 0 \\ \delta_{t_i} & r_{ij} = 1 \end{cases}$
```

Figure 2: Generative process for our method. f_t is the classifier, returning a probability distribution over predicted labels, and f_r is the reliability estimator, returning the probability that the annotator is accurate for the instance. $\text{Uniform}(T)$ is a uniform distribution over the categories in T. δ_{t_i} is the deterministic distribution that only takes on the value t_i.

3 Methodology

3.1 Model

In the description of our model we let N be the number of training instances, M the number of annotators, $\mathbf{x}_i$ the ith training instance, t_i its true underlying label, T the set of values t_i can take on, r_{ij} whether annotator j is reliable for the ith instance, and a_{ij} the label that annotator j gave the ith instance. Below we describe the components of the model in more detail.

Probabilistic Model: Our model is inspired by the method proposed by Hovy et al. (2013), and it shares the same graphical representation (see Figure 1). The distributions of the model, however, are defined differently, as can be seen in Figure 2, due to the inclusion of a classifier and a reliability estimator.

We assume that the underlying label t_i depends only on the corresponding instance, while the reliability r_{ij} depends on the instance and the identity of the annotator. If $r_{ij} = 0$, then the annotator j is unreliable for instance $\mathbf{x}_i$, and a label is chosen randomly from among the available categories. Otherwise, the annotation a_{ij} is set to be the correct label.

Classifier: The classifier $f_t(\mathbf{x}_i)$ provides the predicted probabilities of an instance belonging to each category, $p(t_i \mid \mathbf{x}_i)$. t_i is the underlying label for instance $\mathbf{x}_i$, the ith instance, and takes a value in the set of categories T. Note that there is no restriction on what classifier is used, other than that it can be trained using expectation maximisation. The inclusion of a classifier directly in the model means that it can be trained while taking into account the uncertainty of the data and predictions, as opposed to first making a hard assignment of a label for each instance and training the classifier post-hoc.

Reliability Estimator: The reliability estimator $f_r(\mathbf{x}_i, j)$ predicts the probability of annotator j producing the correct label for instance $\mathbf{x}_i$, $p(r_{ij} \mid \mathbf{x}_i)$. r_{ij} is a binary variable, with 1 and 0 representing annotator j being reliable and unreliable for instance $\mathbf{x}_i$, respectively. The reliability estimator is modelled as a feed-forward neural network, where j is encoded as a one-hot vector. The exact representation of $\mathbf{x}_i$ depends on the model used for the classifier. If the classifier is a neural network, the output of the last hidden layer is used; otherwise, the original feature vector is used.

3.2 Learning

Pre-training

As the number of parameters in our model is much larger than that of previous studies (Yan et al., 2010, 2014; Wang and Bi, 2017) due to the introduction of both a classifier and a reliability estimator, the model is much harder to train from scratch. Therefore, before we start training the model, we first pre-train the classifier using labels predicted by a simpler method as targets, using e.g. majority voting or the method proposed by Dawid and Skene (1979). Although these labels may be noisy, we have observed empirically that a better initialisation strategy does result in better performance (see Section 5). For the reliability estimator, for each instance $\mathbf{x}_i$ we compare each annotation a_{ij} to the labels predicted in the previous step. If a_{ij} is the same as the predicted label, we take the corresponding r_{ij} to be 1, and 0 otherwise. We then pre-train the reliability estimator f_r to predict these values for $\mathbf{r}$.

EM Training

We first consider training our model using expectation maximisation (EM; Dempster et al. 1977).

This involves maximising the expectation of the complete log likelihood of the model with respect to the posterior of the latent variables in the model. For the posterior of the model, we fix the parameters of the model and denote them $\boldsymbol{\theta}^{(k)}$ at iteration k of the algorithm. We only maximise the expectation with respect to the parameters $\boldsymbol{\theta}$ of the complete log likelihood.

The expectation is calculated as:

$$
\begin{aligned}
Q(\boldsymbol{\theta} \mid \boldsymbol{\theta}^{(k)}) &= \mathbb{E}[\log p(\mathbf{a}, \mathbf{t}, \mathbf{r} \mid \mathbf{x}, \boldsymbol{\theta})] \\
&= \sum_{i=1}^{N} \mathbb{E}\left[\log p(t_i \mid \mathbf{x}_i, \boldsymbol{\theta})\right] \\
&+ \sum_{i=1}^{N} \sum_{j=1}^{M} \mathbb{E}\left[\log p(r_{ij} \mid \mathbf{x}_i, \boldsymbol{\theta})\right] \\
&+ \sum_{i=1}^{N} \sum_{j=1}^{M} \mathbb{E}\left[\log p(a_{ij} \mid t_i, r_{ij}, \mathbf{x}_i, \boldsymbol{\theta})\right],
\end{aligned} \tag{1}
$$

where each expectation is calculated with respect to the posterior $p(\mathbf{t}, \mathbf{r} \mid \mathbf{a}, \mathbf{x}, \boldsymbol{\theta}^{(k)})$.

E Step: For the E step we compute the posterior with fixed parameters $\boldsymbol{\theta}^{(k)}$, $\pi_{ij}(t, r) = p(t_i = t, r_{ij} = r \mid \mathbf{a}_i, \mathbf{x}_i)$, as:

$$
\begin{aligned}
\pi_{ij}(t, r) &= p(t_i = t, r_{ij} = r \mid \mathbf{a}_i, \mathbf{x}_i) \\
&\propto p(t_i = t \mid \mathbf{x}_i) p(r_{ij} = r \mid \mathbf{x}_i) \\
&\cdot p(a_{ij} \mid t_i = t, r_{ij} = r, \mathbf{x}_i) \cdot \prod_{j' \neq j} \gamma_{ij'}^{(k)}(t)
\end{aligned} \tag{2}
$$

$$
\begin{aligned}
\gamma_{ij}^{k}(t) = \sum_{r' \in \{0,1\}} &\big(p(r_{ij} = r' \mid \mathbf{x}_i) \\
&\cdot p(a_{ij} \mid t_i = t, r_{ij} = r', \mathbf{x}_i)\big),
\end{aligned} \tag{3}
$$

where we drop the dependency on $\boldsymbol{\theta}^{(k)}$ for brevity. Note that $\pi_{ij}(t, r) = 0$ when $r = 1$ and $a_{ij} \neq t$.

We can then compute the marginalised posteriors, needed for Equation (1), as follows:

$$
p(t_i = t \mid \mathbf{a}_i, \mathbf{x}_i) = \sum_{r \in \{0,1\}} \pi_{i1}(t, r) \tag{4}
$$

$$
p(r_{ij} = r \mid \mathbf{a}_i, \mathbf{x}_i) = \sum_{t \in T} \pi_{ij}(t, r), \tag{5}
$$

where the posterior $p(t_i, r_{i1} \mid \mathbf{a}_i, \mathbf{x}_i)$ of the model is chosen arbitrarily to marginalise over to get the posterior for t_i.

M Step: Using the posterior calculated in the E step we can compute the expectation of the complete log likelihood, $Q(\boldsymbol{\theta} \mid \boldsymbol{\theta}^{(k)})$, and calculate its gradient with respect to the parameters $\boldsymbol{\theta}$. We then use gradient ascent to update the classifier and reliability estimator jointly.

Algorithm 1 Training procedure

```
Input:
    $\mathbf{a}$, the annotations
    $\mathbf{x}$, the instances
    $L$, the number of inner iterations
    $m$, the training mode: 0 for expectation maximisation, 1 for cross entropy (training alternatingly), 2 for cross entropy (training jointly)

Pre-train $\boldsymbol{\theta} = \{\boldsymbol{\theta}_t, \boldsymbol{\theta}_r\}$ (Section 3.2)
$k \leftarrow 0$
while stopping criteria not met do
    $k \leftarrow k + 1$
    Calculate $\pi_{ij}(t, r)$ (Equation (2))                ▷ E step

end while
```

Cross Entropy Training

As an alternative training procedure, we also consider training the model using cross entropy. As with expectation maximisation, we first calculate the posterior $\pi_{ij}(t, r)$ using the fixed parameters $\boldsymbol{\theta}^{(k)}$. The networks f_t and f_r are then trained to minimise the cross entropy between the priors $p(t_i \mid \mathbf{x}_i)$ and $p(r_{ij} \mid \mathbf{x}_i)$, and the corresponding posteriors $p(t_i \mid \mathbf{a}_i, \mathbf{x}_i)$ and $p(r_{ij} \mid \mathbf{a}_i, \mathbf{x}_i)$.

The networks can be trained in an alternating fashion, with f_r being trained while f_t is kept fixed, and the other way around. Denoting the parameters of f_t as $\boldsymbol{\theta}_t$ and f_r as $\boldsymbol{\theta}_r$, the loss functions for the respective networks then become

$$
\begin{aligned}
L(\boldsymbol{\theta}_t \mid \boldsymbol{\theta}^{(k)}) &= -\frac{1}{N} \sum_{i,t,r} \pi_{i1}(t, r) \log p(t_i \mid \mathbf{x}_i) \\
L(\boldsymbol{\theta}_r \mid \boldsymbol{\theta}^{(k)}) &= -\frac{1}{NM} \sum_{i,j,t,r} \pi_{ij}(t, r) \log p(r_{ij} \mid \mathbf{x}_i)
\end{aligned} \tag{6}
$$

Alternatively, they can be trained jointly by minimising the total cross entropy.

$$
L(\boldsymbol{\theta} \mid \boldsymbol{\theta}^{(k)}) = L(\boldsymbol{\theta}_t \mid \boldsymbol{\theta}^{(k)}) + L(\boldsymbol{\theta}_r \mid \boldsymbol{\theta}^{(k)}) \tag{7}
$$

The training algorithm is summarised in Algorithm 1. The algorithm is run until either a maximum number of iterations is reached, or the objective function stops improving.

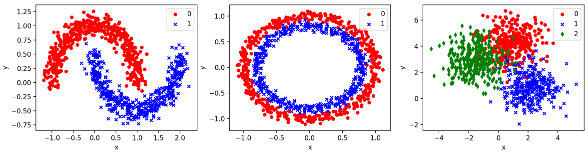

Figure 3: Three 2-dimensional datasets.

4 Evaluation Settings

4.1 Data

Simulated Annotators

2-Dimensional Datasets: In order to see whether our method can work well on simple cases, we create three 2-dimensional synthetic datasets, which we refer to as moon, circle and 3-class as shown in Figure 3.

Text Classification: For text classification we use the datasets Question Classification (Li and Roth, 2002), which contains short questions along with the type of answer expected, and Sentence Classification (Chambers, 2013), which consists of sentences selected from medical publications. Examples of instance/class pairs for the text classification datasets include ”Where is the Orinoco?” (class: ”location”) for the Question Classification dataset, and ”New types of potent force clamps are discovered.” (class: ”author’s own work”) for the Sentence Classification dataset.

For these datasets that do not include crowd annotations, we synthesise annotations by simulating different annotators as follows: 1) **Narrow Expert**: has expertise in a single domain (i.e. class). For the instances of this class, the annotator will always provide the correct label. For other classes, a correct label will be provided with a probability of 0.65; otherwise, a random label will be selected with uniform probability; 2) **Broad Expert**: has expertise in every domain and only makes mistakes with a probability of 0.05; 3) **Random Annotator**: selects labels at random; 4) **Adversarial Annotator**: deliberately provides incorrect labels with a probability of 0.8.

For each of the datasets, we generated annotations using one narrow expert per class, one broad expert, one random annotator and one adversarial annotator, for a total of $|T| + 3$ annotators, where $|T|$ is the number of classes in the dataset.

In order to evaluate the generality of our model, we also apply it to another task in which we have 5 annotators with different overall reliabilities for the text classification tasks. They produce incorrect labels with probabilities 0.1, 0.3, 0.5, 0.7, 0.9 respectively.

Real-World Crowdsourcing Annotators

Recognising Textual Entailment: Finally, we evaluate our model on a real-world dataset for the recognising textual entailment (RTE) task (Snow et al., 2008). Given a text pair, the annotator decides whether the hypothesis sentence can be inferred from the text fragment. The dataset includes both ground truth and crowdsourced labels from 164 annotators.

Table 1 shows the number of instances of each class[2] in the above-mentioned datasets.

4.2 Experimental and Model Settings

Our model was implemented using the Chainer deep learning framework[3] (Tokui et al., 2015).

Classifier: As shown in Table 2, in each experiment the output of the classifier is generated by a feed-forward neural network (FNN). Each FNN consists of an input layer, two hidden layers and a softmax output layer. The number of hidden units in each layer is listed in the third column of the table. The ReLU activation function (Nair and

---

[2] The classes in the Sentence Classification dataset are defined as follows: AIMX—the goal of the paper; OWNX—the author’s own work; CONT—the comparison including contrast and critique of past work; BASE—the past research that provides the basis for the work; MISC—any other sentences.

[3] `https://chainer.org/`

Hinton, 2010) was applied after each hidden layer. The output size of all the Long Short-Term Memory (LSTM; Hochreiter and Schmidhuber, 1997) layers in our experiments is 100.

For the 2-dimensional classification task, each instance is simply represented using its position in 2-dimensional space. For the text classification tasks, we investigated 3 methods of representing the sentences: bag-of-words (BoW) weighted by Term Frequency–Inverse Document Frequency (TFIDF), an average word embedding (Avg.) and the output at the last step of an LSTM layer (Embed.→LSTM). For the embedding we use word2vec embeddings pre-trained on Google News (Mikolov et al., 2013) for the question classification and RTE tasks, and a pre-trained embedding (Pyysalo et al., 2013) trained on a combination of English Wikipedia, PubMed and PMC texts for the sentence classification task.

For the RTE task, we implemented two classifiers. For the first one, each instance (i.e. a sentence pair) was represented as a concatenation of the average word embedding for each sentence (Cat. Avg.). We also implemented Bowman et al. (2015), which runs each sentence through an LSTM, concatenates the outputs, and then feeds the concatenated output to an FNN with tanh activations.

Reliability Estimator: We model the reliability estimator as an FNN. Its structure is the same as the classifier, albeit with different sizes of the two hidden layers. For the experiments listed in Table 2, the number of units of each hidden layer in the FNN are 5, 100, 25, 25, 50, and 100 respectively. The input to the estimator is the concatenation of the instance $\mathbf{x}_i$ (i.e. its original feature vector or the output of the last hidden layer of the classifier) and a one-hot vector representing the annotator identity.

Learning Settings: For every experiment we use the Adam (Kingma and Ba, 2015) optimiser with a weight decay rate 0.001, a gradient clipping of 5.0, $\alpha = 0.001$, $\beta_1 = 0.9$ and $\beta_2 = 0.999$. We pre-train the classifier and reliability estimator for 200 epochs, using both majority voting and the model proposed by Dawid and Skene (1979). The maximum number of outer iterations is set to 500 and 20 for EM training and cross entropy training respectively. The number of inner iterations is 50 in both cases.

True Label Prediction and Reliability Estimation: After training, for each instance $\mathbf{x}_i$ we take its underlying label to be the most probable label according to the posterior of t_i (see Equation (4)). We compared our predicted labels to the following state-of-the-art baselines: Majority Voting (MV), DS (Dawid and Skene, 1979), GLAD (Whitehill et al., 2009), LFC (Raykar et al., 2010), CUBAM (Welinder et al., 2010), Yan et al. (2010), KOS (Karger et al., 2011), VI (Liu et al., 2012), BCC (Kim and Ghahramani, 2012), MINIMAX (Zhou et al., 2012), MACE (Hovy et al., 2013), CATD (Li et al., 2014a), PM (Li et al., 2014b) and EM-MV and Opt (Zhang et al., 2014).

Note that CUBAM, Yan et al. (2010), KOS and VI are only suitable for aggregating binary labels, and Yan et al. (2010) is the state-of-the-art method that models per-instance reliability. We take the reliability of annotator j on instance $\mathbf{x}_i$ to be the posterior probability that r_{ij} is 1 (see Equation (5)).

5 Results and Analysis

We measure the inter-annotator agreement (IAA) of each dataset. Fleiss's kappa (Fleiss et al., 2013), denoted by κ, is measured for the 2-dimensional and text classification datasets, and Krippendorff's alpha (Krippendorff, 1970) is calculated for the RTE dataset[4]. We find that the IAA values indicate slight agreement among annotators for all datasets.

Our experiments using different settings are shown as follows: our model is denoted by *O*, with *M* and *D* denoting the model pre-trained using MV and DS respectively. *E* denotes training using expectation maximisation, while *C* denotes cross entropy training. *AL* and *JT* denote cross entropy training done alternatingly and jointly, respectively.

In the rest of this section, Tables 3 to 7 and Tables 8 to 10 present the results on the synthetic datasets and RTE dataset respectively. For the synthetic datasets, in Tables 3 to 6, we first consider a scenario where we have multiple narrow experts (N), one broad expert (B), one random annotator (R) and one adversarial annotator (A). In Table 7, we further consider a scenario with 5 annotators,

---

[4] Although there are 164 annotators in total in this dataset, each instance was labelled by only 10 of these annotators. Therefore we use Krippendorff's alpha which is applicable to incomplete data to measure the inter-annotator agreement.

Table 3: F1 scores of predicted labels on the 2-dimensional datasets when using the output of the last hidden layer of the classifier to represent an instance for the reliability estimator.

each of differing reliability, as explained in Section 4.1.

Table 3 shows that our method performs well on the 2-dimensional datasets, obtaining higher label prediction F1 scores than the baselines. We omit the analysis of the true label prediction and reliability estimation results on these datasets as all models performed similarly, choosing instead to focus the discussion on the results for the NLP tasks.

5.1 Classifier and Reliability Estimator

In order to explore the separate performance contribution of classifier and reliability estimator, we compare the performance of our model to a classifier pre-trained using DS labels, as well as a variant of our model without the reliability estimator, i.e. setting all the annotators have the same reliability on all the instances.

As shown in Tables 4, 7 and 8, the pre-trained classifier performed worse than some aggregation methods. This indicates that the noise in the labels predicted by DS has an adverse effect on the training of the classifier. The much lower performance of the model with the reliability estimator removes hints at the importance of modelling per-annotator reliability to ensure accurate predictions.

Table 4: F1 scores of predicted labels on the text classification datasets.

5.2 Instance Representation for Reliability Estimator

For the representation of the instance $\mathbf{x}_i$ as it is fed to the reliability estimator, we compared the performance of using the original feature vector of $\mathbf{x}_i$ to using the last hidden layer output of the classifier (which we refer to as the "full model").

We found that using the hidden layer representation can not only improve the label prediction performance (see Tables 4, 7 and 8), but also sped up the training compared to using the feature vector directly. The hidden layer representation allows us to reduce the number of parameters in the model, by sharing parameters with the classifier.

5.3 Full Model on Synthetic Datasets

Based on the results of the full model in Table 4, we can conclude that per-instance reliability modelling is beneficial to the label prediction task, and using the average pre-trained embedding can result in slightly better performance. It is worth noting that the method used to pre-train the model had a noticeable effect on its performance, with better F1 scores being obtained when using DS pre-training. In the following experiments we only consider models pre-trained using the DS algorithm.

In order to investigate whether our method can successfully capture per-instance annotator reliability, for each annotator, we counted the number of correctly labelled instances and calculated the

Table 8: Performance of predicted labels on the RTE dataset (Krippendorff's alpha = 0.0995).

average reliability for each class among the top 100 instances with the highest per-instance reliability as shown in Table 5 and 6[5]. The cells with grey background colour indicate which domain, or class, the annotator has expertise in. It can be seen that all annotators obtain high accuracy on these instances. In general our method also captured the varying expertise of each narrow annotator, estimating their reliability on instances belonging to the corresponding classes as particularly high.

For these experiments in Table 7, we also investigated the performance when using two different classification models. As seen in this table, both of them outperformed all baselines significantly.

5.4 Full Model on RTE Dataset

Table 8 presents the label prediction performance on the RTE dataset. As not every annotator has provided labels for every instance in this dataset, for both the EM and cross entropy training we simply omitted missing instance/annotator pairs when calculating the loss functions. As seen in the table, most of the baselines obtained high performance as the textual entailment recognition task is easy for non-expert annotators. However, our full model still achieved better prediction performance than all of the baseline methods.

We also investigated the effectiveness of our model for removing noisy labels. We compare our model to the five best-performing baselines (DS, LFC, CUBAM, VI and EM-MV in Table 8). Each of these models are trained on the RTE dataset, after which the least reliable annotation for each instance is removed. We use the per-instance reliability for our model, the global reliability score of each annotator for LFC, CUBAM and VI, and the per-category annotator reliability for DS and EM-MV as the measure of the reliability of each annotation. For each of these models, we then retrain the models in Table 8 using the denoised dataset; the difference in performance can be seen in Table 9. We can see that using per-instance reliability results in the largest improvement, while only considering the annotators' overall reliability may

---

[5] We omit the results for the sentence classification task for lack of space, as we consider the results on the question classification dataset to be representative.

cause a reduction in performance.

In order to analyse the per-instance reliability of the human annotators, for each annotator we rank the instances according to the annotator's per-instance reliability. We look at the top 15 and bottom 15 instances, then count how many of them were correctly labelled (Cor. Labels) as well as the average reliability on these instances (Avg. Reliability). Table 10 shows the results of five annotators[6]. It can be seen that each annotator has considerably different reliabilities across instances.

5.5 Training Stability

Pre-training: As discussed in Section 3.2, the predicted labels produced by a simpler method are used for pre-training. Although these labels are not perfect, we assume that our method can still learn some useful information from them for a better starting point than random parameter initialisation.

EM and Cross Entropy Training: From Tables 3, 4, 7 and 8, it can be seen that, in most cases, using cross entropy achieved much better and more stable performance than the models learned using EM training. We also noticed that the objective function would improve when using cross entropy training, and tended to converge faster in our experiments—generally within just a few epochs. Therefore, we recommend to use this training method in practice.

Early Stopping: When using both EM and cross entropy training, we found that even if the objective function improved between iterations, the label prediction performance would eventually start to decrease. It is worth to investigate the reason for this phenomenon. To counteract this issue we used early stopping, where training is halted when the objective function does not improve more than 0.001 between iterations. Another option is to reduce the maximum number of outer iterations, e.g. to 20.

6 Conclusion and Future Work

We propose a novel probabilistic model which learns from noisy labels produced by multiple annotators for NLP crowdsourcing tasks by incorporating a classifier and a reliability estimator. Our work constitutes the first effort to model the per-instance reliability of annotators for both binary and multi-class NLP labelling tasks. We investigate two methods of training our model using the EM algorithm and cross entropy. Experimental results on 6 datasets including synthetic and real datasets demonstrate that our method can not only capture the per-instance reliability of each annotator, but also obtain better label prediction and the least reliable annotator detection performance compared to state-of-the-art baselines.

For future work, we plan to apply our model to other NLP tasks such as relation extraction and named entity recognition. We also plan to investigate the use of variational inference (Jordan et al., 1999) as a means of training our model. Using variational inference might improve the stability and performance of our model.

Abstract

This paper explores a new natural language processing task, review-driven multi-label music style classification. This task requires systems to identify multiple styles of music based on its reviews on websites. The biggest challenge lies in the complicated relations of music styles. To tackle this problem, we propose a novel deep learning approach to automatically learn and exploit style correlations. Experiment results show that our approach achieves large improvements over baselines on the proposed dataset. Furthermore, the visualized analysis shows that our approach performs well in capturing style correlations.[1]

1 Introduction

As music style (e.g., Jazz, Pop, and Rock) is one of the most frequently used labels for music, music style classification is an important task for applications of music recommendation, music information retrieval, etc. Several methods have been proposed for automatic music style classification (Qin and Ma, 2005; Zhou et al., 2006; Wang et al., 2009; Choi et al., 2017). Most of them mainly focus on using audio information to identify styles. Motivated by the fact that a pieces of music could has different styles, several studies (Wang et al., 2009; Oramas et al., 2017) also aim at multi-label music style classification.

Although these methods make promising progress, they are limited in two aspects. First, not all audio data is available in real-world applications because of copyright restrictions, which limits the generalization ability. Second, some of them are based on a strong assumption that a piece of music should be assigned with only one style. Different from these studies, we focus on using easily obtained reviews in conjunction with multi-label music style classification. The motivation comes from the fact that lots of user reviews contain rich style-related information, which can be used for music style classification.

The major challenge of this task lies in the complicated correlations of music styles. For example, Soul Music[2] contains elements of R&B and Jazz. These three labels can be used alone or in combination. Traditional multi-label classification methods may mistake the true label [Soul Music, R&B, Jazz] for the false label [R&B, Jazz]. If well learned, style relations are useful knowledge for improving the performance, e.g., increasing the probability of Soul Music if we find that it is heavily linked with two high probability labels: R&B and Jazz. Therefore, to better exploit style correlations, we propose a novel deep learning approach with two parts: a label-graph based neural network, and a soft training mechanism with correlation based continuous label representation.

Our contributions are listed as follows:

- To the best of our knowledge, this work is the first to explore review-driven multi-label music style classification.
- To learn the relations among music styles, we propose a label-graph based neural network and a soft training mechanism with correlation-based label representation.

2 Related work

This paper is related with music style classification and multi-label classification. In this section, we give a detailed introduction about the related studies.

Table 1: An illustration of review-driven multi-label music style classification. For easy interpretation, we select a simple and clear example where styles can be easily inferred from reviews. In practice, the correlation between styles and associated reviews is relatively complicated.

2.1 Music Style Classification

Previous work mainly focuses on using audio information to identify music styles. Traditional machine learning algorithms are adopted in these studies, such as Support Vector Machine (SVM) (Xu et al., 2003), Hidden Markov Model (HMM) (Chai and Vercoe, 2001; Pikrakis et al., 2006), and Decision Tree (DT) (Zhou et al., 2006). In addition to audio information, Fell and Sporleder (2014) also propose to classify music by statistical analysis of lyrics. Motivated by the fact that a piece of music could has different styles, several studies (Wang et al., 2009; Oramas et al., 2017) also aim at multi-label music style classification. Different from these studies, we focus on using easily obtained reviews in conjunction with multi-label music style classification.

2.2 Multi-Label Classification

Multi-label classification has been widely applied to diverse problems, including image classification (Qi et al., 2007; Wang et al., 2008), audio classification (Boutell et al., 2004; Sanden and Zhang, 2011), web mining (Kazawa et al., 2004), information retrieval (Zhu et al., 2005; Gopal and Yang, 2010), etc. Compared with the existing multi-label learning methods (Wei et al., 2018; Li et al., 2018b,a; Yang et al., 2018; Lin et al., 2018), our method has the following novelties: a label graph that explicitly models the relations of styles; a soft training mechanism that introduces correlation-based continuous label representation.

3 Review-Driven Multi-Label Music Style Classification

3.1 Task Definition

Given several reviews from a piece of music, this task requires models to predict a set of music styles. Assume that $X = \{\boldsymbol{x}_1, \dots, \boldsymbol{x}_i, \dots, \boldsymbol{x}_K\}$ denotes the input K reviews, and $\boldsymbol{x}_i = x_{i,1}, \dots, x_{i,J}$ represents the i^{th} review with J words. The term $Y = \{y_1, y_2, \dots, y_M\}$ denotes the gold set with M labels, and M varies in different samples. The target of review-driven multi-label music style classification is to learn the mapping from input reviews to style labels.

3.2 Dataset

The dataset is collected from a popular Chinese music review website,[3] where registered users are allowed to comment on all released music albums. Each sample includes a music title, a set of human annotated styles, and associated reviews. An example is shown in Table 1.

In order to build a high-quality dataset, we refer to the literature about music styles. We merge similar music styles and delete music styles that violate the music classification list. 22 styles are defined in our dataset.[4] For user reviews, we first delete reviews with too little information by rule-based methods and then select top 40 voted reviews. Music samples with too few reviews are also deleted. The constructed datataset contains over 7.1k samples, 288K reviews, and 3.6M words.

4 Proposed Approach

The proposed approach contains two parts: a label-graph based neural network and a soft training mechanism with continuous label representation. An illustration of the proposed method is shown in Figure 1.

4.1 Label-Graph Based Neural Network

The first layer is a hierarchical attention layer (Yang et al., 2016) that lets the model to pay more or less attention to individual words

---

[3] `https://music.douban.com`

[4] Alternative Music, Britpop, Classical Music, Country Music, Dark Wave, Electronic Music, Folk Music, Heavy Metal Music, Hip-Hop, Independent Music, Jazz, J-Pop, New-Age Music, OST, Piano Music, Pop, Post-Punk, Post-Rock, Punk, R&B, Rock, and Soul Music.

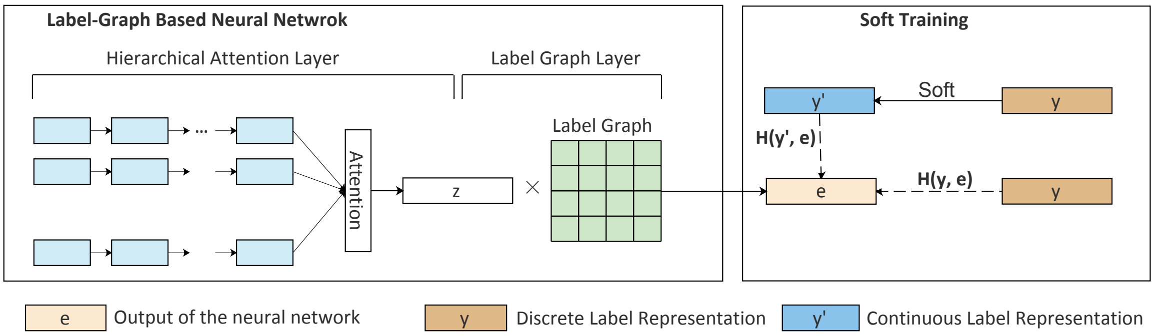

Figure 1: An illustration of the proposed approach. Left: The label-graph based neural network. Right: The soft training method. The label graph defines the relations of labels. $\boldsymbol{e}$ is the label probability distribution. Soft training means that we combine the continuous label representation $\boldsymbol{y}'$ and the discrete label representation $\boldsymbol{y}$ together to train the model. The hierarchical attention layer is responsible for extracting style-related information. The label graph layer and soft training are used for exploiting label correlations.

and reviews when constructing "raw" label probability distribution $\boldsymbol{z}$.

Label Graph. To explicitly take advantage of the label correlations when classifying music styles, we add a label graph layer to the network. This layer takes $\boldsymbol{z}$ as input and generates a "soft" label probability distribution $\boldsymbol{e}$.

Formally, we denote $\mathcal{G} \in R_{m \times m}$ as the label graph, where m is the number of labels, $\mathcal{G}$ is initialized by an identity matrix. An element $\mathcal{G}[l_i, l_j]$ is a real-value score indicating how likely label l_i and label l_j are related. The graph $\mathcal{G}$ is a part of parameters and can be learned by back-propagation.

Then, given the "raw" label probability distribution $\boldsymbol{z}$ and the label graph $\mathcal{G}$, the output of this layer is:

$$\boldsymbol{e} = \mathrm{sigmoid}(\boldsymbol{z} \cdot \mathcal{G}). \tag{1}$$

The probability of l_j is not only determined by the current classification result, but also determined by other labels probabilities and their correlations to l_j. For example, the probability of a label heavily linked with many high-probability labels will be increased.

4.2 Soft Training

Given a predicted label probability distribution $\boldsymbol{e}$ and a target discrete label representation $\boldsymbol{y}$, the typical loss function is computed as

$$L(\theta) = \mathcal{H}(\boldsymbol{y}, \boldsymbol{e}) = -\sum_{i=1}^{m} y_i \log e_i, \tag{2}$$

where θ denotes all parameters, and m is the number of the labels. The function $\mathcal{H}$ denotes the cross entropy between two distributions.

However, the widely used discrete label representation does not apply to the task of music style classification, because the music styles are not mutually exclusive and highly related to each other. The discrete distribution without label relations makes the model over-distinguish the related labels. Therefore, it is hard for the model to learn the label correlations.

Instead, we propose a soft training method by combining a discrete label representation $\boldsymbol{y}$ with a correlated-based continuous label representation $\boldsymbol{y}'$. The probability gap between two similar labels in $\boldsymbol{y}'$ should not be large.

A straight-forward approach to produce the continuous label representation is to use the label graph matrix $\mathcal{G}$ to transform the discrete representation $\boldsymbol{y}$ into a continuous form:

$$\boldsymbol{y}' = \boldsymbol{y} \cdot \mathcal{G}. \tag{3}$$

Based on the discrete label representation $\boldsymbol{y}$ and continuous label representation $\boldsymbol{y}'$, we define the loss function as

$$Loss(\theta) = \mathcal{H}(\boldsymbol{e}, \boldsymbol{y}) + \mathcal{H}(\boldsymbol{e}, \boldsymbol{y}'), \tag{4}$$

where the loss $\mathcal{H}(\boldsymbol{e}, \boldsymbol{y})$ aims to correctly classify labels, and the loss $\mathcal{H}(\boldsymbol{e}, \boldsymbol{y}')$ aims to avoid the over-distinguishing problem and to better learn label correlations.

5 Experiment

In this section, we evaluate our approach on the proposed dataset. We first introduce evaluation metrics, then show experiment results and give a detailed analysis. The training details can be found at Appendices.

Models	**OE(-)**	**HL(-)**	**Macro F1(+)**	**Micro F1(+)**
ML-KNN	77.3	0.094	23.6	38.1
Binary Relevance	74.4	0.083	24.7	41.8
Classifier Chains	67.5	0.107	29.9	44.3
Label Powerset	56.2	0.096	37.7	50.3
MLP	71.5	0.081	29.8	45.8
CNN	37.9	0.099	32.5	49.3
LSTM	30.5	0.089	33.0	53.9
HAN	25.9	0.079	52.1	61.0
+Label Graph	23.4	0.077	54.2	62.8
+ Soft Training	**22.6**	**0.074**	**54.4**	**64.5**

Table 2: Comparisons between our approach and the baselines on the test set. OE and HL denote one-error and hamming loss respectively. HAN denotes the hierarchical attention network. "(+)" represents that higher scores are better and "(-)" represents that lower scores are better. It can be seen that the proposed approach significantly outperforms the baselines.

5.1 Evaluation Metrics

Multi-label classification requires different evaluation metrics compared with traditional single-label classification. In this paper, we use the following widely-used evaluation metrics for multi-label classification.

- F1-score: We calculate macro F1 and micro F1, respectively. Macro F1 computes the metric independently for each label and then takes the average as the final score. Micro F1 aggregates the contributions of all labels to compute the average score.
- One-Error: One-error evaluates the fraction of examples whose top-ranked label is not in the gold label set.
- Hamming Loss: Hamming loss counts the fraction of the wrong labels to the total number of labels.

5.2 Baselines

We implement several widely-used multi-label classification methods as baselines, such as ML-KNN (Zhang and Zhou, 2007), Binary Relevance (Tsoumakas et al., 2010), Classifier Chains (Read et al., 2011), Label Powerset (Tsoumakas and Vlahavas, 2007). The details of baselines can be found at Appendices.

5.3 Results

The results on the test set are summarized in Table 2. The proposed approach significantly outperforms the baselines, with micro F1 of 64.5, macro F1 of 54.4, and one-error of 22.6, improving the metrics by 10.6, 21.4, and 7.9 respectively. The improvements are attributed to two parts, a hierarchical attention network and a label correlation mechanism. Only using the hierarchical attention network outperforms the baselines, which shows the effectiveness of hierarchically paying attention to different words and sentences. The greater F1-score is achieved by adding the proposed label graph, which demonstrates that the proposed label graph helps a lot by taking advantage of label correlations.

It can be clearly seen that with the help of soft training, the proposed method achieves the best performance. Especially, the micro F-score is improved from 62.8 to 64.5, and the one-error is reduced from 23.4 to 22.6. With the new loss function, the model not only knows how to distinguish the right labels from the wrong ones, but also can learn the label correlations that are useful knowledge, especially when the input data contains too much style unrelated words for the model to extract all necessary information.

5.4 Visualization Analysis

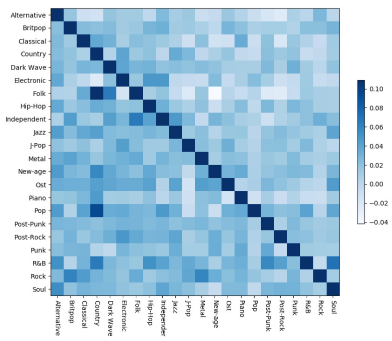

Figure 2: A heatmap of the automatically learned label graph. Deeper color represents closer relation. We can see that some obvious relations are well captured by the model, e.g., "Heavy Metal Music (Metal)" and "Rock", "Country Music (Country)" and "Folk".

Figure 2 shows a whole heatmap of the automatically learned label graph, for convenience of display, we have subtracted the label graph by an identity matrix. We can see from the picture that some obvious music style relations are well captured. For "Country Music", the most related label is "Folk Music". In reality, these two music styles are highly similar and the boundary between them is not well-defined. For three kinds of rock music, "Heavy Metal Music", "Britpop Music", and "Alternative Music", the label graph correctly captures that the most related label for them is “Rock”. For a more complicated relation where “Soul Music” is highly linked with two different labels, “R&B” and “Jazz”, the label graph also correctly capture such relation. These examples demonstrate that the proposed approach performs well in capturing relations among music styles.

5.5 Selected Exmaples

Ground Truth	Without LCM	With LCM
Britpop[5], Rock	Britpop	Britpop, Rock
Hip-Hop[6], Pop, R&B[7]	Electronic Music, Pop	Pop, R&B
Pop, R&B	Pop, Rock, Britpop	Pop, R&B
Country Music, Folk, Pop	Country Music, Pop	Country Music, Pop, Folk
Classical Music, New-Age Music[8], Piano Music	Piano Music, Classical Music	Piano Music, New-Age Music, Classical Music

Table 3: Examples generated by the methods with and without the label correlation mechanism (LCM). The labels correctly predicted by two methods are shown in blue. The labels correctly predicted by the method with the label correlation mechanism are shown in orange. We can see that the method with the label correlation mechanism classifies music styles more precisely.

For clearer understanding, we compare several examples generated with and without the label correlation mechanism in Table 3. By comparing gold labels and predicted labels generated by different methods, we find that the proposed label correlation mechanism identifies the related styles more precisely. This is mainly attributed to the learned label correlations. For example, the correct prediction in the first example shows that the label correlation mechanism captures the close relation between “Britpop” and “Rock”, which helps the model to generate an appropriate prediction.

5.6 Error Analysis

Although the proposed method has achieved significant improvements, we also notice that there are some failure cases. In this section, we give the detailed error analysis.

First, the proposed method performs worse on the styles with low frequency in the training set. Table 4 compares the performance on the top 5 music styles of highest and lowest frequencies. As we can see, the top 5 fewest music styles get much worse results than top 5 most music styles. This is because the label distribution is highly imbalanced where unpopular music styles have too little training data.

Second, we find that some music items are wrongly classified into the styles that are similar with the gold styles. For example, a sample with a gold set [Country Music] is wrongly classified into [Folk] by the model. The reason is that some music styles share many common elements and only subtly differ from each other. It poses a great challenge for the model to distinguish them. For future work, we would like to research how to effectively address this problem.

Most Styles	% of Samples	Micro F1
Rock	30.4	75.8
Independent Music	30.0	64.8
Pop	26.2	67.1
Folk Music	21.9	73.7
Electronic Music	13.9	61.8
Fewest Styles	**% of Samples**	**Micro F1**
Jazz	4.3	37.5
Heavy Metal Music	3.9	55.6
Hip-Hop	3.1	7.5
Post-punk	2.5	17.1
Dark Wave	1.3	17.4

Table 4: The performance of the proposed method on the most and fewest styles.

6 Conclusions

In this paper, we focus on classifying multi-label music styles with user reviews. To meet the challenge of label correlations, we propose a label-graph neural network and a soft training mechanism. Experiment results have showed the effectiveness of the proposed approach. The visualization of label graph also shows that our method performs well in capturing label correlations.

A Appendices

A.1 Training Details

In the proposed method and baselines, we use skip gram (Mikolov et al., 2013) to get pre-trained word embeddings of reviews. The Jieba toolkit is used to split sentences into words. To help with the training of the label graph, we use soft target mechanism on the continuous label representations (Hinton et al., 2015; Sun et al., 2017; Liu et al., 2017) and add the negative of the l2 loss of the difference between the label graph and the identity matrix to the loss function. For evaluation, we introduce a hyper-parameter p. If the probability of a style is greater than p, we consider it as one of the final music styles. We tune hyper-parameters based on the performance on the validation set. We set p to 0.2, hidden size to 128, embedding size to 128, vocabulary size to 135K, learning rate to 0.001, and batch size to 128. The optimizer is Adam (Kingma and Ba, 2014) and the maximum training epoch is set to 100. We choose parameters with the best Micro F1 scores on the validation set and then use the selected parameters on the test set.

A.2 Baselines

We implement the following widely-used multi-label classification methods for comparison. Their inputs are the music representations which are produced by averaging review representations. The review representation is obtained by averaging word embeddings.

- ML-KNN (Zhang and Zhou, 2007): It is a multi-label learning approach derived from the traditional K-Nearest Neighbor (KNN) algorithm.
- Binary Relevance (Tsoumakas et al., 2010): It decomposes a multi-label learning task into a number of independent binary learning tasks. It learns several single binary models without considering the dependencies among labels.
- Classifier Chains (Read et al., 2011): It takes label dependencies into account and keeps the computational efficiency of the binary relevance method.
- Label Powerset (Tsoumakas and Vlahavas, 2007): All classes assigned to an example are combined into a new and unique class in this method.
- MLP: It feeds the music representations into a multi-layer perceptron, and generates the probability of music styles through a sigmoid layer.

Different from the above baselines, the following two methods only take word embeddings as inputs. Similar to MLP, they produce label probability distribution by a sigmoid function.

- CNN: It includes two layers of CNN which has multiple convolution kernels.
- LSTM: It includes two layers of LSTM, which processes words and sentences separately to get the music representations.

Fact Discovery from Knowledge Base via Facet Decomposition

Abstract

During the past few decades, knowledge bases (KBs) have experienced rapid growth. Nevertheless, most KBs still suffer from serious incompletion. Researchers proposed many tasks such as knowledge base completion and relation prediction to help build the representation of KBs. However, there are some issues unsettled towards enriching the KBs. Knowledge base completion and relation prediction assume that we know two elements of the fact triples and we are going to predict the missing one. This assumption is too restricted in practice and prevents it from discovering new facts directly. To address this issue, we propose a new task, namely, fact discovery from knowledge base. This task only requires that we know the head entity and the goal is to discover facts associated with the head entity. To tackle this new problem, we propose a novel framework that decomposes the discovery problem into several facet discovery components. We also propose a novel autoencoder based facet component to estimate some facets of the fact. Besides, we propose a feedback learning component to share the information between each facet. We evaluate our framework using a benchmark dataset and the experimental results show that our framework achieves promising results. We also conduct extensive analysis of our framework in discovering different kinds of facts. The source code of this paper can be obtained from `https://github.com/thunlp/FFD`.

1 Introduction

Recent years have witnessed the emergence and growth of many large-scale knowledge bases (KBs) such as Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2015), YAGO (Suchanek et al., 2007) and Wikidata (Vrandečić and Krötzsch, 2014) to store facts of the real world. Most KBs typically organize the complex structured information about facts in the form of triples (*head entity*, `relation`, *tail entity*), e.g., (*Bill Gates*, `CEOof`, *Microsoft Inc.*). These KBs have been widely used in many AI and NLP tasks such as text analysis (Berant et al., 2013), question answering (Bordes et al., 2014a), and information retrieval (Hoffmann et al., 2011).

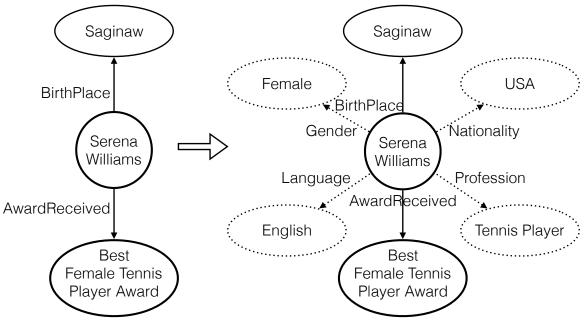

Figure 1: In the FDKB task, only the head entity is given. The relation and tail entity should be discovered simultaneously given the head entity.

The construction of these KBs is always an ongoing process due to the endless growth of real-world facts. Hence, many tasks such as knowledge base completion (KBC) and relation prediction (RP) are proposed to enrich KBs.

The KBC task usually assumes that one entity and the relation r are given, and another entity is missing and required to be predicted. In general, we wish to predict the missing entity in $(h, r, ?)$ or $(?, r, t)$, where h and t denote a head and tail entity respectively. Similarly, the RP task predicts the missing relation given the head and tail entities and their evidence sentences, i.e. filling $(h, ?, t)$. Nevertheless, the assumption of knowing two parts of the triple is too strong and is usually restricted in practice.

In many cases, we only know the entity of in-

Proceedings of NAACL-HLT 2019, pages 2892–2901
Minneapolis, Minnesota, June 2 - June 7, 2019.

terest, and are required to predict both its attributive relations and the corresponding entities. As shown in Figure 1, the task is to predict the fact triples when given only the head entity, i.e. filling $(h, ?, ?)$. Since any entity can serve as the head entity for identifying its possible fact triples, this task should be more practical for real-world settings. This task is non-trivial since less information is provided for prediction. We name the task as Fact Discovery from Knowledge Base (FDKB).

Some existing methods such as knowledge base representation (KBR) can be applied to tackle the FDKB task with simple modifications. KBR models typically embed the semantics of both entities and relations into low-dimensional semantic space, i.e., embeddings. For example, TransE (Bordes et al., 2013) learns low-dimensional and real-valued embeddings for both entities and relations by regarding the relation of each triple fact as a translation from its head entity to the tail entity. TransE can thus compute the valid score for each triple by measuring how well the relation can play a translation between the head and tail entities. Many methods have been proposed to extend TransE to deal with various characteristics of KBs (Ji et al., 2015, 2016; He et al., 2015; Lin et al., 2015a).

To solve the FDKB task using KBR, one feasible way is to exhaustively calculate the scores of all (r, t) combinations for the given head entity h. Afterwards, the highly-scored facts are returned as results. However, this idea has some drawbacks: (1) It takes all relations to calculate ranking scores for each head entity, ignoring the nature of the head entity. The combination of all possible relations and tail entities will lead to huge amount of computations. (2) A large set of candidate triples immerses the correct triples into a lot of noisy triples. Although the probability of invalid facts getting a high score is small, with the large size of the candidate set, the total number of invalid facts with high score is non-negligible.

To address the above issues, we propose a new framework named as fact facet decomposition (FFD). The framework follows human being's common practice to identify unknown facts: One typically firstly investigates which relation that a head may have, and then predicts the tail entity based on the predicted relation. This procedure actually utilizes information from several perspectives. Similarly, FFD decomposes fact discovery into several facets, i.e., head-relation facet, tail-relation facet, and tail inference facet, and model each facet respectively. The candidate fact is considered to be correct when all of the facets are trustworthy. We propose a novel auto-encoder based entity-relation component to discover the relatedness between entities and relations. Besides, we also propose a feedback learning component to share the information between each facet.

We have conducted extensive experiments using a benchmark dataset to show that our framework achieves promising results. We also conduct an extensive analysis of the framework in discovering different kinds of facts. The contributions of this paper can be summarized as follows: (1) We introduce a new task of fact discovery from knowledge base, which is more practical. (2) We propose a new framework based on the facet decomposition which achieves promising results.

2 Related Work

In recent years, many tasks (Wang et al., 2017) have been proposed to help represent and enrich KBs. Tasks such as knowledge base completion (KBC) (Bordes et al., 2013; Wang et al., 2014; Ji et al., 2015, 2016; Wang et al., 2017) and relation prediction (RP) (Mintz et al., 2009; Lin et al., 2015a; Xie et al., 2016) are widely studied and many models are proposed to improve the performance on these tasks. However, the intention of these tasks is to test the performance of models in representing KBs and thus they cannot be used directly to discover new facts of KBs. Moreover, our FDKB task is not a simple combination of the KBC and RP task since both of these two tasks require to know two of the triples while we assume we only know the head entity.

A common approach to solving these tasks is to build a knowledge base representation (KBR) model with different kinds of representations. Typically, one element of the triples is unknown. Then, all entities are iterated on the unknown element and the scores of all combinations of the triples are calculated and then sorted.

Many works focusing on KBR attempt to encode both entities and relations into a low-dimensional semantic space. KBR models can be divided into two major categories, namely translation-based models and semantic matching models (Wang et al., 2017).

Translation-based models such as TransE (Bordes et al., 2013) achieves promising performance in KBC with good computational efficiency. TransE regards the relation in a triple as a translation between the embedding of head and tail entities. It means that TransE enforces that the head entity vector plus the relation vector approximates the tail entity vector to obtain entity and relation embeddings. However, TransE suffers from problems when dealing with 1-to-N, N-to-1 and N-to-N relations. To address this issue, TransH (Wang et al., 2014) enables an entity to have distinct embeddings when involving in different relations. TransR (Lin et al., 2015b) models entities in entity space and uses transform matrices to map entities into different relation spaces when involving different relations. Then it performs translations in relation spaces. In addition, many other KBR models have also been proposed to deal with various characteristics of KBs, such as TransD (Ji et al., 2015), KG2E (He et al., 2015), PTransE (Lin et al., 2015a), TranSparse (Ji et al., 2016).

Semantic matching models such as RESCAL (Nickel et al., 2011), DistMult(Yang et al., 2014), Complex (Trouillon et al., 2016), HolE (Nickel et al., 2016) and ANALOGY (Liu et al., 2017) model the score of triples by the semantic similarity. RESCAL simply models the score as a bilinear projection of head and tail entities. The bilinear projection is defined with a matrix for each relation. However, the huge amount of parameters makes the model prone to overfitting. To alleviate the issue of huge parameter space, DistMult is proposed to restrict the relation matrix to be diagonal. However, DistMult cannot handle the asymmetric relations. To tackle this problem, Complex is proposed assuming that the embeddings of entities and relations lie in the space of complex numbers. This model can handle the asymmetric relations. Later, Analogy is proposed by imposing restrictions on the matrix rather than building the matrix with vector. It achieves the state-of-the-art performance. Besides, (Bordes et al., 2011; Socher et al., 2013; Chen et al., 2013; Bordes et al., 2014b; Dong et al., 2014; Liu et al., 2016) conduct the semantic matching with neural networks. An energy function is used to jointly embed relations and entities.

3 Problem Formulation

We denote $\mathcal{E}$ as the set of all entities in KBs, $\mathcal{R}$ is the set containing all relations. $|\mathcal{E}|$ and $|\mathcal{R}|$ stand for the size of each set respectively. A fact is a triple (h, r, t) in which $h, t \in \mathcal{E}$ and $r \in \mathcal{R}$. $\mathcal{T}$ is the set of all true facts.

When a head entity set $\mathcal{H}$ is given, a new fact set is to be discovered based on these head entities. The discovered fact set is denoted as $\mathcal{T}_d = \{(h, r, t) | h \in \mathcal{H}\}$. Our goal is to find a fact set $\mathcal{T}_d$ that maximize the number of correct discovered facts:

$$\begin{aligned} &\max_{\mathcal{T}_d} |\mathcal{T}_d \cap \mathcal{T}| \\ &\text{s.t. } |\mathcal{T}_d| = K, \end{aligned} \tag{1}$$

in which K is a user-specified size.

4 Methodology

4.1 Fact Facet Decomposition Framework

Problem (1) is intractable since the set $\mathcal{T}$ is unknown. We tackle this problem by estimating a fact confidence score function $c(h, r, t)$ for each fact in $\mathcal{T}_d$ and maximize the total score. The problem is then formulated as:

$$\begin{aligned} &\max_{\mathcal{T}_d} \sum_{(h,r,t) \in \mathcal{T}_d} c(h, r, t) \\ &\text{s.t. } |\mathcal{T}_d| = K. \end{aligned} \tag{2}$$

To integrate the information from various facets of the fact, our framework, known as Fact Facet Decomposition (FFD) framework, decomposes the fact discovery problem into several facet-oriented detection tasks. A fact is likely to be correct if all facets provide supportive evidence. The facets are as follows:

1. Head-relation facet: A fact is likely true, if the head entity has a high probability of containing the relation. This is denoted as $f_h(r)$;
2. Tail-relation facet: A fact is likely true, if the tail entity has a high probability of containing the relation. This is denoted as $f_t(r)$;
3. Tail inference facet: A fact is likely true, if the score of the tail entity is high with respect to the given head and relation. This is denoted as $f_{h,r}(t)$.

Therefore, the facet confidence score can be expressed as:

$$c(h, r, t) = \lambda_1 f_h(r) + \lambda_2 f_t(r) + \lambda_3 f_{h,r}(t), \tag{3}$$

where $\lambda_1, \lambda_2, \lambda_3$ are weight parameters. The head-relation facet and the tail-relation facet can be both

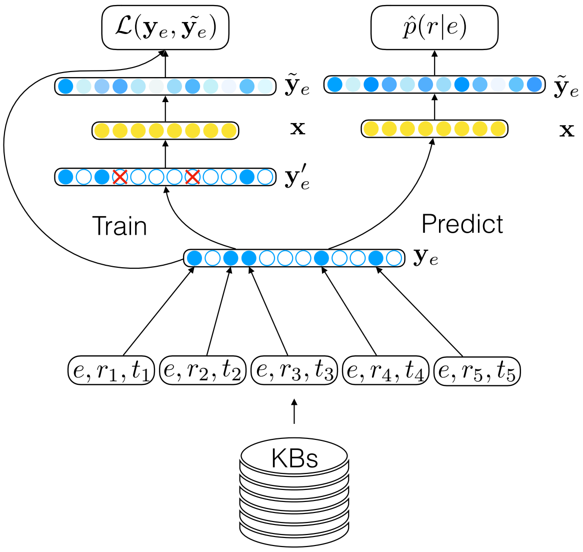

Figure 2: The structure of the entity-relation component.

modeled with an entity-relation facet component. The tail inference facet can be modeled by a KBR component.

4.1.1 Entity-relation Facet Component

The entity-relation component estimates the probability of a relation given an entity. The structure is shown in Figure 2. It is modeled as the log of the estimated conditional probability:

$$f_e(r) = \log \hat{p}(r|e), \tag{4}$$

where $e = h$ or t. $\hat{p}(r|e)$ aims at measuring the probability of a relation that this entity may have. In order to estimate this probability, the existing relations of a head or tail entity is used to infer other related relations. For example, if a head entity has an existing fact in which the relation is "BirthPlace", we may infer that this head entity may be a person and some relations such as "Gender", "Language" may have a high probability of association with this head entity. Therefore, the problem is transformed into a problem that estimates the relatedness between relations. To infer the probability of each relation based on existing relations, we employ a denoising auto-encoder (Vincent et al., 2008) which can recover almost the same representation for partially destroyed inputs. Firstly, facts related to an entity is extracted from the KBs. Then, this entity is encoded by the existing relations. Let $\mathbf{y}_e \in \mathbb{R}^{|\mathcal{R}|}$ be the 0-1 representation of relations that e has. $\mathbf{y}_{ei}$ indicates whether the entity e has the relation i or not. During the training phase, non-zero elements in $\mathbf{y}_e$ is randomly set to zero and the auto-encoder is trained to recover the corrupted elements. The corrupted vector is denoted as $\mathbf{y}'_e$.

Formally, our structure encoder first maps the corrupted one-hot vector $\mathbf{y}'_e$ to a hidden representation $\mathbf{x} \in \mathbb{R}^{d_1}$ of the entity through a fully connected layer:

$$\mathbf{x} = \tanh(\mathbf{W}_f \mathbf{y}'_e + \mathbf{b}_f), \tag{5}$$

where $\mathbf{W}_f \in \mathbb{R}^{d_1 \times |\mathcal{R}|}$ is the translation matrix and $\mathbf{b}_f \in \mathbb{R}^{d_1}$ is the bias vector. $\mathbf{x}$ is the vector representation of the entities in a hidden semantic space. In this space, similar entities are close to each other while entities of different types are far from each other. If some relations are missing, the fully connected layer will also map the entity into a nearby position.

Afterwards, $\mathbf{x}$ is used to recover the probability distribution for all relations through a fully connected layer and a sigmoid layer:

$$\tilde{\mathbf{y}}_e = \mathrm{sigmoid}(\mathbf{W}_g \mathbf{x} + \mathbf{b}_g), \tag{6}$$

where $\mathbf{W}_g \in \mathbb{R}^{|\mathcal{R}| \times d_1}$ and $\mathbf{b}_g \in \mathbb{R}^{|\mathcal{R}|}$ is the weight matrix and bias vector of the reverse mapping respectively. $\tilde{\mathbf{y}}_e$ is the recovered probability distribution of each relation (therefore, the sum of each element in $\tilde{\mathbf{y}}_e$ does not necessarily equal to 1). This layer will map the entity representation in the semantic space into a probability vector over all relations. Since similar entities are located in the adjacent area, they are likely to have a similar relation probability. Therefore, the probability of missing relations will also be high though the relations are unknown.

We use the original one-hot representation of the relations and the recovered relation probability to calculate a loss function:

$$\begin{aligned}\mathcal{L}(\mathbf{y}_e, \tilde{\mathbf{y}}_e) = -\sum_{e=1}^{|\mathcal{E}|}\sum_{i=1}^{|\mathcal{R}|}\{\mathbf{y}_{ei}\log(\tilde{\mathbf{y}}_{ei}) + \\ (1-\mathbf{y}_{ei})\log(1-\tilde{\mathbf{y}}_{ei})\}.\end{aligned} \tag{7}$$

The loss function forces the output $\tilde{\mathbf{y}}_{ei}$ to be consistent with $\mathbf{y}_{ei}$ which makes it capable to discover all related relations from known relations. It can be optimized with an Adam (Kingma and Ba, 2015) based optimizer.

When predicting new facts, the one-hot representation $\mathbf{y}_e$ is sent into the auto-encoder directly instead of using the corrupted representation. The result $\tilde{\mathbf{y}}_e$ is the estimated probability of each relation, i.e.

$$\hat{p}(r = i|e) = \tilde{\mathbf{y}}_{ei}. \tag{8}$$

This probability will be high if relation i is closely related to the existing relations of the entity e.

4.1.2 Tail Inference Facet Component

We use a KBR component to model the tail inference facet $f_{h,r}(t)$. Three KBR models are investigated namely DistMult, Complex, and Analogy.

The DistMult model defines the score function as $f_r(h,t) = \mathbf{h}^T \text{diag}(\mathbf{r})\mathbf{t}$, in which $\mathbf{h}, \mathbf{r}, \mathbf{t}$ are vector representation of the head, relation and tail respectively. The learning objective is to maximize the margin between true facts and false facts. It can decrease the score of the wrong facts and increase the the score of the true facts at the same time.

The Complex model employs complex number as the KBR embedding. Therefore, the score function is defined as $f_r(h,t) = \text{Re}(\mathbf{h}^T \text{diag}(\mathbf{r})\bar{\mathbf{t}})$, in which $\mathbf{h}, \mathbf{r}, \mathbf{t}$ are complex vectors and $\bar{\mathbf{t}}$ stands for the conjugate of $\mathbf{t}$.

The Analogy model does not restrict the relation matrix to be diagonal. Therefore, the score function is $f_r(h,t) = \mathbf{h}^T \mathbf{M_r} \mathbf{t}$, in which $\mathbf{M_r}$ is the matrix corresponding to the relation r. Since many relations satisfy normality and commutativity requirements, the constraints can thus be set as $W_r W_r^T = W_r^T W_r, \forall r \in \mathcal{R}$ and $W_r W_{r'} = W_{r'} W_r, \forall r, r' \in \mathcal{R}$. Solving such a problem is equivalent to optimizing the same objective function with the matrix constrained to almost-diagonal matrices(Liu et al., 2017).

After the score function is calculated, the tail inference facet $f_{h,r}(t)$ is modeled by a softmax function:

$$f_{h,r}(t) = \log \hat{p}(t|h,r) = \log \frac{e^{f_r(h,t)}}{\sum_{t' \in \mathcal{E}} e^{f_r(h,t')}}. \tag{9}$$

It should be noted that the normalizing step is only conducted on the tail entities since the head and relation are the input of the model. We only use these three models due to the limited space. Other models can be embedded into our framework easily in the same way.

4.2 Fact Discovery Algorithm

As mentioned above, we need to calculate $f_h(r)$, $f_t(r)$ and $f_{h,r}(t)$. $f_h(r)$ and $f_t(r)$ are computed by the entity-relation component while $f_{h,r}(t)$ is computed by the tail inference component. Recall that a fact is likely to be true when all the facets exhibit strong support. In other words, we can prune away the fact if one of the facets is low and stop calculating other facets. Based on this strategy, we design two additional constraints on Problem (2). Therefore, this method can be viewed as a shrink of the constraint space of the optimization problem. The new problem can be expressed as:

$$\begin{aligned} \max_{\mathcal{T}_d} \quad & \sum_{(h,r,t) \in \mathcal{T}_d} \{\lambda_1 f_h(r) + \lambda_2 f_t(r) + \lambda_3 f_{h,r}(t)\} \\ \text{s.t.} \quad & h \in \mathcal{H}; |\mathcal{T}_d| = K \\ & f_h(r) > \tau_h; \ \sum_r \mathbb{1}(f_h(r) > \tau_h) = n_h \\ & f_t(r) > \tau_t; \ \sum_r \mathbb{1}(f_t(r) > \tau_t) = n_t, \end{aligned} \tag{10}$$

where $\mathbb{1}_A(x)$ is an indicator function. $\mathbb{1}_A(x) = 1$ if $x \in A$ and $\mathbb{1}_A(x) = 0$ otherwise. n_h and n_t are the user-specified parameters indicating top-n_h or top-n_t relations are considered. λ_1, λ_2 and λ_3 are fixed hyperparameters.

Problem (10) is actually a mixed integer linear programming problem. We start to solve this problem from the constraints. Since $f_t(r)$ is independent of the given $\mathcal{H}$, it can be preprocessed and can be reused for other queries. When a head entity h is given, we firstly calculate $f_h(r)$ and get top-n_h relations ranked by $f_h(r)$. Then, for each relation, $f_t(r)$ is used to get the top-n_t entities. Afterwards, the tail inference facet $f_{h,r}(t)$ will be calculated for all remaining relations and entities and top-n_f triples will be cached. Finally, top-$\bar{K}$ facts ranked by the facet confidence score $c(h,r,t)$ is returned as the new facts discovered for the entity h, where $\bar{K} = K/|\mathcal{H}|$ stands for the average fact number for each head entity.

4.3 Feedback Learning

The three facets depict the characteristics of the KBs from different perspectives. For example, the head-relation facet indicates which relation the head entity may have. The tail-relation facet can be interpreted in a similar manner. We propose a feedback learning (FL) component for the facets to share the information in different perspective with each other. FL feeds the predicted facts back to the training set to enhance the training procedure and iterates predicting and training several times. In the iteration, the information from different perspectives is shared with each facet via the newly added facts.

Specifically, after predicting the top-n_h facts for each head entity, we select top-n_{fb} ($n_{fb} < n_h$) most probable facts according to the score of each triple and then feed them into the existing knowledge base for re-training the FFD model. We repeat the above updating operation several rounds.

5 Experiment

5.1 Dataset

We evaluate our framework by re-splitting a widely used dataset FB15k (Bordes et al., 2013), which is sampled from Freebase. It contains $1,345$ relations and $14,951$ entities. In FB15k, some of the testing set's head entities do not appear in the training set as head. To evaluate our framework, we construct the new dataset. We re-split FB15k into training ($\mathcal{T}_{train}$), validation ($\mathcal{T}_{valid}$) and testing ($\mathcal{T}_{test}$) set, and make sure that there is no overlap between the three sets. For all head entities in $\mathcal{H}$, a relation ratio $R\%$ is used to assign the facts into training and testing set. $R\%$ relations of a head entity are in the training set while the other $1 - R\%$ are in the testing set. In order to evaluate the task, we require that the head entities in $\mathcal{H}$ is the same as the testing head entity and is a subset of the training head set, i.e. $\mathcal{H} = \{h|(h,r,t) \in \mathcal{T}_{test}, \exists r,t \in \mathcal{E}\} \subset \{h|(h,r,t) \in \mathcal{T}_{train}, \exists r,t \in \mathcal{E}\}$. We set $R = 50$. After the splitting, the training, testing and validation set size is $509,339$, $41,861$ and $41,013$ respectively.

5.2 Comparison Models

To demonstrate the effectiveness of our framework, we provide several strong comparison models that can be used in solving this task.

5.2.1 Matrix Factorization Models (SVD and NMF)

MF models firstly count the frequency of all relation-tail pairs. Some low-frequency relation-tail pairs are ignored to save computational time. Afterwards, we build a (head, relation-tail) co-occurrence matrix $M^C \in \mathbb{R}^{|\mathcal{E}| \times p}$, in which p is the size of the relation-tail pair set. Each element M^C_{ij} in the matrix represents whether the head entity i has the relation-tail pair j or not. Then, the matrix will be decomposed by the product of two matrices, i.e.

$$M^C \approx WH, \tag{11}$$

in which $W \in \mathbb{R}^{|\mathcal{E}| \times k}, H \in \mathbb{R}^{k \times p}$. k is the hidden category number of the head and relation-tail pairs. The decomposition can be achieved in several ways with different assumptions. Two kinds of matrix decomposition models are used namely SVD (Halko et al., 2011) and NMF (Lee and Seung, 1999).

In the prediction stage, a new matrix is constructed by $M'^C = WH$. For each row in M'^C, we record top-$\bar{K}$ relation-tail pairs and their scores. The MF models always suffer from the sparsity problem since a lot of relation-tail pairs are ignored.

5.2.2 KBR+ Models (DistMult+, Complex+ and Analogy+)

The most straightforward method of estimating the fact confidence score $c(h,r,t)$ is to use KBR model directly to evaluate each triples' score. We exhaustively score all possible combinations of relations and tails and use the highly-scored facts to make up the set $\mathcal{T}_d$. We select some state-of-the-art models including DistMult (Yang et al., 2014), Complex (Trouillon et al., 2016) and Analogy (Liu et al., 2017). We denote them as DistMult+, Complex+ and Analogy+.

After a KBR model learns a score function $f_r(h,t)$, the probability of each (r,t) pair with respect to a given head entity can be estimated by a softmax function:

$$\hat{p}(r,t|h) = \frac{e^{f_r(h,t)}}{\sum_{r' \in \mathcal{R}} \sum_{t' \in \mathcal{E}} e^{f_{r'}(h,t')}}. \tag{12}$$

Afterwards, the score of each fact is sorted and top-$\bar{K}$ relation-tail pairs for a head entity are regarded as the predicted results.

5.3 Experimental Setup

There are 2,000 head entities in the testing set. Therefore, we predict the corresponding relation and tail entity with respect to these 2,000 head entities. In MF models, only relation-tail pairs that occur more than 3 times in the training set are considered (24,615 pairs in total). For each head entity, we set $\bar{K} = 50$. In KBR+, we also set $\bar{K} = 50$. For our framework, we set $n_h = n_t = 30$, $n_f = 10$, $\bar{K} = 50$, $\lambda_1 = 1.0$, $\lambda_2 = 1.0$, $\lambda_3 = 0.5$. The auto-encoder iterates for 1,000 epochs and the learning rate for Adam is 0.005. For the feedback learning component, we set $n_{fb} = 20,000$. With this setting, each model returns 100,000 facts.

We use four evaluation metrics, including precision, recall MAP, and F1 in relation prediction. Precision is defined as the ratio of the true positive candidates' count over the number of all the retrieved candidates' count. Recall is defined as the ratio of the true positive candidates' count over all the positive facts' count in the testing set. MAP (Manning et al., 2008) is a common evaluation method in information retrieval tasks. F1 is defined as the harmonic mean of the precision and recall.

5.4 Experimental Results

The experimental result is shown in Table 1. From the experiment result, we observe that:

Method	MAP	precision	recall	F1
SVD	0.0873	0.0897	0.2143	0.1265
NMF	0.0827	0.0857	0.2048	0.1209
DistMult+	0.1086	0.1068	0.2552	0.1506
Complex+	0.2384	0.1608	0.3842	0.2267
Analogy+	0.2367	0.1606	0.3837	0.2265
FFD (DistMult)	0.2486	0.1939	0.4633	0.2734
FFD (Complex)	0.2723	0.1991	0.4758	0.2808
FFD (Analogy)	**0.2769**	**0.2001**	**0.4779**	**0.2821**
FFD (Analogy) w/o FL	0.2308	0.1978	0.4725	0.2788

Table 1: Results of our framework and comparison models.

1. FFD based model outperforms other models in all metrics. It illustrates the advantage of our decomposition design. Moreover, in FFD, using Analogy to predict $c(h, r, t)$ outperforms Complex. One reason is that the discovery algorithm harness the relatively large parameter space of Analogy and avoids some occasionally emerging wrong facts;
2. The relation of the head entity can be correctly predicted. This is because, in training, we remove some relations and the auto-encoder is trained to learn to recover the missing relations based on the remaining relations.
3. The MF based models (i.e. SVD and NMF) perform not as good as KBR+ models and FFD. The reason is partially due to the sparsity problem in MF models. A lot of relation-tail pairs have not been used as the feature and thus cannot be predicted;

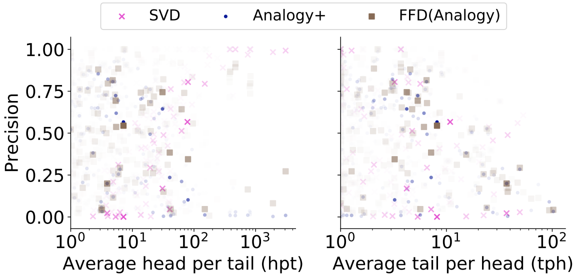

Figure 3: Precision on each relation. Deep color stand for the number of fact is large.

4. Different from the traditional KBC task, Complex performs slightly better than Analogy. One reason is that Analogy's constraint is looser than Complex. Therefore, it may easily predict wrong facts due to error propagation;
5. The ablation experiment shows that the feedback learning can improve the performance effectively.

To illustrate the capability of handling different kinds of relations, we plot the accuracy with respect to different kinds of relations. We use heads per tail (hpt) and tails per head (tph) index to represent the difficulty of each relation. If the relation's index is high, it means that each head of the relation may have more tails or vice versa. These relations are more difficult to predict. This is the similar problem of 1-N, N-1 and N-N relation in KBC task. The plot is shown in Figure 3. From the figure, we can observe that:

1. FFD can be adapted to all kinds of relations with different hpt and tph;
2. MF, KBR+, FFD models can handle relations with relatively high hpt but fail with high tph. This is because our goal is to predict relation and tail based on the head. Therefore, the choice may be harder to make with high tph;
3. As the hpt grows, the precision of SVD model also grows. The reason is that as hpt grows, the sparsity problem is alleviated. Therefore, the performance of SVD grows.

5.5 Sparsity Investigation

The MF model suffers from the sparsity problem since a lot of relation-pair does not appear in the training set. We examine the training set and observe that 97.46% relation-tail pairs does not appear and 0.34% relation-tail pairs appear for only one time. These pairs can hardly provide any information for the MF models either.

Relation Ratio	train	test	valid
10%	451,214	41,861	41,013
20%	462,395		
30%	475,841		
40%	491,498		
50%	509,339		

Table 2: Statistics of dataset with different relation ratio.

To test whether our framework is capable of dealing with the data sparsity problem. We remove training facts which contains head entities in $\mathcal{H}$ according to a specific ratio. We decrease the relation ratio $R\%$ from 50% to 10% to explore the effectiveness of our framework in discovering new facts. The dataset statistics is shown in Table 2. We apply FFD (Analogy) on each dataset. As shown in Table 3, precision, F1 and recall decrease since the data becomes more and more sparse. MAP increase slightly since it is averaged on all extracted facts. When the extracted facts number decreases, some facts rank at the tail with low scores are excluded.

Relation Ratio	MAP	precision	recall	F1
50%	0.2101	0.1851	0.4421	0.2609
40%	0.2099	0.1768	0.4224	0.2493
30%	0.2167	0.1686	0.4029	0.2378
20%	0.2236	0.1623	0.3878	0.2289
10%	0.2497	0.1534	0.3664	0.2162

Table 3: Result of dataset in different relation ratio.

5.6 Case Study

We provide a case study to demonstrate the characteristics of different models and show that our FFD can utilize more information. We choose the head entity "Stanford Law School" (Freebase ID: /m/021s9n). The predicted facts of SVD, Analogy+ and FFD (Analogy) are shown in Table 4. From the table, we can observe that:

1. FFD (Analogy) can predict facts such as ("Located In", "Stanford") and ("Mail Address City", "Stanford") while other methods fail to. It implies that this model can predict some relation with multiple possible tails;

2. Analogy+ outperforms SVD in general while fails to exceed FFD (Analogy). The reason is that it fails to predict some general facts like ("Located In", "USA") or ("Tuition Measurement", "US Dollar"). This may due to the high scores given to some wrong facts;

3. The SVD model can only predict those facts whose relation and tail belong to the selected relation-tail pairs while Analogy+ and FFD (Analogy) can predict more facts;

4. SVD model prefers to predict some basic facts such as "Located In" and "Tuition Measurement". This is because those relations appear a lot of times in the training set and have limited possible tail entities. Therefore, it is easy for SVD model to make such prediction.

6 Conclusions and Future Work

In this paper, we introduce a new task of fact discovery from knowledge base, which is quite important for enriching KBs. It is challenging due to the limited information available about the given entities for prediction. We propose an effective framework for this task. Experimental results on real-world datasets show that our model can effectively predict new relational facts. We also demonstrate that the feedback learning approach is useful for alleviating the issue of data sparsity for the head entities with few facts.

Facts discovery from knowledge base is essential for enriching KBs in the real world. Despite the fact that our work shows some promising results, there still remains some challenges: (1) There exists much more internal information such as relational paths and external information such as text, figures and videos on the web, which can be used to further improve the performance. (2) The feedback learning approach in this paper is to simply utilize those confident predicted relational facts to enhance the model. Reinforcement learning may help us dynamically select those informative and confident relational facts.

Abstract

To extract the relationship between two entities in a sentence, two common approaches are (1) using their shortest dependency path (SDP) and (2) using an attention model to capture a context-based representation of the sentence. Each approach suffers from its own disadvantage of either missing or redundant information. In this work, we propose a novel model that combines the advantages of these two approaches. This is based on the basic information in the SDP enhanced with information selected by several attention mechanisms with kernel filters, namely RbSP (Richer-but-Smarter SDP). To exploit the representation behind the RbSP structure effectively, we develop a combined deep neural model with a LSTM network on word sequences and a CNN on RbSP. Experimental results on the SemEval-2010 dataset demonstrate improved performance over competitive baselines. The data and source code are available at `https://github.com/catcd/RbSP`.

1 Introduction

One of the most fundamental tasks in natural language processing, as well as in information extraction, is Relation Extraction (RE), i.e., determining the semantic relation between pairs of named entities or nominals in a sentence or a paragraph. Take the following sentences from the SemEval-2010 task 8 dataset (Hendrickx et al., 2009) as examples:

(i) We put the soured $[cream]_{e1}$ *in the butter* $[churn]_{e2}$ *and started stirring it.*

(ii) The agitating $[students]_{e1}$ *also put up a* $[barricade]_{e2}$ *on the Dhaka-Mymensingh highway.*

Here the nominals 'cream' and 'churn' in sentence (i) are of relation `Entity-Destination(e1,e2)` while nominals 'students' and 'barricade' in sentence (ii) are of relations `Product-Producer(e2,e1)`.

The research history of RE has witnessed the development as well as the competition of a variety of RE methodologies. All of them are proven to be effective and have different strengths by leveraging different types of linguistic knowledge, however, also suffer from their own limitations. Some early studies stated that the shortest dependency path (SDP) in dependency tree is usually concise and contains essential information for RE (Bunescu and Mooney, 2005; Fundel et al., 2006). By 2016, this approach became dominant with many studies demonstrating that using SDP brings better experimental results than previous approaches that used the whole sentence (Xu et al., 2015a,b; Mehryary et al., 2016; Cai et al., 2016; Le et al., 2018). However, using the SDP may lead to the omission of useful information (i.e., negation, adverbs, prepositions, etc.). Recognizing this disadvantage, some studies have sought to improve SDP approaches, such as adding the information from the sub-tree attached to each node in the SDP (Liu et al., 2015) or applying a graph convolution over pruned dependency trees (Zhang et al., 2018b).

Another approach to extract the relation between two entities is using whole sentence in which both are mentioned. This approach seems to be slightly weaker than using the SDP since not all words in a sentence contribute equally to classify relations and this leads to unexpected noises (Nguyen and Grishman, 2015). However, the emergence and development of attention mechanism (Bahdanau et al., 2015) has re-vitalized this approach. For RE, the attention mechanism is capable of picking out the relevant words concerning target entities/relations, and then we can find critical words which determine primary useful se-

mantic information (Zhou et al., 2016; Verga et al., 2018). We therefore need to determine the object of attention, i.e., nominals themselves, their entity types or relation label. However, conventional attention mechanism on sequence of words cannot make use of structural information on dependency tree. Moreover, it is hard for machines to learn the attention weights from a long sequence of input text.

In this work we propose an enhanced representation for relations that combines the advantages of the above approaches. Basically, we focus on condensed semantic and syntactic information on the SDP. Compensating for the limitations of the SDP may still lead to missing information so we enhance this with syntactic information from the full dependency parse tree. Our idea is based on fundamental notion that the syntactic structure of a sentence consists of binary asymmetrical relations between words (Nivre, 2005). Since these dependency relations hold between a head word (parent, predicate) and a dependent word (children, argument), we try to use all child nodes of a word in the dependency tree to augment its information. Depending on a specific set of relations, it will turn out that not all children are useful to enhance the parent node; we select relevant children by applying several attention mechanisms with kernel filters. This new representation of relation is named Richer-but-Smarter SDP (RbSP).

Recently, deep neural networks (DNNs) have been effectively used to learn robust syntactic and semantic representations behind complex structures. Thus, we propose a novel DNN framework which combines Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Convolutional Neural Networks (CNN) (LeCun et al., 1989) with a multi-attention layer.

Our work has three main contributions:

- We proposed a novel representation of relation based on attentive augmented SDP that overcomes the disadvantages of traditional SDP.
- We improved the attention mechanism with kernel filters to capture the features from context vectors.
- We proposed an advanced DNN architecture that utilizes the proposed Richer-but-Smarter Shortest Dependency Path (RbSP) and other types of linguistic and architectural features.

2 Related Work

RE has been widely studied in NLP community for many years. Unsupervised (Hasegawa et al., 2004; Yan et al., 2009; Quan et al., 2014), semi-supervised (Chen et al., 2006; Carlson et al., 2010; Ammar et al., 2017) and distant supervision (Verga et al., 2018; Ji et al., 2017) methods have been proven effective for the task of detecting relations from unstructured text. However, in this paper, we mainly focus on supervised approaches, which usually have higher accuracy. In earlier RE studies, researchers focused on extracting various kinds of linguistic features, including both syntactic features and semantic cues (Chan and Roth, 2010; Nguyen and Grishman, 2014). However, all the feature-based methods depend strongly on the quality of designed features from an explicit linguistic pre-processing step.

Based on the idea that SDPs contain the essential information for RE, many studies exploit it with several refinements. Typical refinements include negative sampling (Xu et al., 2015a) and BRCNN (Cai et al., 2016) which model the directed shortest path. Liu et al. (2015) suggested incorporating additional network architectures to further improve the performance of SDP-based methods, which uses a recursive neural network to model the sub-tree. Some works utilized information over the whole dependency tree, such as Li et al. (2017) used dynamic extended tree conditioned LSTM for RE and Panyam et al. (2018) exploited whole dependency graph for relation extraction in biomedical text.

Recently, with the introduction and development of attention mechanism, many works tend to use whole sentence or paragraph and focus on the most relevant information using attention technique. Some studies apply a single attention layer, that focus on the word itself (Shen and Huang, 2016; Zhang et al., 2018a); word position (Zhang et al., 2017) and global relation embedding (Su et al., 2018). Other works apply several attention layers, such as word, relation and pooling attention (Wang et al., 2016), multi-head attention (Verga et al., 2018) and word- and entity-based attention (Jat et al., 2017). Luo et al. (2018) used a bidirectional Long Short-Term Memory architecture with an attention layer and a tensor layer for organizing the context information and detecting the connections between two nominals.

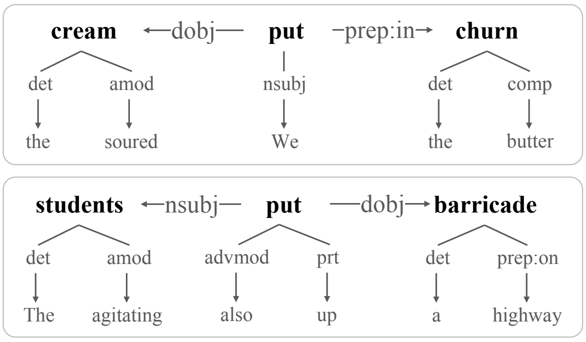

Figure 1: Examples of SDPs and attached child nodes.

3 Richer-but-Smarter SDP

As previously mentioned, we utilize the condensed information in the SDP to learn the relation between two nominals. The simple structure of the SDP is one of its weaknesses since there exists some useful information in dependency tree that does not appear in the SDP. This information can be leveraged to represent the relation more precisely. Two examples in Figure 1 belong to different relation types, but the paths between two nominals in these examples contain only one token (“**put**”). However, the meaning of token “**put**” in two SDPs are completely different. In this situation, it is difficult for the machine to distinguish the two shortest dependency paths from these instances.

We notice that the child nodes attached to the shortest dependency paths and their dependency relation from their parent can provide supplemental information for relation classification. In the previous examples, the sub-structure “−prt→ **up**” provides semantic information about token ‘**put**” in the specific sentence to make it discriminated from the stand-alone one. Based on similar observations, we propose the idea of combining subtree information with original SDP to form a more precise structure for classifying relations. In this RbSP structure each token t is represented by itself and its attached children on the dependency tree.

4 Proposed Model

The overall architecture of our proposed model is shown in Figure 2. Given a sentence and its dependency tree, we build our model on the SDP between two nominals and its directed children on the tree. Here, we mainly focus on the SDP representation, which is composed of dependency embeddings, token embeddings, and token's augmented information. After SDP representation phase, each token and dependency relation is transformed into a vector. This sequence of vectors is then fed to a convolutional neural network to capture the convolved features that can be used to determine which relation two nominals are of.

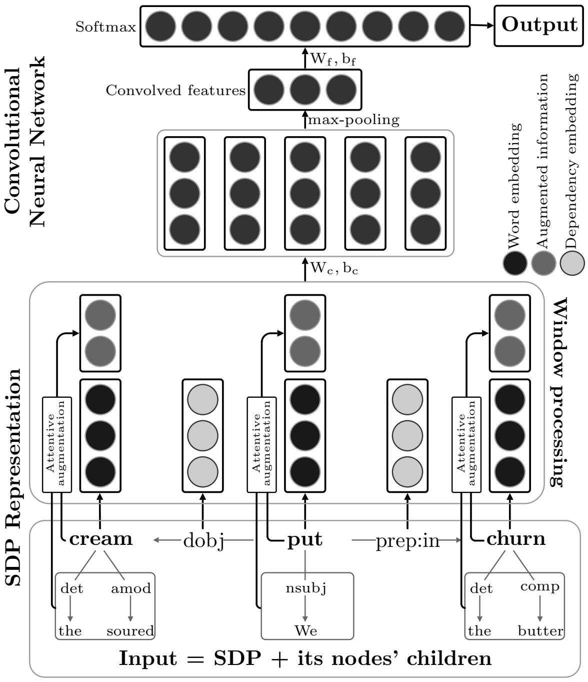

Figure 2: The architecture of RbSP model for relation classification. A CNN model is applied to the output of the SDP representation. Our proposed model takes the Augmented SDP between two nominals that includes dependencies, tokens and their children as input.

4.1 SDP Representation

The goal of this phase is to represent each component on the shortest path (dependency relation and token) by a corresponding vector. We concatenate the dependency type and dependency direction to form the embedding for a dependency relation, a non-linear transformer is followed to produce the final D-dimensional representation $\mathbf{d}_i \in \mathbb{R}^D$ of i-th dependency relation as follow:

$$\mathbf{d}_i = \tanh\left(\left[\mathbf{d}_i^{typ} \oplus \mathbf{d}_i^{dir}\right] \mathbf{W}_d + \mathbf{b}_d\right) \qquad (1)$$

where $\mathbf{d}^{typ} \in \mathbb{R}^{dim_{typ}}$ and $\mathbf{d}^{dir} \in \mathbb{R}^{dim_{dir}}$ are dependency type and direction respectively; $\mathbf{W}_d \in \mathbb{R}^{(dim_{typ}+dim_{dir})\times D}$ and $\mathbf{b}_d \in \mathbb{R}^D$ are trainable parameters of the network.

For token representation, as mentioned above, we assume that each token should be interpreted by itself and its children. Then, the word information $\mathbf{t}_i$ of each token on the SDP is concatenated with its attentive augmented information $\mathbf{a}_i$ based on the attached children (which is calculated by Multi-layer attention with Kernel filters, see Section 4.2). In this work, we utilize four types of embeddings to represent the word information of each token, including:

- ***Pre-trained fastText embeddings*** (Bojanowski et al., 2017): which learned the word representation based on its external context.
- ***Character-based embeddings***: we use an internal LSTM to learn the information about word morphology (like the prefix or suffix).
- ***POS tag embeddings***: we embed the token's grammatical tag using a randomly initialized look-up table and update this parameter on model learning phase.
- ***WordNet embeddings***: which is in form of a sparse vector that figure out which basic WordNet synsets the token belongs to.

To take advantage of the original sentence sequence information, we use a recurrent neural network with LSTM units to pick up the information along the sentence $\mathbf{S} = \{\mathbf{t}_i\}_{i=1}^{n}$ as follow:

$$\mathbf{H} = \overleftrightarrow{\text{biLSTM}}(\mathbf{S}) = \{\mathbf{h}_i\}_{i=1}^{n} \tag{2}$$

Each token t_i is then augmented by the corresponding hidden state $\mathbf{h}_i$ from $\mathbf{H}$. Finally, this concatenation is transformed into an X-dimensional vector to form the representation $\mathbf{x}_i \in \mathbb{R}^X$ of the token. I.e.,

$$\mathbf{x}_i = \tanh\left(\left[\mathbf{t}_i \oplus \mathbf{a}_i \oplus \mathbf{h}_i\right] \mathbf{W}_x + \mathbf{b}_x\right) \tag{3}$$

where $\mathbf{W}_x$ and $\mathbf{b}_x$ are trainable parameters of the network.

4.2 Multi-layer attention with Kernel filters

To capture the appropriate augmented information from the child nodes of each token, we propose a novel multi-layer attention with kernel filters architecture. As illustrated in Figure 3, we employ two sequential attention layers on the children of a token to produce children context vectors. Afterward, to utilize all informative child nodes and preserve the integrity of the word information, we capture the token's augmented information using kernel filters instead of using the average of context vectors weighted by multi-layer attention.

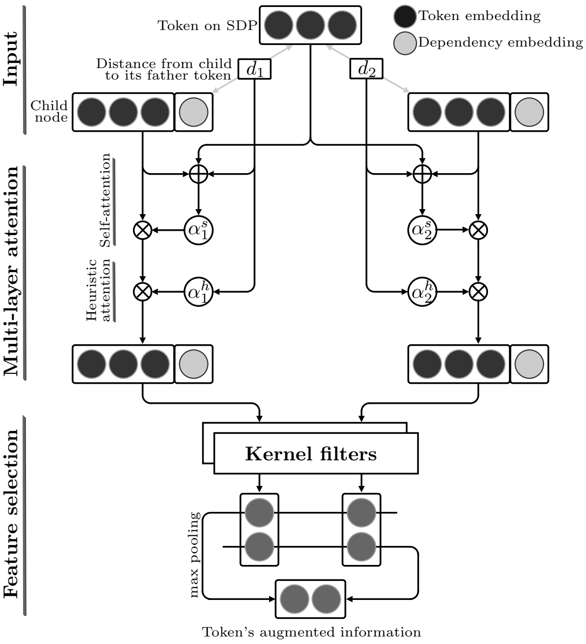

Figure 3: The multi-layer attention architecture to extract the augmented information from the children of a token on SDP. $\bigoplus$ denotes the concatenation of components. $\bigotimes$ denotes the scalar multiplication. Kernel filters are applied on context vectors to capture the features by convolution operation.

Given a token t and their child nodes, we first represent every token by a real-valued vector to provide lexical semantic features. Token t is transformed into a token embedding vector $\mathbf{t} \in \mathbb{R}^{dim}$ which is the concatenation of its word embedding and part-of-speech (POS) tag embedding. To utilize all the information in the sub-structure of token's children, we form a child node not only by its token embedding as in parent node but also by the dependency relation from its direct ancestor on the sentence's parse tree. Suppose t has a set C of M children, i.e., $C = \{c_1, c_2, ..., c_M\}$. Our model represents each child in C with a real-valued vector $\mathbf{c}_i \in \mathbb{R}^{dim+dim_{dep}}$. To additionally capture information about the child node to the target token, we incorporate the position embeddings d_i to reflect the relative distances between the i-th child's token to the target token on the original sentence.

We then apply a simple self-attentive network to child nodes $\{\mathbf{c_i}\}_{i=1}^{M}$ where the attention weights are calculated based on the concatenation of themselves with parent information and distance from parent, as follow:

$$\begin{aligned}\bar{\mathbf{C}} &= \left\{\mathbf{c}_i \oplus \mathbf{t} \oplus d_i\mathbf{w}_d\right\}_{i=1}^{M} = \left\{\bar{\mathbf{c}}_i\right\}_{i=1}^{M} \\ \mathbf{e} &= \left\{\bar{\mathbf{c}}_i\mathbf{W}_e + b_e\right\}_{i=1}^{M} = \left\{e_i\right\}_{i=1}^{M} \\ \alpha_i^s &= \frac{\exp(e_i)}{\sum_{k=1}^{M}\exp(e_k)}\end{aligned} \tag{4}$$

where $\oplus$ denotes the concatenation operation; $\mathbf{w}_d \in \mathbb{R}^{dim_d}$ is the base distance embedding; $\mathbf{W}_e \in \mathbb{R}^{(2dim+dim_{dep}+dim_d)\times 1}$ and $b_e \in \mathbb{R}$ are weight and bias term. The self-attentive context vector $\mathbf{a}^s$ of the target token is the weighted sum of the self-attentive children context vectors based on the weights as follows:

$$\begin{aligned}\mathbf{c}_i^s &= \alpha_i^s\mathbf{c}_i \\ \mathbf{a}^s &= \sum_i \mathbf{c}_i^s\end{aligned} \tag{5}$$

We observe that the importance of a child node to the parent node depends on the distance between them on the original sentence. Therefore, we apply a heuristic attentive layer on the self-attentive children context vectors based on the distances $d_1, d_2, ..., d_M$ to keep track of how close each child is to the target token. We heuristically choose the activation function for the distances $d_1, d_2, ..., d_M$ as $f(d) = \beta d^2$ with $\beta = -0.03$, and a $\mathrm{softmax}$ layer is followed to calculate the heuristic attention weight. I.e.,

$$\begin{aligned}\alpha_i^h &= \frac{\exp(\beta d_i^2)}{\sum_{k=1}^{N}\exp(\beta d_k^2)} \\ \mathbf{c}_i^h &= \alpha_i^h\mathbf{c}_i \\ \mathbf{a}^h &= \sum_i \mathbf{c}_i^h\end{aligned} \tag{6}$$

The multi-attentive context vector $\mathbf{a}^h$ is a synthetic representation of all child nodes with the target token node taken into account. Since the child nodes are usually distinct from each other, an average vector is not suitable to represent the children information. We propose to use the kernel filters to capture the relevant and important information from the output of the multi-attention layer. K kernel filters are applied to each child's attentive vector to produce K features from each child. I.e.,

$$\mathbf{F} = \left\{\mathrm{ReLU}\left(\mathbf{c}_i^h\mathbf{W}_f + \mathbf{b}_f\right)\right\}_{i=1}^{M} \tag{7}$$

where $\mathbf{W}_f \in \mathbb{R}^{(2dim+dim_{dep}+dim_d)\times K}$ is the weight of K kernel filters; and $\mathbf{b}_f \in \mathbb{R}^K$ is bias term. Finally, to produce the final augmented information $\mathbf{a}$, we apply a max-pooling (Boureau et al., 2010) layer to the feature matrix $\mathbf{F}$ and select the most important features as follow:

$$\mathbf{a} = \left\{\max\left(\mathbf{F}_k^{\intercal}\right)\right\}_{k=1}^{K} \tag{8}$$

4.3 CNN on RbSP

After SDP representation layer, the input SDP is transformed into:

$$\mathbf{SDP} = \left[\mathbf{x}_1, \overleftarrow{\mathbf{d}_1}, \mathbf{x}_2, ..., \mathbf{x}_{N-1}, \overrightarrow{\mathbf{d}_{N-1}}, \mathbf{x}_N\right] \tag{9}$$

where the over arrow on $\mathbf{d}_i$ denotes the direction of the dependency relation. We build the CNN model on this $\mathbf{SDP}$; our model is similar to the model of Xu et al. (2015a). In general, let us define the vector $\mathbf{x}_{i:i+j}$ as the concatenation of j tokens and $j-1$ dependency relation between them. I.e.,

$$\mathbf{x}_{i:i+j} = \mathbf{x}_i \oplus \mathbf{d}_i \oplus \mathbf{x}_{i+1} \oplus ... \oplus \mathbf{d}_{i+j-2} \oplus \mathbf{x}_{i+j-1} \tag{10}$$

The convolution operation with region size r applies k filters to all possible window of r successive tokens to produce convolved feature map. We then gather the most important features by applying a max pooling (Boureau et al., 2010) layer over the entire feature map. I.e., the convolutional layer computes the i-th element of the convolved feature vector $\mathbf{f}$ as follows:

$$\mathbf{f}_i = \max_{0\le j\le N-r+1}\left[\mathbf{x}_{j:j+r}\mathbf{W}_c + \mathbf{b}_c\right]_i \tag{11}$$

where $\mathbf{W}_c \in \mathbb{R}^{(rX+(r-1)D)\times k}$ and $\mathbf{b}_c \in \mathbb{R}^k$ are the weight matrix and bias vector of the convolutional layer. The output $\mathbf{f}$ of the convolutional layer is then fed to a softmax classifier to predict a $(K+1)$-class distribution over labels $\hat{\mathbf{y}}$:

$$\hat{\mathbf{y}} = \mathrm{softmax}\left(\mathbf{f}\mathbf{W}_y + \mathbf{b}_y\right) \tag{12}$$

where $\mathbf{W}_y$ and $\mathbf{b}_y$ are parameter of the network to be learned.

4.4 Model Training

The proposed model can be stated as a parameter tuple $\theta = (\mathbf{W}, \mathbf{b})$. To compute the model parameters θ, we define the training objective for a data sample as:

$$L(\theta) = -\sum_{i=0}^{K} \mathbf{y}_i \log \hat{\mathbf{y}}_i + \lambda \left\|\theta\right\|^2 \qquad (13)$$

where $\mathbf{y} \in \{0,1\}^{(K+1)}$ indicating the one-hot vector represented ground truth; and λ is a regularization coefficient. By minimizing $L(\theta)$ using mini-batch gradient descent (GD) with Adam optimizer (Kingma and Ba, 2014), θ is updated through neural network structures.

4.5 Additional techniques

For this paper, we directly utilize the pre-trained fastText word embeddings model (Bojanowski et al., 2017) which is trained on Wikipedia data. The look-up tables for dependency embeddings, word characters, POS tags are randomly constructed using the Glorot initializer (Glorot and Bengio, 2010) and are treated as the parameters to be learned during the training phase.

Since the CNN model takes the fixed size matrix as input, we pad the inputs in each batch of data dynamically to the longest input length of the batch. We further use the batch normalization (Ioffe and Szegedy, 2015) which is able to enable higher learning rates and reduces over-fitting.

During the training phase, we make use of several techniques, including: *clipping the gradients* if their norm exceeds a given threshold (Goldberg, 2017); applying *dropout* (Srivastava et al., 2014) with the probability of 0.5 on embeddings layer, CNN hidden states, and penultimate layer; and using *early stopping* (Caruana et al., 2001) by validation loss.

Further, to reduce the impact of random effects on our model, we employ the ensemble mechanism (Krogh and Sollich, 1997). For this study, we run the model for 20 times and uses the strict majority vote to obtain the final results.

5 Experimental Evaluation

5.1 Dataset

Our model was evaluated on SemEval-2010 Task 8 dataset (Hendrickx et al., 2009), which contains $10,717$ annotated relation classification examples and is separated into two subsets: $8,000$ instances for training and $2,717$ for testing. We randomly split 10 percents of the training data for validation. There are 9 directed relations and one undirected `Other` class.

We conduct the training-testing process 20 times and calculate the averaged results. For evaluation, the predicted labels were compared to the golden annotated data using standard precision (P), recall (R), and F1 score metrics.

5.2 Performance of the RbSP Model

Table 1 summarizes the performance of our model and comparative models. For a fair comparison with other researches, we implemented a baseline model, in which we remove all the proposed augmented information (multi-layer attention with kernel filters and LSTM on original sentence). This baseline model is similar to the model of Xu et al. (2015a) with some technical improvements and additional information sources. It yields higher F1 than competitors which are based on SDP without any data augmentation methods. This result is also comparative when is placed next to the result of basic Attention-CNN model.

The results also demonstrate the effectiveness of our proposed methods that brings an improvement of 1.5% in F1, compared to the baseline result. Our RbSP model yields an F1-score of 86.3%, outperforms other comparative models, except Multi-Att-CNN model of Wang et al. (2016) with multi-level attention CNN. However, we have tried to re-implement the Multi-Att-CNN, but we failed to reproduce the positive result in the original paper. The performance of our re-implementation is about 84.9% of F1. This result has a high consensus with Luo et al. (2018) since they also tried to re-build this model, and their re-implemented result is not much different from us, as 85.5%.

It is worth to note that when comparing with another augmented method of Liu et al. (2015), our multi-layer attention with kernel filters architecture brings more significant improvement. Relatively, in comparison of efficiency of augmented methods on the baseline model, the full-tree augmentation only brings 1% improvement of F1 while our attentive augmentation boosts up to 1.5%. Unlike the method of using the whole subtree to supplement information for the target node, our method only uses the most relevant nodes that are direct children to represent augmented infor-

Table 1: The comparison of our RbSP model with other comparative models on SemEval-2010 task 8 dataset. The reported results are macro-averaged F1 scores of (9+1)-way evaluation with directionality taken into account. Since the comparative models did not report the precision (P) and recall (R), we also report the F1 score only. [†]: We failed to reproduce good result with the Multi-Att-CNN model, the performance of our implementation is just about 84.9. [‡]: Another re-implemented result of Multi-Att-CNN model reported by Luo et al. (2018).

mation. In addition, our method further focuses on the most important children through two attention layers.

We also observe that during many training-testing processes, the results may vary. The standard deviation of 20 runs is about 0.27. We perform the ensemble strategy by majority voting on the results of 20 runs, and it drives our model to achieve a better result of 86.7%. This result is outperformed other comparative models.

5.3 Contribution of different components

Figure 4 shows the changes in F1 when removing each proposed component from the RbSP model. The F1 reductions illustrate the contributions of all proposals to the final result. However, the impact levels vary with different components. Between two proposed component, the multi-layer attention with kernel filters (augmented information) plays a vital role when contributing 1.22% to the final performance while the contribution of the LSTM on the original sentence is 0.33%.

An interesting observation comes from the interior of the multi-layer attention with kernel filters. The impact of removing the whole augmented information is much higher than the total impact of removing multi-layer attention or kernel filters (1.22 vs. 0.42+0.18 = 0.6). These results demonstrate that the combination of constituent parts is thoroughly utilized by our sequential augmented architecture.

Another experiment is on investigating the meaning of each attention component. The result lightly reduces when we remove the self-attention or heuristic attention component. The results also prove that our proposed heuristic attention method is simple but effective. Its improvement is equivalent to the self-attention which is a complex attention mechanism. Among the input of multi-layer attention, the word embedding has a great influence on the model performance. However, children POS tag and relation to parent are also essential components to have the good results.

5.4 Results Analysis

We studied model outputs to analyze system errors in the cases of using the baseline model and using the proposed model with RbSP representation.

In Figure 5, we considered four types of errors: If the model makes a wrong decision and labels an `Other` relation (negative) as an actual relation (positive), it indicates 1 `FP` (False Positive) error.

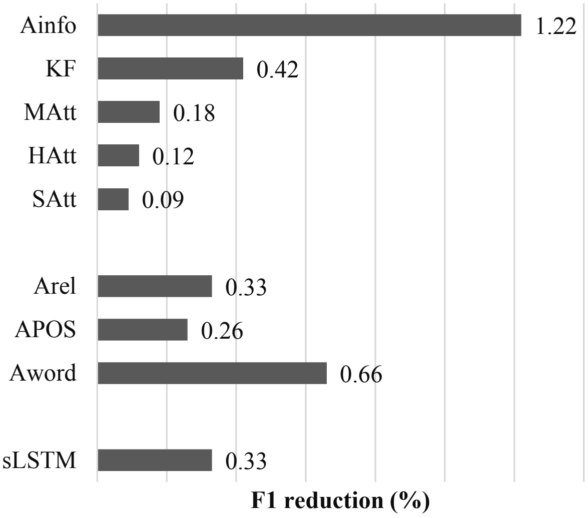

Figure 4: Comparing the contribution of proposed components by removing these components from the model: self-attention (SAtt), heuristic attention (HAtt), multi-layer attention (MAtt), kernel filers (KF), augmented information (Ainfo), augmentation using word embedding (Aword), augmentation using POS tag (APOS), augmentation using dependency relation (Arel), and LSTM on original sentence (sLSTM). F1 reduction is calculated by the average result of 20 runs.

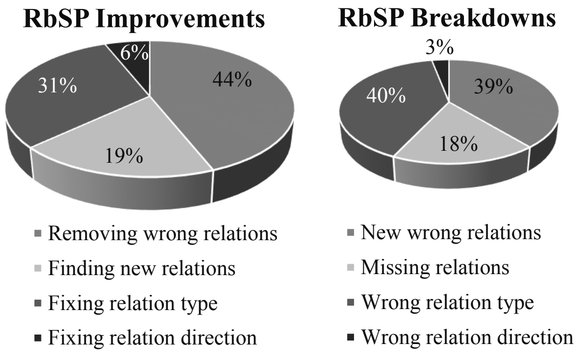

Figure 5: Comparing the effects of using RbSP in two aspects, (i) RbSP improved performance and (ii) RbSP yielded some additional wrong results. Four types of errors are analyzed, note that actual relations are considered as positive relations while `Other` is considered as negative: Labelling an `Other` relation as an actual relation; labelling an actual relation as `Other`; Confusion between types of relations; Direction errors.

Vice versa, if it labels an actual relation as `Other`, it brings 1 `FN` (False Negative). In the case that model confused between two types of relations, the model will be penalized twice, with 1 `FP` and 1 `FN`. Direction error, i.e., the model predicts the relation correctly but its direction wrongly, also brings 1 `FP` and 1 `FN`. The proportions of the left and the right of Figure 5 are quite consistent. In which, RbSP seems to have the most impact on determining whether an instance is positive or negative. RbSP also changes the decision of the relation type in quite many cases. It also influences the decision-making about relation's directionality, but not much.

Totally, the use of RbSP helps to correct more than 150 errors of the baseline model. However, it also yields some new errors (about 70 errors). Therefore, the difference of $F1$ between the baseline model and our RbSP model is only 1.5%, as stated in table 1.

Table 2 gives some realistic examples of different results when using the RbSP and not. We observed that the baseline model seems to be stuck in over-fitting problem, for examples, it classified all SDP with *prep:with* as `Instrument-Agency` and all SDP with *prep:in* as `Member-Collection` (examples $1-2$). RbSP is really useful for solving these cases partly since it uses attentive augmentation information to distinguish the same SDP or the same preposition with different meanings. RbSP is also proven to be stronger in examples $3-4$ to find new results and examples $5-7$ to fix wrong results. In our statistic, the use of RbSP bring the big advantage for the relations `Component-Whole`, `Message-Topic`, `Entity-Destination`, `Product-Producer` and `Instrument-Agency`. The results are almost constant for `Member-Collection` relations. Vice versa, we regret to state that using RbSb brings some worse results (examples $8-11$), especially for `Cause-Effect` and `Content-Container` relations.

Many errors seem attributable to the parser or our model's limitations that still cannot be overcome by using the RbSP (Examples $12-13$). We listed here some highlight problems to prioritize future researches (a) information on the SDP and its child nodes is still insufficient or redundant to make the correct prediction, (b) the direction of relations is still challenging since some errors appeared because we predict the relation correctly but its direction wrongly (c) the over-fitting problem (leading to wrong prediction - `FP`) and (d) lacking in generality (cannot predict new relation - `FN`).

Table 2: The examples of error from RbSP and Baseline models. The predicted labels are from the best runs. [†]SIDs are sentence IDs in the testing dataset. [*]Abbreviation of relations: CC (Content-Container), CE (Cause-Effect), CW (Component-Whole), ED (Entity-Destination), EO (Entity-Origin), IA (Instrument-Agency), MC (Member-Collection), MT (Message-Topic), PP (Product-Producer). [*]Abbreviation of relation directions: 12 (e1,e2), 21 (e2,e1).

6 Conclusions

In this paper, we have presented RbSP, a novel representation of relation between two nominals in a sentence that overcomes the disadvantages of traditional SDP. Our RbSP is created by using multi-layer attention to choose relevant information to augment a token in SDP from its child nodes. We also improved the attention mechanisms with kernel filters to capture the features on the context vector. We evaluated our model on SemEval-2010 task 8 dataset, then compared the results with very recent state-of-the-art models. Experiments were also constructed to verify the rationality and effectiveness of each of the model's components and information sources. The results demonstrated the advantage and robustness of our model, includes the LSTM on the original sentence, combination of self-attention and heuristic mechanisms and several augmentation inputs as well. The analysis of the results still points our some weaknesses of the model. We aim to address them and further extensions of our model in future works. We released our source code and data on the public repository to support the re-producibility of our work and facilitate other related studies.

Abstract

When answering natural language questions over knowledge bases (KBs), different question components and KB aspects play different roles. However, most existing embedding-based methods for knowledge base question answering (KBQA) ignore the subtle inter-relationships between the question and the KB (e.g., entity types, relation paths and context). In this work, we propose to directly model the two-way flow of interactions between the questions and the KB via a novel Bidirectional Attentive Memory Network, called BAMnet. Requiring no external resources and only very few hand-crafted features, on the WebQuestions benchmark, our method significantly outperforms existing information-retrieval based methods, and remains competitive with (hand-crafted) semantic parsing based methods. Also, since we use attention mechanisms, our method offers better interpretability compared to other baselines.

1 Introduction

With the rapid growth in large-scale knowledge bases (KBs) such as DBPedia (Auer et al., 2007) and FreeBase (Google, 2018), knowledge base question answering (KBQA) has drawn increasing attention over the past few years. *Given questions in natural language (NL), the goal of KBQA is to automatically find answers from the underlying KB*, which provides a more natural and intuitive way to access the vast underlying knowledge resources.

One of the most prominent challenges of KBQA is the lexical gap. For instance, the same question can be expressed in various ways in NL while a KB usually has a canonical lexicon. It is therefore nontrivial to map an NL question to a structured KB. The approaches proposed to tackle the KBQA task can be roughly categorized into two groups: semantic parsing (SP) and information retrieval (IR) approaches. SP-based approaches address the problem by constructing a semantic parser that converts NL questions into intermediate logic forms, which can be executed against a KB. Traditional semantic parsers (Wong and Mooney, 2007) require annotated logical forms as supervision, and are limited to narrow domains with a small number of logical predicates. Recent efforts overcome these limitations via the construction of hand-crafted rules or features (Abujabal et al., 2017; Hu et al., 2018) schema matching (Cai and Yates, 2013), and using weak supervision from external resources (Krishnamurthy and Mitchell, 2012).

Unlike SP-based approaches that usually assume a pre-defined set of lexical triggers or rules, which limit their domains and scalability, IR-based approaches directly retrieve answers from the KB in light of the information conveyed in the questions. These IR-based approaches usually do not require hand-made rules and can therefore scale better to large and complex KBs. Recently, deep neural networks have been shown to produce strong results on many NLP tasks. In the field of KBQA, under the umbrella of IR-based approaches, many embedding-based methods (Bordes et al., 2014b; Hao et al., 2017) have been proposed and have shown promising results. These methods adopt various ways to encode questions and KB subgraphs into a common embedding space and directly match them in that space, and can be typically trained in an end-to-end manner.

Compared to existing embedding-based methods that encode questions and KB subgraphs independently, we introduce a novel **B**idirectional **A**ttentive **M**emory **net**work, called **BAMnet** that captures the mutual interactions between questions and the underlying KB, which is stored in a content-addressable memory. We assume that the world knowledge (i.e., the KB) is helpful for better understanding the questions. Similarly, the questions

Proceedings of NAACL-HLT 2019, pages 2913–2923
Minneapolis, Minnesota, June 2 - June 7, 2019.

themselves can help us focus on important KB aspects. To this end, we design a *two-layered bidirectional attention network*. The *primary attention network* is intended to focus on important parts of a question in light of the KB and important KB aspects in light of the question. Built on top of that, the *secondary attention network* is intended to enhance the question and KB representations by further exploiting the two-way attention. Through this idea of *hierarchical two-way attention*, we are able to distill the information that is the most relevant to answering the questions on both sides of the question and KB.

We highlight the contributions of this paper as follows: 1) we propose a novel bidirectional attentive memory network for the task of KBQA which is intended to directly model the two-way interactions between questions and the KB; 2) by design, our method offers good interpretability thanks to the attention mechanisms; 3) on the WebQuestions benchmark, our method significantly outperforms previous information-retrieval based methods while remaining competitive with (hand-crafted) semantic parsing based methods.

2 Related work

Two broad classes of SP-based and IR-based approaches have been proposed for KBQA. The former attempts to convert NL questions to logic forms. Recent work focused on approaches based on weak supervision from either external resources (Krishnamurthy and Mitchell, 2012; Berant et al., 2013; Yao and Van Durme, 2014; Hu et al., 2018; Yih et al., 2015; Yavuz et al., 2016), schema matching (Cai and Yates, 2013), or using hand-crafted rules and features (Unger et al., 2012; Berant et al., 2013; Berant and Liang, 2015; Reddy et al., 2016; Bao et al., 2016; Abujabal et al., 2017; Hu et al., 2018; Bast and Haussmann, 2015; Yih et al., 2015). A thread of research has been explored to generate semantic query graphs from NL questions such as using coarse alignment between phrases and predicates (Berant et al., 2013), searching partial logical forms via an agenda-based strategy (Berant and Liang, 2015), pushing down the disambiguation step into the query evaluation stage (Hu et al., 2018), or exploiting rich syntactic information in NL questions (Xu et al., 2018a,b). Notably, another thread of SP-based approaches try to exploit IR-based techniques (Yao and Van Durme, 2014; Bast and Haussmann, 2015; Yang et al., 2014; Yih et al., 2015; Bao et al., 2016; Yavuz et al., 2016; Liang et al., 2016) by computing the similarity of two sequences as features, leveraging a neural network-based answer type prediction model, or training end-to-end neural symbolic machine via REINFORCE (Williams, 1992). However, most SP-based approaches more or less rely on handcrafted rules or features, which limits their scalability and transferability.

The other line of work (the IR-based) has focused on mapping answers and questions into the same embedding space, where one could query any KB independent of its schema without requiring any grammar or lexicon. Bordes et al. (2014b) were the first to apply an embedding-based approach for KBQA. Later, Bordes et al. (2014a) proposed the idea of subgraph embedding, which encodes more information (e.g., answer path and context) about the candidate answer. In follow-up work (Bordes et al., 2015; Jain, 2016), memory networks (Weston et al., 2014) were used to store candidates, and could be accessed iteratively to mimic multi-hop reasoning. Unlike the above methods that mainly use a bag-of-words (BOW) representation to encode questions and KB resources, (Dong et al., 2015; Hao et al., 2017) apply more advanced network modules (e.g., CNNs and LSTMs) to encode questions. Hybrid methods have also been proposed (Feng et al., 2016; Xu et al., 2016; Das et al., 2017), which achieve improved results by leveraging additional knowledge sources such as free text. While most embedding-based approaches encode questions and answers independently, (Hao et al., 2017) proposed a cross-attention mechanism to encode questions according to various candidate answer aspects. Differently, in this work, our method goes one step further by modeling the bidirectional interactions between questions and a KB.

The idea of bidirectional attention proposed in this work is similar to those applied in machine reading comprehension (Wang and Jiang, 2016; Seo et al., 2016; Xiong et al., 2016). However, these previous works focus on capturing the interactions between two bodies of text, in this work, we focus on modeling the interactions between one body of text and a KB.

3 A modular bidirectional attentive memory network for KBQA

Given an NL question, the goal is to fetch answers from the underlying KB. Our proposed BAMnet

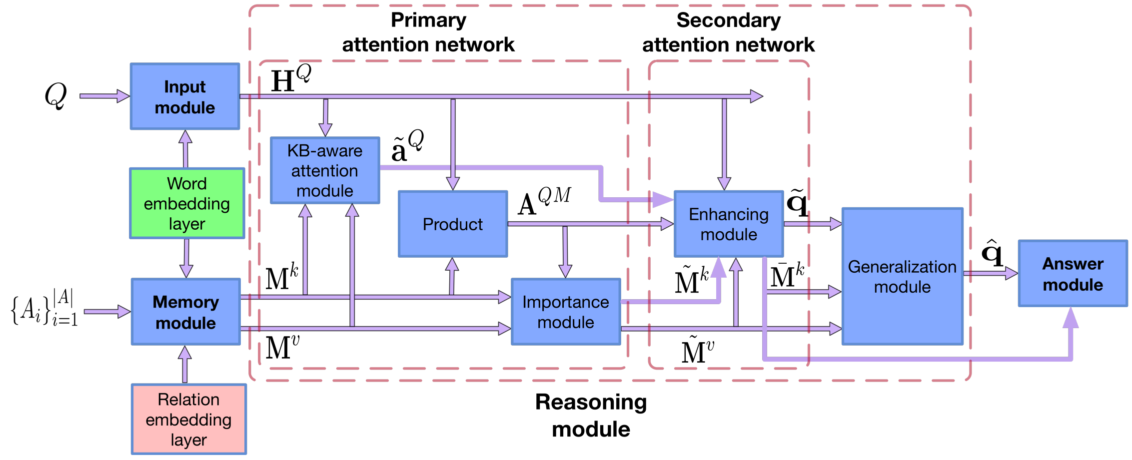

Figure 1: Overall architecture of the BAMnet model.

model consists of four components which are the *input module*, *memory module*, *reasoning module* and *answer module*, as shown in Fig. 1.

3.1 Input module

An input NL question $Q = \{q_i\}_{i=1}^{|Q|}$ is represented as a sequence of word embeddings (q_i) by applying a word embedding layer. We then use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to encode the question as $\mathbf{H}^Q$ (in $\mathbb{R}^{d\times|Q|}$) which is the sequence of hidden states (i.e., the concatenation of forward and backward hidden states) generated by the BiLSTM.

3.2 Memory module

Candidate generation Even though all the entities from the KB could in principle be candidate answers, this is computationally expensive and unnecessary in practice. We only consider those entities which are "close" to the main topic entity of a question. An answer is the text description (e.g., a name) of an entity node. For example, *Ohio* is the topic entity of the question "Who was the secretary of state of Ohio in 2011?" (see Fig. 2). After getting the topic entity, we collect all the entities connected to it within h hops as candidate answers, which we denote as $\{A_i\}_{i=1}^{|A|}$.

KB representation For each candidate answer from the KB, we encode three types of information: answer type, path and context.

Answer type Entity type information is an important clue in ranking answers. For example, if a question uses the interrogative word *where*, then candidate answers with types relevant to the concept of location are more likely to be correct. We use a BiLSTM to encode its text description to get a d-dimensional vector $\mathbf{H}_i^{t_1}$ (i.e., the concatenation of last forward and backward hidden states).

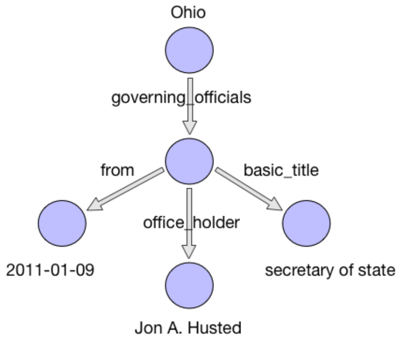

Figure 2: A working example from Freebase. Relations in Freebase have hierarchies where high-level ones provide too broad or even noisy information about the relation. Thus, we choose to use the lowest level one.

Answer path We define an answer path as a sequence of relations from a candidate answer to a topic entity. For example, for the *Ohio* question (see Fig. 2), the answer path of *Jon A. Husted* can be either represented as a sequence of relation ids [*office_holder, governing_officials*] or the text description [*office, holder, governing, officials*]. We thus encode an answer path as $\mathbf{H}_i^{p_1}$ via a BiLSTM, and as $\mathbf{H}_i^{p_2}$ by computing the average of its relation embeddings via a relation embedding layer.

Answer context The answer context is defined as the surrounding entities (e.g., sibling nodes) of a candidate which can help answer questions with constraints. For example, in Fig. 2, the answer context of *Jon A. Husted* includes the government position title *secretary of state* and starting date *2011-01-09*. However, for simple questions without constraints, the answer context is unnecessary and can potentially incorporate noise. We tackle this issue with two strategies: 1) we use a novel *importance module* (explained later) to focus on important answer aspects, and 2) we only consider those context nodes that have overlap with the question. Specifically, for each context node (i.e., a sequence of words) of a candidate, we first compute the longest common subsequence between it and the question, we then encode it via a BiLSTM only if we get a non-stopwords substring. Finally, the answer context of a candidate answer will be encoded as the average of all context node representations, which we denote as $\mathbf{H}_i^c$.

Key-value memory module In our model, we use a key-value memory network (Miller et al., 2016) to store candidate answers. Unlike a basic memory network (Weston et al., 2014), its addressing stage is based on the key memory while the reading stage uses the value memory, which gives greater flexibility to encode prior knowledge via functionality separation. Thus, after encoding the answer type, path and context, we apply linear projections on them as follows:

$$\begin{aligned} \mathbf{M}_i^{k_t} &= f_t^k(\mathbf{H}_i^{t_1}) & \mathbf{M}_i^{v_t} &= f_t^v(\mathbf{H}_i^{t_1}) \\ \mathbf{M}_i^{k_p} &= f_p^k([\mathbf{H}_i^{p_1};\mathbf{H}_i^{p_2}]) & \mathbf{M}_i^{v_p} &= f_p^v([\mathbf{H}_i^{p_1};\mathbf{H}_i^{p_2}]) \\ \mathbf{M}_i^{k_c} &= f_c^k(\mathbf{H}_i^{c}) & \mathbf{M}_i^{v_c} &= f_c^v(\mathbf{H}_i^{c}) \end{aligned} \tag{1}$$

where $\mathbf{M}_i^{k_t}$ and $\mathbf{M}_i^{v_t}$ are d-dimensional key and value representations of answer type A_i^t, respectively. Similarly, we have key and value representations for answer path and answer context. We denote $\mathbf{M}$ as a key-value memory whose row $\mathbf{M}_i = \{\mathbf{M}_i^k, \mathbf{M}_i^v\}$ (both in $\mathbb{R}^{d\times 3}$), where $\mathbf{M}_i^k = [\mathbf{M}_i^{k_t};\mathbf{M}_i^{k_p};\mathbf{M}_i^{k_c}]$ comprises the keys, and $\mathbf{M}_i^v = [\mathbf{M}_i^{v_t};\mathbf{M}_i^{v_p};\mathbf{M}_i^{v_c}]$ comprises the values. Here $[,]$ and $[;]$ denote row-wise and column-wise concatenations, respectively.

3.3 Reasoning module

The reasoning module consists of a generalization module, and our novel *two-layered bidirectional attention network* which aims at capturing the two-way interactions between questions and the KB. The *primary attention network* contains the KB-aware attention module which focuses on the important parts of a question in light of the KB, and the importance module which focuses on the important KB aspects in light of the question. The *secondary attention network* (*enhancing module* in Fig. 1) is intended to enhance the question and KB vectors by further exploiting the two-way attention.

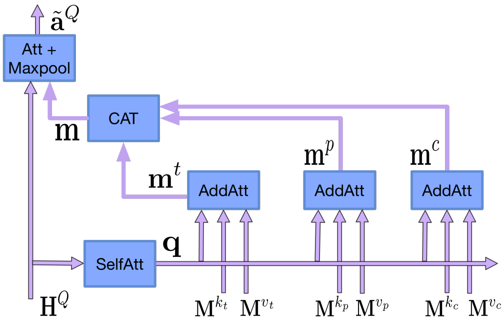

Figure 3: KB-aware attention module. CAT: concatenation, SelfAtt: self-attention, AddAtt: additive attention.
