En-Ru. We use 13.88M sentences as baseline training data, containing both a real bilingual corpus and a synthetic back-translation corpus (Sennrich et al., 2015a). The synthetic corpus is translated from "NewsCommonCrawl", which can be obtained from the WMT task. The news domain contains four different test sets published by WMT2018 over the recent years, namely "news2015", "news2016", "news2017", and "news2018", respectively, each having one reference. The e-commerce domain contains four files totalling 7169 sentences, namely "subject17", "desc17", "subject18", and "desc18", respectively, each having one reference. The sentences are extracted from e-commerce websites, in which "subject"s are the goods names shown on a listing page. "desc"s refer to information in a commodity's description page. "subject17" and "desc17" are released[5]. Our development set is "news2015".

Ch-En. We use 7.42M sentences as our baseline training data, containing both real bilingual corpus and synthetic back-translation corpus (Sennrich et al., 2015a). We use seven public development and test data sets, four in the news domain, namely "NIST02", "NIST03", "NIST04", "NIST05", respectively, each with four references, and three in the spoken language domain, namely "CSTAR03", "IWSLT2004", "IWLST2005", respectively, each with 16 references. "NIST03" is used for development.

5.2 Experimental Settings

We use six self-attention layers for both the encoder and the decoder. The embedding size and the hidden size are set to 512. Eight heads are used for self-attention. A feed-forward layer with 2048 cells and Swish (Ramachandran et al., 2018) is used as the activation function. Adam (Kingma and Ba, 2014) is used for training; warmup step is 16000; the learning rate is 0.0003. We use label smoothing (Junczys-Dowmunt et al., 2016) with a confidence score of 0.9, and all the drop-out (Gal and Ghahramani, 2016) probabilities are set to 0.1.

We extract a SMT phrase table on the bilingual training corpus by using moses (Koehn et al., 2007) with default setting, which is used for matching sentence pairs to generate augmented training data. We apply count-based pruning (Zens et al., 2012) to the phrase table, the threshold is set to 10.

During **decoding**, similar to Hasler et al. (2018), Alkhouli et al. (2018) and Post and Vilar (2018), we make use of references to obtain gold constraints. Following previous work, pre-specified translations for each source sentence are sampled from references and used by all systems for fair comparison.

In all the baseline systems, the vocabulary size is set to 50K on both sides. For "Data augmentation", to allow the source-side dictionary to cover target-side words, the target- and source-side vocabularies are merged for a new source vocabulary. For "Shared embeddings", the source vocabulary remains the same as the baselines, where the source-side target words use embeddings from target-side vocabulary.

5.3 System Configurations

We use an in-house reimplementation of Transformer, similar to Google's Tensor2Tensor. For the baselines, we reimplement Crego et al. (2016), as well as Post and Vilar (2018). BPE (Sennrich et al., 2015b) is used for all experiments, the operation is set to 50K. Our test sets cover news and e-commerce domains on En-Ru, and news and spoken language domains on Ch-En.

Baseline 1: Using Placeholder. We combine Luong et al. (2014) and Crego et al. (2016). For

generating placeholder tags during training, following Crego et al. (2016), we use a named entity translation dictionary which is extracted from Wikidata[6]. The dictionary is released together with e-commerce test sets, which is mentioned before. For Ch-En, the dictionary contains 285K person names, 746K location names and 1.6K organization names. For En-Ru, the dictionary contains 471K person names, 254K location names and 1.5K organization names. Additionally, we manually corrected a dictionary which contains 142K brand names and product names translation for En-Ru. By further leveraging word alignment in the same way as Luong et al. (2014), the placeholder tags are annotated with indices. We use FastAlign (Dyer et al., 2013) to generate word alignment. The amount of sentences containing placeholder tags is controlled to a ratio of 5% of the corpus. During decoding, pre-specified translations described in Section 5.2 are used.

Baseline 2: Lexical Constraints. We re-implement Post and Vilar (2018), integrating their algorithm into our Transformer. Target-side words or phrases of pre-specified translations mentioned in Section 5.2 are used as lexical constraints.

Our System. During training, we use the method described in Section 3.1 to obtain the augmented training data. The SMT phrase table mentioned in Section 5.2 is used for "Indexing" and "Sampling". During decoding, pre-specified translations mentioned in Section 5.2 are used. The augmented data contain sampled sentences with one or two replacements on the source side. By applying the two sampling steps described in Section 3.1, about 10M and 6M augmented Ch-En and En-Ru sentences are generated, respectively. The final training corpora consists of both the augmented training data and the original training data.

5.4 Results

Comparison with Baselines. Our Transformer implementation can give comparable performance with state-of-the-art NMT (Junczys-Dowmunt et al., 2018), see "Transformer" and "Marian" in Table 1, which also shows a comparison of different methods on En-Ru. The *lexical constraint* method gives improvements on both the news and the e-commerce domains, compared with the Transformer baseline. The *placeholder* method also gives an improvement on the e-commerce

Pre-Specified Translation: **计划生育 —> planned parenthood**

Source: 上 个 月 ， 民主 党 否决 了 共和 党 提出 的 一 项 提议 ， 该 提议 要求 拨款 11 亿 美元 抗击 寨 卡 但 包含 禁止 资助 计划 生育 协会 提供 与 病毒 相关 的 避孕 条件 的 条款 ， 而 寨 卡 病毒 可以 通过 性 途径 传播 。

Transformer: last month , the democratic party of the republic rejected a proposal by the republican party to grant $ 1.1 billion to fight against the zika but contained provisions prohibiting the **family planning** association from providing virus - related contraceptive conditions and the zika virus could be transmitted sexually .

Baseline1(Placeholder): last month , the party rejected a proposal from the republican party that would require $ 1.1 billion to fight zika , but would include provisions that prohibit **program** **planned parenthood** from providing virus - related contraceptive conditions , and zika could be transmitted sexually .

Baseline2(Lexi. Cons.): last month , the democratic party of the republic rejected a proposal by the republican party to grant $ 1.1 billion to fight against the zika but contained provisions that prohibit the family planning association from providing contraceptive conditions related to the virus and the zika virus could be transmitted through a sexual route **, the u . s . national security council has been banned from funding for the** **planned parenthood** .

Ours: last month , the democratic party rejected a republican proposal calling for $ 1.1 billion to fight zika , which contains provisions that prohibit the association of **planned parenthood** from providing virus - related contraceptive conditions , and the zika virus could be transmitted sexually .

Reference: last month , democrats blocked consideration of a republican measure that would have allocated $ 1.1 billion to fight zika but included provisions that would have banned funding for **planned parenthood** to provide contraception related to the virus , which can be sexually transmitted .

Figure 3: Sample outputs.

domain. The average improvement is calculated over all the test set results in each domain. In the news domain, the average improvement of *our method* is 3.48 BLEU higher compared with *placeholder*, and 2.94 over *lexical constraints*. In the e-commerce domain, the average improvement of *our method* is 1.34 BLEU compared with *placeholder*, and 2.63 with *lexical constraints*. Both shared embedding and pointer network are effective. Table 2 shows the same comparison on Ch-En. In the spoken language domain, the average improvement is 1.35 BLEU compared with *placeholder*, and 0.42 with *lexical constraints*. In the news domain, the average improvement is 1.38 BLEU compared with *placeholder*, and 0.74 with *lexical constraints*.

We find that the *placeholder* method can only bring improvements on the En-Ru e-commerce test sets, since the pre-specified translations of the four e-commerce test sets are mostly *entities*, such as brand names or product names. Using placeholder tags to represent these entities leads to relatively little loss of word meaning. But on many of the other test sets, pre-specified translations are mostly vocabulary words. The placeholder tags fail to keep their word meaning during translation, leading to lower results.

The speed contrast between unconstrained NMT, lexical constraint and our method is shown in Table 3. The decoding speed of our method is equal to unconstrained NMT, and faster than the lexical constraint method, which confirms our intuition introduced earlier.

Beam Size	5	10	20	30
Unconstrained & Ours	416	312	199	146
Lexical Constraint	102	108	74	50

Table 3: Decoding speed (words/sec), Ch-En dev set.

Sample Outputs. Figure 3 gives a comparison of different system's translations. Given a Chinese source sentence, the baseline system fails to translate "计划生育" adequately, as "family planning" is not a correct translation of "计划生育". In the pre-specified methods, the correct translation ("计划生育" to "planned parenthood") is achieved through different ways.

For the *placeholder* method, the source phrase "计划生育" is replaced with the placeholder tag "tag_1" during pre-processing. After translation, output "tag_1" is replaced with "planned parenthood" as a post-processing step. However, the underlined word "program" is generated before "planned parenthood", which has no relationship with any source-side word. The source-side word "协会", which means "association", is omitted in translation. Through deeper analysis, the specific phrase "program tag_1" occurs frequently in the training data. During decoding, using the hard tag leads to the loss of the source phrase's original meaning. As a result, the word "program" is incorrectly generated along with "tag_1".

The *lexical constraints* method regards the tar-

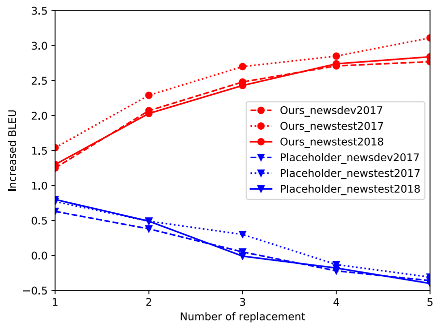

Figure 4: Increased BLEU on Ch-En test sets.

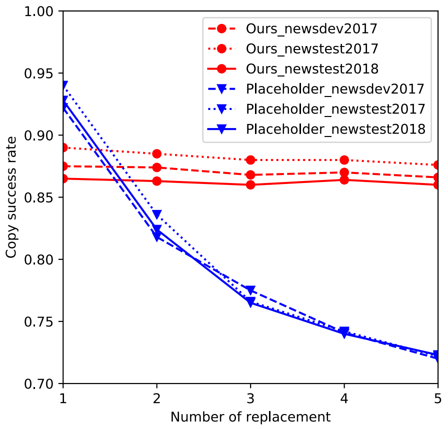

Figure 5: Copy success rate on Ch-En test sets.

get side of the pre-specified translation as a lexical constraint. Here the altered beam search algorithm fails to predict the constraint "planned parenthood" during previous decoding steps. Although the constraint finally comes into effect, over translation occurs, which is highlighted by the underlined words. This is because the method enforces hard constraints, preventing decoding to stop until all constraints are met.

Our method makes use of pre-specified translation by replacing the source-side phrase "计划生育" with the target-side translation "planned parenthood", copying the desired phrase to the output along with the decoding procedure. The translation "association of planned parenthood from providing" is the exact translation of the source-side phrase "计划(planned) 生育(parenthood) 协会(association) 提供(providing)", and agrees with the reference, "planned parenthood to provide".

5.5 Analysis

Effect of Using More Pre-specified Translations. Even though the augmented training data have only one or two replacements on the source side, the model can translate a source sentence with up to five replacements. Figure 4 shows that compared with unconstrained Transformer, the translation quality of our method keeps increasing when the number of replacements increases, since more pre-specified translations are used.

We additionally measure the effect on the Ch-En WMT test sets, namely "newsdev2017", "newstest2017", "newstest2018", respectively, each having only one reference instead of four. The baseline BLEU scores on these three test sets are 18.49, 20.01 and 19.05, respectively. Our method gives BLEU scores of 20.56, 22.3, 21.08, respectively, when using one or two pre-specified translations for each sentence. The increased BLEU when utilizing different number of pre-specified translations is shown in Figure 4. We found that the improvements on WMT test sets are more significant than on NIST, since pre-specified translations are sampled from one reference only, enforcing the output to match this reference. The placeholder method does not give consistent improvements on news test sets, due to the same reason as mentioned earlier.

As shown in Figure 5, the copy success rate of our method does not decrease significantly when the number of replacements grows. Here, a *copy success* refers a pre-specified target translation that can occur in the output. The placeholder method achieves a higher copy success rate than ours when the number of replacements is 1, but the copy success rate decreases when using more pre-specified translations. The copy success rate of the lexical constraint method is always 100%, since it imposes hard constraints rather than soft constraints. However, as discussed earlier, overall translation quality can be harmed as a cost of satisfying decoding constraints by their method.

In the presented experiment results, the highest copy success rate of our method is 90.54%, which means a number of source-side target words or phrases are not successfully copied to the translation output. This may be caused by the lack of training samples for certain target-side words or phrases. In En-Ru, we additionally train a model with augmented data that is obtained by matching

	NIST02	NIST03	NIST04	NIST05
Data Aug.	83.89%	85.71%	86.71%	87.45%
+Share&Point	87.72%	88.31%	89.18%	90.54%

Table 4: Copy success rate on Ch-En test sets.

	news15	news16	news17	news18

Table 5: BLEU scores of non code-switched (original) input on En-Ru test sets.

an SMT phrase table without any pruning strategy. The copy success rate can reach 98%, even without using "shared embedding" and "pointer network" methods.

Effect of Shared Embeddings and Pointer Network. The gains of *shared embeddings* and *pointer network* are reflected in both the copy success rate and translation quality. As shown in Table 4, when using one pre-specified translation for each source sentence, the copy success rate improves on various test sets by integrating shared embeddings and pointer network, demonstrating that more pre-specified translations come into effect. Table 1 and Table 2 earlier show the improvement of translation quality.

Translating non Code-Switched Sentences. Our method preserves its strength on translating non code-switched sentences. As shown in Table 5, the model trained on the augmented corpus has comparable strength on translating unreplaced sentences as the model trained on the original corpus. In addition, on some test sets, our method is slightly better than the baseline when translating non code-switched source sentences. This can be explained from two aspects: First, the augmented data make the model more robust to perturbed inputs; Second, the pointer network makes the model better by copying certain source-side words (Gulcehre et al., 2016), such as non-transliterated named entities.

6 Conclusion

We investigated a data augmentation method for constraining NMT with pre-specified translations, utilizing code-switched source sentences and their translations as augmented training data. Our method allows the model to learn to translate source-side target phrases by "copying" them to the output, achieving consistent improvements over previous lexical constraint methods on large NMT test sets. To the best of our knowledge, we are the first to leverage code switching for NMT with pre-specified translations.

7 Future Work

In the future, we will study how the copy success rate and the BLEU scores interact when different sampling strategies are taken to obtain augmented training corpus and when the amount of augmented data grows. Another direction is to validate the performance when applying this approach to language pairs that contain a number of identical letters in their alphabets, such as English to French and English to Italian.

Abstract

The problem of learning to translate between two vector spaces given a set of aligned points arises in several application areas of NLP. Current solutions assume that the lexicon which defines the alignment pairs is noise-free. We consider the case where the set of aligned points is allowed to contain an amount of noise, in the form of incorrect lexicon pairs and show that this arises in practice by analyzing the edited dictionaries after the cleaning process. We demonstrate that such noise substantially degrades the accuracy of the learned translation when using current methods. We propose a model that accounts for noisy pairs. This is achieved by introducing a generative model with a compatible iterative EM algorithm. The algorithm jointly learns the noise level in the lexicon, finds the set of noisy pairs, and learns the mapping between the spaces. We demonstrate the effectiveness of our proposed algorithm on two alignment problems: bilingual word embedding translation, and mapping between diachronic embedding spaces for recovering the semantic shifts of words across time periods.

1 Introduction

We consider the problem of mapping between points in different vector spaces. This problem has prominent applications in natural language processing (NLP). Some examples are creating bilingual word lexicons (Mikolov et al., 2013), machine translation (Artetxe et al., 2016, 2017a,b, 2018a,b; Conneau et al., 2017), hypernym generation (Yamane et al., 2016), diachronic embeddings alignment (Hamilton et al., 2016) and domain adaptation (Barnes et al., 2018). In all these examples one is given word embeddings in two different vector spaces, and needs to learn a mapping from one to the other.

The problem is traditionally posed as a supervised learning problem, in which we are given two sets of vectors (e.g.: word-vectors in Italian and in English) and a *lexicon* mapping the points between the two sets (known word-translation pairs). Our goal is to learn a mapping that will correctly map the vectors in one space (e.g.: English word embeddings) to their known corresponding vectors in the other (e.g.: Italian word embeddings). The mapping will then be used to translate vectors for which the correspondence is unknown. This setup was popularized by Mikolov et al. (2013).

The supervised setup assumes a perfect lexicon. Here, we consider what happens in the presence of *training noise*, where some of the lexicon's entries are incorrect in the sense that they don't reflect an optimal correspondence between the word vectors.

2 Background

2.1 The Supervised Translation Problem

We are given two datasets, $X = x_1, ..., x_m$ and $Y = y_1, ..., y_n$, coming from d-dimensional spaces $\mathcal{X}$ and $\mathcal{Y}$. We assume that the spaces are related, in the sense that there is a function $f(x)$ mapping points in space $\mathcal{X}$ to points in space $\mathcal{Y}$. In this work, we focus on linear mappings, i.e. a $d \times d$ matrix Q mapping points via $y_i = Qx_i$. The goal of the learning is to find the translation matrix Q. In the supervised setting, $m = n$ and we assume that $\forall i \ f(x_i) \approx y_i$. We refer to the sets X and Y as the *supervision*. The goal is to learn a matrix $\hat{Q}$ such the Frobenius norm is minimized:

$$\hat{Q} = \arg\min_{Q} \|QX - Y\|_F^2. \qquad (1)$$

2.2 Existing Solution Methods

Gradient-based The objective in (1) is convex, and can be solved via least-squares method or via stochastic gradient optimization iterating over the

Minneapolis, Minnesota, June 2 - June 7, 2019.

pairs (x_i, y_i), as done by Mikolov et al. (2013) and Dinu and Baroni (2014).

Orthogonal Procrustes (OP) Artetxe et al. (2016) and Smith et al. (2017) argued and proved that a linear mapping between sub-spaces must be orthogonal. This leads to the modified objective:

$$\hat{Q} = \underset{Q, s.t: Q^TQ=I}{\arg\min} \|QX - Y\|_F^2 \tag{2}$$

Objective (2) is known as the *Orthogonal Procrustes Problem*. It can be solved algebraically by using a singular value decomposition (SVD). Schnemann (1966) proved that the solution to 2 is: $\hat{Q} = UV^T$ s.t. $U\Sigma V^T$ is the SVD of YX^T.

The OP method is used in Xing et al. (2015); Artetxe et al. (2016, 2017a,b, 2018a,b); Hamilton et al. (2016); Conneau et al. (2017); Ruder et al. (2018).

2.3 The Unsupervised Translation Problem

The supervised alignment problem can be expended to the semi-supervised (Artetxe et al., 2017b; Lample et al., 2017; Ruder et al., 2018) or unsupervised (Zhang et al., 2017; Conneau et al., 2017; Artetxe et al., 2018b; Xu et al., 2018; Alvarez-Melis and Jaakkola, 2018) case, where a very small lexicon or none at all is given. In iterative methods, the lexicon is expended and used to learn the alignment, later the alignment is used to predict the lexicon for the next iteration and so on. In adversarial methods, a final iterative step is used after the lexicon is built to refine the result. We will focus on the supervised stage in the unsupervised setting, meaning estimating the alignment once a lexicon is induced.

3 The Effect of Noise

The previous methods assume the supervision set X, Y is perfectly correct. However, this is often not the case in practice. We consider the case where a percentage p of the pairs in the supervision set are "noisy": applying the gold transformation to a noisy point x_j will not result in a vector close to y_j. The importance of the quality of word-pairs selection was previously analyzed by Vulić and Korhonen (2016). Here, we equate "bad pairs" to noise, and explore the performance in the presence of noise by conducting a series of synthetic experiments. We take a set of points X, a random transformation Q and a gold set $Y = QX$. We define *error* as $\|Y - \hat{Y}\|_F^2$ where $\hat{Y} = \hat{Q}X$ is the prediction according to the learned transform $\hat{Q}$. Following the claim that linear transformations between word vector spaces are orthogonal, we focus here on orthogonal transformations.

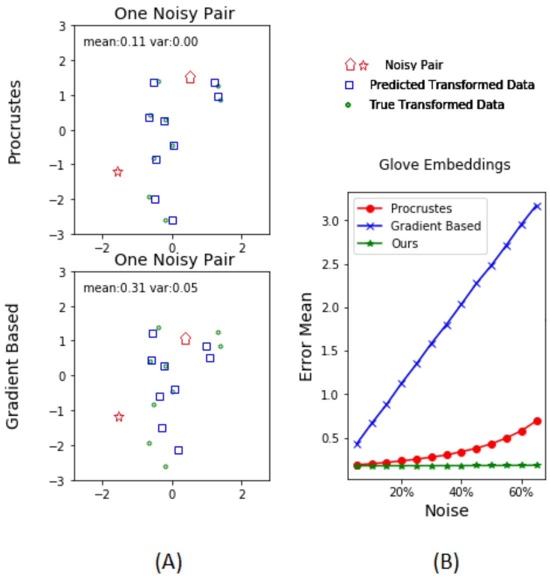

Figure 1: Noise influence. (A): the effect of a noisy pair on 2D alignment. (B) mean error over non-noisy pairs as a function of noise level.

Low Dimensional Synthetic Data We begin by inspecting a case of few 2-dimensional points, which can be easily visualized. We compare a noise-free training to the case of a single noisy point. We construct X by sampling $n = 10$ points of dimension $d = 2$ from a normal distribution. We take nine points and transformed them via an orthogonal random transform Q. We then add a single noisy pair which is generated by sampling two normally distributed random points and treating them as a pair. The error is measured only on the nine aligned pairs.

When no noise is applied, both Gradient-based and Procrustes methods are aligned with 0 error mean and variance. Once the noisy condition is applied this is no longer the case. Figure 1(A) shows the noisy condition. Here, the red point (true) and box (prediction) represent the noisy point. Green dots are the true locations after transformation, and the blue boxes are the predicted ones after transformation. Both methods are affected by the noisy sample: all ten points fall away from their true location. The effect is especially severe for the gradient-based methods.

High Dimensional Embeddings The experiment setup is as before, but instead of a normal distribution we use (6B, 300d) English Glove Embeddings (Pennington et al., 2014) with lexicon of size $n = 5000$. We report the mean error for various noise levels on an unseen aligned test set of size 1500.

In Figure 1(B) we can see that both methods are effected by noise. As expected, as the amount of noise increases the error on the test set increases. We can again see that the effect is worse with gradient-based methods.

4 Noise-aware Model

Having verified that noise in the supervision severely influences the solution of both methods, we turn to proposing a noise-aware model.

The proposed model jointly identifies noisy pairs in the supervision set and learns a translation which ignores the noisy points. Identifying the point helps to clean the underlying lexicon (dictionary) that created the supervision. In addition, by removing those points our model learns a better translation matrix.

Generative Model We are given $x \in \mathbb{R}^d$ and we sample a corresponding $y \in \mathbb{R}^d$ by first sampling a Bernoulli random variable with probability α:

$$z \sim \text{Bernoulli}(\alpha)$$

$$y \sim \begin{cases} N(\mu_y, \sigma_y^2 I) & z = 0\,(\text{‘noise’}) \\ N(Qx, \sigma^2 I) & z = 1\,(\text{‘aligned’}) \end{cases}$$

The density function y is a mixture of two Gaussians:

$$f(y|x) = (1-\alpha)N(\mu_y, {\sigma_y}^2 I) + \alpha N(Qx, \sigma^2 I).$$

The likelihood function is:

$$L(Q, \sigma, \mu_y, \sigma_y) = \sum_t \log f(y_t|x_t)$$

EM Algorithm We apply the EM algorithm (Dempster et al., 1977) to maximize the objective in the presence of latent variables. The algorithm has both soft and hard decision variants. We used the hard decision one which we find more natural, and note that the posterior probability of z_t was close to 0 or 1 also in the soft-decision case.

It is important to properly initialize the EM algorithm to avoid convergence to a local optima. We initialize Q by applying OP on the entire lexicon (not just the clean pairs). We initialize the variance, σ, by calculating $\sigma^2 = \frac{1}{n \cdot d} \sum_{t=1} \|Qx_t - y_t\|^2$. We initialize, μ_y, σ_y by taking the mean and variance of the entire dataset. Finally, we initialize α to 0.5.

The (hard version) EM algorithm is shown in Algorithm box 1. The runtime of each iteration is dominated by the OP algorithm (matrix multiplication and SVD on a $d \times d$ matrix). Each iteration contains an additional matrix multiplication and few simple vector operations. Figure 1(B) shows it obtains perfect results on the simulated noisy data.

Algorithm 1 Noise-aware Alignment

```
Data: List of paired vectors: $(x_1, y_1), ..., (x_n, y_n)$
Result: $Q$, $\sigma$, $\mu_y$, $\sigma_y$
while $|\alpha_{curr} - \alpha_{prev}| > \epsilon$ do
    E step:
        $w_t = p(z_t=1|x_t, y_t) = \frac{\alpha N(Qx_t, \sigma^2 I)}{f(y_t|x_t)}$
        $h_t = 1(w_t > 0.5)$
        $n_1 = \sum_t h_t$
    M step:
        Apply OP on the subset $\{t|h_t = 1\}$ to find Q.
        $\sigma^2 = \frac{1}{d \cdot n_1} \sum_{t|h_t=1} \|Qx_t - y_t\|^2$
        $\mu_y = \frac{1}{(n-n_1)} \sum_{t|h_t=0} y_t$
        $\sigma_y^2 = \frac{1}{d(n-n_1)} \sum_{t|h_t=0} \|\mu_y - y_t\|^2$
        $\alpha_{prev} = \alpha_{curr}$
        $\alpha_{curr} = \frac{n_1}{n}$
end
```

5 Experiments

5.1 Bilingual Word Embedding

Experiment Setup This experiment tests the noise-aware solution on an unsupervised translation problem. The goal is to learn the “translation matrix”, which is a transformation matrix between two languages by building a dictionary. We can treat the unsupervised setup after retrieving a lexicon as an iterative supervised setup where some of the lexicon pairs are noisy. We assumes the unsupervised setting will contain higher amount of noise than the supervised one, especially in the first iterations. We follow the experiment setup in Artetxe et al. (2018b). But instead of using OP for learning the translation matrix, we used our Noise-Aware Alignment (NAA), meaning we jointly learn to align and to ignore the noisy pairs. We used the En-It dataset provided by Dinu and Baroni (2014) and the extensions: En-De, En-Fi and En-Es of Artetxe et al. (2018a, 2017b).

Method	En→It			En→De			En→Fi			En→Es		
	best	avg	iters	best	avg	iters	best	avg	iters	best	avg	iters
Artetxe et al., 2018b	**48.53**	48.13	573	48.47	48.19	773	33.50	32.63	988	37.60	37.33	808
Noise-aware Alignment	**48.53**	**48.20**	471	**49.67**	**48.89**	568	**33.98**	**33.68**	502	**38.40**	**37.79**	551

Table 1: Bilingual Experiment P@1. Numbers are based on 10 runs of each method. The En→De, En→Fi and En→Es improvements are significant at $p < 0.05$ according to ANOVA on the different runs.

Experiment Results In Table 1 we report the best and average precision@1 scores and the average number of iterations among 10 experiments, for different language translations. Our model improves the results in the translation tasks. In most setups our average case is better than the former best case. In addition, the noise-aware model is more stable and therefore requires fewer iterations to converge. The accuracy improvements are small but consistent, and we note that we consider them as a lower-bound on the actual improvements as the current test set comes from the same distribution of the training set, and also contains similarly noisy pairs. Using the soft-EM version results in similar results, but takes roughly 15% more iterations to converge.

Table 2 lists examples of pairs that were kept and discarded in En-It dictionary. The algorithm learned the pair (dog → dog) is an error. Another example is the translation (good → santo) which is a less-popular word-sense than (good → buon / buona). When analyzing the En-It cleaned dictionary we see the percentage of potentially misleading pairs (same string, numbers and special characters) is reduced from 12.1% to 4.6%.

English	Italian	Latent Variable
dog	cane	Aligned
dog	cani	Aligned
dog	dog	Noise
good	buon	Aligned
good	buona	Aligned
good	santo	Noise
new	new	Noise
new	york	Noise
new	nuove	Aligned

Table 2: A sample of decisions from the noise-aware alignment on the English → Italian dataset.

5.2 Diachronic (Historical) Word Embedding

Experiment Setup The goal is to align English word-embedding derived from texts from different time periods, in order to identify which words changed meaning over time. The assumption is that most words remained stable, and hence the supervision is derived by aligning each word to itself. This problem contains noise in the lexicon by definition. We follow the exact setup fully described in Hamilton et al. (2016), but replace the OP algorithm with our Noise-aware version [1]. We project 1900s embeddings to 1990s embeddings vector-space. The top 10 distant word embeddings after alignment are analyzed by linguistic experts for semantic shift.

Experiment Results 45.5% of the input pairs were identified as noise. After the post processing of removing the non-frequent words as described in the experiment setup we end up with 121 noisy words. Our algorithm successfully identifies **all** the top-changing words in Hamilton et al. (2016) as noise, and learns to ignore them in the alignment. In addition, we argue our method provides better alignment. Table 3 shows the Nearest Neighbor (NN) of a 1990s word, in the 1900s vector-space after projection. We look at the top 10 changed words in Hamilton et al. (2016) and 3 unchanged words. We compare the alignment of the OP projection to the Noise-aware Alignment (NAA). For example, with our solution the word *actually* whose meaning shifted from ”in fact” to express emphasize or surprise, is correctly mapped to *really* instead of *believed*. The word *gay* shifted from *cheerful* to *homosexual*, yet is still mapped to *gay* with NAA. This happens because the related embeddings (*homosexual*, *lesbian* and so on) are empty embeddings in 1900s, leaving *gay* as the next-best candidate, which we argue is better than OP's *society*. The words *car, driver, eve* whose meaning didn't change, were incorrectly aligned with OP to *cab, stepped, anniversary* instead of to themselves.

---

[1] Pre-possessing: removing proper nouns, stop words and empty embeddings. Post-processing: removing words whose frequency is below 10^{-5} in either years.

1990s Word	1900s NN aligned with OP	1900s NN aligned with NAA	Latent Variable
wanting	need	wishing	Noise
gay	society	gay	Noise
check	give	send	Noise
starting	begin	beginning	Noise
major	general	successful	Noise
actually	believed	really	Noise
touching	touched	touching	Noise
harry	hello	john	Noise
headed	halfway	toward	Noise
romance	artists	romance	Noise
car	cab	car	Aligned
driver	stepped	driver	Aligned
eve	anniversary	eve	Aligned

Table 3: Diachronic Semantic Change Experiment. Upper-part: noisy pairs. Bold: real semantic shifts. Underlined: global genre/discourse shifts. Unmarked: corpus artifacts. Bottom-part: clean pairs: Italics: unchanged words, no semantic shift.

6 Conclusion

We introduced the problem of embedding space projection with *noisy* lexicons, and showed that existing projection methods are sensitive in the presence of noise. We proposed an EM algorithm that jointly learns the projection and identifies the noisy pairs. The algorithm can be used as a drop-in replacement for the OP algorithm, and was demonstrated to improve results on two NLP tasks. We provide code at https://github.com/NoaKel/Noise-Aware-Alignment.

Abstract

Multilayer architectures are currently the gold standard for large-scale neural machine translation. Existing works have explored some methods for understanding the hidden representations, however, they have not sought to improve the translation quality rationally according to their understanding. Towards understanding for performance improvement, we first artificially construct a sequence of nested relative tasks and measure the feature generalization ability of the learned hidden representation over these tasks. Based on our understanding, we then propose to regularize the layer-wise representations with all tree-induced tasks. To overcome the computational bottleneck resulting from the large number of regularization terms, we design efficient approximation methods by selecting a few coarse-to-fine tasks for regularization. Extensive experiments on two widely-used datasets demonstrate the proposed methods only lead to small extra overheads in training but no additional overheads in testing, and achieve consistent improvements (up to +1.3 BLEU) compared to the state-of-the-art translation model.

1 Introduction

Neural machine translation (NMT) has witnessed great successes in recent years (Bahdanau et al., 2014; Wu et al., 2016). Current state-of-the-art (SOTA) NMT models are mainly constructed by a stacked neural architecture consisting of multiple hidden layers from bottom-up, where a classifier is built upon the topmost layer to solve the target task of translation (Gehring et al., 2017; Vaswani et al., 2017). Most works tend to focus on the translation performance of the classifier defined on the topmost layer, however, they do not deeply understand the learned representations of hidden layers. Shi et al. (2016) and Belinkov et al. (2017) attempt to understand the hidden representations through the lens of a few linguistic tasks, while Ding et al. (2017) and Strobelt et al. (2018) propose appealing visualization approaches to understand NMT models including the representation of hidden layers. However, employing the analyses to motivate new methods for better translation, the ultimate goal of understanding NMT, is not achieved in these works.

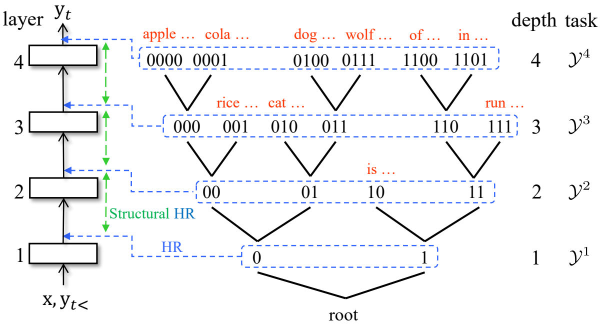

Figure 1: The structural hierarchical regularization framework. On the left is a 4-layer NMT decoder; on the right is a hierarchical clustering tree and the tree-induced relative tasks at every tree depth.

In our paper, we aim at understanding the hidden representation of NMT from an alternative viewpoint, and particularly we propose simple yet effective methods to improve the translation performance based on our understanding. We start from a fundamental question: what are the characteristics of the hidden representation for better translation modeling? Inspired by the lessons from transfer learning (Yosinski et al., 2014), we propose to empirically verify the argument: good hidden representation for a target task should be able to generalize well across *any* similar tasks. Unlike Shi et al. (2016) and Belinkov et al. (2017) who employ one or two linguistic tasks involving human annotated data to evaluate the feature generalization ability of the hidden representation,

which might make understanding bias to a specific task, we instead construct a nested sequence of *many* relative tasks with entailment structure induced by a hierarchical clustering tree over the output label space (target vocabulary). Each task is defined as predicting the cluster of the next token according to a given source sentence and its translation prefix. Similar to Yu et al. (2018), Zamir et al. (2018) and Belinkov et al. (2017), we measure the feature generalization ability of the hidden representation regarding each task. Our observations are (§2):

- The hidden representations learned by NMT indeed has decent feature generalization ability for the tree-induced relative tasks compared to the randomly initialized NMT model and a strong baseline with lexical features.
- The hidden representations from the higher layers generalize better across tasks than those from the lower layers. And more similar tasks have closer performances.

Based on the above findings, we decide to regularize and improve the hidden representations of NMT for better predictive performances regarding those relative tasks, in hope of achieving improved performance in terms of the target translation task. One natural solution is to feed all relative tasks to every hidden layer of the NMT decoder under the framework of multi-task learning. This may make the full coverage of the potential regularization effect. Unfortunately, this vanilla method is inefficient in training because there are more than one hundred task-layer combinations. [1] Based on the second finding, to approximate the vanilla method, we instead feed a single relative task to each hidden layer as a regularization auxiliary in a coarse-to-fine manner (§3.1). Furthermore, we design another regularization criterion to encourage predictive decision consistency between a pair of adjacent hidden layers, which leads to better approximated regularization effect (§3.2). Our method is simple to implement and efficient for training and testing. Figure 1 illustrates the representation regularization framework.

To summarize, our contributions are as follows:

- We propose an approach to understand hidden representation of multilayer NMT by measuring their feature generalization ability across relative tasks constructed by a hierarchical clustering tree.
- We propose two simple yet effective methods to regularize the hidden representation. These two methods serve as trade-offs between regularization coverage and efficiency with respect to the tree-induced tasks.
- We conduct experiments on two widely used datasets and obtain consistent improvements (up to +1.3 BLEU) over the current SOTA Transformer (Vaswani et al., 2017) model.

2 Understanding Hidden Representation

In this section, we first introduce some background knowledge and notations of the multilayer NMT model. Then, we present a simple approach to better understand hidden representation through transfer learning. By analyzing the feature generalization ability, we draw some constructive conclusions which are used for designing regularization methods in Section 3.

2.1 Background and Notations

Suppose $\mathrm{x} = \langle \mathrm{x}_1, \cdots, \mathrm{x}_{|\mathrm{x}|}\rangle$ is a source sentence, i.e. a sequence of source tokens, and a target sentence $\mathrm{y} = \langle \mathrm{y}_1, \cdots, \mathrm{y}_{|\mathrm{y}|}\rangle$ is a translation of x, where each y_t in y belongs to $\mathcal{Y}$, the target vocabulary. A translation model minimizes the following chain-rule factorized negative log-likelihood loss:

$$\begin{aligned}\ell_{mle} &= -\log P(\mathrm{y} \mid \mathrm{x}; \theta)\\ &= -\sum_t \log P(\mathrm{y}_t \mid \mathrm{x}, \mathrm{y}_{<t}; \theta),\end{aligned} \tag{1}$$

where θ denotes the overall parameter of the translation model. According to Eq.(1), an alternative view of the translation problem can be cast to token-level stepwise **classification** (Daumé et al., 2009): predict the target token y_t given a context consisting of x and $\mathrm{y}_{<t} = \langle \mathrm{y}_1, \cdots, \mathrm{y}_{t-1}\rangle$ corresponding to each factor $P(\mathrm{y}_t \mid \mathrm{x}, \mathrm{y}_{<t}; \theta)$.

The SOTA multilayer NMT models parameterize $P(\mathrm{y}_t \mid \mathrm{x}, \mathrm{y}_{<t}; \theta)$ via powerful multilayer encoder and stacked layers of feature transformations $\langle h^1, \cdots, h^L\rangle$ at the decoder side:

$$P(\mathrm{y}_t \mid \mathrm{x}, \mathrm{y}_{<t}; \theta) = P(\mathrm{y}_t \mid \mathrm{x}, \mathrm{y}_{<t}, h^L; \theta), \tag{2}$$

where $h^l(\mathrm{x}, \mathrm{y}_{<t}) = \phi^l\big(\mathrm{x}, \mathrm{y}_{<t}; h^{l-1}; \theta\big)$ is the l^{th} hidden layer recursively defined by ϕ^l on h^{l-1}.

---

[1] There are about 22 tasks that we have constructed and 6 layers in SOTA NMT models (Vaswani et al., 2017).

We also use $h^l(\mathrm{x}, \mathrm{y}_{<t})$ to represent the output hidden representation of layer l for a specific context. Note that, ϕ^l bears several types of instantiation and is an active area of research (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017).

2.2 Feature Generalization Ability of Hidden Representations

Inspired by feature transfer learning (Yosinski et al., 2014), we attempt to understand hidden representations of NMT by evaluating their generalization abilities across any tasks that are related to translation. There are some researchers who study hidden representations of NMT by using linguistic tasks such as morphology, named entity, part-or-speech or syntax (Shi et al., 2016; Belinkov et al., 2017, 2018). They typically rely on human annotated resources to train a model for each linguistic task, so their methods can not be used for languages which lack human annotations. Moreover, their considered tasks are too few to have a good coverage over task space for measuring transferability (Yu et al., 2018; Zamir et al., 2018), and their understanding results may bias to a specific task. As a result, to evaluate the feature generalization ability of hidden representation, we artificially construct plenty of relative tasks which do not employ any human annotation. This makes our evaluation approach more general.

Definition of the relative tasks Suppose $\mathcal{Y}^k$ denotes any partition (or clustering) regarding the output label space (target vocabulary) $\mathcal{Y}$. That is, $\mathcal{Y}^k$ is a set of subsets $\mathcal{Y}_i^k \subset \mathcal{Y}$ where $i = 1 ... |\mathcal{Y}^k|$, such that $\forall i, j, \mathcal{Y}_i^k \cap \mathcal{Y}_j^k = \emptyset$ and $\cup_i \mathcal{Y}_i^k = \mathcal{Y}$. We define the following relative task: given a context $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$, predict the subset or the cluster to which the t^{th} token y_t belongs in $\mathcal{Y}^k$, denoted as $\mathcal{Y}^k(\mathrm{y}_t)$. To simplify notation, we regard $\mathcal{Y}^k$ both as a relative task and as a partition.

It is clear that the above type of tasks are similar to the task of translation according to the description in Section §2.1. Furthermore, different k represents different relative task and thus we actually obtain a great many relative tasks in total. However, it is impossible to evaluate the hidden representation on all those tasks; moreover, due to relationship between tokens (Hu et al., 2016) in $\mathcal{Y}$, not all partitions are reasonable. As a consequence, motivated by the analysis of VC Dimension (Vapnik, 1995), we construct a sequence of nested partitions with an entailment structure: [2] $\mathcal{Y}^1 \preceq \cdots \preceq \mathcal{Y}^K$. The benefit is that a spectrum of task hardness can be constructed due to the increased partition or task cardinalities.

As a matter of fact, we instantiate the above nested partitions through brown clustering (Brown et al., 1992; Stratos et al., 2014) over $\mathcal{Y}$ to get a hierarchical clustering tree and then consider each tree depth along the tree as a partition representing a relative task $\mathcal{Y}^k$ (as shown in Figure 1). In the following experiments, we run brown clustering algorithm over a Ch⇒En dataset (§4) and construct a tree of English with depth 21. Without loss of generality, we regard the task $\mathcal{Y}^{22}$ at a virtual 22 depth of the tree as equivalent to the translation task $\mathcal{Y}$. Actually, $\mathcal{Y}$ and $\mathcal{Y}^{22}$ have the same cardinality but are different in definition. [3]

Evaluating generalization We use multi-class logistic regression to fit the layer-wise hidden representation learned by a well-trained 6-layer Transformer (Vaswani et al., 2017) over each training instance $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$. Specifically, given a context $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$, for each task $\mathcal{Y}^k$ and a hidden representation $h^l(\mathrm{x}, \mathrm{y}_{<t})$ of this context, which is fixed as constant, we predict the cluster $\mathcal{Y}^k(\mathrm{y}_t)$ according to the following probability:

$$P\big(\mathcal{Y}^k(\mathrm{y}_t) \mid h^l(\mathrm{x}, \mathrm{y}_{<t}); \theta^l_{\mathcal{Y}^k}\big), \tag{3}$$

where $\theta^l_{\mathcal{Y}^k}$ is the parameter of the logistic regression model for task $\mathcal{Y}^k$ at l^{th} layer. The difference between Eq.(3) and Eq.(2) is that the former is the linear model parameterized by $\theta^l_{\mathcal{Y}^k}$ while the latter is the NMT model parameterized by θ.

Since there are $L = 6$ layers in Transformer's decoder and $K = 22$ relative tasks, we have more than one hundred such linear models defined with Eq. (3) in total. Therefore, it is costly to train them independently. Since the loss for each linear model is convex, joint training leads to exactly the same optimum as independent training and thus we employ mini-batch stochastic gradient descent to minimize the joint loss as follows:

$$-\sum_k \sum_l \sum_t \log P\big(\mathcal{Y}^k(\mathrm{y}_t) \mid h^l(\mathrm{x}, \mathrm{y}_{<t}); \theta^l_{\mathcal{Y}^k}\big). \tag{4}$$

---

[2] Here what we mean entailment relation ($\preceq$) between two partitions $\mathcal{Y}^k$ and $\mathcal{Y}^{k+1}$ is: $\forall \mathcal{Y}_i^{k+1}, \exists! \mathcal{Y}_j^k, s.t. \mathcal{Y}_i^{k+1} \subseteq \mathcal{Y}_j^k$.

[3] Please refer to Appendix A for detailed preprocessing of the tree to get nested partitions.

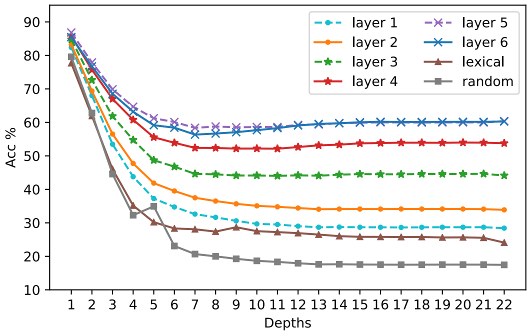

Figure 2: The transfer learning performances.

After training, we fix each $\theta^l_{\mathcal{Y}^k}$ and then measure the feature generalization ability of each h^l by validating on the task $\mathcal{Y}^k$ regarding a heldout dataset, following Yu et al. (2018). For validation, we report accuracy on a heldout dataset through the strategy of maximum a posteriori (MAP). [4]

Analysis To figure out how good the learned hidden representations are, we consider two **baselines** to extract features regarding each context $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$ to train logistic regression models for comparison. For the first baseline, the features of the context are the hidden representations from the last layer of a randomly initialized Transformer; for the second, the features are derived by lexical feature templates, which include the source-side bag-of-words (BOW) features and target-side BOW features indexed by relative positions of y_t's previous with up to m (Markov length) tokens. [5]

As shown in Figure 2, the lexical baseline delivers comparable accuracies for fine-grained tasks with respect to well learned Transformer's first layer, thanks to its discriminant ability with abundant lexical features. For example, its accuracy reaches about 26% for the task with cardinality $|\mathcal{Y}^{21}|$. The random baseline performs worse for tasks with cardinality $|\mathcal{Y}^{8}|$, which indicates that random representations in NMT have limited generalization abilities to fine-grained tasks as expected. The well-trained low-layer hidden representations yield much higher accuracies than the random baseline and are even better than the lexical baseline. This shows that the hidden representations from a well-trained NMT have good generalization abilities across relative tasks. In addition, as the layer goes up, the performance of hidden representations increase significantly over different relative tasks, which clearly demonstrates that more complex neural architecture leads to stronger expressibility. This provides a quantitative evidence to support the statement in Bengio et al. (2009), Goodfellow et al. (2016).

3 Structural Hierarchical Regularization

In this section, we propose two simple methods, which respect the above findings, to enhance the hidden representations in NMT such that they generalize well across those relative tasks.

3.1 Hierarchical Regularization

A natural method to improve feature generalization of hidden representation is to jointly train the target task with all relative tasks for all hidden layers, which we call full-coverage method. As mentioned in Section §2.2, this method will lead to training more than one hundred tasks ($K \times L$) in total, where K denotes the depth of the hierarchical clustering tree (aka. the number of tasks) and L the number of hidden layers. Unfortunately, since each task involves a softmax operation which may be the computation bottleneck for the task $\mathcal{Y}^k$ with large cardinality, this method is inefficient for training.

As a solution to approximate the potential regularization effect of the full-coverage method, we confine each hidden layer to engage in a single relative task. Motivated by the observation that representations from higher layers have better expressibility than lower layers, as claimed in §2.2, we instead employ a coarse-to-fine strategy to select one task for each layer: finer-grained tasks for higher layers while coarser-grained task for lower layers. Specifically, suppose $1 \leq s(l) \leq K$ is the selected index regarding task $\mathcal{Y}^{s(l)}$ for the l^{th} layer, then it subjects to $s(l) < s(l+1)$ for each l. In addition, to encourage the diversity among the selected L tasks, we require $s(l+1) - s(l)$ to be large enough for all l. Formally, the loss of the hierarchical regularization (HR) method is:

$$\ell_{hr} = -\sum_{l} \sum_{t} \log P(\mathcal{Y}^{s(l)}(\mathrm{y}_t) \mid \mathrm{x}, \mathrm{y}_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}}), \quad (5)$$

where $P(\mathcal{Y}^{s(l)}(\mathrm{y}_t) \mid \mathrm{x}^j, \mathrm{y}^j_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}})$ is similar to Eq. 3 except that it treats the parameters θ in NMT as parameters besides $\theta^l_{\mathcal{Y}^{s(l)}}$. Compared to Eq. 4, it includes fewer terms for summation.

---

[4] The accuracy is measured by whether $\arg\max_{z \in \mathcal{Y}^k} P(z \mid h^l(\mathrm{x}, \mathrm{y}_{<t}); \theta^l_{\mathcal{Y}^k})) = \mathcal{Y}^k(\mathrm{y}_t)$.

[5] Please refer to Appendix B for more details are.

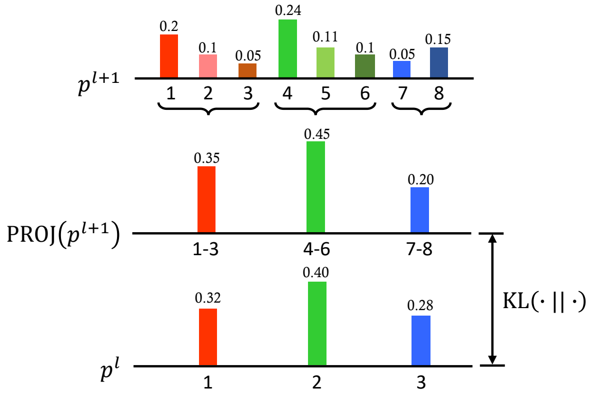

Figure 3: The conceptual graph of the KL consistency loss in SHR. Here, the multinomial probability vector p^l is calculated through $P(\cdot \mid \mathrm{x}, \mathrm{y}_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}})$.

3.2 Structural Hierarchical Regularization

The HR method is very simple and computationally efficient, however, using one task to regularize a layer may not be a good approximation of the full-coverage method, since HR method might lead to inconsistent decisions for two different layers, which is formalized through the following entailment structure as introduced in Section 2.2:

$$\arg\max_{\mathrm{z}\in\mathcal{Y}^{s(l_1)}} P(\mathrm{z} \mid \mathrm{x}, \mathrm{y}_{<t}, h^{l_1}; \theta, \theta^{l_1}_{\mathcal{Y}^{s(l_1)}}) \supset \arg\max_{\mathrm{z}\in\mathcal{Y}^{s(l_2)}} P(\mathrm{z} \mid \mathrm{x}, \mathrm{y}_{<t}, h^{l_2}; \theta, \theta^{l_2}_{\mathcal{Y}^{s(l_2)}}), \quad (6)$$

where $s(l)$ is the selected task for the l^{th} layer by HR, $1 \leq l_1 < l_2 \leq L$ and $P(\mathrm{z}|\mathrm{x}, \mathrm{y}_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}})$ is similar to Eq. (3) for the task $\mathcal{Y}^{s(l)}$ and l^{th} layer except that it does not treat the NMT parameters θ as constant. However, it always occurs on the training data that $\mathcal{Y}^{s(l_1)}(\mathrm{y}_t) \subset \mathcal{Y}^{s(l_2)}(\mathrm{y}_t)$.

To alleviate this inconsistency issue for better approximating the full-coverage method, we leverage the above structural property by adding another regularization term. Firstly, we project the distribution $P(\cdot|\mathrm{x}, \mathrm{y}_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}})$ into the domain of $\mathcal{Y}^{s(l-1)}$. Then we calculate KL divergence between the projected distribution and $P(\cdot|\mathrm{x}, \mathrm{y}_{<t}, h^{l-1}; \theta, \theta^{l-1}_{\mathcal{Y}^{s(l-1)}})$. Figure 3 illustrates the idea. Since it is inefficient to consider all pairs of l_1 and l_2, so we instead consider the consistency between all adjacent layers. Formally, we obtain the following loss function:

$$\ell_{shr} = \ell_{hr} + \frac{1}{L-1}\sum_{l} \mathrm{KL}\Big(P(\cdot|\mathrm{x}, \mathrm{y}_{<t}, h^l; \theta, \theta^l_{\mathcal{Y}^{s(l)}}) \mid\mid \mathrm{PROJ}\big[P(\cdot|\mathrm{x}, \mathrm{y}_{<t}, h^{l+1}; \theta, \theta^{l+1}_{\mathcal{Y}^{s(l+1)}})\big]\Big), \quad (7)$$

where PROJ is the projection defined in Figure 3, and other notations are defined as before.

Method	# Param.		Speed	
	Zh⇒En	**En⇒De**	**Train**	**Test**
Baseline	90.2M	88.0M	1.82	1.33
FHR	+60.9M	+63.2M	0.72	
HR	+3.2M	+3.1M	1.65	
SHR	+3.2M	+3.1M	1.40	

Table 1: Train and test efficiency comparison, measured by steps/s (second) and sentences/s respectively.

We call the above regularization as structural hierarchical regularization (SHR) since it takes advantage of the structure of the tree. In our experiments, we add HR (Eq.(5)) and SHR (Eq.(7)) losses respectively into the negative log-likelihood regarding Eq. (1) for training all parameters θ and $\theta^l_{\mathcal{Y}^{s(l)}}$. One of our advantage is that we only use θ for testing and thus our testing is as efficient as that for the baseline NMT model.

4 Experiments

4.1 Setup

We conduct experiments on two widely-used corpora. We choose from the LDC corpora about 1.8M sentence pairs for Zh⇒En translation with word-level vocabulary of 30k for both languages. We use the WMT14 En⇒De task which consists 4.5M sentence pairs and the vocabulary is built by joint BPE with 32k merging operations. Besides the baseline, we also conduct experiments on 3 regularization variants:

- **Baseline**: the Transformer base model proposed in Vaswani et al. (2017).
- **FHR**: fine-grained HR based Transformer, which adopts the original label space as task for all selected layers for regularization. This variant is used to demonstrate that low layers which are weak in expressibility can mess up hard tasks which are unsuitable to learn.
- **HR** and **SHR**: as proposed in Section 3.

Method	MT02	MT03	MT04	MT05	MT06	MT08	Avg.
Zhao et al. (2018)	N/A	44.98	45.51	43.93	43.95	33.33	42.34
Baseline	46.08	44.09	46.50	44.45	45.26	37.10	43.48
FHR	45.46	43.56	47.51	44.00	45.45	37.22	43.58
HR	46.28	44.04	47.80	44.56	45.56	38.17	44.08
SHR	**47.05**	**44.80**	**48.15**	**45.55**	**46.30**	**39.02**	**44.78**

Table 2: BLEU comparison on the LDC dataset.

Choice of relative tasks Based on the heuristics in Section 3.1, we first choose the task with the largest cardinality from the hierarchical clustering tree without the virtual depth, because this task is most related to translation (close cardinalities). Then we balance task diversity through a 5 times cardinality difference between tasks from the previous chosen task. As a result, we can obtain 4 tasks with $s(l) = 5, 8, 11, 20$ for the Zh⇒En task and $s(l) = 5, 7, 10, 21$ for the En⇒De task, where $l = 2, 3, 4, 5$ of the 6-layer decoder. [6]

4.2 Efficiency Comparison

Table 1 summarizes the total number of parameters for the baseline and 3 regularization variants. As in Eq. (5), HR introduces extra parameters compared with the baseline. Besides, calculating the second term in Eq. (7) requires modest overheads. Therefore, training our SHR is slower than training the baseline. Although the proposed HR and SHR introduce extra parameters during training, they do not involve them during testing and thus testing is as efficient as the baseline.

4.3 Translation Quality on Zh⇒En Dataset

Table 2 shows the evaluation results of the baseline and 3 regularization variants on the Zh⇒En dataset. Since there are no recent work reporting Transformer's performance on this dataset, we choose a recurrent SOTA model to show that our baseline is already better than it, which is a common knowledge that Transformer can outperform recurrent NMT models. Our HR method surpasses the baseline 0.6 BLEU point, while the SHR method can improve upon HR by about a further 0.8 point, namely about 1.4 points over the baseline. Interestingly, the FHR method only performs on par with baseline, which indicates that forcing low layers to learn fine-grained tasks will not lead to beneficial intermediate representations since they struggle to learn a well-structured representation space. This matches the finding in Section 2: low layers may not be expressible enough to perform well on tasks with large cardinalities.

4.4 Analyses on Zh⇒En Dataset

In the following, we conduct several quantitative experiments to demonstrate the advantages of our proposed two regularization methods over the baseline. Note that, since we need to guarantee that the decoded sequence has the same length with the reference for one-by-one token comparison, the following experiments are all conducted with teacher forcing and greedy decoding.

4.4.1 Better Feature Generalization Ability

In the same manner as Section 2, we learn softmax weights for all relative tasks by fixing model weights learned by HR and SHR methods. Figure 4(a), (b) show the Δ feature generalization ability (absolute accuracy difference) of HR and SHR over baseline. Since layer 1 is not selected as the regularized layer, no significant gap is observed. However, since layer 1 is close to the loss directly imposed on layer 2, improvements about 5% and 8% are obtained. Since in the baseline, layer 5, 6 are already close or with the ultimate fine-grained loss, HR method shows very small gain. But our SHR method can still improve about 4% absolute points. Except for layer 1, it is also evident to see larger gaps (more than 20%) at lower layers than higher layers due to the fact that lower layers, which are distant from the topmost loss in the baseline, require more supervision signals to shape their latent representation space.

4.4.2 Improved Decision Consistency

We measure decision consistency for a specific layer and decision consistency between a pair of layers using two metrics. The first metric is measured by conditional accuracy, which is the possibilities of the classifier parameterized by $\theta^l_{\mathcal{Y}^k}$ correctly predicting $\mathcal{Y}^k(\mathrm{y}_t)$ if the classifier parameterized by $\theta^l_{\mathcal{Y}^{k'}}$ correctly predicts $\mathcal{Y}^{k'}(\mathrm{y}_t)$ for any

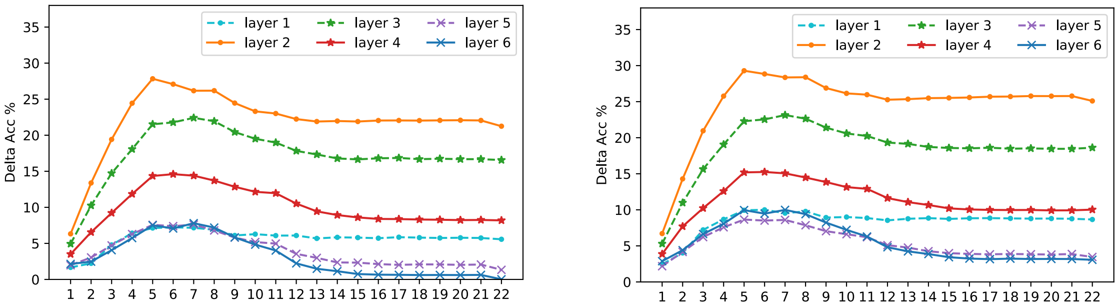
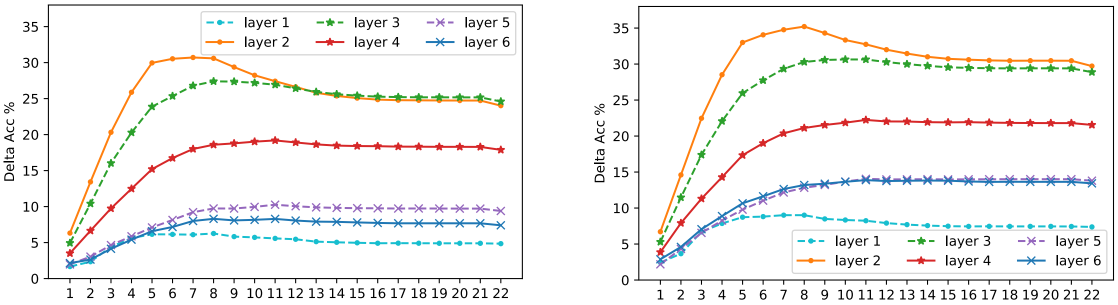
[6] Please refer to Appendix C for detailed information.



(a) HR vs Baseline (b) SHR vs Baseline

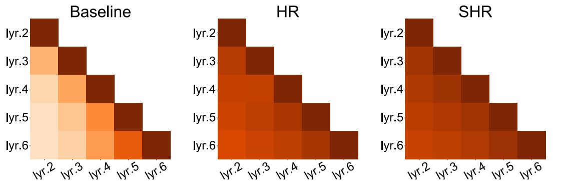


(c) HR vs Baseline (d) SHR vs Baseline

Figure 4: (a), (b) are the Δ feature generalization ability (absolute accuracy difference) of HR and SHR method compared to baseline; (c), (d) are the conditional absolute accuracy difference of HR and SHR over baseline.

$k' < k$. The second metric is measured by the counts of consistent decision pairs between any pair of regularized layers as defined in Eq. (6).

Figure 4(c), (d) shows the absolute conditional accuracy difference of our HR and SHR over baseline. In accordance with the observations in previous subsection, except for layer 1, other layers show significant gains (HR more than 7%, SHR more than 10%) over baseline. Decision consistency for each layer proves the well-shaped layer-wise representation and potentially paves the way for better inter-layer decision consistency.



(a) (b) (c)

Figure 5: The consistency correlation between different regularized layers (lyr.2 to lyr.6) of the baseline and our two regularization methods.

Figure 5 illustrates the consistency counts between any regularized layer pairs, including those without KL-based regularization. Deeper color represents more consistency counts. It is evident that the baseline has a very poor consistency between any layers. Our HR method is almost 2 times better, and the SHR obtains further improvement. A better decision consistency can couple the decision between relative tasks, so that by reaching a high accuracy on easier tasks can benefit the harder ones. Another interesting observation is that non-adjacent layers without KL loss also obtain significant improvements on decision consistency, because the KL term is actually transitive between layers where the predictive distributions are in accordance with the tree structure.

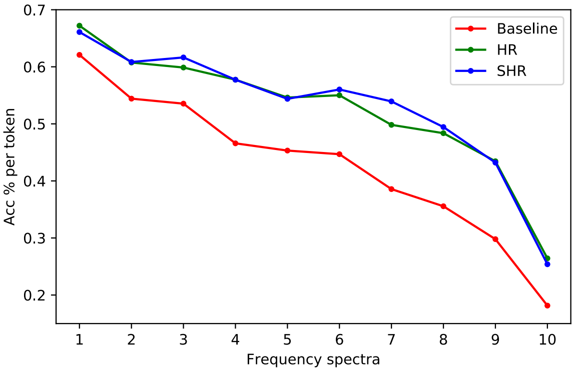


Figure 6: Development set accuracy among the baseline and our proposed regularization variants over different word frequency bins.

4.4.3 Promoted Low-Frequency Word Performance

In this subsection, we clarify that the coarse-to-fine regularized representations can also benefit low-frequency words. We divide the vocabulary into ten equally-sized bins, and summarize token accuracy for each bin over the development set. As shown in Figure 6, the x-axis represents the frequency spectra, that is, we sort the bins by word frequency from rank 1 (the most frequent words) to 10 (the rare words). We can see that both HR and SHR methods demonstrate a gradually increased gap over the baseline as the word frequency decreases, which means our methods become better for less frequent word bins. However the gap shrinks at the 10^{th} bin. This may be the fact that for those words that appears with less than 50 counts, both methods are helpless.

For baseline, it is hard to train well-shaped hidden representations for low-frequent words; in addition, due to the distance between the loss and the low layers, it is also hard to train weights due to the unstable gradient signal. By adding our regularization terms, every level of the multilayer decoder will receive supervision signals directly and lower layers will receive coarser grained thus higher frequency signals to shape their representations.

4.5 Translation Quality on En⇒De Dataset

Table 3 shows the evaluation results of the baseline and the 3 regularization variants on the En⇒De dataset. Notice that we use the base model while Chen et al. (2018) and Ott et al. (2018) use big models. The FHR method still does not show significant improvement over the baseline (less than 0.2 BLEU point), which verifies the hypothesis that we make by analyzing the Zh⇒En results. Our HR method is already stronger than Chen et al. (2018) which uses a multilayer RNN as decoder. Compared to the current state-of-the-art in Ott et al. (2018) who utilize huge batch size and over 100 GPUs on the Transformer big model, our SHR method can be on par with them. This comparison indicates that better regularized hidden representations can be potentially powerful than increasing model capacity when using the same optimization method.

5 Related Work

Since the dawn of NMT, many works have proposed for understanding what has been encoded in the learned hidden representations. Shi et al. (2016) are the first to investigate source syntax encoded in source hidden representations. Similarly, Belinkov et al. (2017) and Belinkov et al. (2018) give detailed analyses of both encoder and decoder's learned knowledge about part-of-speech and semantic tags at different layers. Unlike those works that employ one or two linguistic tasks, we instead construct plenty of artificial tasks without any human annotations to analyze the hidden representations. This makes our approach more general and may potentially lead to less biased conclusions.

Method	MT13	MT14
Chen et al. (2018)	N/A	28.49
Ott et al. (2018)	**26.70**	**29.30**
Baseline	25.99	27.75
FHR	26.10	27.91
HR	26.48	28.87
SHR	**26.64**	**29.18**

Table 3: BLEU comparison on the WMT14 dataset. Here MT13 and MT14 denote newstest2013 and newstest2014, which are used as development and test set respectively.

Based on our understanding of the hidden representations, we further develop simple methods to improve NMT through representation regularization. Many works regularize NMT with lexical knowledge such as BOW (Weng et al., 2017) and morphology (Niehues and Cho, 2017; Zaremoodi et al., 2018), or syntactic knowledge (Kiperwasser and Ballesteros, 2018; Eriguchi et al., 2017). One significant difference is that we take into account the structure among plenty of artificial tasks and design a well motivated regularization term to encourage the structural consistency of tasks, which further improves NMT performance. In addition, our coarse-to-fine way to select tasks for regularization is also inspired by recent works using a coarse-to-fine mechanism for learning better word embeddings in NMT (Zhang et al., 2018) and predicting intermediate solutions for semantic parsing (Dong and Lapata, 2018).

6 Conclusion

In this work, we present a simple approach for better understanding NMT learned layer-wise representations with transfer learning over plenty of artificially constructed relative tasks. This approach is general as it requires no human annotated data, only demanding target monolingual corpus. Based on our understanding, we propose two efficient yet effective methods for representation regularization which further pushes forward the SOTA NMT performances. In the future, we want to dig deeply into the subspace regularities of the learned representations for more fine-grained understanding.

A Hierarchical Clustering Tree Induced Relative Tasks

In this appendix, we demonstrate a more detailed introduction to the partition of $\mathcal{Y}$, the hierarchical clustering tree constructed by $\mathcal{Y}$ and the tree-induced relative tasks, which are introduced in Section 2.2, through an example.

Suppose our vocabulary $\mathcal{Y}$ only consists of a few words, that is, $\mathcal{Y} = \{\text{cat, dog, run, jump, is}\}$. Any partition of $\mathcal{Y}$ denoted as $\mathcal{Y}^k$ is a set of subsets of $\mathcal{Y}$. As shown in Figure 7, this partition is actually { { cat, dog }, { jump, run }, { is } }.

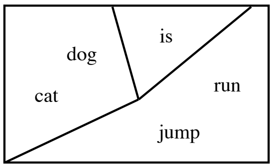

Figure 7: One example partition of the vocabulary $\mathcal{Y}$.

Then suppose the constructed hierarchical clustering tree looks like the tree in Figure 8(a). In this tree, not all the leaves are at the same depth, so we left-branches the leaves with {cat, dog} at depth 1 to stretch to depth 2. Then by adding a virtual level at depth 3, we can construct a relative task with the same cardinality as the fine-grained translation task $\mathcal{Y}$, as shown in Figure 9(b).

B Lexical Feature-based Baseline

In this appendix, we describe the lexical feature-based baseline that we use in Section 2.2 to compare with the layer-wise representations learned by Transformer. There are two types of feature template: a) the source-side bag-of-word (BOW) features; and b) the target-side order-aware BOW features. Specifically, given a context $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$, we extract features according to the above templates:

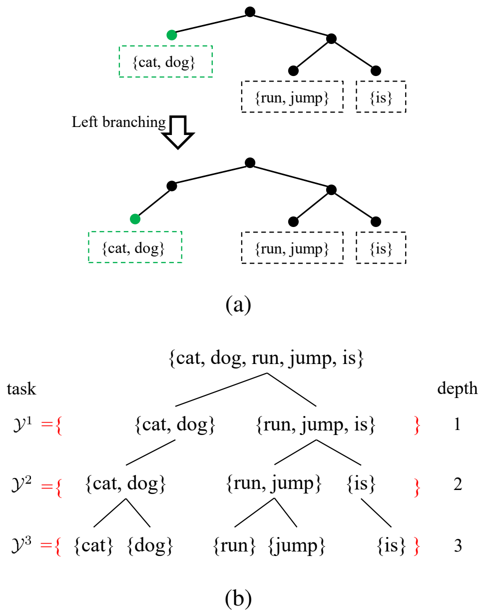

Figure 8: (a) The original hierarchical clustering tree, with left branching to have all leaves at the same tree depth; (b) The hierarchical clustering tree with depth 2, and a virtual task is constructed at depth 3.

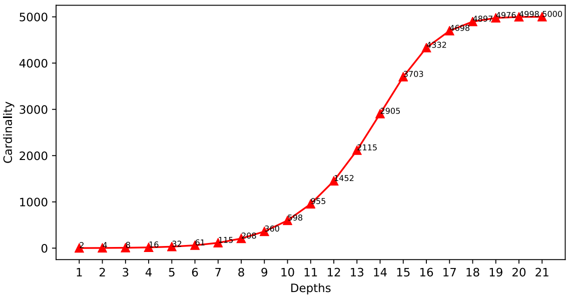
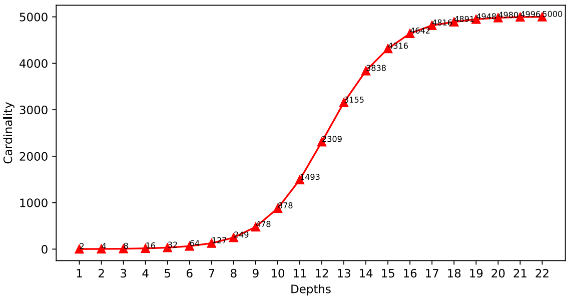


(a) Task cardinalities for English (Zh⇒En).



(b) Task cardinalities for German (En⇒De).

Figure 9: Task cardinalities.

- the BOW representation of the source sentence x: that is, if the source vocabulary is $\mathcal{X}$, the source BOW feature vector has length of $|\mathcal{X}|$, with each entry the appearances of that token in x.

- the order-aware BOW representation within k-Markov dependency chain: that is, we extract feature from $\mathrm{y}_{t-k:t-1}$ by considering both the token identity and the relative distance of that token to the predicted one y_t. This feature template constructs a feature vector of $k \times |\mathcal{Y}|$ entries ($\mathcal{Y}$ the target vocabulary), with each entry set to 1 when appears in the chain, otherwise 0.

- the order-unaware BOW representation outside the k-Markov dependency chain, that is, we extract feature from the $\mathrm{y}_{0:t-k-1}$ with the same philosophy of the source-side BOW feature and obtain a feature vector of size $\mathcal{Y}$.

So in total, the feature vector extracted from the context $\langle \mathrm{x}, \mathrm{y}_{<t} \rangle$ has a size $(|\mathcal{X}| + k \times |\mathcal{Y}|)$, which will be around 300k if the vocabulary size is around 30k and the Markov order $k = 10$.

C Detailed Experiment Information

In this appendix, we describe the detailed experiment information: the construction of the hierarchical clustering tree (Brown et al., 1992; Stratos et al., 2014), the model configuration, and the training details.

We construct two hierarchical clustering trees for the two target languages, English (Zh⇒En) and German (En⇒De) in our experiments, with Percy Liang's Brown Clustering algorithm implementation. [7] In both languages, we set the number of clusters to 5000 (a hyperparameter in the algorithm, $c = 5000$), that is, we will obtain trees with 5000 leaves. We set c to 5000 since the total vocabulary of the two languages are around 30k, and 5000 clusters will get a token coverage of 6 (30k/5000=6) for each leave if the clusters are balanced. By using left-branching introduced in Appendix A, we can finally get two trees with every depths as a relative task. The statistics of each relative task's cardinality for each tree are shown in Figure 9(a) and (b) respectively. For selecting the depths in a coarse-to-fine manner, we follow the heuristics mentioned in Section 3.1, that is, we select depths which are diverse enough so as to have better coverage of all the relative tasks. Specifically, we follow a quotient between two adjacent selected tasks of 5, and select from the task which has the cardinality of 5000, then we select tasks of cardinalities around 1000, 200, 40 respectively.

Table 4: BLEU comparison on the LDC dataset with independently regularized layers.

For the Zh⇒En dataset, we select tasks at depths 5, 8, 11, 20 with cardinalities 32, 208, 955, 5000; for the En⇒De dataset, we select tasks at depths 5, 7, 10, 21 with cardinalities 32, 127, 878, 5000.

The model configuration strictly follows that of the base model in Vaswani et al. (2017) with word embedding size of 512, hidden size of 512, feed-forward projection size of 2048, layer and head number of 6 and 8. The dropout rates of the embedding, attention and residual block are all set to 0.1. All architectural settings are in accordance with the base model of Vaswani et al. (2017).

We use Adam (Kingma and Ba, 2014) as the default optimizer with an initial learning rate of 0.0001. Training batch size is set to 8192 × 4 tokens per batch, that is, we use data parallelism with 4 P40 or M40 GPUs and 8192 tokens per GPU. We train the Zh⇒En models from scratch for about 240k iterations about 2 weeks on 4 M40 GPUs for both the baseline and the 3 regularization variants. For the En⇒De models, we first attempt to train all the methods from scratch up to 200k iterations, but do not see significant improvement on BLEU score (around 0.6 points on test). So we use the pretrained baseline to initialize our proposed methods, and further train them for about 200k iterations, which results in the reported improvement in Section 4.5.

D Experiments of Independent Layer Regularization on Zh⇒En

As suggested by the reviewers, we conduct independent layer regularization by imposing a relative task with cardinality of 5000 on layer 2 to 5 with the six layer Transformer. The performances are demonstrated in Table 4. It seems that independent layer regularization can as well brings about descent improvements over the baseline. And regularizing layer 2 of the decoder performs better than our HR method. It is surprising that lower layers are more urgent to be regularized than higher layers. This phenomenon may raise the question that how on earth the intermediate layer representations help with final prediction. One hypothesis may be drawn from our paper is that: in baseline, the coherence among the layer-wise representations may be weak so that some non-linear transformations from lower layer may not lead to essential predictive power of the final layer representation. And by using KL divergence to externally constrain their decision consistency may take better advantage of lower layers. As one of the reviewer pointed out, Universal Transformer (Dehghani et al., 2018) with base model's hyperparameters achieves 28.90 on WMT14 En⇒De newstest14, with 1/6 enc-dec parameters (not considering embeddings). Its architectural inductive bias is motivated from iterative refinement of the layer-wise representation so the decoder at each time step builds an RNN like reasoning process to refine upon previous layer's representation. We think this might be a more effective inductive bias in ResNet architecture which is adopted by Transformer, since Jastrzebski et al. (2017) provides evidence that ResNet does iterative representation inference (residual as refined quantity). Future directions may include relating the dimension reduced representations (Law et al., 2018) to the coarse-to-fine structural bias, or experiments on Universal Transformer architecture to probe its learned representations.

Content Differences in Syntactic and Semantic Representations

Daniel Hershcovich[1,2] **Omri Abend**[2] **Ari Rappoport**[2]

Abstract

Syntactic analysis plays an important role in semantic parsing, but the nature of this role remains a topic of ongoing debate. The debate has been constrained by the scarcity of empirical comparative studies between syntactic and semantic schemes, which hinders the development of parsing methods informed by the details of target schemes and constructions. We target this gap, and take Universal Dependencies (UD) and UCCA as a test case. After abstracting away from differences of convention or formalism, we find that most content divergences can be ascribed to: (1) UCCA's distinction between a Scene and a non-Scene; (2) UCCA's distinction between primary relations, secondary ones and participants; (3) different treatment of multi-word expressions, and (4) different treatment of inter-clause linkage. We further discuss the long tail of cases where the two schemes take markedly different approaches. Finally, we show that the proposed comparison methodology can be used for fine-grained evaluation of UCCA parsing, highlighting both challenges and potential sources for improvement. The substantial differences between the schemes suggest that semantic parsers are likely to benefit downstream text understanding applications beyond their syntactic counterparts.

1 Introduction

Semantic representations hold promise due to their ability to transparently reflect distinctions relevant for text understanding applications. For example, syntactic representations are usually sensitive to distinctions based on POS (part of speech), such as between compounds and possessives. Semantic schemes are less likely to make this distinction since a possessive can often be paraphrased as a compound and vice versa (e.g., "US president"/"president of the US"), but may distinguish different senses of possessives (e.g., "some of the presidents" and "inauguration of the presidents").

Nevertheless, little empirical study has been done on what distinguishes semantic schemes from syntactic ones, which are still in many cases the backbone of text understanding systems. Such studies are essential for (1) determining whether and to what extent semantic methods should be adopted for text understanding applications; (2) defining better inductive biases for semantic parsers, and allowing better use of information encoded in syntax; (3) pointing at semantic distinctions unlikely to be resolved by syntax.

The importance of such an empirical study is emphasized by the ongoing discussion as to what role syntax should play in semantic parsing, if any (Swayamdipta et al., 2018; Strubell et al., 2018; He et al., 2018; Cai et al., 2018). See §8.

This paper aims to address this gap, focusing on *content* differences. As a test case, we compare relatively similar schemes (§2): the syntactic Universal Dependencies (UD; Nivre et al., 2016), and the semantic Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013).

We UCCA-annotate the entire web reviews section of the UD EWT corpus (§3), and develop a converter to assimilate UD and UCCA, which use formally different graphs (§4). We then align their nodes, and identify which UCCA categories match which UD relations, and which are unmatched.

Most content differences are due to (§5):

1. UCCA's distinction between words and phrases that evoke Scenes (events) and ones that do not. For example, eventive and non-eventive nouns are treated differently in UCCA, but similarly in UD.
2. UCCA's distinction between primary relations, secondary relations and Participants, in contrast to UD's core/non-core distinction.

Proceedings of NAACL-HLT 2019, pages 478–488
Minneapolis, Minnesota, June 2 - June 7, 2019.

3. Different treatment of multi-word expressions (MWEs), where UCCA has a stronger tendency to explicitly mark them.

4. UCCA's conflation of several syntactic realizations of inter-clause linkage, and disambiguation of other cases that UD treats similarly.

We show that the differences between the schemes are substantial, and suggest that UCCA parsing in particular and semantic parsing in general are likely to benefit downstream text understanding applications. For example, only 72.9% of UCCA Participants are UD syntactic arguments, i.e., many semantic participants cannot be recovered from UD.[1] Our findings are relevant to other semantic representations, given their significant overlap in content (Abend and Rappoport, 2017).

A methodology for comparing syntactic and semantic treebanks can also support fine-grained error analysis of semantic parsers, as illustrated by Szubert et al. (2018) for AMR (Banarescu et al., 2013). To demonstrate the utility of our comparison methodology, we perform fine-grained error analysis on UCCA parsing, according to UD relations (§6). Results highlight challenges for current parsing technology, and expose cases where UCCA parsers may benefit from modeling syntactic structure more directly.[2]

2 Representations

The conceptual and formal similarity between UD and UCCA can be traced back to their shared design principles: both are designed to be applicable across languages and domains, to enable rapid annotation and to support text understanding applications. This section provides a brief introduction to each of the schemes, whereas the next sections discuss their content in further detail.[3]

UCCA is a semantic annotation scheme rooted in typological and cognitive linguistic theory. It aims to represent the main semantic phenomena in text, abstracting away from syntactic forms. Shown to be preserved remarkably well across translations (Sulem et al., 2015), it has been applied to improve text simplification (Sulem et al., 2018b), and text-to-text generation evaluation (Birch et al., 2016; Choshen and Abend, 2018; Sulem et al., 2018a).

Participant	A	Linker	L
Center	C	Connector	N
Adverbial	D	Process	P
Elaborator	E	Quantifier	Q
Function	F	Relator	R
Ground	G	State	S
Parallel Scene	H	Time	T

Table 1: Legend of UCCA categories (edge labels).

Formally, UCCA structures are directed acyclic graphs (DAGs) whose nodes (or *units*) correspond either to words, or to elements viewed as a single entity according to some semantic or cognitive consideration. Edges are labeled, indicating the role of a child in the relation the parent represents. Figure 1 shows a legend of UCCA abbreviations. A *Scene* is UCCA's notion of an event or a frame, and is a description of a movement, an action or a state which persists in time. Every Scene contains one primary relation, which can be either a Process or a State. Scenes may contain any number of Participants, a category which also includes abstract participants and locations. They may also contain temporal relations (Time), and secondary relations (Adverbials), which cover semantic distinctions such as manner, modality and aspect.[4]

Scenes may be *linked* to one another in several ways. First, a Scene can provide information about some entity, in which case it is marked as an Elaborator. This often occurs in the case of participles or relative clauses. For example, "(child) who went to school" is an Elaborator Scene in "The child who went to school is John". A Scene may also be a Participant in another Scene. For example, "John went to school" in the sentence: "He said John went to school". In other cases, Scenes are annotated as Parallel Scenes (H), which are flat structures and may include a Linker (L), as in: "When$_L$ [he arrives]$_H$, [he will call them]$_H$".

Non-Scene units are headed by units of the category Center, denoting the type of entity or thing described by the whole unit. Elements in non-Scene units include Quantifiers (such as "*dozens* of people") and Connectors (mostly coordinating conjunctions). Other modifiers to the Center are marked as Elaborators.

UCCA distinguishes *primary* edges, corresponding to explicit relations, from *remote* edges,

---

[1] This excludes cases of shared argumenthood, which are partially covered by *enhanced UD*. See §4.1.

[2] Our conversion and analysis code is public available at `https://github.com/danielhers/synsem`.

[3] See Supplementary Material for a definition of each category in both schemes, and their abbreviations.

[4] Despite the similar terminology, UCCA Adverbials are not necessarily adverbs syntactically.

which allow for a unit to participate in several super-ordinate relations. See example in Figure 1. Primary edges form a tree, whereas remote edges (dashed) enable reentrancy, forming a DAG.

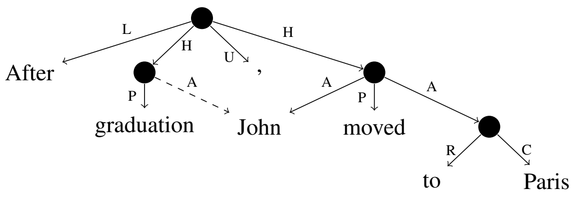

Figure 1: UCCA graph. Dashed: remote edge.

UD is a syntactic dependency scheme used in many languages, aiming for cross-linguistically consistent and coarse-grained treebank annotation. Formally, UD uses bi-lexical trees, with edge labels representing syntactic relations.

One aspect of UD similar to UCCA is its preference of lexical (rather than functional) heads. For example, in auxiliary verb constructions (e.g., “is eating”), UD marks the lexical verb (*eating*) as the head, while other dependency schemes may select the auxiliary *is* instead. While the approaches are largely inter-translatable (Schwartz et al., 2012), lexical head schemes are more similar in form to semantic schemes, such as UCCA and semantic dependencies (Oepen et al., 2016).

Being a dependency representation, UD is structurally underspecified in an important way: it is not possible in UD to mark the distinction between an element modifying the head of the phrase and the same element modifying the whole phrase (de Marneffe and Nivre, 2019).

An example UD tree is given in Figure 2. UD relations will be written in `typewriter` font.

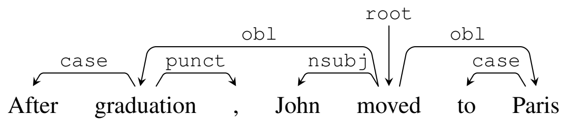

Figure 2: UD tree.

3 Shared Gold-standard Corpus

We annotate 723 English passages (3,813 sentences; 52,721 tokens), comprising the web reviews section of the English Web Treebank (EWT; Bies et al., 2012). Text is annotated by two UCCA annotators according to v2.0 of the UCCA guidelines[5] and cross-reviewed. As these sentences are included in the UD English_EWT treebank, this is a *shared* gold-standard UCCA and UD annotated corpus.[6] We use the standard train/development/test split, shown in Table 2.

	Train	**Dev**	**Test**
# Passages	347	192	184
# Sentences	2,723	554	535
# Tokens	44,804	5,394	5,381

Table 2: Data split for the shared gold-standard corpus.

4 Comparison Methodology

To facilitate comparison between UCCA and UD, we first assimilate the graphs by abstracting away from formalism differences, obtaining a similar graph format for both schemes. We then match pairs of nodes in the converted UD and UCCA trees if they share all terminals in their yields.

UD annotates bi-lexical dependency trees, while UCCA graphs contain non-terminal nodes. In §4.1, we outline the unified DAG converter by Hershcovich et al. (2018a,b),[7] which we use to reach a common format. In §4.2, we describe a number of extensions to the converter, which abstract away from further non-content differences.

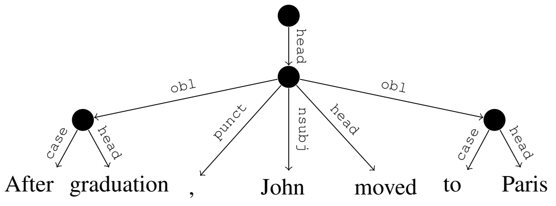

Figure 3: Converted UD tree. Non-terminals and *head* edges are introduced by the unified DAG converter.

4.1 Basic Conversion

Figure 3 presents the same tree from Figure 2 after conversion. The converter adds one pre-terminal per token, and attaches them according to the original dependency tree: traversing it from the root, for each head it creates a non-terminal parent with the edge label *head*, and adds the dependents as children of the created non-terminal. Relation subtypes are stripped, leaving only universal relations. For example, the language-specific definite article label `det:def` is replaced by the universal `det`.

---

[6] Our data is available at `https://github.com/UniversalConceptualCognitiveAnnotation/UCCA_English-EWT`.

[7] `https://github.com/huji-nlp/semstr`

Reentrancies. Remote edges in UCCA enable reentrancy, forming a DAG together with primary edges. UD allows reentrancy when including *enhanced dependencies* (Schuster and Manning, 2016),[8] which form (bi-lexical) graphs, representing phenomena such as predicate ellipsis (e.g., gapping), and shared arguments due to coordination, control, raising and relative clauses.

UCCA is more inclusive in its use of remote edges, and accounts for the entire class of implicit arguments termed *Constructional Null Instantiation* in FrameNet (Ruppenhofer et al., 2016). For example, in "The Pentagon is bypassing official US intelligence channels [...] in order to create strife" (from EWT), remote edges mark *Pentagon* as a shared argument of *bypassing* and *create*. Another example is "if you call for an appointment [...] so you can then make one", where a remote edge in UCCA indicates that *one* refers to *appointment*. Neither is covered by enhanced UD.

In order to facilitate comparison, we remove remote edges and enhanced dependencies in the conversion process. We thus compare basic UD and UCCA trees, deferring a comparison of UCCA and enhanced UD to future work.

4.2 Extensions to the Converter

We extend the unified DAG converter to remove further non-content differences.

Unanalyzable units. An unanalyzable phrase is represented in UCCA as a single unit covering multiple terminals. In multi-word expressions (MWEs) in UD, each word after the first is attached to the previous word, with the `flat`, `fixed` or `goeswith` relations (depending on whether the expression is grammaticalized, or split by error). We remove edges of these relations and join the corresponding pre-terminals to one unit.

Promotion of conjunctions. The basic conversion generally preserves terminal yields: the set of terminals spanned by a non-terminal is the same as the original dependency yield of its head terminal (e.g., in Figure 3, the yield of the non-terminal headed by *graduation* is "After graduation", the same as that of "graduation" in Figure 2).

Since UD attaches subordinating and coordinating conjunctions to the subsequent conjunct, this results in them being positioned in the same conjunct they relate (e.g., *After* will be included in the first conjunct in "After arriving home, John went to sleep"; *and* will be included in the second conjunct in "John and Mary"). In contrast, UCCA places conjunctions as siblings to their conjuncts (e.g., "[After] [arriving home], [John went to sleep]" and "[John] [and] [Mary]").

To abstract away from these convention differences, we place coordinating and subordinating conjunctions (i.e., `cc`-labeled units, and `mark`-labeled units with an `advcl` head such as *when*, *if*, *after*) as siblings of their conjuncts.

5 Analysis of Divergences

Using the shared format, we turn to analyzing the content differences between UCCA and UD.[9]

5.1 Confusion Matrix

Table 3 presents the confusion matrix of categories between the converted UD and UCCA, calculated over all sentences in the training and development sets of the shared EWT reviews corpus. We leave the test set out of this evaluation to avoid contamination for future parsing experiments.

In case of multiple UCCA units with the same terminal yield (i.e., units with a single non-remote child), we take the top category only, to avoid double-counting. Excluding punctuation, this results in 60,434 yields in UCCA and 58,992 in UD. Of these, 52,280 are common, meaning that a UCCA "parser" developed this way would get a very high F1 score of 87.6%, if it is provided with the gold UCCA label for every converted edge.

Some yields still have more than one UCCA category associated with them, due to edges with multiple categories (**A**|**P** and **A**|**S**). For presentation reasons, 0.15% of the UCCA units in the data are not presented here, as they belong to rare ($<0.1\%$) multiple-category combinations.

Only 82.6% of UD's syntactic arguments (`ccomp`, `csubj`, `iobj`, `nsubj`, `obj`, `obl` and `xcomp`) are UCCA Participants, and only 72.9% of the Participants are syntactic arguments—a difference stemming from the Scene/non-Scene (§5.2) and argument/adjunct (§5.3) distinctions. Moreover, if we identify predicates as words having at least one argument and Scenes as units with at least one Participant, then only 92.1% of UD's predicates correspond to Scenes (many are secondary relations within one scene), and only 80%

---

Table 3: UD-UCCA confusion matrix calculated based on EWT gold-standard annotations from the training and development sets (§3), after applying our extended converter to UD (§4), by matching UD vertices and UCCA units with the same terminal yield. The last column (row), labeled No Match, shows the number of edges of each UD (UCCA) category that do not match any UCCA (UD) unit. Zero counts are omitted.

of Scenes correspond to predicates (e.g., eventive nouns, which are not syntactic predicates).

Examining the *head* row in Table 3 allows us to contrast the schemes' notions of a head. *head*-labeled units have at least one dependent in UD, or are single-clause sentences (technically, they are non-terminals added by the converter). Of them, 75.7% correspond to Processes, States, Parallel Scenes or Centers, which are UCCA's notions of semantic heads, and 11.6% are left unmatched, mostly due to MWEs analyzed in UD but not in UCCA (§5.4). Another source of unmatched units is inter-Scene linkage, which tends to be flatter in UCCA (§5.5). The rest are mostly due to head swap (e.g., "*all* of Dallas", where *all* is a Quantifier of *Dallas* in UCCA, but the head in UD).

In the following subsections, we review the main content differences between the schemes, as reflected in the confusion matrix, and categorize them according to the UD relations involved.

5.2 Scenes vs. Non-Scenes

UCCA distinguishes between Scenes and non-Scenes. This distinction crosses UD categories, as a Scene can be evoked by a verb, an eventive or stative noun (*negotiation*, *fatigue*), an adjective or even a preposition ("this is *for* John").

Core syntactic arguments. Subjects and objects are usually Participants (e.g., "*wine* was excellent"). However, when describing a Scene, the subject may be a Process/State (e.g., "but *service* is very poor"). Some wh-pronouns are the subjects or objects of a relative clause, but are Linkers or Relators, depending on whether they link Scenes or non-Scenes, respectively. For example, "who" in "overall, Joe is a happy camper *who* has found a great spot" is an `nsubj`, but a Linker. Other arguments are Adverbials or Time (see §5.3), and some do not match any UCCA unit, especially when they are parts of MWEs (see §5.4).

Adjectival modifiers are Adverbials when modifying Scenes ("*romantic* dinner"), States when describing non-Scenes ("*beautiful* hotel") or when semantically predicative ("such a *convenient* location"), or Elaborators where defining inherent properties of non-Scenes ("*medical* school").

Nominal and clausal modifiers. Most are Participants or Elaborators, depending on whether they modify a Scene (e.g., "discount *on services*" and "our decision *to buy when we did*" are Participants, but "*my car's* gears and brakes" and "Some of the younger kids *that work there*" are Elaborators). Unmatched `acl` are often free relative clauses (e.g., in "the prices were worth what *I got*", *what* is the `obj` of *worth* but a Participant of *I got*).

Case markers. While mostly Relators modifying non-Scenes (e.g., "the team *at* Bradley

Chevron”), some case markers are Linkers linking Scenes together (e.g., “very informative website *with* a lot of good work”). Others are Elaborators (e.g., “*over* a year”) or States when used as the main relation in verbless or copula clauses (e.g., “it is right *on* Wisconsin Ave”).

Coordination. Coordinating conjunctions (`cc`) are Connectors where they coordinate non-Scenes (e.g., “Mercedes *and* Dan”) or Linkers where they coordinate Scenes (e.g., “outdated *but* not bad”). Similarly, conjuncts and list elements (`conj`, `list`) may be Parallel Scenes (H), or Centers when they are non-Scenes.[10]

Determiners. Articles are Functions, but determiners modifying non-Scenes are Elaborators (e.g., “I will never recommend this gym to *any* woman”). Where modifying Scenes (mostly negation) they are marked as Adverbials. For example, “*no* feathers in stock”, “*what* a mistake”, and “the rear window had *some* leakage” are all Adverbials.

5.3 Primary and Secondary Relations

UD distinguishes core arguments, adverb modifiers, and obliques (in English UD, the latter mostly correspond to prepositional dependents of verbs). UCCA distinguishes Participants, including locations and abstract entities, from secondary relations (Adverbials), which cover manner, aspect and modality. Adverbials can be verbs (e.g., *begin*, *fail*), prepositional phrases (*with disrespect*), as well as modals, adjectives and adverbs.

Adverbs and obliques. Most UD adverb modifiers are Adverbials (e.g., “I *sometimes* go”), but they may be Participants, mostly in the case of semantic arguments describing location (e.g., *here*). Obliques may be Participants (e.g., “wait *for Nick*”), Time (e.g., “for *over 7 years*”) or Adverbials—mostly manner adjuncts (*by far*).

Clausal arguments are Participant Scenes (e.g., “it was great *that they did not charge a service fee*”, “did not really know *what I wanted*” or “I asked them *to change it*”). However, when serving as complements to a secondary verb, they will not match any unit in UCCA, as it places secondary verbs on the same level as their primary relation. For example, *to pay* is an `xcomp` in “they have to pay”, while the UCCA structure is flat: *have to* is an Adverbial and *pay* is a Process. Single-worded clausal arguments may correspond to a Process/State, as in “this seems *great*”.

Auxiliary verbs are Functions (e.g., “*do* not forget”), or Adverbials when they are modals (e.g., “you *can* graduate”). Semi-modals in UD are treated as clausal heads, which take a clausal complement. For example, in “able to do well”, UD treats *able* as the head, which takes *do well* as an `xcomp`. UCCA, on the other hand, treats it as an Adverbial, creating a mismatch for `xcomp`.

5.4 Multi-Word Expressions

UD and UCCA treat MWEs differently. In UD they include names, compounds and grammaticalized fixed expressions. UCCA treats names and grammaticalized MWEs as unanalyzable units, but also a range of semantically opaque constructions (e.g., light verbs and idioms). On the other hand, compounds are not necessarily unanalyzable in UCCA, especially if compositional.

Compounds. English compounds are mostly nominal, and are a very heterogeneous category. Most compounds correspond to Elaborators (e.g., “*industry* standard”), or Elaborator Scenes (e.g., “*out-of-place* flat-screen TV”), and many are unanalyzable expressions (e.g., “*mark* up”). Where the head noun evokes a Scene, the dependent is often a Participant (e.g., “*food* craving”), but can also be an Adverbial (e.g., “*first time* buyers”) depending on its semantic category. Other compounds in UD are phrasal verbs (e.g., “figure *out*”, “cleaned *up*”), which UCCA treats as unanalyzable (leading to unmatched units).

Core arguments. A significant number of subjects and objects are left unmatched as they form parts of MWEs marked in UCCA as unanalyzable. UD annotates MWEs involving a verb and its argument(s) just like any other clause, and therefore lacks this semantic content. Examples include light verbs (e.g., “give *a try*”), idioms (“bites *the dust*”), and figures of speech (e.g., “when *it* comes to”, “offer *a taste* (of)”), all are UCCA units.

Complex prepositions. Some complex prepositions (e.g., *according to* or *on top of*), not encoded as MWEs in UD, are unanalyzable in UCCA.

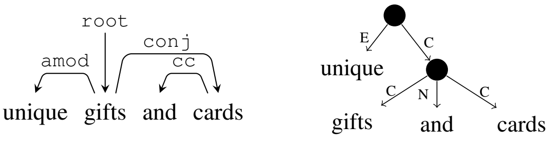
5.5 Linkage

Head selection. UCCA tends to flatten linkage, where UD, as a dependency scheme, selects a head

---

[10] While in UD the conjunction `cc` is attached to the following conjunct, in UCCA coordination is a flat structure. This is a convention difference that we normalize (§4.2).

and dependent per relation. This yields scope ambiguities for coordination, an inherently flat structure. For instance, "unique gifts and cards" is ambiguous in UD as to whether *unique* applies only to *gifts* or to the whole phrase—both annotated as in Figure 4a. UCCA, allowing non-terminal nodes, disambiguates this case (Figure 4b).



(a) UD (b) UCCA

Figure 4: Coordination in UD and UCCA.

Clausal dependents. UD categorizes clause linkage into coordination, subordination, argumenthood (complementation), and parataxis. UCCA distinguishes argumenthood but conflates the others into the Parallel Scene category. For example, "We called few companies before *we decided to hire them*" and "Check out The Willow Lounge, *you'll be happy*" are Parallel Scenes.

Note that while in UD, `mark` (e.g., *before*) is attached to the dependent adverbial clause, a UCCA Linker lies outside the linked Scenes. To reduce unmatched `advcl` instances, this convention difference is fixed by the converter (§4.2). Many remaining unmatched units are due to conjunctions we could not reliably raise. For instance, the marker *to* introducing an `xcomp` is ambiguous between Linker (purposive *to*) and Function (infinitive marker). Similarly, wh-pronouns may be Linkers ("he was willing to budge a little on the price *which* means a lot to me"), but have other uses in questions and free relative clauses. Other mismatches result from the long tail of differences in how UD and UCCA construe linkage. Consider the sentence in Figure 5. While *moment* is an oblique argument of *know* in UD, *From the moment* is analyzed as a Linker in UCCA.

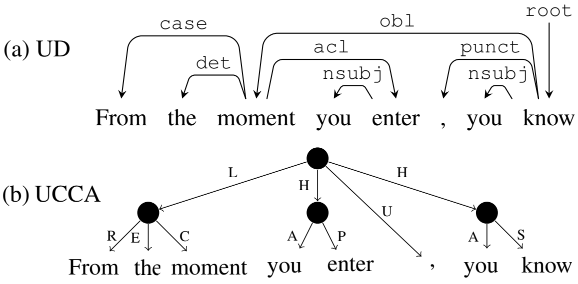


Figure 5: Clause linkage in UD and UCCA.

5.6 Other Differences

Appositions in UD always follow the modified noun, but named entities in them are UCCA Centers, regardless of position (e.g., in "its sister store Peking Garden", the UD head *its sister store* is an Elaborator, while *Peking Garden* is the Center).

Copulas. UCCA distinguishes copular constructions expressing identity (e.g., "This *is* the original Ham's restaurant") where the copula is annotated as State, and cases of attribution (e.g., "Mercedes and Dan *are* very thorough") or location (e.g., "Excellent chefs *are* in the kitchen"), where the copula is a Function.

Discourse markers and interjections. Units relating a Scene to the speech event or to the speaker's opinion are Ground (e.g., "*no*, Warwick in New Jersey" and "*Please* visit my website"). On the other hand, discourse elements that relate one Scene to another are Linkers (e.g., *anyway*).

Vocatives are both Ground and Participants if they participate in the Scene *and* are the party addressed. For example, *Mark* in "Thanks *Mark*" is both the person addressed and the one thanked.[11]

Expletives and subjects. Expletives are generally Functions, but some instances of *it* and *that* are analyzed as `nsubj` in UD and as Function in UCCA (e.g., "*it*'s like driving a new car").

Excluded relations. We exclude the following UD labels, as they are irrelevant to our evaluation: `root` (always matches the entire sentence); `punct` (punctuation is ignored in UCCA evaluation); `dep` (unspecified dependency), `orphan` (used for gapping, which is represented using remote edges in UCCA—see §4.1); `fixed`, `flat` and `goeswith` (correspond to parts of unanalyzable units in UCCA, and so do not represent units on their own—see §4.2); `reparandum` and `dislocated` (too rare in EWT).

6 Fine-Grained UCCA Parsing Evaluation

In §5 we used our comparison methodology, consisting of the conversion to a shared format and matching units by terminal yield, to compare gold-standard UD and UCCA. In this section we ap-

---

[11] The **A**|**G** column is omitted from Table 3 as this category combination occurs in only 0.02% of edges in the corpus.

ply the same methodology to parser outputs, using gold-standard UD for fine-grained evaluation.

6.1 Experimental Setup

Data. In addition to the UCCA EWT data (§3), we use the reviews section of the UD v2.3 English_EWT treebank (Nivre et al., 2018),[12] annotated over the exact same sentences. We additionally use UDPipe v1.2 (Straka et al., 2016; Straka and Straková, 2017), trained on English_EWT,[13] for feature extraction. We apply the extended converter to UD as before (§4.2).

Parser. We train TUPA v1.3 (Hershcovich et al., 2017, 2018a) on the UCCA EWT data, with the standard train/development/test split. TUPA uses POS tags and syntactic dependencies as features. We experiment both with using gold UD for feature extraction, and with using UDPipe outputs.

Evaluation by gold-standard UD. UCCA evaluation is generally carried out by considering a predicted unit as correct if there is a gold unit that matches it in terminal yield and labels. Precision, Recall and F-score (F1) are computed accordingly. For the fine-grained analysis, we split the gold-standard, predicted and matched UCCA units according to the labels of the UD relations whose dependents have the same terminal yield (if any).

6.2 Results

Table 4 presents TUPA's scores on the UCCA EWT development and test sets. Surprisingly, using UDPipe for feature extraction results in better scores than gold syntactic tags and dependencies.

	Primary			Remote		
Features	**LP**	**LR**	**LF**	**LP**	**LR**	**LF**
Development						
Gold UD	72.1	71.2	71.7	61.2	38.1	47.0
UDPipe	73.0	72.1	72.5	53.7	40.8	46.4
Test						
Gold UD	72.2	71.2	71.7	60.9	36.8	45.9
UDPipe	72.4	71.7	72.1	60.3	38.5	47.0

Table 4: Labeled precision, recall and F1 (in %) for primary and remote edges output by TUPA on the UCCA EWT development (top) and test (bottom) sets, using either gold-standard UD or UDPipe for TUPA features.

Table 5 shows fine-grained evaluation by UD relations. TUPA does best on auxiliaries and determiners, despite the heterogeneity of corresponding UCCA categories (see Table 3), possibly by making lexical distinctions (e.g., modals and auxiliary verbs are both UD auxiliaries, but are annotated as Adverbials and Functions, respectively).

Copulas and coordinating conjunctions pose a more difficult distinction, since the same lexical items may have different categories depending on the context: State/Function for copulas, due to the distinction between identity and attribution, and Connector/Linker for conjunctions, due to the distinction between Scenes and non-Scenes. However, the reviews domain imposes a strong prior for both (Function and Linker, respectively), which TUPA learns successfully.

Inter-clause linkage (`conj`, `advcl`, `xcomp`, `ccomp`, `parataxis`, `acl` and `csubj`) is a common source of error for TUPA. Although the match between UCCA and UD is not perfect in these cases, it is overall better than TUPA's unlabeled performance, despite using gold-standard syntactic features. Our results thus suggest that encoding syntax more directly, perhaps using syntactic scaffolding (Swayamdipta et al., 2018) or guided attention (Strubell et al., 2018), may assist in predicting unit boundaries. However, TUPA often succeeds at making distinctions that are not even encoded in UD. For example, it does reasonably well (71%) on distinguishing between noun modifiers of Scene-evoking nouns (Participants) and modifiers of other nouns (Elaborators), surpassing a majority baseline based on the UD relation (51%). Lexical resources that distinguish eventive and relational nouns from concrete nouns may allow improving it even further. In the similar case of compounds, lexical resources for light verbs and idioms may increase performance.

7 Discussion

NLP tasks often require semantic distinctions that are difficult to extract from syntactic representations. Consider the example "after graduation, John moved to Paris" again. While *graduation* evokes a Scene (Figure 1), in UD it is an oblique modifier of *moved*, just like *Paris* is (Figure 2). The Scene/non-Scene distinction (§5.2) would assist structural text simplification systems in paraphrasing this sentence to two sentences, each one containing one Scene (Sulem et al., 2018a).

Another example is machine translation—translating the same sentence into Hebrew, which does not have a word for *graduation*, would re-

Table 5: Fine-grained evaluation of TUPA (with gold-standard UD features) on the EWT development set. (a) Columns are sorted by labeled F1, measuring performance on each subset of edges. Unlabeled F1 ignores edge categories, evaluating unit boundaries only. (b) Total number of instances of each UD relation; of them, matching UCCA units in gold-standard and in TUPA's predictions; their intersection, with/without regard to categories. (c) Percentage of correctly categorized edges; for comparison, percentage of most frequent category (see Table 3). (d) Average number of words in corresponding terminal yields.

quire a clause to convey the same meaning. The mapping would therefore be more direct using a semantic representation, and we would benefit from breaking the utterance into two Scenes.

8 Related Work

The use of syntactic parsing as a proxy for semantic structure has a long tradition in NLP. Indeed, semantic parsers have leveraged syntax for output space pruning (Xue and Palmer, 2004), syntactic features (Gildea and Jurafsky, 2002; Hershcovich et al., 2017), joint modeling (Surdeanu et al., 2008; Hajič et al., 2009), and multi-task learning (Swayamdipta et al., 2016, 2018; Hershcovich et al., 2018a). Empirical comparison between syntactic and semantic schemes, however, is still scarce. Rudinger and Van Durme (2014) mapped Stanford Dependencies (precursor to UD) to Hobbsian Logical Form, identifying semantic gaps in the former. PredPatt (White et al., 2016), a framework for extracting predicate-argument structures from UD, was evaluated by Zhang et al. (2017) on a large set of converted PropBank annotations. Szubert et al. (2018) proposed a method for aligning AMR and UD subgraphs, finding that 97% of AMR edges are evoked by one or more words or syntactic relations. Damonte et al. (2017) refined AMR evaluation by UD labels, similar to our fine-grained evaluation of UCCA parsing.

Some syntactic representation approaches, notably CCG (Steedman, 2000), directly reflect the underlying semantics, and have been used to transduce semantic forms using rule-based systems (Basile et al., 2012). A related line of work tackles the transduction of syntactic structures into semantic ones. Reddy et al. (2016) proposed a rule-based method for converting UD to logical forms. Stanovsky et al. (2016) converted Stanford dependency trees into proposition structures (PROPS), abstracting away from some syntactic detail.

9 Conclusion

We evaluated the similarities and divergences in the content encoded by UD and UCCA. We annotated the reviews section of the English Web Treebank with UCCA, and used an automated methodology to evaluate how well the two schemes align, abstracting away from differences of mere convention. We provided a detailed picture of the content differences between the schemes. Notably, we quantified the differences between the notions of syntactic and semantic heads and arguments, finding substantial divergence between them. Our findings highlight the potential utility of using semantic parsers for text understanding applications (over their syntactic counterparts), but also expose challenges semantic parsers must address, and potential approaches for addressing them.

Attentive Mimicking:
Better Word Embeddings by Attending to Informative Contexts

Abstract

Learning high-quality embeddings for rare words is a hard problem because of sparse context information. Mimicking (Pinter et al., 2017) has been proposed as a solution: given embeddings learned by a standard algorithm, a model is first trained to reproduce embeddings of frequent words from their surface form and then used to compute embeddings for rare words. In this paper, we introduce *attentive mimicking*: the mimicking model is given access not only to a word's surface form, but also to all available contexts and learns to attend to the most informative and reliable contexts for computing an embedding. In an evaluation on four tasks, we show that attentive mimicking outperforms previous work for both rare and medium-frequency words. Thus, compared to previous work, attentive mimicking improves embeddings for a much larger part of the vocabulary, including the medium-frequency range.

1 Introduction

Word embeddings have led to large performance gains in natural language processing (NLP). However, embedding methods generally need many observations of a word to learn a good representation for it.

One way to overcome this limitation and improve embeddings of infrequent words is to incorporate surface-form information into learning. This can either be done directly (Wieting et al., 2016; Bojanowski et al., 2017; Salle and Villavicencio, 2018), or a two-step process is employed: first, an embedding model is trained on the word level and then, surface-form information is used either to fine-tune embeddings (Cotterell et al., 2016; Vulić et al., 2017) or to completely recompute them. The latter can be achieved using a model trained to reproduce (or *mimic*) the original embeddings (Pinter et al., 2017). However, these methods only work if a word's meaning can at least partially be predicted from its form.

A closely related line of research is embedding learning for *novel words*, where the goal is to obtain embeddings for previously unseen words from at most a handful of observations. While most contemporary approaches exclusively use context information for this task (e.g. Herbelot and Baroni, 2017; Khodak et al., 2018), Schick and Schütze (2019) recently introduced the *form-context model* and showed that joint learning from both surface form and context leads to better performance.

The problem we address in this paper is that often, only few of a word's contexts provide valuable information about its meaning. Nonetheless, the current state of the art treats all contexts the same. We address this issue by introducing a more intelligent mechanism of incorporating context into mimicking: instead of using all contexts, we learn – by way of self-attention – to pick a subset of especially informative and reliable contexts. This mechanism is based on the observation that in many cases, reliable contexts for a given word tend to resemble each other. We call our proposed architecture *attentive mimicking* (AM).

Our contributions are as follows: (i) We introduce the attentive mimicking model. It produces high-quality embeddings for rare and medium-frequency words by attending to the most informative contexts. (ii) We propose a novel evaluation method based on VecMap (Artetxe et al., 2018) that allows us to easily evaluate the embedding quality of low- and medium-frequency words. (iii) We show that attentive mimicking improves word embeddings on various datasets.

2 Related Work

Methods to train surface-form models to mimic word embeddings include those of Luong et al.

Proceedings of NAACL-HLT 2019, pages 489–494
Minneapolis, Minnesota, June 2 - June 7, 2019.

(2013) (morpheme-based) and Pinter et al. (2017) (character-level). In the area of fine-tuning methods, Cotterell et al. (2016) introduce a Gaussian graphical model that incorporates morphological information into word embeddings. Vulić et al. (2017) retrofit embeddings using a set of language-specific rules. Models that directly incorporate surface-form information into embedding learning include fastText (Bojanowski et al., 2017), LexVec (Salle and Villavicencio, 2018) and Charagram (Wieting et al., 2016).

While many approaches to learning embeddings for novel words exclusively make use of context information (Lazaridou et al., 2017; Herbelot and Baroni, 2017; Khodak et al., 2018), Schick and Schütze (2019)'s form-context model combines surface-form and context information.

Ling et al. (2015) also use attention in embedding learning, but their attention is *within* a context (picking words), not *across* contexts (picking contexts). Also, their attention is based only on word type and distance, not on the more complex factors available in our attentive mimicking model, e.g., the interaction with the word's surface form.

3 Attentive Mimicking

3.1 Form-Context Model

We briefly review the architecture of the form-context model (FCM), see Schick and Schütze (2019) for more details.

FCM requires an embedding space of dimensionality d that assigns high-quality embeddings $v \in \mathbb{R}^d$ to frequent words. Given an infrequent or novel word w and a set of contexts $\mathcal{C}$ in which it occurs, FCM can then be used to infer an embedding $v_{(w,\mathcal{C})}$ for w that is appropriate for the given embedding space. This is achieved by first computing two distinct embeddings, one of which exclusively uses surface-form information and the other context information. The surface-form embedding, denoted $v^{\text{form}}_{(w,\mathcal{C})}$, is obtained from averaging over a set of n-gram embeddings learned by the model; the context embedding $v^{\text{context}}_{(w,\mathcal{C})}$ is obtained from averaging over all embeddings of context words in $\mathcal{C}$.

The two embeddings are then combined using a weighting coefficient α and a $d \times d$ matrix A, resulting in the form-context embedding

$$v_{(w,\mathcal{C})} = \alpha \cdot A v^{\text{context}}_{(w,\mathcal{C})} + (1-\alpha) \cdot v^{\text{form}}_{(w,\mathcal{C})} \,.$$

The weighing coefficient α is a function of both embeddings, modeled as

$$\alpha = \sigma(u^\top [v^{\text{context}}_{(w,\mathcal{C})}; v^{\text{form}}_{(w,\mathcal{C})}] + b)$$

with $u \in \mathbb{R}^{2d}$, $b \in \mathbb{R}$ being learnable parameters and σ denoting the sigmoid function.

3.2 Context Attention

FCM pays equal attention to all contexts of a word but often, only few contexts are actually suitable for inferring the word's meaning. We introduce *attentive mimicking* (AM) to address this problem: we allow our model to assign different weights to contexts based on some measure of their "reliability". To this end, let $\mathcal{C} = \{C_1, \ldots, C_m\}$ where each C_i is a multiset of words. We replace the context-embedding of FCM with a weighted embedding

$$v^{\text{context}}_{(w,\mathcal{C})} = \sum_{i=1}^{m} \rho(C_i, \mathcal{C}) \cdot v_{C_i}$$

where v_{C_i} is the average of the embeddings of words in C_i and ρ measures context reliability.

To obtain a meaningful measure of reliability, our key observation is that reliable contexts typically agree with many other contexts. Consider a word w for which six out of ten contexts contain words referring to sports. Due to this high inter-context agreement, it is then reasonable to assume that w is from the same domain and, consequently, that the four contexts not related to sports are less informative. To formalize this idea, we first define the similarity between two contexts as

$$s(C_1, C_2) = \frac{(M v_{C_1}) \cdot (M v_{C_2})^\top}{\sqrt{d}}$$

with $M \in \mathbb{R}^{d \times d}$ a learnable parameter, inspired by Vaswani et al. (2017)'s scaled dot-product attention. We then define the reliability of a context as

$$\rho(C, \mathcal{C}) = \frac{1}{Z} \sum_{i=1}^{m} s(C, C_i)$$

where $Z = \sum_{i=1}^{m} \sum_{j=1}^{m} s(C_i, C_j)$ is a normalization constant, ensuring that all weights sum to one.

The model is trained by randomly sampling words w and contexts $\mathcal{C}$ from a large corpus and mimicking the original embedding of w, i.e., minimizing the squared distance between the original embedding and $v_{(w,\mathcal{C})}$.

4 Experiments

For our experiments, we follow the setup of Schick and Schütze (2019) and use the Westbury Wikipedia Corpus (WWC) (Shaoul and Westbury, 2010) for training of all embedding models. To obtain training instances $(w, \mathcal{C})$ for both FCM and AM, we sample words and contexts from the WWC based on their frequency, using only words that occur at least 100 times. We always train FCM and AM on skipgram embeddings (Mikolov et al., 2013) obtained using Gensim (Řehůřek and Sojka, 2010).

Our experimental setup differs from that of Schick and Schütze (2019) in two respects: (i) Instead of using a fixed number of contexts for $\mathcal{C}$, we randomly sample between 1 and 64 contexts and (ii) we fix the number of training epochs to 5. The rationale behind our first modification is that we want our model to produce high-quality embeddings both when we only have a few contexts available and when there is a large number of contexts to pick from. We fix the number of epochs simply because our evaluation tasks come without development sets on which it may be optimized.

To evaluate our model, we apply a novel, intrinsic evaluation method that compares embedding spaces by transforming them into a common space (§4.1). We also test our model on three word-level downstream tasks (§4.2, §4.3, §4.4) to demonstrate its versatile applicability.

4.1 VecMap

We introduce a novel evaluation method that explicitly evaluates embeddings for rare and medium-frequency words by downsampling frequent words from the WWC to a fixed number of occurrences.[1] We then compare "gold" skipgram embeddings obtained from the original corpus with embeddings learned by some model trained on the downsampled corpus. To this end, we transform the two embedding spaces into a common space using VecMap (Artetxe et al., 2018), where we provide all but the downsampled words as a mapping dictionary. Intuitively, the better a model is at inferring an embedding from few observations, the more similar its embeddings must be to the gold embeddings in this common space. We thus measure the quality of a model by computing the average cosine similarity between its embeddings and the gold embeddings.

model	**number of occurrences** 1	2	4	8	16	32	64	128
skipgram	8.7	18.2	30.9	42.3	52.3	59.5	66.7	**71.2**
fastText	**45.4**	44.3	45.7	50.0	55.9	56.7	62.6	67.7
Mimick	10.7	11.7	12.1	11.0	12.5	11.0	10.6	9.2
FCM	37.9	**45.3**	49.1	53.4	**58.3**	55.4	59.9	58.8
AM	38.0	45.1	**49.6**	**53.7**	**58.3**	55.6	60.2	58.9
FCM†	32.3	36.9	41.9	49.1	57.4	59.9	67.3	70.1
AM†	32.8	37.8	42.8	49.8	57.7	**60.5**	**67.6**	70.4

Table 1: Average cosine similarities for the VecMap evaluation, scaled by a factor of 100. †: Downsampled words were included in the training set.

model	**maximum word frequency** 10	50	100	500	1000
skipgram	–0.16	0.21	0.33	0.55	**0.66**
fastText	–0.20	0.10	0.23	0.50	0.61
Mimick	0.00	0.01	–0.03	0.40	0.56
FCM	0.21	0.37	0.37	0.55	0.63
AM	**0.27**	**0.39**	**0.40**	**0.56**	0.64

Table 2: Spearman's ρ for various approaches on SemEval2015 Task 10E

As baselines, we train skipgram and fastText on the downsampled corpus. We then train Mimick (Pinter et al., 2017) as well as both FCM and AM on the skipgram embeddings. We also try a variant where the downsampled words are included in the training set (i.e., the mimicking models explicitly learn to reproduce their skipgram embeddings). This allows the model to learn representations of those words not completely from scratch, but to also make use of their original embeddings. Accordingly, we expect this variant to only be helpful if a word is not too rare, i.e. its original embedding is already of decent quality. Table 1 shows that for words with a frequency below 32, FCM and AM infer much better embeddings than all baselines. The comparably poor performance of Mimick is consistent with the observation of Pinter et al. (2017) that this method captures mostly syntactic information. Given four or more contexts, AM leads to consistent improvements over FCM. The variants that include downsampled words during training (†) still outperform skipgram for 32 and more observations, but perform worse than the default models for less frequent words.

4.2 Sentiment Dictionary

We follow the experimental setup of Rothe et al. (2016) and fuse Opinion lexicon (Hu and Liu,

Table 3: Results on the Name Typing dataset for various word frequencies f. The model that uses a linear combination of AM embeddings with skipgram is denoted AM+skip.

2004) and the NRC Emotion lexicons (Mohammad and Turney, 2013) to obtain a training set of words with binary sentiment labels. On that data, we train a logistic regression model to classify words based on their embeddings. For our evaluation, we then use SemEval2015 Task 10E where words are assigned a sentiment rating between 0 (completely negative) and 1 (completely positive) and use Spearman's ρ as a measure of similarity between gold and predicted ratings.

We train logistic regression models on both skipgram and fastText embeddings and, for testing, replace skipgram embeddings by embeddings inferred from the mimicking models. Table 2 shows that for rare and medium-frequency words, AM again outperforms all other models.

4.3 Name Typing

We use Yaghoobzadeh et al. (2018)'s name typing dataset for the task of predicting the fine-grained named entity types of a word, e.g., PRESIDENT and LOCATION for "Washington". We train a logistic regression model using the same setup as in §4.2 and evaluate on all words from the test set that occur ≤100 times in WWC. Based on results in §4.1, where AM only improved representations for words occurring fewer than 32 times, we also try the variant *AM+skip* that, in testing, replaces $v_{(w,\mathcal{C})}$ with the linear combination

$$\hat{v}_w = \beta(f_w) \cdot v_{(w,\mathcal{C})} + (1 - \beta(f_w)) \cdot v_w$$

where v_w is the skipgram embedding of w, f_w is the frequency of w and $\beta(f_w)$ scales linearly from 1 for $f_w = 0$ to 0 for $f_w = 32$.

Table 3 gives accuracy and micro F1 for several word frequency ranges. In accordance with results from previous experiments, AM performs drastically better than the baselines for up to 16 occurrences. Notably, the linear combination of skipgram and AM achieves by far the best overall results.

4.4 Chimeras

The Chimeras (CHIMERA) dataset (Lazaridou et al., 2017) consists of similarity scores for pairs of made-up words and regular words. CHIMERA provides only six contexts for each made-up word, so it is not ideal for evaluating our model. Nonetheless, we can still use it to analyze the difference of FCM (no attention) and AM (using attention). As the surface-form of the made-up words was constructed randomly and thus carries no meaning at all, we restrict ourselves to the context parts of FCM and AM (referred to as FCM-ctx and AM-ctx). We use the test set of Herbelot and Baroni (2017) and compare the given similarity scores with the cosine similarities of the corresponding word embeddings, using FCM-ctx and AM-ctx to obtain embeddings for the made-up words. Table 4 gives Spearman's ρ for our model and various baselines; baseline results are adopted from Khodak et al. (2018). We do not report results for Mimick as its representations for novel words are entirely based on their surface form. While AM performs worse than previous methods for 2–4 sentences, it drastically improves over the best result currently published for 6 sentences. Again, context attention consistently improves results: AM-ctx performs better than FCM-ctx, regardless of the number of contexts. Since A La Carte (Khodak et al., 2018), the method performing best for 2–4 contexts, is conceptually similar to FCM, it most likely would similarly benefit from context attention.

While the effect of context attention is more pronounced when there are many contexts available, we still perform a quantitative analysis of one exemplary instance of CHIMERA to better understand what AM learns; we consider the made-up word "petfel", a combination of "saxophone" and "harmonica", whose occurrences are shown in Table 5. The model attends most to sentences

model	2 sent.	4 sent.	6 sent.
skipgram	0.146	0.246	0.250
additive	**0.363**	0.370	0.360
additive – sw	0.338	0.362	0.408
Nonce2Vec	0.332	0.367	0.389
A La Carte	**0.363**	**0.384**	0.394
FCM-ctx	0.337	0.359	0.422
AM-ctx	0.342	0.376	**0.436**

Table 4: Spearman's ρ for the Chimeras task given 2, 4 and 6 context sentences for the made-up word

sentence	ρ
• i doubt if we ll ever hear a man play a **petfel** like that again	0.19
• also there were some other assorted instruments including a **petfel** and some wind chimes	0.31
• they finished with new moon city a song about a suburb of drem which featured beautifully controlled **petfel** playing from callum	0.23
• a programme of jazz and classical music showing the **petfel** as an instrument of both musical genres	0.27

Table 5: Context sentences and corresponding attention weights for the made-up word "petfel"

(2) and (4); consistently, the embeddings obtained from those sentences are very similar. Furthermore, of all four sentences, these two are the ones best suited for a simple averaging model as they contain informative, frequent words like "instrument", "chimes" and "music".

5 Conclusion

We have introduced attentive mimicking (AM) and showed that attending to informative and reliable contexts improves representations of rare and medium-frequency words for a diverse set of evaluations.

In future work, one might investigate whether attention mechanisms on the word level (cf. Ling et al., 2015) can further improve the model's performance. Furthermore, it would be interesting to investigate whether the proposed architecture is also beneficial for languages typologically different from English, e.g., morphologically rich languages.

Abstract

Research in the area of style transfer for text is currently bottlenecked by a lack of standard evaluation practices. This paper aims to alleviate this issue by experimentally identifying best practices with a Yelp sentiment dataset. We specify three aspects of interest (style transfer intensity, content preservation, and naturalness) and show how to obtain more reliable measures of them from human evaluation than in previous work. We propose a set of metrics for automated evaluation and demonstrate that they are more strongly correlated and in agreement with human judgment: direction-corrected Earth Mover's Distance, Word Mover's Distance on style-masked texts, and adversarial classification for the respective aspects. We also show that the three examined models exhibit tradeoffs between aspects of interest, demonstrating the importance of evaluating style transfer models at specific points of their tradeoff plots. We release software with our evaluation metrics to facilitate research.

1 Introduction

Style transfer in text is the task of changing an attribute (style) of an input, while retaining non-attribute related content (referred to simply as *content* for brevity in this paper).[1] For instance, previous work has modified text to make it more positive (Shen et al., 2017), romantic (Li et al., 2018), or politically slanted (Prabhumoye et al., 2018).

Some style transfer models enable modifications by manipulating latent representations of the text (Shen et al., 2017; Zhao et al., 2018; Fu et al., 2018), while others identify and replace style-related words directly (Li et al., 2018). Regardless of approach, they are hard to compare as there is currently neither a standard set of evaluation practices, nor a clear definition of which exact aspects to evaluate. In Section 2, we define three key aspects to consider. In Section 3, we summarize issues with previously used metrics. Many rely on human ratings, which can be expensive and time-consuming to obtain.

To address these issues, in Section 4, we consider how to obtain more reliable measures of human judgment for aspects of interest, and automated methods more strongly correlated with human judgment than previously used methods. Lastly, in Section 5, we show that the three examined models exhibit aspect tradeoffs, highlighting the importance of evaluating style transfer models at specific points of their tradeoff plots. We release software with our evaluation metrics at `https://github.com/passeul/style-transfer-model-evaluation`.

2 Aspects of Evaluation

We consider three aspects of interest on which to evaluate output text x' of a style transfer model, potentially with respect to input text x:

1. *style transfer intensity* $STI(SC(x), SC(x'))$ quantifies the difference in style, where $SC(\cdot)$ maps an input to a style distribution
2. *content preservation* $CP(x, x')$ quantifies the similarity in content between the input and the output
3. *naturalness* $NT(x')$ quantifies the degree to which the output appears as if it could have been written by humans

Style transfer models should be compared across all three aspects to properly characterize differences. For instance, if a model transfers from negative to positive sentiment, but alters content such as place names, it preserves content poorly.

---

[1] This definition of style transfer makes a simplifying assumption that "style" words can be distinguished from "content" words, or words carrying relatively less or no stylistic weight, such as "cafè" in "What a nice cafè." The definition is motivated by penalizing unnecessary changes to content words, e.g. "What a nice cafè" to "This is an awful cafè."

Proceedings of NAACL-HLT 2019, pages 495–504
Minneapolis, Minnesota, June 2 - June 7, 2019.

	Style Transfer			Content Preservation			Naturalness	
	HRC(x')	HRD(x')	SC(x')	HRC(x,x')	HRR(x,$\{x'\}$)	BLEU(x,x')	HRC(x')	PPL(x')
CAAE		x	x		x		x^{F}	
ARAE		x	x	x		x	x	x^{F}
DAR	x		x	x		x	x^{G}	

Table 1: Summary of past evaluation techniques. HRC is human rating on a continuous scale (e.g. 1 to 5). HRD is on discrete options (e.g. positive/negative). HRR is human ranking (most to least similar) of outputs, with respect to given input x. $\{x'\}$ is the set of x' from models trained on different parameters. SC is a style classifier. PPL is perplexity. Superscripts denote that evaluation is done for fluency (F) or grammar (G), which we consider subsets of naturalness. Readers can see the original papers for details on methods falling under these techniques.

If it preserves content well, but sequentially repeats words such as "the", the output is unnatural. Conversely, a model that overemphasizes text reconstruction would yield high content preservation and possibly high naturalness, but little to no style transfer. All three aspects are thus critical to analyze in a system of style transfer evaluation.

3 Related Work

We review previously used approaches for evaluating the outputs of style transfer models. Due to the high costs related to obtaining human evaluations, we focus on three models: the cross-aligned autoencoder (CAAE), adversarially regularized autoencoder (ARAE), and delete-and-retrieve (DAR) models (Shen et al., 2017; Zhao et al., 2018; Li et al., 2018). Table 1 illustrates the spread of evaluation practices in these papers using our notation from Section 2, showing that they all rely on a different combination of human and automated evaluation. For human evaluation, the papers use different instruction sets and scales, making it difficult to compare scores. Below we describe the automated metrics used for each aspect. Some rely on training external models on the corpus of input texts, X, and/or the corpus of output texts, X'. We encourage readers seeking details on how to compute the metrics to reference the algorithms in the original papers.

Style Transfer Previous work has trained classifiers on X and corresponding style labels, and measured the number of outputs classified as having a target style (Shen et al., 2017; Zhao et al., 2018; Li et al., 2018). Results from this *target style scoring* approach may not be directly comparable across papers due to different classifiers used in evaluations.

Content Preservation To evaluate content preservation between x and x', previous work has used BLEU (Zhao et al., 2018; Li et al., 2018), an n-gram based metric originally designed to evaluate machine translation models (Papineni et al., 2002). BLEU does not take into account the aim of style transfer models, which is to alter style by necessarily changing words. Intended differences between x and x' are thus penalized.

Naturalness Past evaluations of naturalness have relied largely on human ratings on a variety of scales under different names: grammaticality, fluency/readability, and naturalness itself (Table 1). An issue with measuring grammaticality is that text with proper syntax can still be semantically nonsensical, e.g. "Colorless green ideas sleep furiously" (Chomsky, 1957). Furthermore, input texts may not demonstrate perfect grammaticality or readability, despite being written by humans and thus being natural by definition (Section 2). This undermines the effectiveness of measures for such specific qualities of output texts.

Zhao et al. (2018) used perplexity to evaluate fluency, which, like grammaticality, we consider a subset of naturalness itself. Low perplexity signifies less uncertainty over which words can be used to continue a sequence, quantifying the ability of a language model to predict gold or reference texts (Brown et al., 1992; Young et al., 2006). However, style transfer outputs are not necessarily gold standard, and the correlation between perplexity and human judgments of those outputs is unknown in the style transfer setting.

4 Methods

We describe how to construct a style lexicon for use in human and automated evaluations. We also describe best practices that we recommend for obtaining scores of those evaluations, as well as how they can be used for evaluating other datasets. Please refer to Section 5 for experimental results.

Negative Sentiment	Positive Sentiment
ruined	mouthwatering
worst	delightfully
failure	wonderfully
lackluster	marvelous
horrible	refreshing

Table 2: Sample of words in a sentiment style lexicon.

4.1 Construction of Style Lexicon

Because the process of style transfer may result in the substitution or removal of more stylistically weighted words, it is ideal to have a lexicon of style-related words to reference. Words in x and/or x' that also appear in the lexicon can be ignored in evaluations of content preservation.

While building a new style lexicon or an extension of existing ones like WordNet-Affect (Strapparava and Valitutti, 2004) may be feasible with binary sentiment as the style, it may not be scalable to manually do so for various other types of styles. Static lexica also might not take context into account. This is an issue for text with words or phrases that are ambiguous in terms of stylistic weight, e.g. “dog” in “That is a man with a dog” vs. “That man is a dog.”

It is more appropriate to automate the construction of a style lexicon per dataset of interest. While multiple options may exist for doing so, we emphasize the simplicity and replicability of training a logistic regression classifier on X and corresponding style labels. We populate the lexicon with features having the highest absolute weights, as those have the most impact on the outcome of the style labels. (Table 2 shows sample words in the lexicon constructed for the dataset used in our experiments.) While sentiment datasets have been widely used in the literature (Shen et al., 2017; Zhao et al., 2018; Li et al., 2018), a lexicon can be constructed for other datasets in the same manner, as long as the dataset has style labels.

Given existing NLP techniques, it may not be possible to correctly identify all style-related words in a text. Consequently, there is a tradeoff between identifying more style-related words and incorrectly marking some other (content) words as style-related. We opt for higher precision and lower recall to minimize the risk of removing content words, which are essential to evaluations of content preservation. This issue is not critical because researchers can compare their style transfer methods using our lexicon.

4.2 Human Evaluation

As seen in Table 1, past evaluations of both style transfer and naturalness consider only output text x'. Existing work from other fields have, however, shown that asking human raters to evaluate two relative comparisons provides more accurate scores than asking them to provide a numerical score for a single observation (Stewart et al., 2005; Bijmolt and Wedel, 1995). With this knowledge, we construct more reliable ways of obtaining human evaluations via *relative scoring* instead of *absolute scoring*.

Style Transfer Intensity Past evaluations have raters mark the degree to which x' exhibits a target style (Li et al., 2018). We instead ask raters to score the difference in style between x and x', on a scale of 1 (identical styles) to 5 (completely different styles). This approach can also used for non-binary cases. Consider text modeled as a distribution over multiple emotions (e.g. happy, sad, scared, etc.), where each emotion can be thought of as a style. One task could be to make a scared text more happy. Presented with x and x', raters would still rate the degree to which they differ in style.

Content Preservation We consider the difficulty of asking raters to ignore style-related words as done in (Shen et al., 2017). Because not all raters may identify the same words as stylistic, their evaluations may vary substantially from one another. To account for this, we ask raters to evaluate content preservation on the same texts, but where we have masked style words using our style lexicon. Under this new “masking” approach, raters have a simpler task, as they are no longer responsible for taking style into account when they rate the similarity of two texts on a scale of 1 to 5.

Naturalness We ask raters to determine whether x or x' (they are not told which is which) is more natural. An x' marked as more natural indicates some success on the part of the style transfer model, as it is able to fool the rater. This is in contrast to previous work, where raters score the naturalness of x' on a continuous scale without taking x into account at all, even though x serves as the basis for comparison of what is considered natural.

4.3 Automated Evaluation

In this section, we describe our approaches to automating the evaluation of each aspect of interest.

No modification Input: the girls up front *incompetent* . Output: the girls up front are *amazing* .
Style removal Input: the girls up front . Output: the girls up front are .
Style masking Input: the girls up front $\langle customstyle \rangle$. Output: the girls up front are $\langle customstyle \rangle$.

Table 3: Text under different settings of style-based modification, as used in evaluations of content preservation. The sample output is from ARAE ($\lambda = 1$).

Style Transfer Intensity Rather than count how many output texts achieve a target style, we can capture more nuanced differences between the style distributions of x and x', using Earth Mover's Distance (Rubner et al., 1998; Pele and Werman, 2009). $EMD(SC(x), SC(x'))$ is the minimum "cost" to turn one distribution into the other, or how "intense" the transfer is. Distributions can have any number of values (styles), so EMD handles binary and non-binary datasets.

Note that even if $argmax(SC(x'))$ is not the target style class, EMD still acknowledges movement towards the target style with respect to $SC(x)$. However, we penalize (negate) the score if $SC(x')$ displays a relative change of style in the wrong direction, away from the target style.

Depending on x, not a lot of rewriting may be necessary to achieve a different style. This is not an issue, as STI relies on a style classifier to quantify not the difference between the content of x and x', but their style distributions. For the style classifier, we experiment with textcnn (Kim, 2014; Lee, 2018) and fastText (Joulin et al., 2017).

Content Preservation We first subject texts to different settings of modification: style removal and style masking. This is to address undesired penalization of metrics on texts expected to demonstrate changes after style transfer (Section 3). For style removal, we remove style words from x and x' using the style lexicon. For masking, we replace those words with a $\langle customstyle \rangle$ placeholder. Table 3 exemplifies these modifications.

For measuring the degree of content preservation, in addition to the widely used BLEU, we consider METEOR and embedding-based metrics. METEOR is an n-gram based metric like BLEU, but handles sentence-level scoring more robustly, allowing it to be both a sentence-level and corpus-level metric (Banerjee and Lavie, 2005).

For the embedding-based metrics, word embeddings can be obtained with methods like Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014). Sentence-level embeddings can be comprised of the most extreme values of word embeddings per dimension (*vector extrema*) (Forgues et al., 2014), or word *embedding averages* (Sharma et al., 2017). *Word Mover's Distance* (WMD), based on EMD, calculates the minimum "distance" between word embeddings of x and of x', where smaller distances signify higher similarity (Kusner et al., 2015). *Greedy matching* greedily matches words in x and x' based on their embeddings, calculates their similarity (e.g. cosine similarity), and averages all the similarities. It repeats the process in the reverse direction and takes the average of those two scores (Rus and Lintean, 2012).

We evaluate with all these metrics to identify the one most strongly correlated with human judgment of content preservation.

Naturalness For a baseline understanding of what is considered "natural," any method used for automated evaluation of naturalness requires the human-sourced input texts. We train unigram and neural logistic regression classifiers (Bowman et al., 2016) on samples of X and X' for each transfer model. Via adversarial evaluation, these classifiers must distinguish human-generated inputs from machine-generated outputs. The more natural an output is, the likelier it is to fool a classifier (Jurafsky and Martin, 2018). We calculate agreement between each type of human evaluation (Section 4.2) and each classifier AC. Agreement is the ratio of instances where humans and AC rate a text as more natural than the other.

We also train LSTM language models (Hochreiter and Schmidhuber, 1997) on X and compute sentence-level perplexities for each text in X' in order to determine the relative effectiveness of adversarial classification as a metric.

5 Experiments and Results

Due to high costs of human evaluation, we focus on CAAE, ARAE, and DAR models with transfer tasks based on samples from the Yelp binary sentiment dataset (Shen et al., 2017).[2] Below we detail

---

[2] Like most literature, including the papers on CAAE, ARAE and DAR, we focus on the binary case. Creating a high-quality, multi-label style transfer dataset for evaluation is a demanding task, which is out of scope for this paper.

Input	would *n't recommend* until management works on friendliness and communication with residents .
ARAE ($\lambda = 1$)	highly *recommend* this place while living in tempe and management .
CAAE ($\rho = 0.5$)	would highly *recommend* management on duty and staff on business .
DAR ($\gamma = 500$)	until management works on friendliness and is a *great* place for communication with residents .

Table 4: Sample outputs of a negative to positive sentiment style transfer task. Italicized words are style-related, according to a style lexicon. They can be masked or removed in evaluations of content preservation (Section 4.3).

the range of parameters each model is trained on in order to compare evaluation practices and generate aspect tradeoff plots. Each of three Amazon Turk raters evaluated 244 texts per aspect, per model. Of those texts, half are originally of positive sentiment transferred to negative, and vice versa.

For brevity, we reference average scores (correlation, kappa, and agreement, each of which is described below) from across all models in our analysis of results. For detailed scores per model, please refer to the corresponding tables.

5.1 Style Transfer Models

For each style transfer model, we choose a wide range of training parameters to allow for variation of content preservation, and indirectly, of style transfer intensity, in X. We show sample outputs from the models for a given input text in Table 4.

CAAE uses autoencoders (Vincent et al., 2008) that are cross-aligned, assuming that texts already share a latent content distribution (Shen et al., 2017). It uses latent states of the RNN and multiple discriminators to align distributions of texts in X' exhibiting one style with distributions of texts in X exhibiting another. Adversarial components help separate style information from the latent space where inputs are represented. We train CAAE on various values (0.01, 0.1, 0.5, 1, 5) of ρ, a weight on the adversarial loss.

CAAE is a baseline for other style transfer models, such as ARAE, which trains a separate decoder per style class (Zhao et al., 2018). We train ARAE on various values (1, 5, 10) of λ, which is also a weight on adversarial loss.

The third model that we evaluate, which also uses CAAE as a baseline, avoids adversarial methods in an approach called Delete-and-Retrieve (DAR) (Li et al., 2018). It identifies and removes style words from texts, searches for related words pertaining to a new target style, and combines the de-stylized text with the search results using a neural model. We train DAR on $\gamma = 15$, where γ is a threshold parameter for the maximum number of style words that can be removed from texts, with respect to the size of the corpus vocabulary. For this single training value, we experiment with a range of γ values (0.1, 1, 15, 500) during test time because, by design, the model does not need to be retrained (Li et al., 2018).

Model	Text Modification Setting	
	Unmasked	Style Masked
CAAE	0.158	**0.289**
ARAE	0.201	**0.321**
DAR	0.161	**0.281**
Average	0.173	**0.297**

DAR	0.103	0.201	**0.259**
Average	0.170	0.312	**0.526**

Table 6: Fleiss' kappas for human judgments of absolute naturalness and relative naturalness of texts.

5.2 Human Evaluation

We use Fleiss' kappa κ of inter-rater reliability (see formula in L. Fleiss and Cohen, 1973) to identify the more effective human scoring task for different aspects of interest. The kappa metric is often levied in a relative fashion, as there are no universally accepted thresholds for agreements that are slight, fair, moderate, etc. For comprehensive experimentation, we compare kappas over the outputs of each style transfer model. The kappa score for ratings of content preservation based on style-masked texts is 0.297. Given the kappa score of 0.173 for unmasked texts, style masking is a more reliable approach towards human evaluation for content preservation (Table 5).

For style transfer intensity, kappas for relative scoring do not show improvement over the previously used approach of absolute scoring of x'. However, we observe the opposite for the aspect of naturalness. Kappas for relative naturalness scoring tasks exceed those of the absolute scoring ones (Table 6). Despite the two types of tasks having

different numbers of categories (2 vs 5), we can compare them by using a threshold τ to bin the absolute score for each text into a "natural" group (x' is considered to be more natural than x) or "unnatural" one (vice versa), like in relative scoring. For example, $\tau = 2$ places texts with absolute scores greater than or equal to 2 into the natural group. Judgments for relative tasks yield greater inter-rater reliability than those of absolute tasks across multiple thresholds ($\tau \in \{2, 3\}$). This suggests that the relative scoring paradigm is preferable in human evaluations of naturalness.

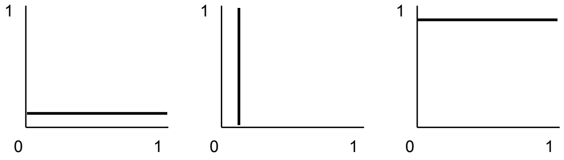
5.3 Automated Evaluation

Per aspect of interest, we compute Pearson correlations between scores from the existing metric and human judgments. (As there were three raters for any given scoring task, we take the average of their scores.) We do the same for our proposed metrics to identify which metric is more reliable for automated evaluation of a given aspect.

For style transfer intensity, across both the fastText and textcnn classifiers, our proposed direction-corrected Earth Mover's Distance metric has higher correlation with human scores than the past approach of target style scoring (Table 7).

For content preservation, METEOR, shown to have higher correlation with human judgments than BLEU for machine translation (Banerjee and Lavie, 2005), shows the same relationship for style transfer. However, across various text modification settings, WMD generally shows the strongest correlation with human scores (Tables 8 and 9). Because WMD is lower when texts are more similar, it is anti-correlated with human scores. We take absolute correlations to facilitate comparison with other content preservation metrics. With respect to text modification, style masking may be more suitable as it, on average for WMD, exhibits a higher correlation with human judgments.

For naturalness, both unigram and neural classifiers exhibit greater agreement on which texts are considered more natural with the humans given relative scoring tasks than with those given absolute scoring tasks (Table 10), although the neural classifier achieves higher agreements on average. We also confirm that sentence-level perplexity is



(a) (b) (c)

Figure 1: Extreme tradeoff plots, with style transfer intensity on the x-axis and content preservation on the y-axis.

(b) Naturalness vs. Style Tradeoffs

Figure 2: Tradeoffs between aspects of evaluation, using metrics most strongly correlated with human scores.

not an appropriate metric. It exhibits no significant correlation with human scores ($\alpha = 0.05$). These results suggest that adversarial classifiers can be useful for automating measurement of naturalness.

5.4 Aspect Tradeoffs

Previous work has compared models with respect to a single aspect of interest at a time, but has only, to a limited degree, considered how relationships between multiple aspects influence these comparisons. In particular, concurrent work by (Li et al., 2018) examines tradeoff plots, but focuses primarily on variants of its own model, while including only a single point on the plots of style transfer models from other papers. For a comprehensive comparison, it is ideal to have plots for all models.

It is helpful to first understand the tradeoff space. For example, we define extreme cases for style transfer intensity and content preservation, where we assume measurement of the latter ignores stylistic content. Consider two classes of suboptimal models. One class produces outputs with a wide range of style transfer intensity, but poor content preservation (Figure 1a). The other class of models produces outputs with low style transfer intensity, but a wide range of content preservation (Figure 1b).

This is in contrast to a model that yields a wide range of style transfer intensity and consistently high content preservation (Figure 1c). If we take that to be an ideal model for a sentiment dataset, we can interpret models with better performance to be the ones whose tradeoff plots are closer to that of the ideal model and farther from those of the suboptimal ones. The plot for an ideal model will likely vary by dataset, especially because the tradeoff between content preservation and style transfer intensity depends on the level of distinction between style words and content words of the dataset.

With this interpretation of the tradeoff space, we construct a plot for each style transfer model (Figure 2), where each point represents a different hyperparameter setting for training (Section 5.1). We collect scores based on the automated metrics most strongly correlated with human judgment: direction-corrected EMD for style transfer intensity, WMD for content preservation, and percent of output texts marked by an adversarial classifier as more natural than input texts. Because WMD scores are lower when texts are more similar, we instead take the normalized inverses of the scores to represent the degree of content preservation.

Across all models, there is a trend of reduction in content preservation and naturalness as style transfer intensity increases. Without the plots, one might conclude that ARAE and DAR perform substantially differently, especially if hyperparameters are chosen such that ARAE achieves the left-most point on its plot and DAR achieves the right-most point on its plot. With the plots, at least for the set of hyperparameters considered, it is evident that they perform comparably (Figure 2a) and do not exhibit the same level of decrease in naturalness as CAAE (Figure 2b).

6 Discussion

Previous work on style transfer models used a variety of evaluation methods (Table 1), making it difficult to meaningfully compare results across papers. Moreover, it is not clear from existing research how exactly to define particular aspects of interest, or which methods (whether human or automated) are most suitable for evaluating and comparing different style transfer models.

To address these issues, we specified key aspects of interest (style transfer intensity, content preservation, and naturalness) and showed how to obtain more reliable measures of them from human evaluation than in previous work. Our proposed automated metrics (direction-corrected EMD, WMD on style-masked texts, and adversarial classification) exhibited stronger correlations with human scores than existing automated metrics on a binary sentiment dataset. While human evaluation may still be useful in future research, automation facilitates evaluation when it is infeasible to collect human scores due to prohibitive cost or limited time.

6.1 Human Evaluation

For style transfer intensity, the relative scoring task (rating the degree of stylistic difference between x and x') did not have greater rater reliability than the previously used task of rating output texts on an absolute scale. This is likely due to task complexity or rater uncertainty, which motivates the need for further exploration of task design for this particular aspect of interest.

For content preservation, our form of human evaluation operates on texts whose style words are masked out, unlike the previous approach (no masking). Our approach addresses the unintentional variable of rater-dependent style identification that could lead to noisy, less reliable ratings.

Identification and masking of words was made possible with a style lexicon. We automatically constructed the lexicon in a way that can be done for any style dataset, as long as style labels are available (Section 4.1). We acknowledge a trade-off between filling the lexicon with more style words and being conservative in order to avoid capturing content words. We justify taking a more conservative approach as content words are naturally critical to evaluations of content preservation.

For naturalness, we introduced a paradigm of relative scoring that uses both the output and input texts. This achieved a higher inter-rater reliability than did absolute scoring, the previous approach.

6.2 Automated Evaluation

For style transfer intensity, we proposed using a metric with EMD as the basis to acknowledge the spectrum of styles that can appear in outputs and to handle both binary and non-binary datasets. The metric also accounts for direction by penalizing scores in the cases where the style distribution of the output text explicitly moves away from the target style. Previous work used external classifiers, whose style distributions for x and x' can be used to calculate direction-corrected EMD, making it a simple addition to the evaluation workflow.

For content preservation, WMD (based on EMD) works in a similar fashion, but with word embeddings of x and of x'. BLEU, used widely in previous work, may yield weaker correlations with human judgment in comparison as it was designed to have multiple reference texts per candidate text (Papineni et al., 2002). Several reference texts, which are more common in machine translation tasks, increase the chance of n-gram (such as $n \geq 3$) overlap with the candidate. In the style transfer setting, however, the only reference text for x' is x. Having a single reference text reduces the likelihood of overlap and the overall effectiveness of BLEU.

For naturalness, strong agreement of adversarial classifiers with relative scores assigned by humans suggest that classifiers are suitable for automated evaluation. One might assume input texts would almost always be rated as more natural by both humans and classifiers, biasing the agreement. This is not the case, as we justify our rating scheme with evidence of outputs being rated as more natural across several models (Figure 2b). Output texts classified as more natural indicate some success for a style transfer model, as it can produce texts with a quality like that of human-generated inputs, which are, by definition, natural.

Finally, with aspect tradeoff plots constructed using scores from the automated metrics, we can directly compare models with respect to multiple aspects simultaneously. Points of intersection, or near intersection, for different models signify that they, at the hyperparameters that yielded those points, can achieve similar results for various aspects. These parameters can be useful for understanding the impact of decisions made during model design and optimization phases.

6.3 Future Research

As we confirmed, sentence-level perplexity of output x' is not meaningful by itself for the automated evaluation of naturalness. The idea of using both x and x', akin to how we train automated classifiers of naturalness (Section 4.3), can be extended to construct a perplexity-based metric that also takes into account the perplexity of input x.

Another avenue for future work could be evaluating on datasets with a different style or number of style classes. It is worth studying the distinction between style words and content words in the vocabulary of each such dataset. Given the definition of style transfer and its simplifying assumption in Section 1, it would be reasonable to expect naturally low content preservation scores for any given style transfer model operating on datasets with less distinction, such as those of formality. This is not so much an issue as it is a dataset-specific trend that can be visualized in corresponding tradeoff plots, which would provide a holistic evaluation of model performance. In any case, results from inter-rater reliability and correlation testing on these additional datasets would overall enable more consistent evaluation practices and further progress in style transfer research.

Acknowledgments

We would like to thank Juncen Li, Tianxiao Shen, and Junbo (Jake) Zhao for guidance in the use of their respective style transfer models. These models serve as markers of major progress in the area of style transfer research, without which this work would not have been possible.

Abstract

Bigrams (two-word sequences) hold a special place in semantic composition research since they are the smallest unit formed by composing words. A semantic relatedness dataset that includes bigrams will thus be useful in the development of automatic methods of semantic composition. However, existing relatedness datasets only include pairs of unigrams (single words). Further, existing datasets were created using rating scales and thus suffer from limitations such as inconsistent annotations and scale region bias. In this paper, we describe how we created a large, fine-grained, bigram relatedness dataset (*BiRD*), using a comparative annotation technique called *Best–Worst Scaling*. Each of BiRD's 3,345 English term pairs involves at least one bigram. We show that the relatedness scores obtained are highly reliable (split-half reliability $r = 0.937$). We analyze the data to obtain insights into bigram semantic relatedness. Finally, we present benchmark experiments on using the relatedness dataset as a testbed to evaluate simple unsupervised measures of semantic composition. BiRD is made freely available to foster further research on how meaning can be represented and how meaning can be composed.

1 Introduction

The term *semantic relatedness* refers to the extent to which two concepts are close in meaning. The ability to assess semantic relatedness is central to the use and understanding of language (Hutchison, 2003; Mohammad and Hirst, 2005; Huth et al., 2016). Manual ratings of semantic relatedness are useful for: (a) obtaining insights into how humans perceive and use language; and (b) developing and evaluating automatic natural language systems.

Existing datasets of semantic relatedness, such as the one by Finkelstein et al. (2002), only focus on pairs of unigrams (single words). However, the concept of semantic relatedness applies more generally to any unit of text. Work in semantic representation explores how best to represent the meanings of words, phrases, and sentences. Bigrams (two-word sequences) are especially important there since they are the smallest unit formed by composing words. Thus it would be useful to have large semantic relatedness datasets involving bigrams.

Existing datasets also suffer from shortcomings due to the annotation schemes employed. Except in the case of a few small but influential datasets, such as those by Miller and Charles (1991) and Rubenstein and Goodenough (1965), annotations were obtained using rating scales. (Annotators were asked to give scores for each pair; usually on a discrete 0 to 5 scale.) Rating scales suffer from significant known limitations, including: inconsistencies in annotations by different annotators, inconsistencies in annotations by the same annotator, scale region bias (annotators often have a bias towards a portion of the scale), and problems associated with a fixed granularity (Presser and Schuman, 1996).

Best–Worst Scaling (BWS) is an annotation scheme that addresses these limitations by employing comparative annotations (Louviere, 1991; Cohen, 2003; Louviere et al., 2015; Kiritchenko and Mohammad, 2017). Annotators are given n items at a time (an n-tuple, where $n > 1$ and commonly $n = 4$). They are asked which item is the *best* (highest in terms of the property of interest) and which is the *worst* (least in terms of the property of interest).[1] When

---

[1] At its limit, when $n = 2$, BWS becomes a *paired comparison* (Thurstone, 1927; David, 1963), but then a much larger set of tuples need to be annotated (closer to N^2).

Proceedings of NAACL-HLT 2019, pages 505–516
Minneapolis, Minnesota, June 2 - June 7, 2019.

working on 4-tuples, best–worst annotations are particularly efficient because each best and worst annotation will reveal the order of five of the six items (i.e., for a 4-tuple with items A, B, C, and D, if A is the best, and D is the worst, then A > B, A > C, A > D, B > D, and C > D). It has been empirically shown that annotating $2N$ 4-tuples is sufficient for obtaining reliable scores (where N is the number of items) (Louviere, 1991; Kiritchenko and Mohammad, 2016). Kiritchenko and Mohammad (2017) showed through empirical experiments that BWS produces more reliable and more discriminating scores than those obtained using rating scales.[2]

In this paper, we describe how we obtained fine-grained human ratings of semantic relatedness for English term pairs involving at least one bigram.[3] The other term in the pair is either another bigram or a unigram. We first selected a set of target bigrams AB (A represents the first word in the bigram and B represents the second word). For each AB, we created several pairs of the form AB–X, where X is a unigram or bigram. As X's we chose terms from a diverse set of language resources:

- terms that are transpose bigrams BA—where the first word is B and the second word is A (taken from occurrences in Wikipedia);
- terms that are related to AB by traditional semantic relations such as hypernymy, hyponymy, holonymy, meronymy, and synonymy (taken from WordNet); and
- terms that are co-aligned with AB in a parallel corpus (taken from a machine translation phrase table).

The dataset includes 3,345 term pairs corresponding to 410 ABs. We refer to this dataset as the *Bigram Relatedness Dataset* (or, *BiRD*).

We use BWS to obtain semantic relatedness by: (1) creating items that are pairs of terms, and (2) prompting four items (pairs) at a time and asking annotators to mark the pair that is most related and the pair that is least related. Once the annotations are complete, we obtain real-valued scores of semantic relatedness for each pair using simple arithmetic on the counts of how often an item is chosen best and worst (Orme, 2009; Flynn and Marley, 2014). (Details in Section 3.) To evaluate the quality of BiRD we determine the consistency of the BWS annotations. A commonly used approach to determine consistency in dimensional annotations is to calculate split-half reliability (Cronbach, 1951). We show that our semantic relatedness annotations have a split-half reliability score of $r = 0.937$, indicating high reliability, that is, if the annotations were repeated then similar scores and rankings would be obtained. (Details in Section 4.)

We use BiRD to (a) obtain insights into bigram semantic relatedness, and (b) to evaluate automatic semantic composition methods.

Examining Bigram Semantic Relatedness: Since very little work exists on the semantic relatedness of bigrams, several research questions remain unanswered, including: What is the distribution and mean of the semantic relatedness between a bigram and its transpose?; What is the average semantic relatedness between a bigram and its hypernym?; Are co-aligned terms from a phrase table a good source of term pairs to be included in a semantic relatedness dataset (specifically, do they cover a wide range of semantic relatedness values)?; etc. In Section 5, we present an analysis of BiRD to obtain insights into these questions.

Evaluating Semantic Composition: A common approach to evaluate different methods of representing words via vectors is through their ability to rank pairs of words by closeness in meaning (Pennington et al., 2014; Levy and Goldberg, 2014; Faruqui and Dyer, 2014). BiRD allows for the evaluation of semantic composition methods through their ability to rank pairs involving bigrams, by semantic relatedness. In Section 6, we present benchmark experiments on using BiRD as a testbed to evaluate various common semantic composition methods using various pre-trained word representations. Specifically, we conduct experiments to gain insights into research questions such as: Which common mathematical operations for vector composition (e.g., vector addition, vector multiplication, etc.) capture the semantics of a bigram more accurately?; Which of the two words in a noun phrase bigram (the head noun or

---

[2] See Kiritchenko and Mohammad (2016, 2017) for further details on BWS and its use in NLP applications.

[3] In a separate project, the second author is developing a semantic relatedness dataset for unigrams using BWS (an order of magnitude larger than existing ones). Project page: http://saifmohammad.com/WebPages/Relatedness.html

the modifier) has greater influence on the semantics of the bigram?; etc.

Contributions: The contributions of this work can be summarized as follows:

- We obtain fine-grained human ratings of semantic relatedness for 3,345 term pairs, each of which includes at least one bigram. The other term in the pair is either another bigram or a unigram.
- We use the comparative annotation technique Best–Worst Scaling, which addresses the limitations of traditional rating scales. This is the first time BWS has been used to create a dataset for semantic relatedness. We show that the ratings obtained are highly reliable.
- We analyse BiRD to obtain insights into semantic relatedness when it involves bigrams. We also develop interactive visualizations that allow for easy exploration of the data. (Available on the project webpage.)
- We present benchmark experiments on using BiRD as a testbed to evaluate methods of semantic composition.

The Bigram Relatedness Dataset, visualizations of the data, and the annotation questionnaire are made freely available through the project's webpage.[4] We hope that the new dataset will foster further research on how meaning is composed in bigrams, on semantic representation in general, and on the understanding of bigram semantic relatedness.

The annotation task described in this paper was approved by the National Research Council Canada's Research Ethics Board (protocol number 2018-72). The board examines the proposed methods to ensure that they adhere to the required ethical standards. Special attention was paid to obtaining informed consent and protecting participant anonymity.

2 Background and Related Work

Semantic Relatedness and Semantic Similarity Closeness of meaning can be of two kinds: semantic similarity and semantic relatedness. Two terms are considered to be semantically similar if there is a taxonomic relationship between them such as hyponymy (hypernymy), or troponymy. Two terms are considered to be semantically related if there is any lexical semantic relation between them—taxonomic or non-taxonomic. Semantically similar items tend to share a number of properties. For example, *apples* and *bananas* (co-hyponyms of fruit) are both edible, they grow on trees, they have seeds, etc. On the other hand, semantically related concepts may not have many properties in common, but there exists some relationship between them which lends them the property of being semantically close. For example, *surgeon* and *scalpel* are semantically related as the former uses the latter for their work.

We focus on semantic relatedness in this work, not only because it is the broader class subsuming semantic similarity, but also because many psychology and neuro-linguistic studies have demonstrated the importance of semantic relatedness. Notable among these are studies on semantic priming and fMRI studies that show that the human brain stores information in a thematic manner (based on relatedness) rather than based on similarity (Hutchison, 2003; Huth et al., 2016).

Word-Pair Datasets: Several semantic similarity and relatedness datasets involving unigram pairs (word pairs) exist. Rubenstein and Goodenough (1965) and Miller and Charles (1991) provided influential but small English word–pair datasets with fine–grained semantic similarity scores. More recent larger datasets including hundreds of pairs were provided by Finkelstein et al. (2002) (for relatedness) and Hill et al. (2015) (for similarity). Similar datasets exist in some other languages as well, such as the one by Gurevych (2006) and Panchenko et al. (2016) for relatedness. However, none of these datasets include items that are bigrams.

Bigram Semantic Similarity Datasets: Mitchell and Lapata (2010) created a semantic similarity dataset for 324 bigram pairs. The terms include adjective–noun, noun–noun, and verb–object bigrams. Annotators were asked to choose an integer between one and seven, indicating a coarse semantic similarity rating. Turney (2012) compiled a dataset of 2,180 bigram–unigram synonym pairs from WordNet synsets. (The bigrams are either noun–noun or adjective–noun phrases.) Other pairs were created taking bigrams and words that do not exist in the same synsets.

---

[4] http://saifmohammad.com/WebPages/BiRD.html

He thus created a dataset of synonyms and non-synonyms. In contrast to these datasets, BiRD has fine-grained relatedness scores.

Other Similarity Datasets: There exist datasets on the semantic similarity between sentences and between documents (Marelli et al., 2014; Agirre et al., 2014; Cera et al., 2017). Those are outside the scope of this work.

Other Natural Language Datasets Created Using BWS: BWS has been used for creating datasets for relational similarity (Jurgens et al., 2012), word-sense disambiguation (Jurgens, 2013), word–sentiment intensity (Kiritchenko and Mohammad, 2016), word–emotion intensity (Mohammad, 2018b), and tweet–emotion intensity (Mohammad and Kiritchenko, 2018). The largest BWS dataset is the NRC Valence, Arousal, and Dominance Lexicon, which has valence, arousal, and dominance scores for over 20,000 English words (Mohammad, 2018a).

3 English Bigram Relatedness Dataset

We first describe how we selected the term pairs to include in the bigram relatedness dataset, followed by how they were annotated using BWS.

3.1 Term Pair Selection

Randomly selecting term pairs will result in most pairs being unrelated. This is sub-optimal in terms of the human annotation effort that is to follow. Further, since our goal is to create a gold standard relatedness dataset, we wanted it to include term pairs across the whole range of semantic relatedness: from maximally unrelated to maximally related. Thus, a key challenge in term-pair selection is obtaining pairs with a wide range of semantic relatedness scores, without knowing their true semantic relatedness in advance. In addition, we also wanted the dataset to satisfy the following criteria:

- For each target bigram AB we wanted to include several pairs of the form AB–X, where X is a unigram or bigram.
  Motivation: Applications of semantic relatedness, such as real-word spelling correction and textual entailment, often require judgments of the form '*is AB–X_1 more related or less related than AB–X_2*'.
- There should exist some pairs AB–X, such that X is BA and a common English bigram.
  Motivation: This is useful for testing sensitivity of semantic composition models to word order.
- The unigrams and bigrams should be commonly used English terms.
  Motivation: Data annotation of common terms is expected to be more reliable. Also, common terms are more likely to occur in application datasets.
- There should exist pairs that are taxonomically related (i.e., semantically similar), for example, hypernyms, hyponyms, holonyms, etc.; and there should exist pairs that are not taxonomically related but semantically related nonetheless.
  Motivation: This increases dataset diversity.
- We focus on noun phrases (adjective–noun and noun–noun bigrams).
  Motivation: Noun phrases are the most frequent phrases.

To pursue these criteria, we compiled a set of term pairs from three diverse sources (Wikipedia, WordNet, and a machine translation phrase table) as described below.

Wikipedia: We chose to collect our target bigrams from the English Wikipedia dump (2018).[5] The corpus was tagged with parts of speech (POS) using the NLTK toolbox.[6] For each of the adjective–noun and noun–noun bigrams AB in the corpus, we checked to see if the bigram BA (its transpose) also exists in the corpus. We will refer to such pairs of bigrams as *transpose bigrams*. Only those transpose bigrams (AB and BA) were selected that were both noun phrases and where both AB and BA occur in the corpus with frequencies greater than a pre-chosen threshold t (we chose $t = 30$). For a pair of transpose bigrams, the bigram with the higher frequency was chosen as AB and the bigram with the lower frequency was chosen as the corresponding BA. The above process resulted in 4,095 transpose pairs (AB–BA).

WordNet: Among the 4,095 ABs, 330 exist in WordNet version 3.0 (Fellbaum, 1998).[7] For each of these, we selected (when available) synonyms (at most five), a hypernym, a hyponym, a holonym, and a meronym from WordNet.

---

[6] https://www.nltk.org/

[7] https://wordnet.princeton.edu/download/current-version

Translation Phrase Table: Word-aligned parallel corpora map words in text of one language to those in text of another language. Often this can lead to more than one word/phrase in one language being mapped to a common word/phrase in the other language. We will refer to such terms as being *co-aligned*. Due to the nature of languages and the various forms that the same text can be translated to, co-aligned terms tend to include not just synonyms but also other semantically related terms, and sometimes even unrelated terms. Thus, we hypothesize that it is beneficial to include pairs of co-aligned terms in a semantic relatedness dataset as they pertain to varying degrees of semantic relatedness.

We used an English–French phrase table from the Portage Machine Translation Toolkit (Larkin et al., 2010) to determine additional pairs AB–X.[8] Specifically, for each AB–F entry in the phrase table (where F is a French term) we keep the five most frequent English unigrams and the five most frequent English bigrams (other than AB) that are also aligned to F. Among the 4,095 ABs, 454 occurred in the phrase table. This resulted in 3,255 AB–X pairs in total (1,897 where X is a unigram, and 1,358 where X is a bigram).

Finally, we chose to filter the term pairs, keeping only those ABs that occurred in at least three unique pairs. (So for a given AB, apart from the AB–BA entry, there should be at least two other entries of the form AB–X, generated using WordNet or the phrase table.) We also manually examined the remaining entries and removed those with obscure terms. The final master term pairs list consists of 3,345 AB–X pairs in total (1,718 where X is a unigram, and 1,627 where X is a bigram), corresponding to 410 ABs. Thus on average, each AB occurred in about 8 distinct pairs. This is yet another aspect that makes BiRD unique, as existing datasets were not designed to include terms in multiple pairs. Table 1 shows the number of adjective–noun pairs, the number of noun–noun pairs, and the total number of pairs in BiRD. (We grouped the hypernym and hyponym pairs into a common class, which we will refer to as the *is-a* pairs. Similarly we group the meronym and holonym pairs into a common class, which we will refer to as the *part-whole* pairs.)

Source	# a–n	# n–n	# both
Wikipedia_transpose	80	330	410
WordNet_synonym	18	70	88
WordNet_is-a	49	220	269
WordNet_part-whole	7	30	37
PhraseTable_co-aligned	440	2,101	2,541
All	**594**	**2,751**	**3,345**

Table 1: Number of pairs from different sources.

3.2 Annotating For Semantic Relatedness

As mentioned in the introduction, we use the comparative annotation method Best–Worst Scaling (BWS) to obtain the annotations. From the list of $N = 3,345$ term pairs, we generated $2N = 6,690$ distinct 4-tuples (each 4-tuple is a set of four term pairs) such that each term pair appears in roughly equal distinct tuples, and no term pair appears more than once in a tuple.[9] (Recall that past research has shown that generating 2N 4-tuples in this manner is sufficient for obtaining fairly reliable scores (Louviere, 1991; Kiritchenko and Mohammad, 2017; Mohammad, 2018a).) The annotators were presented with one tuple at a time and were asked to specify which of the four pairs is most close in meaning (or most related) and which term is the least close (or least related).

Detailed annotation instructions (with examples of appropriate and inappropriate responses) were provided. Notably, we made it clear that if terms in the pair have several meanings, then the annotators should consider the meanings that are closest to each other. We also asked the annotators to be mindful of word order (i.e., the meaning of a bigram AB may be different from the meaning of its transpose BA).

We set up the annotation task on the crowdsourcing platform, Figure Eight.[10] We did not collect personally identifiable information from the annotators. The compensation that the annotators would receive was clearly stated. We selected a pool of annotators fluent in English and with a history of high-quality annotations. Annotators were told that they could annotate as many instances as they wished. As mentioned in the Introduction, prior to the annotation, the planned procedure was approved by the National Research Council Canada's Research Ethics Board (protocol number 2018-72).

---

[8] French was chosen as it is close to English and there exist English–French parallel corpora of sufficient size.

[9] If 2N 4-tuples are generated from N items, and each item is to occur in an equal number of tuples, then each item will occur in eight tuples.

[10] https://www.figure-eight.com/

# Term Pairs	# Tuples	# Annotations per Tuple	# Annotations	# Annotators	SHR
3,345	6,690	8 (for most tuples), >8 (for some)	57,482	427	0.9374

Table 2: BiRD annotation statistics. SHR = split-half reliability (as measured by Pearson correlation).

About 2% of the data was annotated beforehand by the authors. These questions are referred to as gold questions. Figure Eight interspersed the gold questions with the other questions. If a crowd worker answered a gold question incorrectly, then they were immediately notified. This served as an additional way to guide the annotators. If an annotator's accuracy on the gold questions fell below 70%, then they were refused further annotation, and all of their annotations were discarded. This served as a mechanism to avoid malicious annotations.

In the task settings for Figure Eight, we specified that we needed annotations from eight people for each 4-tuple.[11] In all, 57,482 pairs of best and worst responses were obtained from 427 annotators.[12]

Annotation Aggregation: The final semantic relatedness scores were calculated from the BWS responses using a simple counting procedure (Orme, 2009; Flynn and Marley, 2014): For each term pair, the semantic relatedness score is the proportion of times the term pair was chosen as the best minus the proportion of times the term pair was chosen as the worst.[13] The scores were linearly transformed to the interval: 0 (lowest semantic relatedness) to 1 (highest semantic relatedness). We refer to the final list of 3,345 English term pairs along with their scores for semantic relatedness as the *Bigram Relatedness Dataset (BiRD)*. Table 2 summarizes key annotation statistics.

4 Reliability of Data Annotations

A commonly used measure of quality in dimensional annotation tasks is the reproducibility of the final scores—the extent to which repeated independent manual annotations produce similar results. To assess this reproducibility, we calculate average *split-half reliability (SHR)* (Cronbach, 1951) as follows: The annotations for each 4-tuple are randomly split into two halves. One set is put in bin 1 and another set in bin 2. Next, two sets of semantic relatedness scores are produced independently from the two bins, 1 and 2, respectively. Then the Pearson correlation between the two sets of scores is calculated. If the annotations are of good quality, then the correlation between the two sets of relatedness scores will be high (closer to 1).[14] This process is repeated 100 times, and the correlations are averaged. The last column in Table 2 shows the result. An SHR of $r = 0.9374$ indicates high reliability.

5 Studying Bigram Semantic Relatedness

Since very little prior work exists on the semantic relatedness of bigrams, several research questions remain unanswered, including:

- If both AB and BA are common English bigrams, then what is the average semantic relatedness between AB and BA?
- What is the range of semantic relatedness between a bigram and its hypernym or hyponym? What is the average semantic relatedness of such pairs? How do these averages and standard deviations vary with respect to the different semantic relations?
- What is the distribution of semantic relatedness values for co-aligned terms?

We now present analyses of the relatedness dataset to obtain insights into these questions.

Figure 1 shows example adjective–noun and noun–noun entries from BiRD. Observe that for the term *ageing population*, the most related term is *ageing society*—a co-aligned term in the phrase table. (Other co-aligned terms have lower relatedness scores.) The transpose bigram *population ageing* is also marked as highly related. WordNet does not provide a synonym for *ageing population*. For the term *adult female*, the WordNet synonym and the transposed bigram (BA) are marked as being most related. Note that the WordNet-provided hyponym *amazon* is marked as less related (probably because that sense of *amazon* is rare). BiRD can be examined

---

[11] Note that since each term pair occurs in eight different 4-tuples, it is involved in $8 \times 8 = 64$ best–worst judgments.

[12] Gold questions were annotated more than eight times.

[13] More complex optimization algorithms exist, such as those described in (Hollis, 2018); however, our past experiments showed that the simple counting procedure obtained the most reliable results.

[14] Scores close to 0 indicate no correlation.

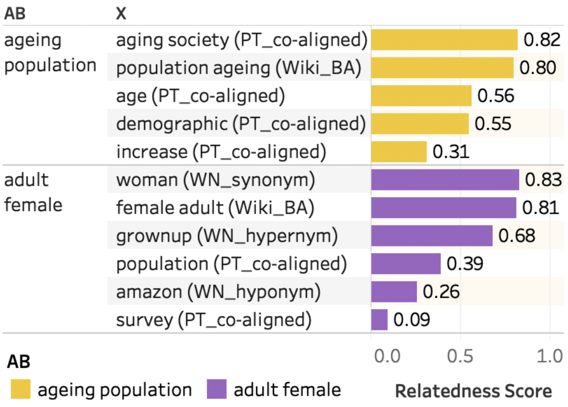

Figure 1: Example entries from BiRD.

for each individual relation and sorted by relatedness scores to determine other example pairs that seemingly should be closely related, but are not highly semantically related in the perception of the average English speaker. These include pairs such as *subject area–discipline* (WordNet synonym) and *frying pan–spider* (WordNet hyponym). The AB–BA pairs with low relatedness, such as *law school–school law, home run–run home,* and *traffic light–light traffic* are especially useful in testing whether measures of semantic composition generate suitably different representations for the terms in such pairs.

Table 3 shows the average semantic relatedness scores as well as standard deviations for the term pairs from various sources.[15] Observe that, on average, the AB–BA pairs and the AB–WordNet synonym pairs are found to be the most related. On average, the AB–WordNet part-whole pairs and the AB–phrase table co-aligned pairs have the lowest semantic relatedness scores. The high average relatedness and low standard deviation (σ) for the transpose bigrams, indicate that these pairs tend to be closely related to each other. The standard deviation is markedly higher for the other sources of word pairs. Manual examination of such pairs (especially those involving WordNet synonyms) revealed that this is often because one of the terms might be related to the other in a rare sense (such as in the *amazon* example). The high standard deviations for hypernyms, hyponyms, meronyms, and holonyms, indicate that pairs connected by this relation in WordNet can still exhibit a wide range of semantic relatedness.

The standard deviations also indicate that 95% of the co-aligned pairs have semantic relatedness between 0.09 and 0.83 (a wide interval). Manual examination revealed that the lowest score pairs were unrelated and the highest score terms were often synonymous. Thus co-aligned pairs from phrase tables are indeed a good source of term pairs for a semantic relatedness dataset, since they include pairs with a wide variety of relatedness values.

Source	**avg. rel.**	σ
Wikipedia_transpose	0.669	0.118

WordNet_is-a	0.550	0.177
WordNet_part-whole	0.453	0.193
PhraseTable_co-aligned	0.463	0.189

Table 3: Average relatedness and standard deviation (σ) scores for term pairs from the various sources.

6 Evaluating Methods of Semantic Composition on BiRD

A popular approach to represent word meaning in natural language systems is through vectors that capture the contexts in which the word occurs. An area of active research is how these word vectors can be composed to create representations for larger units of text such as phrases and sentences (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Socher et al., 2012; Tai et al., 2015). Even though there is a large body of work on how to represent the meanings of sentences (Le and Mikolov, 2014; Kiros et al., 2015; Lin et al., 2017), there is relatively less work on how best to compose the meanings of two words to represent the meaning of a bigram. One reason for this is a lack of suitable evaluation resources. A common approach to evaluate representations of unigrams is through their ability to rank pairs of words by closeness in meaning (Pennington et al., 2014; Levy and Goldberg, 2014; Faruqui and Dyer, 2014). BiRD allows for the evaluation of semantic composition methods through their ability to rank pairs involving bigrams, by semantic relatedness.

Here, we present benchmark experiments on commonly used semantic composition methods by measuring their ability to rank the term pairs in BiRD by relatedness scores. The underlying assumption is that the more accurately a method of semantic composition can determine the representation of a bigram, the more accurately systems can determine the relatedness of that bigram with other terms.

---

[15] The scores for just the adjective–noun pairs and just the noun—noun pairs are similar.

We focus on unsupervised approaches as we wanted to identify how well basic composition operations perform. The applicability of BiRD is much broader though, and it can be used: (1) for evaluating the large number of proposed supervised methods of semantic composition; (2) for evaluating the large number of measures of semantic relatedness; (3) to study the mechanisms underpinning semantic composition; etc. We leave those for future work.

We test three vector space models to obtain word representations: GloVe (Pennington et al., 2014), fastText (Grave et al., 2018), and a traditional model based on matrix factorization of a word–context co-occurrence matrix (Turney et al., 2011). We test four mathematical composition operations: (1) vector addition, (2) element-wise vector multiplication, (3) tensor product with circular convolution (Widdows, 2008), and (4) dilation (Mitchell and Lapata, 2010). In adjective–noun and noun–noun bigrams, the second word usually plays a role of a head noun, and the first word is a modifier. We test the performance of two baseline methods that do not employ vector composition: one that represents a bigram with the vector for the first word and one that represents a bigram with the vector for the second word.

Word representations: We use GloVe word embeddings pre-trained on 840B-token CommonCrawl corpus[16] and fastText word embeddings pre-trained on Common Crawl and Wikipedia using CBOW.[17] For the traditional model, we use the exact word–context co-occurrence matrix described in Turney et al. (2011).[18] They created the matrix from a corpus of 5 × 10^{10} tokens gathered from university websites. The rows correspond to terms (single words from WordNet) and the columns correspond to contexts (single words from WordNet appearing to the left or to the right of the term). Each cell of the matrix is the positive pointwise mutual information between the term and the context. The matrix is decomposed to $\mathbf{U_d \Sigma_d V_d^\top}$ (d denotes dimensionality) via truncated singular value decomposition. Word vectors are obtained from the matrix $\mathbf{U_d \Sigma_d^p}$, where rows correspond to the d-dimensional word vectors and p is the weight factor for singular values in $\mathbf{\Sigma_d}$. We set parameter p to 0.5, and the dimensionality of word vectors to $d = 300$ for all three vector space models.

Unsupervised Compositional Models: For a bigram $w_1 w_2$, let $u \in \mathbb{R}^{1\times d}$ and $v \in \mathbb{R}^{1\times d}$ denote the vectors for words w_1 and w_2, respectively. Each of the methods below applies a different composition function f on the word vectors u and v to obtain the vector representation p for the bigram $w_1 w_2$: $p = f(u, v)$:

- *Addition* (Salton and McGill, 1986): add the two word vectors ($p = u + v$).
- *Multiplication* (Mitchell and Lapata, 2010): element-wise multiplication of the two vectors ($p = u \odot v$, where $p_i = u_i \cdot v_i$).
- *Tensor product with convolution* (Widdows, 2008): outer product of two vectors resulting in matrix Q ($q_{ij} = u_i v_j$). Then, circular convolution is applied to map Q to vector p. This is equivalent to: $p_i = \sum_j u_j \cdot v_{i-j}$.
- *Dilation* (Mitchell and Lapata, 2010): decompose v to parallel and orthogonal components to u, and then stretch the parallel component along u ($p_i = v_i \sum_j u_j u_j + (\lambda - 1) u_i \sum_j u_j v_j$, where λ is the dilation factor). We set $\lambda = 2$.

For the two baseline experiments that do not employ vector composition, *head only*: $p = v$ and *modifier only*: $p = u$.

Semantic Relatedness: The relatedness score for a term pair AB–X in the Bigram Relatedness Dataset (BiRD) is computed by taking the cosine between the vectors representing AB and X, where X can be a unigram or a bigram.

Evaluation: As evaluation metric, we use the Pearson correlation of the relatedness scores predicted by a method with the gold relatedness scores in BiRD. Some words in BiRD do not occur in some of the corpora used to create the word vectors. Thus we conduct experiments on a subset of BiRD (3,159 pairs) for which word vectors exist for all models under consideration. To determine if the differences between the correlation scores are statistically significant, we perform Steiger's Z significance test (Steiger, 1980).

Method	**GloVe**	**fastText**	**Matrix Factor.**
Baselines			
head only	0.342	0.403	0.339
modifier only	0.438	0.495	0.425
Composition methods			
addition	**0.564**	**0.601**	**0.582**
multiplication	0.182	0.328	0.244
tensor product	0.374	0.382	0.451
dilation	0.523	0.495	0.496

Table 4: Pearson correlations of model predictions with BiRD relatedness ratings. Highest scores are in bold.

Results: Table 4 shows the results. Observe that among the three methods of word vector representations, the best results are obtained using fastText (word–context matrix factorization model being a close second). Among the methods of semantic composition, the additive models perform best (for all three ways of representing word vectors). The scores are statistically significantly higher than those of the second best (dilation). The element-wise vector multiplication and tensor product with convolution perform poorly (even worse than the baseline methods). These results differ substantially from the observations by Mitchell and Lapata (2010). In particular, in their work the multiplication model showed the best results, markedly outperforming the addition model. Our results are consistent with the findings of Turney (2012), where too the addition model performed better than the multiplication model. It should be noted though that unlike BiRD which has scores for semantic relatedness, the Mitchell and Lapata (2010) and Turney (2012) datasets have scores for semantic similarity. Further work is required to determine whether certain composition models are better suited for estimating one or the other.

Surprisingly, the baseline model that uses the vector for the modifier word obtains better results than the one that uses the vector for the head noun. (The difference is statistically significant.) To better understand this, we compute relatedness correlations using the *weighted addition* of the two word vectors ($p = \alpha u + (1 - \alpha)v$), where α is a parameter that we vary between 0 and 1, in steps of 0.1. Figure 2 shows the results. Observe that giving more weight (but not too much weight) to the modifier word than the head word is beneficial. $\alpha = 0.7$ and $\alpha = 0.8$ produce the highest correlations. These results raise further questions under what conditions is the role of the modifier particularly prominent, and why. We leave that for future work.

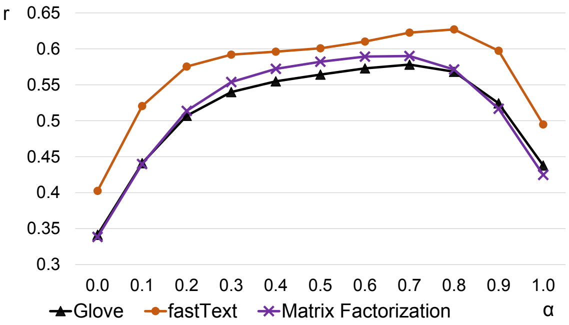

Figure 2: Pearson correlation coefficient (r) of the model predictions using weighted addition with BiRD relatedness ratings. α is varied from 0 to 1 in steps of 0.1. $\alpha = 0.7$ and $\alpha = 0.8$ produce the highest scores.

7 Conclusions

We created a dataset with fine-grained human ratings of semantic relatedness for term pairs involving bigrams. We used the comparative annotation technique Best–Worst Scaling, which addresses the limitations of traditional rating scales. We showed that the ratings obtained are highly reliable (high SHR, $r = 0.937$). We analyzed the dataset to obtain insights into the distributions of semantic relatedness values for pairs associated through various relations such as WordNet assigned lexical semantic relations, transposed bigrams, and co-aligned terms in a parallel corpus. We show that co-aligned terms can be related to varying degrees (from unrelated to synonymous), thereby making them a useful source of term pairs to include in relatedness datasets. Finally, we presented benchmark experiments on using BiRD as a testbed to evaluate various unsupervised methods of semantic composition. We found that the additive models performed best and that giving more weight to the modifier word can improve results further. We make BiRD freely available to foster further research. In the short term, it will be interesting to explore the use of supervised semantic composition methods, including resources and models such as BERT (Devlin et al., 2018) and ELMo (Peters et al., 2018), to determine bigram relatedness.

Outlier Detection for Improved Data Quality and Diversity in Dialog Systems

Abstract

In a corpus of data, outliers are either *errors*: mistakes in the data that are counterproductive, or are *unique*: informative samples that improve model robustness. Identifying outliers can lead to better datasets by (1) removing noise in datasets and (2) guiding collection of additional data to fill gaps. However, the problem of detecting both outlier types has received relatively little attention in NLP, particularly for dialog systems. We introduce a simple and effective technique for detecting both erroneous and unique samples in a corpus of short texts using neural sentence embeddings combined with distance-based outlier detection. We also present a novel data collection pipeline built atop our detection technique to automatically and iteratively mine unique data samples while discarding erroneous samples. Experiments show that our outlier detection technique is effective at finding errors while our data collection pipeline yields highly diverse corpora that in turn produce more robust intent classification and slot-filling models.

1 Introduction

High-quality annotated data is one of the fundamental drivers of progress in Natural Language Processing (e.g. Marcus et al., 1993; Koehn, 2005). In order to be effective at producing an accurate and robust model, a dataset needs to be correct while also diverse enough to cover the full range of ways in which the phenomena it targets occur. Substantial research effort has considered dataset correctness (Eskin, 2000; Dickinson and Meurers, 2003; Rehbein and Ruppenhofer, 2017), particularly for crowdsourcing (Snow et al., 2008; Jiang et al., 2017), but addressing diversity in data has received less attention, with the exception of using data from diverse domains (Hovy et al., 2006). Outlier detection, the task of finding examples in a dataset that are atypical, provides a means of approaching the questions of correctness and diversity, but has mainly been studied at the document level (Guthrie et al., 2008; Zhuang et al., 2017), whereas texts in dialog systems are often no more than a few sentences in length.

We propose a novel approach that uses sentence embeddings to detect outliers in a corpus of short texts. We rank samples based on their distance from the mean embedding of the corpus and consider samples farthest from the mean outliers. Outliers come in two varieties: (1) *errors*, sentences that have been mislabeled whose inclusion in the dataset would be detrimental to model performance, and (2) *unique* samples, sentences that differ in structure or content from most in the data and whose inclusion would be helpful for model robustness. Building upon this approach, we propose a novel crowdsourcing pipeline that distinguishes errors from unique samples and uses the unique samples to guide workers to give more diverse samples.

Experimentally, we find that our outlier detection technique leads to efficient detection of both artificial and real errors in our datasets. We also use the proposed crowdsourcing pipeline to collect new datasets and build models for the dialog system tasks of intent classification and slot-filling. We find that the proposed pipeline produces more diverse data, which in turn results in models that are more robust.

2 Background and Related Work

2.1 Outlier Detection

Outlier detection (Rousseeuw and Leroy, 1987), also called outlier analysis (Aggarwal, 2015) or anomaly detection (Chandola et al., 2009), is the task of identifying examples in a dataset that dif-

Proceedings of NAACL-HLT 2019, pages 517–527
Minneapolis, Minnesota, June 2 - June 7, 2019.

fer substantially from the rest of the data.

For almost two decades, a body of work in NLP has investigated applying these ideas to data in order to identify annotation errors (Abney et al., 1999). Approaches have included the use of scores from trained models for POS tagging (Abney et al., 1999; Eskin, 2000; van Halteren, 2000; Dligach and Palmer, 2011; Fukumoto and Suzuki, 2004), count-based methods that compare examples from across the corpus (Nakagawa and Matsumoto, 2002; Hollenstein et al., 2016), characterizing data based on feature vectors projected down into a low-dimensional space (Guthrie et al., 2008), and tracking the difficulty of learning each example during training (Amiri et al., 2018). One particularly effective approach has been to find *n*-grams that match but have different labels, as shown for annotations including POS tags (Dickinson and Meurers, 2003), syntactic parses (Dickinson and Meurers, 2005; Dickinson, 2010; Dickinson and Smith, 2011), and predicate-argument relations (Dickinson and Lee, 2008). Our work instead uses continuous representations of text derived from neural networks.

While finding errors is an extremely useful application of outlier detection, also of interest are examples that are correct even though they are outliers, as these can be the most interesting and informative examples in a dataset. We term these examples *unique*. The problems of detecting and leveraging the unique examples in a dataset has received less attention, and the work that does exist focuses on identifying complete documents or segments of documents that are outliers out of a broader set of documents: Guthrie et al. (2007) used manually defined feature vectors to identify segments of documents with anomalous style, topic, or tone, and Kumaraswamy et al. (2015) and Zhuang et al. (2017) construct statistical models, identifying complete documents that are outliers within a set based on semantic variation.

Finally, a related but distinct topic is novelty detection (Soboroff and Harman, 2005; Lee, 2015; Ghosal et al., 2018), in which two sets of documents are provided, one that is assumed to be known, and one that may contain new content. The task is to identify novel content in the second set. While outlier detection methods are often applied to this problem, the inclusion of the known document set makes the task fundamentally different from the problem we consider in this work.

2.2 Data Collection

We build on prior work employing online crowd workers to create data by paraphrasing. In particular, we refine the idea of iteratively asking for paraphrases, where each round prompts workers with sentences from the previous round, leading to more diverse data (Negri et al., 2012; Jiang et al., 2017; Kang et al., 2018). We also apply the idea of a multi-stage process, in which a second set of workers check paraphrases to ensure they are correct (Buzek et al., 2010; Burrows et al., 2013; Coucke et al., 2018). Most notably, by incorporating our outlier detection method, we are able to automate detecting detrimental data points while also prompting workers in subsequent rounds to paraphrase more unique examples.

3 Outlier Detection

We propose a new outlier detection approach using continuous representations of sentences. Using that approach, we explored two applications: (1) identifying errors in crowdsourced data, and (2) guiding data collection in an iterative pipeline.

3.1 Method

We detect outliers in a dataset as follows:

1. Generate a vector representation of each instance.
2. Average vectors to get a mean representation.
3. Calculate the distance of each instance from the mean.
4. Rank by distance in ascending order.
5. (Cut off the list, keeping only the top $k\%$ as outliers.)

The final step is parenthesized as in practice we use a dynamic threshold approach, allowing the user to go through as much or as little of the list as they like.

The intuition behind this approach is that we expect our representations to capture the semantic structure of the space for each class. An example that is far away from other examples in the set is therefore less semantically similar in some sense, making it an outlier. Importantly, it may be an outlier for two distinct reasons: (1) it is not a valid instance of this class (i.e., an *error*), or (2) it is an unusual example of the class (i.e., *unique*).

This approach is applied independently to each class of data. As example applications we consider two dialog system tasks: intent classification and slot-filling. For classification, data for each possible intent label is considered separately, meaning we find outliers in the data by considering one intent class at a time. For slot-filling, we group the data into classes based on combinations of slots.

This outlier detection method is rather simple as it relies only on a sentence embedding method, a distance metric, and a threshold k; no other hyperparameters are involved. Moreover, the method requires no training. We shall see in Section 4 that this method performs well compared to baseline methods, no matter what sentence embedding method is used. We use Euclidean distance as our distance metric.[1]

3.1.1 Sentence Representations

Vector representation of sentences is an active area of research and we leverage the following approaches, each of which has been shown to have state of the art results in different use cases:

Universal Sentence Encoder (USE; Cer et al., 2018) A Deep Averaging Network method, which averages word embeddings and passes the result through a feedforward network. The USE is trained using a range of supervised and unsupervised tasks.

Smooth Inverse Frequency (SIF; Arora et al., 2017) A weighted average of word embeddings, with weights determined by word frequency within a corpus. We consider word embeddings from GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018).

Average An unweighted average of word embeddings. While simple, this approach has been shown to be effective for classification (Zhang and Wallace, 2017) and other downstream tasks (Zhu et al., 2018). Again, we consider GloVe and ELMo word embeddings as inputs.

3.1.2 Model Combination

In addition to ranked lists produced by using these core sentence embeddings, we also investigated aggregating the ranked lists using the Borda count, a rank aggregation technique that has previously been used for combining web search results (Dwork et al., 2001).

The Borda count aggregates multiple ranked lists of the same set of items into a single ranked list. First, points are assigned to each item in each list, with an item in position i in a ranked list of length N receiving $N - i$ points. Next, points for items are summed across all of the lists. Finally, the items are ranked by their total number of points, producing a final ranking.

3.2 Application: Error Detection

Our proposed use of outlier detection to identify errors requires no further processing. When used in practice, a user looks through the sorted list of examples, either stopping at a given fraction, or when errors become infrequent enough.

3.3 Application: Uniqueness-driven Data Collection

One core insight in this work is that outlier detection can be used for more than just finding errors. The outliers that are not errors are likely to be the most interesting and informative examples in our dataset. We propose to use these examples to guide data collection in an iterative process, with the goal of yielding more diverse data.

To demonstrate this idea, we developed a novel crowdsourcing pipeline for data collection. Following prior work in crowdsourcing for dialog (Kang et al., 2018; Jiang et al., 2017), we ask crowd workers to write paraphrases of seed sentences with known intents and slot values. This provides linguistic diversity in our data in a way that is easily explained to workers. For instance, given the seed sentence "*What is my savings account balance?*" a worker might write "*How much money do I have in my savings account?*".

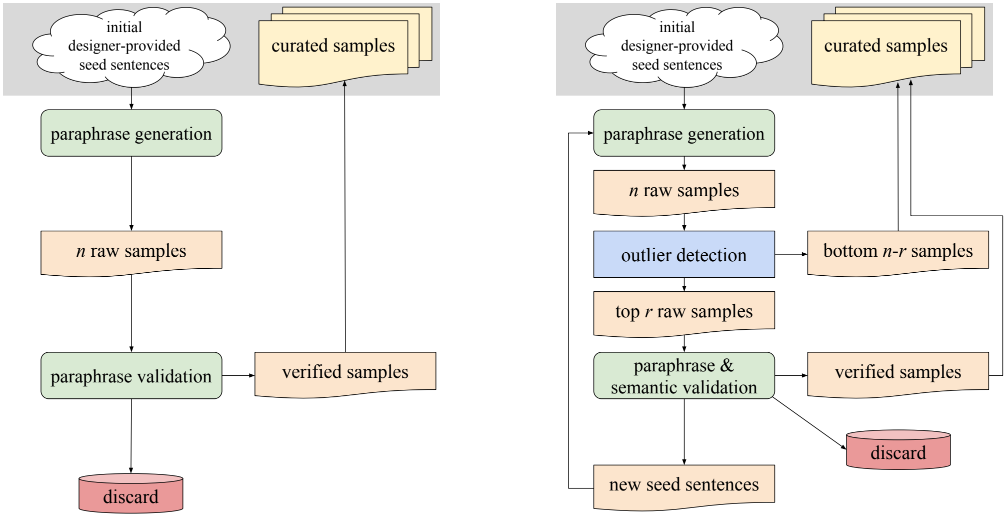
Figure 1a shows a common crowdsourcing pipeline. The task designer writes seed sentences that target an intent (for classification) or a slot (for slot-filling). Crowd workers read the seed and write paraphrases. These paraphrases are then passed to another set of workers who validate if they are in fact accurate paraphrases.

There are two major downsides to this standard pipeline. First, the validation step increases the cost-per-example. Second, the diversity of paraphrases depends on the given seed sentences (Jiang et al., 2017), creating a challenge for the task designer to think creatively.

We introduce a new pipeline, shown in Figure 1b that uses outlier detection to (1) reduce the number of sentences being checked, and (2) collect more diverse examples. Our new approach

---

[1] We found similar results in experiments with a density-based metric, Local Outlier Factor (Breunig et al., 2000).



(a) Standard Pipeline (b) Our Uniqueness-driven Pipeline

Figure 1: Data collection pipelines. Our outlier detection method is incorporated into the uniqueness-driven data collection pipeline to guide crowd workers to write more diverse paraphrases. Boxes with rounded corners are manual processes performed by crowd workers, boxes with curved bases are data, and the box with square corners is our outlier detection method. In (b), r is the number of outliers detected from n samples.

uses outlier detection to select only a subset of sentences to be checked: namely, the ones ranked as most likely to be outliers. This reduces effort by focusing on the sentences most likely to be incorrect.

To try to increase diversity, we also introduce a process with several *rounds* of data collection. Outlier paraphrases collected in one round are used to seed the next round of data collection. We could directly use the sentences labeled as correct in the validation step, but while these sentences are correct, they may have diverged from the desired semantics (e.g. diverged from the desired intent class). To avoid confusion in the next round, we add a step in which workers are shown the most similar sentence from another intent (based on sentence embedding distance) and asked if the new seed is more similar to its intended intent or the alternative example. Only seeds judged as closer to their intended intent are retained.

This iterative process is intended to collect more diverse data by priming workers to think about ways of phrasing the intent that are not well covered in the current data. At the same time, we avoid the correctness issues Jiang et al. (2017) observed by incorporating the validation step.

4 Experiments

We perform two sets of experiments to probe the effectiveness of our outlier detection method. First, we consider error detection, comparing various ranking methods in artificial and real data scenarios. Second, we use our uniqueness-driven pipeline to collect data, measuring the impact on data diversity and model robustness. All experiments were conducted on English language data.

4.1 Error Detection

We measure error detection effectiveness in two settings, one artificial and the other more realistic.

Artificial First, following prior work, we consider an artificial dataset in which we inject noise by mixing data from different intents (Guthrie et al., 2007, 2008; Zhuang et al., 2017; Amiri et al., 2018). This provides an easy way to control the amount and type of anomalous data, but does lead to an easier task as the incorrect examples are generally more different than naturally collected errors would be. The specific data we consider is a set of 20 intents from an in-production dialog system. To generate outliers for a given intent class X_i, we randomly sample $p \cdot |X_i|$ sentences from other intents (e.g. $p = 0.04$, or 4%).

Real We collected a new set of sentences for ten intents. Workers were given three seed sentences per intent and asked to write five paraphrases per seed.[2] Each seed was given to 15 crowd workers, leading to 2250 samples overall, after which

---

[2] Crowd workers were paid 20¢ per HIT.

Method		MAP					Recall@k=10%				
		1%	2%	4%	8%	Real	1%	2%	4%	8%	Real

Table 1: Outlier detection effectiveness for error detection in an artificial setting (constructed by randomly adding content from other intents) and a real setting (manually checked utterances from a crowdsourced set). The artificial results are represented by different values of p (1%, 2%, 4%, and 8%), where p represents different amounts of errors injected into each intent class. Our proposed neural methods are consistently more effective, reducing the manual effort required to identify errors.

Intent	Label	Example
withdrawal	*seed*	what is my withdrawal limit?
	inlier	how high is my withdrawal ceiling?
	error	How much money do I have available
balance	*seed*	what's my balance?
	inlier	Let me know how much money I have.
	error	What can I afford?
phone	*seed*	what's my bank's phone number
	inlier	I need to call my bank
	error	information on my bank
checks	*seed*	i need to order more checks
	inlier	I need to stock up on more checks
	error	No checkbox, more?

Table 2: Examples from the Real dataset. The "How much money do I have available" example was labeled an error since it is too similar to the balance intent. The "What can I afford?", "information on my bank", and "No checkbox, more?" examples are labeled as errors since they are too vague and ambiguous.

duplicates were discarded. To identify errors, the authors independently checked each sentence and discussed any disagreements to determine a consensus label (either *inlier* or *error*). Examples of seed sentences, along with inliers and errors is shown in Table 2.

4.1.1 Evaluation Metrics

Since our core outlier detection method produces a ranked list, we are interested in evaluating how effective it is at ranking errors near the top. We use Mean Average Precision (MAP) as an overall measure of list quality. MAP is the mean over intents of:

$$\frac{1}{|\text{errors for intent}|}\sum_{e\,\in\,\text{errors}}\frac{|\text{errors at or above } e|}{e}$$

where e is the position of an error in the list.

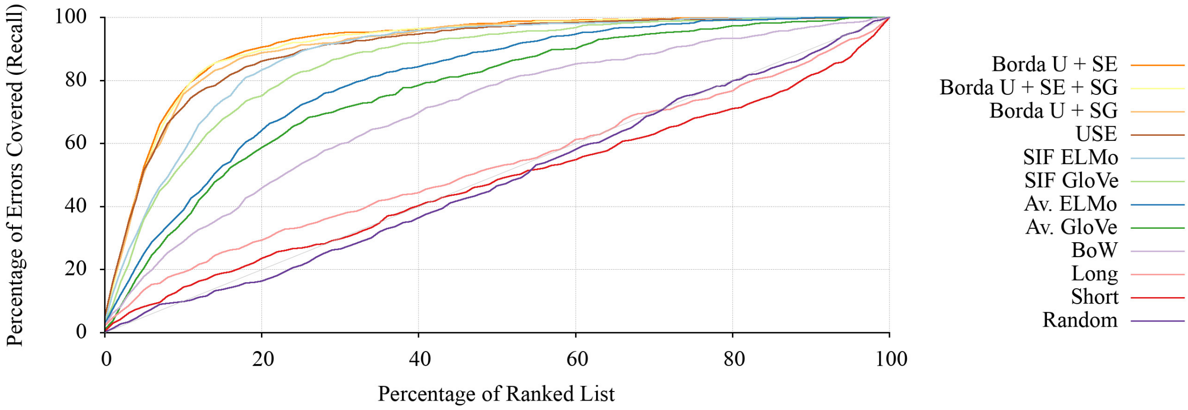
While this gives an overall qualitative measure for comparison, we are also interested in understanding the precision–recall tradeoff when choosing a threshold k on the ranked lists. We consider defining the cutoff as a percentage k of the list and measure the percentage of errors that are covered for each possible cutoff. This measure is equivalent to Recall@k, that is,

$$\text{Recall@}k = \frac{|\text{ errors above } k|}{|\text{errors}|}.$$

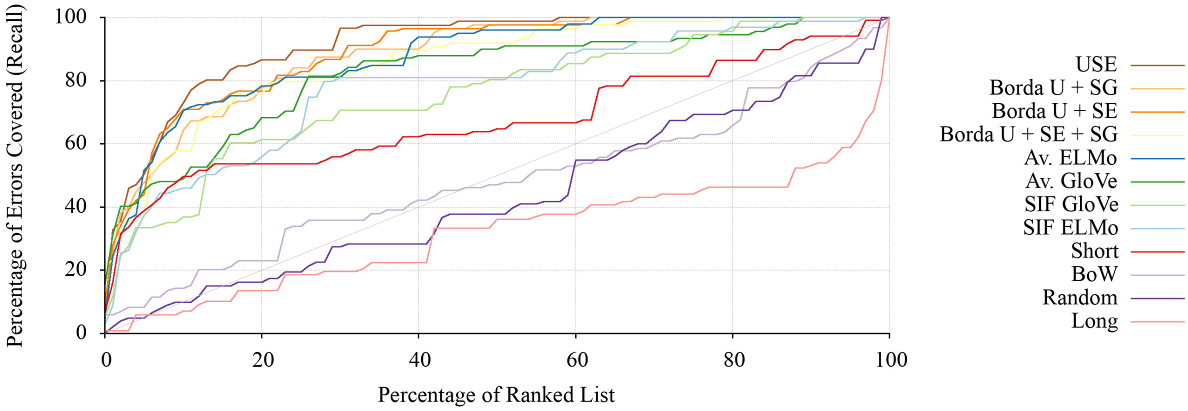
We average these values across intents to get an overall value for each cutoff percentage k.

4.1.2 Baselines

For comparison, we consider four simple baselines: randomly ordering the samples (Random), sorting from shortest to longest (Short), sorting from longest to shortest (Long), and calculating distances in the vector space defined by a bag of words (BoW).



(a) Artificial data.



(b) Real data.

Figure 2: Cumulative distribution of errors in ranked lists: a higher line indicates that the method places more errors earlier in the list. Results are less smooth for the real data as there are only 51 errors in the set. For each plot, the legend is in the same order as the lines at 20% (i.e., in (a) the top line is Borda U+SE, while in (b) it is USE). Neural ranking methods are consistently more effective, with USE covering over 80% of errors in the first 20% of the list.

4.1.3 Results

Table 1 presents MAP and Recall@k for error detection in the two settings (Artificial and Real). The neural methods outperform the baselines in both settings, demonstrating the effectiveness of our proposed approach. However, the relative performance of the neural methods differs substantially between the two settings. Specifically, (1) SIF performs better than an unweighted average on artificial data, but on real data we see the opposite trend, (2) combining rankings with Borda appears to help on the artificial data, but not on the real data, (3) ranking by length is surprisingly effective on the real data, and (4) results tend to be lower on the real data than the artificial (even at lower values of p). This last point suggests that the commonly used artificial setting does not perfectly capture the types of errors that occur in practice.

show average exchange rate from ten usd to cad last year

Figure 3: Example annotated sentence for the slot-filling task. The slot names are (in order of appearance) metric, amount, currency, and date.

For (3), we note that the Short baseline method performs particularly well vis-à-vis other baselines on the real data, but not comparatively well on the artificial data. This can be explained by observing that the length of the average error in the real data is roughly 6 tokens, while the average inlier length is 8 tokens. Lengths of errors and inliers are roughly the same (roughly 8 tokens) in the artificial dataset, due to the outlier selection scheme.

While the values in Table 1 allow an overall comparison of the methods, they do not provide a clear qualitative sense of the distribution of errors in the lists. Figure 2 shows the distribution for each method in the two settings. The effective-

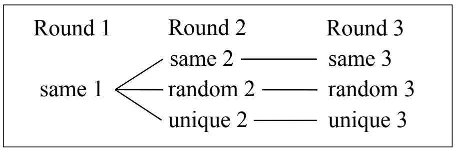


Figure 4: Data collection rounds. The final datasets combine data from all three rounds along each path.

ness of the neural methods, and USE in particular, is again clear. In the real data, when considering just the first 20% of the list, USE covers over 85% of the errors on average. One easy example was "*No checkbox, more?*" when the intent was to order more checks. This is clearly an error, which would at the very least need to have *checkbox* replaced by *checkbook*. In contrast, one hard example for USE was "*How much money do my banks*" when the intent was to request the user's balance. Until the last word, this example looks like it will be a valid balance request. These examples show that the system is qualitatively fitting our expectations for error detection.

4.2 Uniqueness-driven Data Collection

The second set of experiments evaluates our proposed uniqueness-driven data collection pipeline. We consider collecting data for two tasks used by dialog systems: intent classification and slot-filling. In each case, we calculate intrinsic measures of data diversity and the robustness of models trained on the data.

Tasks We consider intent classification with 10 intents related to banking, and slot-filling for foreign exchange rate requests with four slots: *amount*, *currency*, *date*, and *metric*. Figure 3 shows an example query with annotated slots.

Approaches As well as our proposed data collection pipeline (`unique`), we consider a variant where the next seed is chosen randomly (`random`), and one where the seeds are the same in every round (`same`). The third case is equivalent to the standard pipeline from Figure 1a. All three pipelines start from the same first round and then vary in the subsequent rounds, as depicted in Figure 4. Each pipeline collected data for three rounds. The final dataset for each approach combines data collected from all three rounds.

In both tasks, we asked workers to rephrase each seed sentence 5 times and showed each seed sentence to 15 workers. For classification there were 3 seed sentences per intent. For slot-filling we defined 4 example scenarios, each corresponding to a specific combination of slots. We used Borda USE+SG with k set to 10% for the outlier detection model.

$$D(a,b) = 1 - \frac{1}{N}\sum_{n=1}^{N}\frac{|n\text{-grams}_a \cap n\text{-grams}_b|}{|n\text{-grams}_a \cup n\text{-grams}_b|}$$

$$\text{Diversity}(X) = \frac{1}{|I|}\sum_{i=1}^{|I|}\frac{1}{|X_i|^2}\left[\sum_{a\in X_i}\sum_{b\in X_i} D(a,b)\right]$$

$$\text{Coverage}(X,Y) = \frac{1}{|I|}\sum_{i=1}^{|I|}\frac{1}{|Y_i|}\sum_{b\in Y_i}\max_{a\in X_i}(1 - D(a,b))$$

Figure 5: Metrics for diversity and coverage from Kang et al. (2018). X and Y are sets of utterances labeled with intents from I, and X_i is the data in X for intent i. The distance metric for comparing a pair of utterances is based on the Jaccard Index over n-grams. We follow the work from Kang et al. (2018) and set N, the max n-gram length, to 3.

4.2.1 Evaluation Metrics

We consider several different metrics to probe how effectively our proposed pipeline improves data quality. In all cases, higher values are better.

Intrinsic We measure the diversity and coverage of each dataset using the metrics introduced in (Kang et al., 2018) and shown in Figure 5.

Extrinsic The main reason to increase dataset diversity is to construct more robust models. To directly evaluate that objective, we randomly divided the datasets collected by each pipeline into training and test sets (85-15 split). Our intuition is that a robust model should perform fairly well across all test sets. Training on a dataset that is not diverse will lead to a brittle model that only does well on data collected with the same seed sentences. For intent classification, we measure accuracy of two models: an SVM (Cortes and Vapnik, 1995) using bag of words feature representation, and FastText (Joulin et al., 2017), a neural network that averages across sentence embeddings and passes the result through feedforward layers. For slot-filling, we measure the F_1-score of a bi-directional LSTM with word vectors that are trained, but initialized with GloVe 300-dimensional embeddings. For all models, we average results across 10 runs.

	Data Collection Round			
	1	2	3	All
Diversity				
`same`	0.911	0.917	0.908	0.916
`random`	–	0.912	0.817	0.920
`unique`	–	**0.935**	**0.944**	**0.947**
Samples				
`same`	2040	2025	2024	5648
`random`	–	2010	2007	5747
`unique`	–	2083	1954	5922

Table 3: Classification: Diversity scores for data collected in each round (top), and the number of samples collected (bottom). The data for the All column combines the previous two sets in the row and the data from (`same` round 1). The `unique` approach produces data that is considerably higher diversity.

		Test Set		
Metric	Training	`same`	`random`	`unique`
SVM Accuracy	`same`	**0.99**	0.97	0.81
	`random`	0.98	**0.98**	0.81
	`unique`	0.99	0.97	**0.98**
FastText Accuracy	`same`	**0.98**	0.97	0.80
	`random`	0.98	**0.99**	0.83
	`unique`	0.98	0.98	**0.98**
Coverage	`same`	**0.68**	0.64	0.45
	`random`	0.67	**0.66**	0.44
	`unique`	0.64	0.58	**0.56**

Table 4: Classifier accuracy when training on one dataset and testing on another (top and middle), and coverage of the test set for each training set (bottom). As expected, the highest scores are when we train and test on the same data, but off the diagonal the `unique` test set (gray column) is considerably harder for models trained on other data while a model trained on `unique` performs consistently well. This accuracy trend is matched in coverage.

	Data Collection Round			
	1	2	3	All
Diversity				
`same`	0.916	0.911	0.893	0.909
`random`	–	0.913	0.910	0.915
`unique`	–	**0.926**	**0.935**	**0.930**
Samples				
`same`	994	911	952	2717
`random`	–	941	923	2808
`unique`	–	977	988	2914

Table 5: Slot-filling: Diversity scores for data collected in each round (top), and the number of samples collected (bottom). The data for the All column combines the previous two sets in the row and the data from (`same` Round 1). As seen for intent classification, the `unique` approach produces data that is of considerably higher diversity.

		Test Set		
Metric	Training	`same`	`random`	`unique`
Slot F_1	`same`	96.4	96.0	93.1
	`random`	96.4	**96.8**	93.6
	`unique`	**96.7**	96.5	**94.9**
Coverage	`same`	**0.812**	0.788	0.726
	`random`	0.736	**0.764**	0.660
	`unique`	0.761	0.752	**0.774**

Table 6: F_1-scores and coverage scores for each train-test pair for the slot-filling experiment. Training on the `unique` data produces a more robust model, with consistently high performance across test sets.

4.2.2 Results

Classification Table 3 presents the number of examples and diversity of data collected in each round with each approach. Diversity is consistently higher with seeds chosen using our proposed `unique` approach. Dataset sizes vary because of the removal of duplicates. The `unique` approach produces a larger final set as there is less duplication across rounds.

Table 4 displays accuracy scores and coverage for each combination of train and test sets. As expected, the highest scores are on the diagonal—training and testing on the same source data. More importantly however, training on the `unique` data produces a model that is robust, performing well across all three test sets. In contrast, training on the `same` or `random` data produces models that perform substantially worse on the `unique` test set. This trend is also present in the coverage scores in the bottom section of the table.

Table 7 shows some of the seed sentences produced by the `unique` and `random` approaches. These examples illustrate the trends in our metrics, with the seeds for the `random` approach often being very similar. Meanwhile, the `unique` approach produces seeds with grammatical variation and the introduction of quite different expressions, such as “ABA” instead of “routing number”.

Intent	Pipeline	Round 2	Round 3
routing	`random`	Where can I find the routing number for my bank? Do you have my bank's routing number? show me my banks routing number	what is the best routing number for my bank can you help find my bank routing number? I need to see the routing number for my bank
	`unique`	acquire my banks routing number how does a person find their correct routing number? I'm looking for the router number for my bank.	what is the correct ABA? How do I find the ABA? Whats the router number?
hours	`random`	Can you tell me when my bank is open? When does my bank open? What time is the bank open	How long is my bank open? What are the hours for my bank? What time will the bank be open
	`unique`	display when the bank closes What is the earliest you are open? look up the hours of operation for my bank	What hours do you carry what are your operating hours? What is the latest I can come in to a physical branch?
checks	`random`	i require ordering more checks. Get me more checks. can you explain to me how to order additional checks	I'd like additional checks Can you get me more checks? Please order more checks for me.
	`unique`	I need to stock up on more checks in what manner would i get more checks Could you rush me some more checks? I'm nearly out.	what is check ordering procedure? what is the fastest method to order checks? Teach me how to get more checks.

Table 7: Seed sentences for selected intents for the classification task. The `unique` approach leads to changes like the use of *ABA* for *routing* (top), and grammatical variations in the sentences for requesting checks (bottom). Examples of seeds for Round 1 include "what is my bank's routing number?", "when does the bank close?", and "how do i order more checks?".

Slot-filling Table 5 shows the number of samples collected per round for each of the data collection pipelines and the diversity of the sets. As in the classifier experiment, we observe that data produced by the `unique` pipeline is of higher diversity than the other two pipelines.

Table 6 displays F_1-scores and coverage for each train–test combination. Again, we see the same trends, with training on `same` or `random` leading to low results on the `unique` dataset, but not the reverse, and similarly for coverage, though the gaps are smaller than for classification.

5 Conclusion

Outliers are often the most interesting parts of our data, but outlier detection has received relatively little attention in NLP beyond its application to finding annotation errors. This paper introduces the first neural outlier detection method for short text and demonstrates its effectiveness across multiple metrics in multiple experiments.

We also propose a way to integrate outlier detection into data collection, developing and evaluating a novel crowdsourcing pipeline. This pipeline supports the creation of higher quality datasets to yield higher quality models by both reducing the number of errors and increasing the diversity of collected data. While the experiments discussed herein are concerned with components of dialog systems, we believe that similar data collection strategies could yield benefits to other areas of NLP as well.

Asking the Right Question: Inferring Advice-Seeking Intentions from Personal Narratives

Abstract

People often share personal narratives in order to seek advice from others. To properly infer the narrator's intention, one needs to apply a certain degree of common sense and social intuition. To test the capabilities of NLP systems to recover such intuition, we introduce the new task of inferring what is the advice-seeking goal behind a personal narrative. We formulate this as a cloze test, where the goal is to identify which of two advice-seeking questions was removed from a given narrative.

The main challenge in constructing this task is finding pairs of semantically plausible advice-seeking questions for given narratives. To address this challenge, we devise a method that exploits commonalities in experiences people share online to automatically extract pairs of questions that are appropriate candidates for the cloze task. This results in a dataset of over 20,000 personal narratives, each matched with a pair of related advice-seeking questions: one actually intended by the narrator, and the other one not. The dataset covers a very broad array of human experiences, from dating, to career options, to stolen iPads. We use human annotation to determine the degree to which the task relies on common sense and social intuition in addition to a semantic understanding of the narrative. By introducing several baselines for this new task we demonstrate its feasibility and identify avenues for better modeling the intention of the narrator.

1 Introduction

> "Computers are useless.
> They can only give you answers." - Pablo Picasso

People often share their personal experiences to elicit advice from others. These personal narratives provide the necessary context for properly understanding the informational goals of the narrators. Endowing automated systems with the capability to infer these advice-seeking intentions could support personalized assistance and more empathetic human-computer interaction.

Personal narrative: I am generally a person who needs a lot of sleep, but today I was not able to sleep more than 6 hours and I am extremely tired. My eyes hurt and two hours later I have programming [lesson] so I have to be alert. I've already drunk a cup of coffee and although I rarely drink coffee, it had no effect on me. I am not at home so I have limited possibilities as for food. I don't want to do anything too unhealthy such as drinking 10 cups of coffee, tho I may consider drinking another one.

Which advice-seeking question is more likely to have been asked by the narrator:
Q1: Is it even possible to be addicted to coffee?
Q2: How can I energize myself?

Figure 1: An abbreviated instance from the `ASQ` dataset. A personal narrative is matched with two plausible advice-seeking questions, only one of which was actually asked by the narrator when sharing the story.

As humans, to properly distill the narrator's intention from the events and situations they describe, we need to apply a certain degree of social intuition (Conzelmann, 2012; Conzelmann et al., 2013; Baumgarten et al., 2015; Kehler and Rohde, 2017). As an example, consider the goals of a narrator sharing the personal story in Figure 1. We are presented with a wealth of information about the narrator's general sleep patterns, about a particular sleep deprivation situation and its physiological effects, about an upcoming lesson, about coffee intake, its effects, and potential health impacts, and about the current location of the narrator and its impact on food supply. Taking these facts separately, we can imagine providing advice on how to get more sleep, on whether to postpone the lesson,

Proceedings of NAACL-HLT 2019, pages 528–541
Minneapolis, Minnesota, June 2 - June 7, 2019.

	Task	**Desired output**
A	Question generation Reading comprehension	What do I need to do in 2 hours?
	Summarization	I must go for a lesson after getting little sleep.
B	Ending generation Narrative chains, story cloze	Lastly, I tried an energizing drink.
C	Event2Mind Desire fulfillment	to learn to code, to be educated
D	**Our task**	How can I energize myself?

Table 1: Contrast with desired outputs in related narrative understanding tasks that focus on the within-story (intradiegetic) aspects of narrative understanding. Tasks are grouped according to the categories discussed in Section 2.1 (which also includes corresponding references). We assumed the second sentence ("My eyes hurt and two hours later I have programming lesson so I have to be alert.") to be the answer span for question generation, and the input for Event2Mind (which operates at sentence level).

on how to get food delivered, or on the risks of caffeine intake. However, given how the narrative is constructed, we can intuit that the more likely goal of the narrator is to get advice on how to overcome the effects of sleep deprivation so that they can be alert for the upcoming programming lesson.

Importantly, the primary goal of our proposed task is not to understand details about the narrator's actions in the story ("Why is the narrator tired?", "When do they need to go to the lesson?"), but to infer the reason why the narrator is sharing this story (i.e., "To get advice on how to stay alert in the next few hours."). That is, we are not concerned with the *intradiegetic* aspects of the narrative, but with the *extradiegetic* intention of the narrator in sharing the story. While an understanding of the former is likely necessary for the latter, it is often not sufficient.

In this work, we introduce a task and a large dataset to evaluate the capabilities of automated systems to infer the narrator's (extradiegetic) intention in constructing and sharing an advice-seeking personal story. This complements existing narrative understanding tasks which focus on testing semantic understanding of events, actors and their (intradiegetic) intentions within the narrative itself. Table 1 contrasts the goals of these existing narrative understanding tasks with that of inferring a narrator's advice-seeking intention, in the context of our introductory example.

Formally, we implement the task as a binary choice cloze test, where the goal is to identify which of two candidate advice-seeking questions was actually asked by the narrator of a given personal narrative. Beyond collecting a large and diverse set of realistic personal stories that contain an advice-seeking question, the main challenge in constructing this task is finding a plausible alternative advice-seeking question for each given narrative. To address this challenge, we develop a methodology for identifying such questions by exploiting both the commonalities in experiences people share online and the diversity of possible advice-seeking intentions that can be tied to similar experiences.

By applying our methodology to a large collection of online personal narratives, we construct a dataset of over 20,000 cloze test instances, covering a very broad spectrum of realistic advice-seeking situations.[1] Each instance contains a narrative that is matched with two advice-seeking questions, one of which is actually asked by the narrator (Q2 in our introductory example), and the other semantically related to the narrative (Q1).

We use human annotations to judge the relative difficulty of different subsets of the test instances and the type of reasoning necessary to solve them. We find that more than half of the instances contain pairs of questions that are not only semantically related to the narratives but also do not contain any explicit factual mismatches with the stories. These are thus unsolvable by pure logical reasoning and require some degree of common sense or social intuition. And indeed, simple

---

[1] The dataset is available at `https://github.com/CornellNLP/ASQ`.

baseline approaches perform worse on these types of instances, highlighting the need for more direct modeling of the intention of the narrator.

To summarize, in this work we:

- formulate the task of inferring advice-seeking intents from personal narratives (Section 2);
- develop a methodology to construct a large dataset of personal narratives matched with plausible options for **a**dvice-**s**eeking **q**uestions (the `ASQ` dataset) to be used for this task (Section 3);
- show the task is viable and evaluate the relative difficulty of its items (Sections 4 & 5).

We end by discussing the practical implications of endowing systems with the capability to infer advice-seeking intentions and use our results to identify avenues for developing better models.

2 Task formulation

To evaluate the capability of automated systems to infer advice-seeking intentions, we formulate a cloze-style binary choice test where the system is presented with a personal narrative and is required to choose between two plausible candidate questions: one actually asked by the narrator and the other one not (as exemplified in Figure 1).

We motivate the task by contrasting it with other (narrative) understanding tasks (Section 2.1), and provide the rationale for this particular formulation by discussing its advantages (Section 2.2).

2.1 Related narrative understanding tasks

There are many tasks involving reading comprehension in general, and story understanding in particular. Given a narrative, there are a few broad categories of questions that may be asked to test different types and degrees of understanding. Table 1 follows directly from the discussion below, by contrasting the goal of our task with those of (intradiegetic) narrative understanding tasks in the context of our introductory example.

A: What happened in the story? The most direct approach to test story understanding is to check whether the reader could comprehend the events and actions that occur within the story. This requires semantic understanding, but nothing more. This type of task can be set up in various forms, as the system can be asked to summarize the story (summarization, see Nenkova (2011); Allahyari et al. (2017) for surveys), generate a question that is answerable from the text (question generation (Du et al., 2017)), or answer a question for which the information can be retrieved or reasoned directly from the story (reading comprehension, see Chen (2018) for a survey; notable datasets include MCTest (Richardson, 2013) and NarrativeQA (Kočiský et al., 2018)).

B: What might happen next? While reading the story, people not only grasp and process the events that already occurred but also have some intuition of its likely trajectory. Related tasks include the narrative cloze task (Chambers and Jurafsky, 2008), the story cloze test (Mostafazadeh et al., 2016; Chaturvedi et al., 2016), and its generative versions (Guan et al., 2019). These tasks might require some common sense reasoning on top of semantic understanding; the fact that they aim to predict the future might require a deeper level of understanding than the previous tasks.

C: What can we infer about the characters? When people read a narrative, they not only grasp the facts explicitly stated in the story, but also make inferences about the actors' mental states, such as their attitudes and desires, as the story unfolds.[2] Oftentimes, such an understanding requires inference, either logical or based on common sense reasoning. Such tasks can aim to generate the likely intents and reactions from the actors involved in the events (Rashkin et al., 2018a,b), or to determine whether a given desire of the protagonist was fulfilled (Rahimtoroghi et al., 2017).

D: What is the intention of the narrator in sharing their story? While these prior tasks cover a wide range of angles to narrative understanding, they take an intradiegetic view by focusing on understanding the story itself. We propose another dimension to this line of work by taking an outside-the-story (extradiegetic) perspective[3] and aiming to understand *why* the story is shared by the narrator, potentially inferred from *how* the narrator decides to construct it. In particular, the task introduced here is to infer the *advice-seeking* intention of the narrator.[4]

---

[2] See Bratman (1987) for an account of the Belief-Desire-Intention model of human practical reasoning.

[3] Recognizing the importance of these two different perspectives for story understanding, Swanson et al. (2017) attempted to classify narrative clauses into intradiegetic vs. extradiegetic levels.

[4] Sharing personal stories can have other goals, e.g., therapeutic (Pennebaker, 1997; Pennebaker and Seagal, 1999).

We argue that solving this task requires not only the semantic understanding and common sense reasoning involved in prior tasks but also a certain degree of social intuition. To uncover the goals of the narrator, one needs to find cues in the narrative construction—what has been selectively included or emphasized, and what might have been purposefully omitted (Labov, 1972). In fact, such intention-understanding tasks are often included in "social intelligence" tests (Conzelmann et al., 2013; Baumgarten et al., 2015).

2.2 Advantages of cloze test formulation

To evaluate the capacity of NLP systems to solve this task, we consider a binary choice cloze test formulation for two main reasons. First, it allows natural ground-truth labels: often, when people share their personal experiences to seek advice, they add explicit requests for the information they are seeking. After removing these requests from the narratives, we can use them as proxies for the narrators' intentions. Second, the binary choice operationalization also has the advantage of non-ambiguity in evaluations and ease of comparisons between systems (as opposed to a generation task).

It is worth noting that our dataset is constructed in a way that allows easy modifications into other task formats if so desired. For instance, the methodology of identifying a plausible false choice for a given narrative could be applied multiple times to extend the task to a more difficult multiple-choice version. Similarly, by ignoring the incorrect question in each instance, our dataset can be used as a source for a new generation task, i.e., generating the advice-seeking question from the given narrative.

3 Task implementation

For a meaningful implementation of the proposed task, the collection of test instances must conform to several expectations, in terms of both the narratives and their (actual) advice-seeking questions. In what follows we outline these desiderata and our method for collecting instances that meet them (Section 3.1).

Furthermore, as with any multiple-choice cloze test formulation, the difficulty of each test instance largely depends on how plausible the alternative answers are. Yet, finding plausible (but not actually correct) alternatives automatically is challenging. Not surprisingly, many of the cloze-style multiple-choice datasets use humans to write these alternatives (Mostafazadeh et al., 2016; Xie et al., 2018), limiting their scalability.

We tackle this challenge by developing a methodology that exploits both the commonalities in human experiences shared online and the diversity in the types of advice needed for similar situations under different circumstances (Section 3.2).

3.1 Collection of candidate instances

Narratives desiderata. As a pre-requisite, we need to start from personal narratives containing advice-seeking needs that are explicitly expressed (as questions), and that can be removed to form the cloze test instances.[5] Ideally, these narratives would cover a broad range of topics, in order to be able to test how well a system can generalize to a diverse range of real-life scenarios, rather than apply only to restricted and artificial settings.

Question desiderata. Not all questions contained within an advice-seeking narrative are suitable for our task. Some of the questions might be too general, while others might be rhetorical. For instance, *Any advice?* holds no particular connection with the context of the narrative in which it appears. To contribute to meaningful test instances, questions need to meet a level of relevance and specificity such that (at least) humans could match them with the narratives from which they are extracted.

Data source. We start from a dataset of over 415,000 advice-seeking posts collected from the subreddit r/Advice, which self-defines as "a place where anyone can seek advice on any subject".[6] We only use publicly available data and will honor the authors' rights to remove their posts.

Applying cloze. For each post, we strip off all questions that appear in any position of the post, including the post title.[7]

We keep the remaining narratives as the cloze texts.[8] Figure 2 shows how the cloze transforma-

---

[5] An interesting future work avenue could be considering narratives that only have implicit advice-seeking intentions.

[6] We start from an existing collection of Reddit posts (Tan and Lee, 2015) which we supplement with The Baumgartner Reddit Corpus retrieved via Pushshift API on Nov. 21, 2018.

[7] To identify questions, we use the simple heuristic of looking for sentences that end with '?' or start with *why, how, am, is, are, do, does, did, can, could, should, would.*

[8] To ensure that the cloze text can provide sufficient context, yet are not overly verbose, we only consider cloze texts that are 50-300 tokens long. This is a choice we made prior to any experiments, and we do not claim it is the optimal range to set up the task.

Selected topics	Question keywords	Example questions
Housing	move live house city apartment roommate	What is it like living with **roommates**? Should I **move** to the **city**?
School	college school class degree study	Should I drop out of **college**? What's the best way for me to **study** for my biology tests?
Work	job boss quit work interview employer	Can I somehow ask to **work** from home? How do I explain during an **interview** why I left a **job**?
Relationships	girl date text tell guy think crush	Does it sound like this **girl** may like me? How can I think of a better greeting for online **dating**?
Personal finances	money car pay rent loan insurance	How do I afford a **car** in my situation? Am I stupid for wanting a student **loan**?
Family	parent convince let mom dad sister	How do I **convince** my **parents** to believe me? How can I try and make a better relationship with my **sister**?

Table 2: Selected narrative topics and example question keywords associated with each topic.

Title: How can I energize myself?

I am generally a person who needs a lot of sleep [...] I don't want to do anything too unhealthy such as drinking 10 cups of coffee, tho I may consider drinking another one. Help? What has worked for you?

Figure 2: Cloze application to the post from which we obtain the introductory test instance. After filtering out questions that are too general, only the title question remains as a candidate for representing the actual advice-seeking intention of the narrator.

tion is applied to the post containing our introductory example.

Selecting ground-truth test answers.[9] We select candidate ground-truth answers for the cloze test as the ?-ending sentences removed from narratives. In order to keep only well-formed information-seeking questions, we filter the candidate questions by keeping only those that start with interrogatives[10] or *any, anyone, help, advice, thoughts*. To further discard questions that are too general, we compute a simple specificity score $S(q)$ of a question q containing the set of words $\{w_1, w_2, \ldots, w_N\}$ as its maximum inverse document frequency (idf):

$$S(q) = S(\{w_1, w_2, \ldots, w_N\}) = \max_{i \in N} \text{idf}(w_i),$$

and filter out questions for which $S(q) < 5$ or questions that have less than 5 words. At the end of this selection process, from the example post in Figure 2, *Help?* and *What has worked for you?* are discarded and the title question is kept as the ground-truth answer to this cloze instance. If multiple questions survive the filtering process, we select one at random.

Diversity evaluation. To verify that the resulting data has broad topical diversity in both narratives and questions, we perform a two-step clustering analysis. First, we use singular value decomposition on tf-idf transformed narratives to obtain their vector representations, we then cluster similar narratives using k-means to surface underlying topics. Next, for each topic, we extract nouns and verbs from the questions attached to each narrative in the topic, and surface common question keywords as those with high document frequency within the topic, correcting for their global document frequency (via subtraction).

To provide a qualitative feel of the diversity of the data, Table 2 shows a selection of the resulting narrative topics and question keywords, together with example questions (corresponding narratives can be found in the data release). We find a

---

[9] As it happens, test answers are actually questions.

[10] We consider the following set of words as interrogatives: *what, when, why, where, which, who, whom, whose, how, am, is, are, was, were, do, does, did, has, have, had, can, could, shall, should, will, would, may, might, must*.

wide range of experiences represented in the narratives, from relationships to student life to apartment rentals. Furthermore, within each narrative topic, there is a variety of question types; for instance, questions related to housing could be about dealing with roommates, paying rent, or choosing a city to live in.

3.2 Finding alternative test answers

To find plausible alternative answer options for each candidate cloze test instance, one direct approach could be to find questions that are semantically related to the ground-truth question. However, there are two underlying problems with this approach. First, the task of finding semantically similar questions is itself very challenging (Haponchyk et al., 2018), given their terseness and lack of context. Second, semantic similarity is arguably a different concept from *plausibility* with respect to a narrative. For example, the two questions in the introductory example are semantically distant, but they are both plausible in the context of the narrative.

Our main intuition in solving this problem is that individuals who are in similar situations tend to have advice-seeking intentions that are related. For each candidate cloze test narrative instance, we can thus search for a similar narrative first (by exploiting commonalities in experiences people share online) and then select an advice-seeking question from that narrative as the *alternative* answer for the test.

Narrative pairing. To operationalize this intuition, we first find pairs of similar narratives based on the cosine similarity of their tf-idf representations.[11] A greedy search based on this similarity metric results in a set of pairs of related narratives (N_1, N_2) with their respective advice-seeking questions (qn_1, qn_2) identified in the previous step.

Narrative masking. At this point, the pair of advice-seeking questions could be used with either narrative to form a test instance. For example, Figure 3 shows the other possible cloze instance corresponding to the introductory example if we were to use the other narrative in the narrative pair. This, however, would arguably be a poor test instance since Q2 is hardly applicable to this other narrative. More generally, we want to ensure that our choice of which narrative (N_i) to include in the cloze test optimizes the plausibility of the question pair (qn_1, qn_2).

Masked narrative: I've noticed something, over the past few years I've gained a habit of drinking coffee. The average day is about six cups, but it can exceed that sometimes (8 or so). The only reason I question my habit is cause I'm up at 4AM right now cause I couldn't fall asleep. I honestly have a headache in the morning until I drink a cup of coffee. I'll have some for essentially no reason, I'll just make some out of a urge almost.

Q1: Is it even possible to be addicted to coffee?
Q2: How can I energize myself?

Figure 3: Alternative cloze test instance corresponding to the introductory example.

To achieve this, we compute the similarity between each narrative in the pair and each of the two respective questions,[12] and select the narrative that maximizes the minimum question-narrative similarity. Formally,

$$N_i = \arg\max_i \textsc{min}\{sim(N_i, qn_1), sim(N_i, qn_2)\}.$$

Importantly, this selection criterion is purposely symmetric with respect to the two questions in order to avoid introducing any unnatural preference between the two that a classifier (with no access to the masked narrative) could exploit.

As a final check, we ensure that in each cloze instance the two questions are neither too similar to each other (and thus indistinguishable) nor too dissimilar (which may indicate unsatisfactory narrative pairings). To this end, we discard instances in which the questions have extremely high or low surface similarity according to their InferSent (Conneau et al., 2017) sentence embeddings.[13]

This process leaves us with a total of 21,865 instances. A detailed account of the number of instances filtered at different stages of the construction process can be found in the Appendix.

---

[11] We consider both unigrams and bigrams, and set a minimum document frequency of 50. We also remove likely duplicates (cosine > 0.8) and cases for which the similarity between narratives is too low (cosine < 0.1). We have also experimented with embedding-based representations to compute cosine similarities from, but they do not seem to produce qualitatively better pairings upon inspection.

[12] To account for the terseness of the questions, we represent both narratives and questions with tf-idf weighted GloVe embeddings (Pennington et al., 2014) and compute the cosine similarity between them.

[13] We set a lower bound of 0.8 and an upper bound of 0.95. We choose this representation because questions are short and thus we anticipate tf-idf representation to be less informative.

4 Human performance

To understand the feasibility of the task, as well as the relative difficulty of the items in the dataset, eight non-author annotators labeled a random sample of 200 instances.[14] Each annotator is asked to choose first, out of the two candidate questions, which they consider to be *more likely* to have been asked by the narrator. Overall, human annotators achieve an accuracy of 90% (Cohen's κ = 0.79),[15] showing that humans can indeed recover the advice-seeking intentions of the narrators, and thus validating the feasibility of the task.[16]

We are also interested in understanding the types of skills needed to solve the task. In particular, we want to estimate the proportion of the task instances that can not be solved by mere factual reasoning. To this end, we ask humans to identify candidate questions that contain a factual mismatch with the narrative, making them **E**xplicitly incompatible; 57% of the annotated instances do not contain any such mismatches in any of the questions. Similarly, we want to estimate how many instances require common sense expectations about the behavior of the protagonist (within the story). So we ask annotators to mark questions as being **I**mplicitly incompatible if they do not contain any factual mismatches, but they are incompatible with what can be inferred implicitly about events and characters in the story.

The questions that are neither explicitly nor implicitly incompatible would be labeled as being **C**ompatible, and as either **L**ikely or **U**nlikely to represent the narrators' intentions. Test items in our data forcing a choice between **C**ompatible questions are expected to be the hardest to solve, as they might require a certain degree of social intuition in addition to factual and common sense reasoning. Table 3 provides an example narrative and one representative question from each of the above-mentioned categories.[17]

Table 4 shows a human performance breakdown according to some of the most common types of instances in our data.[18] As expected, instances involving only compatible questions (C + C) are harder to solve,[19] as they might require some social intuition, whereas when explicit contradictions exist (C + E), they are perfectly solvable. We also note that humans can perfectly solve the subset of task instances (L + {U, I}) that exhibit perceived qualitative differences between the actual and the alternative questions, but nevertheless, require more than semantic understanding (and sometimes require social intuition).

Narrative: I asked a girl that I really like if she would like to get coffee sometime. She said she's really busy but that we'll see. I can't get her off my mind and I spend all day waiting for her to tell me she's free.

Explicitly incompatible (E):
How to deal with my roommate?

Implicitly incompatible (I):
What to do if I asked a girl out and now regret it?

Compatible (C) but unlikely (U):
Which coffee place would you recommend?

Compatible (C) and likely (L):
Would it seem desperate if I asked her again in a more direct way a week later?

Table 3: Example questions in each plausibility category for an example narrative.

Pair type	SIM	FT-LM	HUMAN	% in data
C + E	86%	88%	100%	38%
C + {C, I}	68%	74%	89%	46%
C + C	66%	73%	84%	32%
L + {U, I}	75%	75%	100%	30%
OVERALL	76%	80%	90%	

Table 4: Breakdown of performances on selected ACTUAL + ALTERNATIVE question pair types. For instance, the pair type C + E corresponds to instances where the ACTUAL question asked by the narrator is compatible and the ALTERNATIVE question is explicitly incompatible.

---

[14] See the Appendix for detailed annotation instructions.

[15] We obtained a second round of annotations on a subset of 75 task instances to compute agreement statistics.

[16] By construction, random accuracy is 50%.

[17] The example is adapted from our instructions to annotators, which includes further explanations for these categories. See the Appendix for details.

[18] See the Appendix for some representative examples for selected question pair types in our data.

[19] We also concede that some of the instances in this category may be unsolvable, e.g., when the wrong question fits the narrative just as well.

Model	Accuracy (held-out)
NARRATIVE-QN-SIM	73.4%
FINETUNED LM	**78.7%**

Table 5: Performance of different baselines.

5 Baseline systems performance

We divide our data into a 8,865-2,500 train-test split and have reserved 10,000 instances as a held-out set.[20] In Table 5 we report accuracy for the best-performing model on the (never-before-seen) held-out for a simple similarity-based method and for a deep learning method.

Narrative-question similarity. We expect that questions would show greater similarity to narratives they are removed from. We thus establish a narrative-question similarity baseline by considering features based on cosine similarities between narrative and questions, with text represented as tf-idf vectors, tf-idf weighted GloVe embeddings, averaged GloVe embeddings, as well as word overlap between content words, all combined in a logistic regression model.

Finetuned transformer LM. We also use a Finetuned Transformer LM model (Radford et al., 2018), which was shown to perform competitively on a diverse set of NLP tasks, achieving state-of-the-art results on the story cloze test.[21]

5.1 Error analysis

Required skills. As shown in Table 4, systems perform worst on items that do not exhibit any (implicit or explicit) mismatches (C + C), and thus might require some social intuition. Importantly, the largest gap between baseline and human performance (25%) is on the subset of items that can not be solved based solely on a semantic understanding (L + {U, I}). These results underline the need for models that can combine common sense reasoning about the events within the story with an intuition about the intention of the narrator.

Question concreteness. Questions may also differ in how concrete they are. In a preliminary analysis aimed at understanding how this property affects performance, we compare words used in ground-truth questions that the best-performing model predicts correctly with those used in questions that are classified incorrectly. We observe that questions that are predicted correctly have significantly higher average inverse document frequencies (t-test $p < 0.01$). Intuitively, these more specific questions may be more concrete in nature, making them easier to connect to the narratives to which they belong. We also find that some common interrogatives have skewed distributions. For instance, questions starting with *Is* are less likely to be classified correctly than those starting with *How*. A cursory manual investigation suggests that this can also be tied by concreteness, with the latter type of questions appearing to be more concrete than the former.

6 Further related work

One broad motivation behind our work is to eventually help better support personalized informational needs (Teevan et al., 2007). This connects to several related lines of work that were not previously discussed.

Query/question intents. Datasets and models are proposed for understanding user intents behind search queries (Radlinski et al., 2010; Fariha et al., 2018), or even more generally, user questions (Haponchyk et al., 2018). To complement this line of work that looks at user intents behind the explicit request, our task aims to uncover user intents when they are implied in personal narratives (without access to the explicit question).

Conversational search/QA. One way to better satisfy user intents is by making such processes collaborative (Morris and Horvitz, 2007; Morris, 2013), or conversational (Radlinski and Craswell, 2017). Conversational QA datasets (Choi et al., 2018; Reddy et al., 2019) have been introduced to help develop systems with such capability.

Social QA. Some questions posed by users are inherently more social in nature, and require more nuanced contextual understanding (Harabagiu, 2008). The social nature may affect how people ask questions (Dahiya and Talukdar, 2016; Rao and Daumé III, 2018), and pose challenges for identifying appropriate answers (Shtok et al., 2012; Zhang et al., 2017).

---

[20] The set annotated by humans is disjoint.

[21] We fine-tune with our training set on top of the pre-trained transformer language model, using the implementation from `https://github.com/huggingface/pytorch-openai-transformer-lm`.

7 Discussion

In this work, we introduce the new task of inferring advice-seeking intentions from personal narratives, a methodology for creating appropriate test instances for this task and the `ASQ` dataset. This task complements existing (intradiegetic) narrative understanding tasks by focusing on extradiegetic aspects of the narrative: in order to understand "Why is the narrator sharing this?", we often need to apply a certain degree of common sense and social intuition.

From a practical perspective, this extradiegetic capability is a prerequisite to properly address personalized information needs that are constrained by personal circumstances described as free-form personal stories. Currently, to address these types of information needs, people seek (or even hire) other individuals with relevant experience or expertise. As with conversational search (Radlinski and Craswell, 2017), we can envision systems that can more directly address complex information needs by better understanding the circumstances and intentions of the user.

Our analysis of the human and baseline performance on different types of test instances points to interesting avenues for future work, both in terms of designing better-performing systems and in terms of constructing better test data. We envision that (intradiegetic) narrative understanding could help identify the components of the narrative that are most relevant to the advice-seeking goal. For example, identifying the narrator's intentions and desires within the story (Rashkin et al., 2018b), and whether these desires are fulfilled (Rahimtoroghi et al., 2017) could help focus the attention of the model, especially when dealing with less concrete questions. Furthermore, a better representation of the structure of the narrative (Ouyang and McKeown, 2014), in terms of discourse acts (Elson, 2012) and sentiment flow (Ouyang and McKeown, 2015), could also help distinguish between spurious and essential circumstances of the narratives.

In terms of improving the task itself and the methodology for creating testing instances that better approximate the inferential task, we note a few possible directions. Firstly, better narrative modeling could lead to higher quality matching. Similarly, better representation of the questions can help select more appropriate candidate options (e.g., currently 6% of the questions are deemed by the annotators to be too general). In addition, the generative version of the task, when appropriately evaluated, could be a closer operationalization for intention inference, and also offer more potential for practical uses.

Finally, future work could expand on our methodology to formulate other more general tasks aiming to understand the reasons why a person is sharing a personal story. While we have focused on narratives shared with the intention of seeking advice, people may also share stories to express emotions, to entertain or educate others. A better understanding of these different (explicit or implicit) intentions could lead to more personalized and empathetic human-computer interaction.

Acknowledgments. The authors thank Tom Davidson, Tsung-Yu Hou, Qian Huang, Hajin Lim, Laure Thompson, Andrew Wang, Xiaozhi Wang and Justine Zhang for helping with the annotations. We are grateful to Thorsten Joachims, Avery Quinn Smith and Todd Cullen for helping us when our server crashed on the day of the deadline while testing the model on the held-out set, to Lillian Lee, Andrew Wang, Justine Zhang and the anonymous reviewers for their helpful comments, and to Fernando Pereira for the early discussions that inspired this research direction. This work is supported in part by NSF CAREER award IIS-1750615 and NSF Grant SES-1741441.

Appendix

A1 Instructions to human annotators

As described in Section 4 of the main paper, we obtained human annotations on a small subset of our data for validation purposes. Annotators were shown instructions which included the definitions for different question-narrative plausibility types, together with two examples to help further clarify the task and the definitions. The exact instructions are reproduced in Table A8, while the examples provided are shown in Table A9.

A2 Distribution of plausibility categories

Table A6 shows the distribution of plausibility categories given out by our human annotators, for both the actual questions which belong to the given narrative (Column 2) and the paired alternative questions (Column 3).

Question type	**% in actual**	**% in altern.**
Compatible and **L**ikely	81%	15%
Compatible but **U**nlikely	10%	21%
Incompatible (**I**mplicit)	5%	16%
Incompatible (**E**xplicit)	2%	41%
Very **G**eneral	3%	8%

Table A6: Data distribution estimated from the human annotated subset. For more than half of the cases, the wrong answer (i.e., the alternative question) could not be simply discarded based on factual mismatches, and the task instance would require additional common sense or social intuition to solve.

# of unique post ids	415,693
# of posts with narrative bodies	339,815
# of narratives with questions	262,721
# of narratives after filtering for length	151,418
# of narratives with specific questions	89,527
# of narratives paired	43,730

Table A7: Counts for narrative instances at different stages of dataset construction.

A3 Further processing details

Table A7 provides the number of instances remaining at each of the processing steps. After masking one narrative from each narrative pair, we have a total of 21,865 narratives, each successfully paired with two plausible candidate questions.

A4 Examples of pair types

In our error analysis, we find that the performance of both our baselines, as well as that of our human annotators, vary depending on question pair type, where pair type is defined as the human-judged plausibility of the ground-truth question and that of the alternative question. To give a better sense of what these pair types look like in practice, Table A10 shows example instances for a few selected pair types.

You will be presented with one narrative and two advice-seeking questions (qn1 and qn2).

Firstly, you will need to indicate which of these questions is **more likely** to be asked by the narrator in the context of the narrative (Column D, in yellow). Use the dropdown menu to select the more likely question among the two. (You must pick one.)

In addition, for **each** question separately, you will need to provide a rating on how plausible the question is in the context of the narrative by choosing one of the following options (dropdown menu in Columns E and F, in green):

1. **Very general**: i.e., this question could follow most narratives, and it's not in any way specific to this narrative.
2. **Compatible and likely**: i.e., the question follows naturally from this narrative.
3. **Compatible but unlikely**: i.e., while there is no direct contradiction (either explicit or implicit) with the narrative, it seems unlikely that the narrator's intention was to ask this question.
4. **Incompatible (explicit)**: i.e., the question is incompatible due to clear factual mismatches with the information explicitly contained in the narrative, or it is completely irrelevant.
5. **Incompatible (implicit)**: i.e., the question is incompatible due to mismatches with something that you can indirectly infer from the narrative.

You should judge each question **separately** when selecting a category. It is possible for both questions to fall into the same category.

Now you need to read the example narratives, questions and explanations in the adjacent cells (B2 and C2) to get a feel of each of the categories, after which you could proceed to the sub-sheet **Items to annotate (see tab at the bottom of this page)** to complete the annotation task.

Optionally, you can also provide comments for each item (scroll to the right to see the comment column): Did you find an item particularly challenging or interesting? Was one of the questions not really asking for an advice? Do share your thoughts with us.

Table A8: Instruction text shown to the annotators.

Example 1	**Example 2**
Narrative: “I am a freshman in college and I have a group of friends that I have been hanging out with for the past couple months. I feel like we have a good time when we hang out, but a lot of the time, the rest of the group will go out and do stuff together, but I won’t be included.” Example questions in each category [and explanations where appropriate]: a) **Very general**: Any advice? b) **Compatible and likely**: Can I ask to be included? c) **Compatible but unlikely**: How to make new friends in college? [explanation: it is more likely that the narrator is trying to be more included in the current group of friends, rather than giving up entirely on them and look for replacement.] d) **Incompatible (explicit)**: Any advice for finding new friends for a senior in college? [Explanation: The narrator is a freshman in college, not a senior. This constitutes a clear factual mismatch between the question and the narrative.] e) **Incompatible (implicit)**: What are some excuses to not hang out with them? [Explanation: We can imply from the narrative that the narrator wants to hang out with the group. This is incompatible with a question asking how NOT to do that.]	Narrative: “I asked a girl that I really like if she would like to get coffee sometime. She said she’s really busy but that we’ll see. I can’t get her off my mind and I spend all day waiting for her to tell me she’s free.” Example questions in each category [and explanations where appropriate]: a) **Very general**: What should I do? b) **Compatible and likely**: Would it seem desperate if I asked her again in a more direct way a week later ? c) **Compatible but unlikely**: Which coffee place would you recommend? [Explanation: While the narrator is trying to invite the girl for coffee, the main concern seems to be whether the attempt would be successful rather the choices between coffee places.] d) **Incompatible (explicit)**: How to deal with my roommate? [Explanation: This question is completely irrelevant to the narrative (no roommate is mentioned).] e) **Incompatible (implicit)**: What to do if I asked a girl out and now regret it? [Explanation: We can infer that the narrator is looking forward to the potential date, which contradicts with the feeling of regret in the question.]

Table A9: Example narratives and questions shown to the annotators.

Pair type	Narrative	Actual question	Alternative question
L + L	Hey everyone I have a bit of a dilemma. It's the first week of school and I am talking three advanced classes, AP world history II, English honors II and Chemistry honors. I am pretty sure that I can handle it but; I am falling behind in chemistry honors and it is the first week. I don't have the mathematical background as the other students. They have taken physics and geometry. I am in a special Algebra class which means I am a year behind in math and science.	Should I drop chemistry honors?	How much do honors courses matter?
L + U	My college roommate/one of my best friends is getting married Saturday. I'm a groomsman, as is our third roommate. Our third roommate gave he and his betrothed their wedding gifts early today: an Xbox One and a crystal decorative bowl from Tiffany. I'm an assistant manager at a sporting goods store making \$8.50 an hour, and between rent, utilities, groceries, gas, and my student loan payments, I usually either barely break even every month or have to borrow money from my parents until my next paycheck. I've checked their registry, and even the less expensive gifts are outside what I can afford (\$30 can make or break me right now).	What to do about a wedding gift if I'm broke?	Where can I buy food that's cheap, and it'll last me until then?
C + I	I just recently switched schools this school year. I'm pretty okay with how it's going so far academics wise but I have no idea how to put myself out there. Everyone has seemed to have made friend groups already or they already know everyone from previous years. I used to be in a private school so no one really knows me from this school except for my close friends that I've known for a long time.	Is there any way that I could gain any popularity before it's too late?	Is it too early to tell if I want to drop out?
L + E	So there is a dream job which is PERFECT for me and of course I really want it. I called the employer last week and she said she was going to call candidates for interviews that week. Then I called this week and she said she was going to call for interviews this week. And please, no advice telling me 'don't call'. I have nothing to lose, so I'm going to call, I would just really appreciate some advice as to how to ask for an interview appropriately - Thank you all!	How do I call an employer asking for an interview?	When I went for the interview she did seem busy so maybe she was too busy to call?
L + G	I'm in a relationship with an amazing girl and feel very happy with her. Recently though I've been having intrusive thoughts about her ex-boyfriends (her having sex with them, etc) which are leading to feelings of jealousy and it's really disrupting my ability to enjoy my time with her.	How to deal with feelings of jealousy?	Is this "normal" – in the sense of, do other people experience this?

Seeing Things from a Different Angle:
Discovering Diverse Perspectives about Claims

Sihao Chen, Daniel Khashabi, Wenpeng Yin, Chris Callison-Burch, Dan Roth
Department of Computer and Information Science, University of Pennsylvania
`{sihaoc,danielkh,wenpeng,ccb,danroth}@cis.upenn.edu`

Abstract

One key consequence of the information revolution is a significant increase and a contamination of our information supply. The practice of fact-checking won't suffice to eliminate the biases in text data we observe, as the degree of factuality alone does not determine whether biases exist in the spectrum of opinions visible to us. To better understand controversial issues, one needs to view them from a diverse yet comprehensive set of *perspectives*.

For example, there are many ways to respond to a *claim* such as *"animals should have lawful rights"*, and these responses form a spectrum of perspectives, each with a *stance* relative to this claim and, ideally, with evidence supporting it. Inherently, this is a natural language understanding task, and we propose to address it as such. Specifically, we propose the task of *substantiated perspective discovery* where, given a *claim*, a system is expected to discover a *diverse* set of *well-corroborated perspectives* that take a *stance* with respect to the claim. Each perspective should be substantiated by *evidence* paragraphs which summarize pertinent results and facts.

We construct PERSPECTRUM, a dataset of claims, perspectives and evidence, making use of online debate websites to create the initial data collection, and augmenting it using search engines in order to expand and diversify our dataset. We use crowdsourcing to filter out noise and ensure high-quality data. Our dataset contains $1k$ claims, accompanied by pools of $10k$ and $8k$ perspective sentences and evidence paragraphs, respectively. We provide a thorough analysis of the dataset to highlight key underlying language understanding challenges, and show that human baselines across multiple subtasks far outperform machine baselines built upon state-of-the-art NLP techniques. This poses a challenge and an opportunity for the NLP community to address.

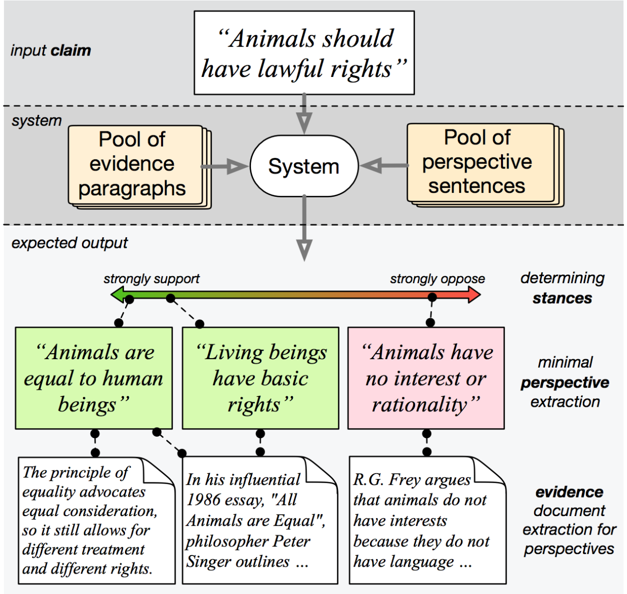

Figure 1: Given a *claim*, a hypothetical system is expected to discover various *perspectives* that are substantiated with *evidence* and their *stance* with respect to the claim.

1 Introduction

Understanding most nontrivial *claims* requires insights from various *perspectives*. Today, we make use of search engines or recommendation systems to retrieve information relevant to a claim, but this process carries multiple forms of *bias*. In particular, they are optimized relative to the claim (query) presented, and the popularity of the relevant documents returned, rather than with respect to the diversity of the *perspectives* presented in them or whether they are supported by evidence.

In this paper, we explore an approach to mitigating this *selection bias* (Heckman, 1979) when studying (disputed) claims. Consider the *claim* shown in Figure 1: *"animals should have lawful rights."* One might compare the biological similarities/differences between humans and other an-

Proceedings of NAACL-HLT 2019, pages 542–557
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

imals to support/oppose the claim. Alternatively, one can base an argument on morality and rationality of animals, or lack thereof. Each of these arguments, which we refer to as *perspectives* throughout the paper, is an opinion, possibly conditional, in support of a given *claim* or against it. A *perspective* thus constitutes a particular attitude towards a given *claim*.

Natural language understanding is at the heart of developing an ability to identify diverse perspectives for claims. In this work, we propose and study a setting that would facilitate discovering *diverse perspectives* and their supporting evidence with respect to a given *claim*. Our goal is to identify and formulate the key NLP challenges underlying this task, and develop a dataset that would allow a systematic study of these challenges. For example, for the claim in Figure 1, multiple (non-redundant) perspectives should be retrieved from a pool of perspectives; one of them is *"animals have no interest or rationality"*, a *perspective* that should be identified as taking an *opposing* stance with respect to the *claim*. Each *perspective* should also be well-supported by *evidence* found in a pool of potential pieces of evidence. While it might be impractical to provide an exhaustive spectrum of ideas with respect to a *claim*, presenting a small but diverse set of *perspectives* could be an important step towards addressing the *selection bias* problem. Moreover, it would be impractical to develop an exhaustive pool of evidence for all perspectives, from a diverse set of credible sources. We are not attempting to do that. We aim at formulating the core NLP problems, and developing a dataset that will facilitate studying these problems from the NLP angle, realizing that using the outcomes of this research in practice requires addressing issues such as trustworthiness (Pasternack and Roth, 2010, 2013) and possibly others. Inherently, our objective requires understanding the relations between *perspective*s and *claim*s, the nuances in the meaning of various *perspectives* in the context of *claim*s, and relations between perspectives and evidence. This, we argue, can be done with a diverse enough, but not exhaustive, dataset. And it can be done without attending to the legitimacy and credibility of sources contributing evidence, an important problem but orthogonal to the one studied here.

To facilitate the research towards developing solutions to such challenging issues, we propose PERSPECTRUM, a dataset of *claims*, *perspectives* and *evidence* paragraphs. For a given *claim* and pools of *perspectives* and *evidence paragraphs*, a hypothetical system is expected to select the relevant perspectives and their supporting paragraphs.

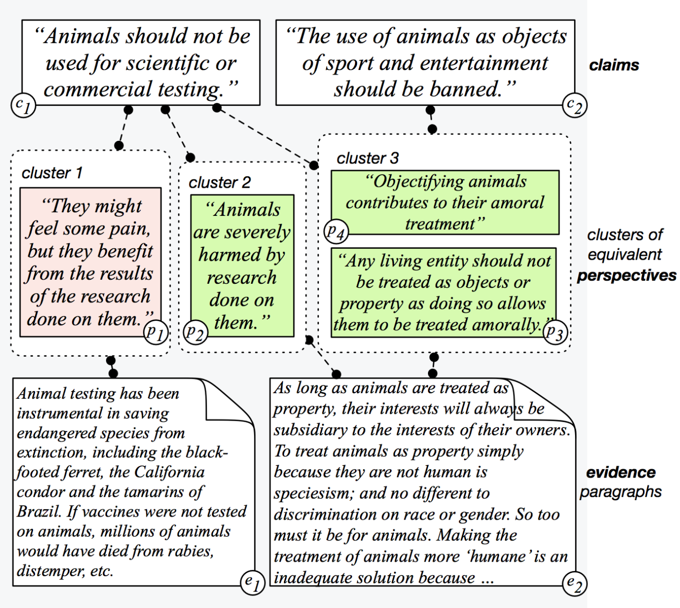

Figure 2: Depiction of a few claims, their *perspectives* and evidences from PERSPECTRUM. The *supporting* and *opposing* perspectives are indicated with green and red colors, respectively.

Our dataset contains 907 claims, 11,164 perspectives and 8,092 evidence paragraphs. In constructing it, we use online debate websites as our initial seed data, and augment it with search data and paraphrases to make it richer and more challenging. We make extensive use of crowdsourcing to increase the quality of the data and clean it from annotation noise.

The contributions of this paper are as follows:

- To facilitate making progress towards the problem of *substantiated perspective discovery*, we create a high-quality dataset for this task.[1]
- We identify and formulate multiple NLP tasks that are at the core of addressing the *substantiated perspective discovery* problem. We show that humans can achieve high scores on these tasks.
- We develop competitive baseline systems for each sub-task, using state-of-the-art techniques.

---

2 Design Principles and Challenges

In this section we provide a closer look into the challenge and propose a collection of tasks that move us closer to *substantiated perspective discovery*. To clarify our description we use to following notation. Let c indicate a target claim of interest (for example, the claims c_1 and c_2 in Figure 2). Each claim c is addressed by a collection of perspectives $\{p\}$ that are grouped into clusters of *equivalent* perspectives. Additionally, each perspective p is supported, relative to c, by at least one evidence paragraph e, denoted $e \vDash p|c$.

Creating systems that would address our challenge in its full glory requires solving the following interdependent tasks:

Determination of argue-worthy claims: not every claim requires an in-depth discussion of perspectives. For a system to be practical, it needs to be equipped with understanding argumentative structures (Palau and Moens, 2009) in order to discern disputed claims from those with straightforward responses. We set aside this problem in this work and assume that all the inputs to the systems are discussion-worthy claims.

Discovery of pertinent perspectives: a system is expected to recognize argumentative sentences (Cabrio and Villata, 2012) that directly address the points raised in the disputed claim. For example, while the perspectives in Figure 2 are topically related to the claims, p_1, p_2 do not directly address the focus of claim c_2 (i.e., *"use of animals" in "entertainment"*).

Perspective equivalence: a system is expected to extract a *minimal* and *diverse* set of perspectives. This requires the ability to discover equivalent perspectives p, p', with respect to a claim c: $p|c \approx p^{'}|c$. For instance, p_3 and p_4 are equivalent in the context of c_2; however, they might not be equivalent with respect to any other claim. The conditional nature of perspective equivalence differentiates it from the *paraphrasing* task (Bannard and Callison-Burch, 2005).

Stance classification of perspectives: a system is supposed to assess the stances of the perspectives with respect to the given claim (supporting, opposing, etc.) (Hasan and Ng, 2014).

Substantiating the perspectives: a system is expected to find valid evidence paragraph(s) in support of each perspective. Conceptually, this is similar to the well-studied problem of textual entailment (Dagan et al., 2013) except that here the entailment decisions depend on the choice of claims.

3 Related Work

Claim verification. The task of *fact verification* or *fact-checking* focuses on the assessment of the truthfulness of a claim, given evidence (Vlachos and Riedel, 2014; Mitra and Gilbert, 2015; Samadi et al., 2016; Wang, 2017; Nakov et al., 2018; Hanselowski et al., 2018; Karimi et al., 2018; Alhindi et al., 2018). These tasks are highly related to the task of textual-entailment that has been extensively studied in the field (Bentivogli et al., 2008; Dagan et al., 2013; Khot et al., 2018). Some recent work study jointly the problem of identifying evidence and verifying that it supports the claim (Yin and Roth, 2018).

Our problem structure encompasses the *fact verification* problem (as verification of *perspectives* from *evidence*; Figure 1).

Stance classification. Stance classification aims at detecting phrases that *support* or *oppose* a given claim. The problem has gained significant attention in the recent years; to note a few important ones, Hasan and Ng (2014) create a dataset of dataset text snippets, annotated with "reasons" (similar to *perspectives* in this work) and stances (whether they support or oppose the claim). Unlike this work, our pool of the relevant "reasons" is not restricted. Ferreira and Vlachos (2016) create a dataset of rumors (claims) coupled with news headlines and their stances. There are a few other works that fall in this category (Boltužić and Šnajder, 2014; Park and Cardie, 2014; Rinott et al., 2015; Swanson et al., 2015; Mohammad et al., 2016; Sobhani et al., 2017; Bar-Haim et al., 2017). Our approach here is closely related to existing work in this direction, as stance classification is part of the problem studied here.

Argumentation. There is a rich literature on *formalizing* argumentative structures from free text. There are a few theoretical works that lay the ground work to characterizing units of arguments and argument-inducing inference (Teufel et al., 1999; Toulmin, 2003; Freeman, 2011).

Others have studied the problem of extracting argumentative structures from free-form text; for example, Palau and Moens (2009); Khatib et al. (2016); Ajjour et al. (2017) studied elements of arguments and the internal relations between them.

Table 1: Comparison of PERSPECTRUM to a few notable datasets in the field.

Feng and Hirst (2011) classified an input into one of the argument schemes. Habernal and Gurevych (2017) provided a large corpus annotated with argument units. Cabrio and Villata (2018) provide a thorough survey the recent work in this direction. A few other works studied other aspects of argumentative structures (Cabrio and Villata, 2012; Khatib et al., 2016; Lippi and Torroni, 2016; Zhang et al., 2017; Stab and Gurevych, 2017).

A few recent works use a similar conceptual design that involves a *claim*, *perspectives* and *evidence*.These works are either too small due to the high cost of construction (Aharoni et al., 2014) or too noisy because of the way they are crawled from online resources (Wachsmuth et al., 2017; Hua and Wang, 2017). Our work makes use of both online content and of crowdsourcing, in order to construct a sizable and high-quality dataset.

4 The PERSPECTRUM Dataset

4.1 Dataset construction

In this section we describe a multi-step process, constructed with detailed analysis, substantial refinements and multiple pilots studies.

We use crowdsourcing to annotate different aspects of the dataset. We used Amazon Mechanical Turk (AMT) for our annotations, restricting the task to workers in five English-speaking countries (USA, UK, Canada, New Zealand, and Australia), more than 1000 finished HITs and at least a 95% acceptance rate. To ensure the diversity of responses, we do not require additional qualifications or demographic information from our annotators.

For any of the annotations steps described below, the users are guided to an external platform where they first read the instructions and try a verification step to make sure they have understood the instructions. Only after successful completion are they allowed to start the annotation tasks.

Throughout our annotations, it is our aim to make sure that the workers are responding objectively to the tasks (as opposed to using their personal opinions or preferences). The screen-shots of the annotation interfaces for each step are included in the Appendix (Section A.3).

In the steps outlined below, we filter out a subset of the data with low rater–rater agreement ρ (see Appendix A.2). In certain steps, we use an information retrieval (IR) system[2] to generate the best candidates for the task at hand.

Step 1: The initial data collection. We start by crawling the content of a few notable debating websites: `idebate.com`, `debatewise.org`, `procon.org`. This yields $\sim 1k$ claims, $\sim 8k$ perspectives and $\sim 8k$ evidence paragraphs (for complete statistics, see Table 4 in the Appendix). This data is significantly noisy and lacks the structure we would like. In the following steps we explain how we denoise it and augment it with additional data.

Step 2a: Perspective verification. For each perspective we verify that it is a complete English sentence, with a clear stance with respect to the given claim. For a fixed pair of *claim* and *perspective*, we ask the crowd-workers to label the perspective with one of the five categories of *support*, *oppose*, *mildly-support*, *mildly-oppose*, or *not a valid perspective*. The reason that we ask for two levels of intensity is to distinguish *mild* or *conditional* arguments from those that express *stronger* positions.

Every 10 claims (and their relevant perspectives) are bundled to form a HIT. Three independent annotators solve a HIT, and each gets paid \$1.5-2 per HIT. To get rid of the ambiguous/noisy perspectives we measure rater-rater agreement on the resulting data and retain only the subset which has a significant agreement of $\rho \geq 0.5$. To account for minor disagreements in the intensity of

---

[2] `www.elastic.co`

perspective stances, before measuring any notion of agreement, we collapse the five labels into three labels, by collapsing *mildly-support* and *mildly-oppose* into *support* and *oppose*, respectively.

To assess the quality of these annotations, two of the authors independently annotate a random subset of instances in the previous step (328 perspectives for 10 claims). Afterwards, the differences were adjudicated. We measure the accuracy adjudicated results with AMT annotations to estimate the quality of our annotation. This results in an accuracy of 94%, which shows high-agreement with the crowdsourced annotations.

Step 2b: Perspective paraphrases. To enrich the ways the perspectives are phrased, we crowdsource paraphrases of our perspectives. We ask annotators to generate two paraphrases for each of the 15 perspectives in each HIT, for a reward of $1.50.

Subsequently, we perform another round of crowdsourcing to verify the generated paraphrases. We create HITs of 24 candidate paraphrases to be verified, with a reward of $1. Overall, this process gives us $\sim$ 4.5 paraphrased perspectives. The collected paraphrases form clusters of equivalent perspectives, which we refine further in the later steps.

Step 2c: Web perspectives. In order to ensure that our dataset contains more realistic sentences, we use web search to augment our pool of perspectives with additional sentences that are topically related to what we already have. Specifically, we use Bing search to extract sentences that are similar to our current pool of perspectives, by querying "claim+perspective". We create a pool of relevant web sentences and use an IR system (introduced earlier) to retrieve the 10 most similar sentences. These candidate perspectives are annotated using (similar to step 2a) and only those that were agreed upon are retained.

Step 2d: Final perspective trimming. In a final round of annotation for perspectives, an expert annotator went over all the claims in order to verify that all the equivalent perspectives are clustered together. Subsequently, the expert annotator went over the most similar claim-pairs (and their perspectives), in order to annotate the missing perspectives shared between the two claims. To cut the space of claim pairs, the annotation was done on the top 350 most similar claim pairs retrieved by the IR system.

Category	Statistic	Value
Claims	# of claims (step 1)	907
	avg. claim length (tokens)	8.9
	median claims length (tokens)	8
	max claim length (tokens)	30
	min claim length (tokens)	3
Perspectives	# of perspectives	11,164
	Debate websites (step 1)	4,230
	Perspective paraphrase (step 2b)	4,507
	Web (step 2c)	2,427
	# of perspectives with stances	5,095
	# of "support" perspectives	2,627
	# of "opposing" perspectives	2,468
	avg size of perspective clusters	2.3
	avg length of perspectives (tokens)	11.9
Evidences	# of total evidences (step 1)	8,092
	avg length of evidences (tokens)	168

Table 2: A summary of PERSPECTRUM statistics

Step 3: Evidence verification. The goal of this step is to decide whether a given evidence paragraph provides enough substantiations for a perspective or not. Performing these annotations exhaustively for any perspective-evidence pair is not possible. Instead, we make use of a retrieval system to annotate only the relevant pairs. In particular, we create an index of all the perspectives retained from *step 2a*. For a given evidence paragraph, we retrieve the top relevant perspectives. We ask the annotators to note whether a given evidence paragraph *supports* a given perspective or not. Each HIT contains a 20 evidence paragraphs and their top 8 relevant candidate perspectives. Each HIT is paid $1 and annotated by at least 4 independent annotators.

In order to assess the quality of our annotations, a random subset of instances (4 evidence-perspective pairs) are annotated by two independent authors and the differences are adjudicated. We measure the accuracy of our adjudicated labels versus AMT labels, resulting in 87.7%. This indicates the high quality of the crowdsourced data.

4.2 Statistics on the dataset

We now provide a brief summary of PERSPECTRUM. The dataset contains about $1k$ claims with a significant length diversity (Table 2). Additionally, the dataset comes with $\sim$ $12k$ perspectives, most of which were generated through paraphrasing (step 2b). The perspectives which convey the same point with respect to a claim are grouped into clusters. On average, each cluster has a size of 2.3 which shows that, on average, many perspectives have

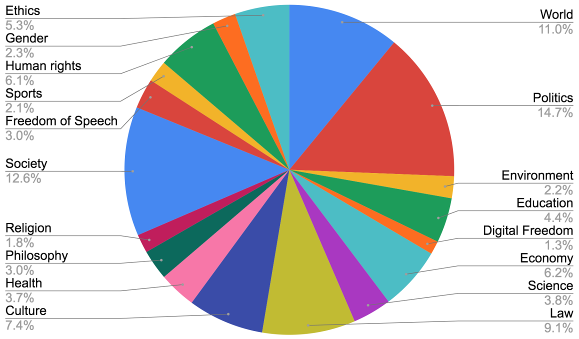

Figure 3: Distribution of claim topics.

equivalents. More granular details are available in Table 2.

To better understand the topical breakdown of claims in the dataset, we crowdsource the set of "topics" associated with each *claim* (e.g., *Law, Ethics, etc.*) We observe that, as expected, the three topics of *Politics, World, and Society* have the biggest portions (Figure 3). Additionally, the included claims touch upon 10+ different topics. Figure 4 depicts a few popular categories and sampled questions from each.

4.3 Required skills

We perform a closer investigation of the abilities required to solve the stance classification task. One of the authors went through a random subset of claim-perspectives pairs and annotated each with the abilities required in determining their stances labels. We follow the common definitions used in prior work (Sugawara et al., 2017; Khashabi et al., 2018). The result of this annotation is depicted in Figure 5. As can be seen, the problem requires understanding of *common-sense*, i.e., an understanding that is commonly shared among humans and rarely gets explicitly mentioned in the text. Additionally, the task requires various types of *coreference* understanding, such as *event coreference* and *entity coreference*.

5 Empirical Analysis

In this section we provide empirical analysis to address the tasks. We create a split of 60%/15%/25% of the data train/dev/test. In order to make sure our baselines are not overfitting to the keywords of each topic (the "topic" annotation from Section 4.2), we make sure to have claims with the same topic fall into the same split.

For simplicity, we define a notation which we will extensively use for the rest of this paper. The clusters of equivalent perspectives are denoted as $[\![p]\!]$, given a representative member p. Let $P(c)$ denote the collection of relevant perspectives to a claim c, which is the union of all the equivalent perspectives participating in the claim: $\{[\![p_i]\!]\}_i$. Let $E([\![p]\!]) = E(p) = \bigcup_i e_i$ denote the set of evidence documents lending support to a perspective p. Additionally, denote the two pools of perspectives and evidence with $\mathcal{U}^p$ and $\mathcal{U}^e$, respectively.

5.1 Systems

We make use of the following systems in our evaluation:

IR (Information Retrieval). This baseline has been successfully used for related tasks like Question Answering (Clark et al., 2016). We create two versions of this baseline: one with the pool of perspectives $\mathcal{U}^p$ and one with the pool of evidences $\mathcal{U}^e$. We use this system to retrieve a ranked list of best matching perspective/evidence from the corresponding index.

BERT (Contextual representations). A recent state-of-the-art contextualized representation (Devlin et al., 2018). This system has been shown to be effective on a broad range of natural language understanding tasks.

Human Performance. Human performance provides us with an estimate of the best achievable results on datasets. We use human annotators to measure human performance for each task. We randomly sample 10 claims from the test set, and instruct two expert annotators to solve each of T1 to T4.

5.2 Evaluation metrics.

We perform evaluations on four different subtasks in our dataset. In all of the following evaluations, the systems are given the two pools of perspectives $\mathcal{U}^p$ and evidences $\mathcal{U}^e$.

T1: Perspective extraction. A system is expected to return the collection of mutually disjoint perspectives with respect to a given claim. Let $\hat{P}(c)$ be the set of output perspectives. Define the precision and recall as $\text{Pre}(c) = \frac{\sum_{\hat{p} \in \hat{P}(c)} \mathbf{1}\{\exists p, s.t. \hat{p} \in [\![p]\!]\}}{|\hat{P}(c)|}$ and $\text{Rec}(c) = \frac{\sum_{\hat{p} \in \hat{P}(c)} \mathbf{1}\{\exists p, s.t. \hat{p} \in [\![p]\!]\}}{|P(c)|}$ respectively. To calculate dataset metrics, the aforementioned per-claim metrics are averaged across all the claims in the test set.

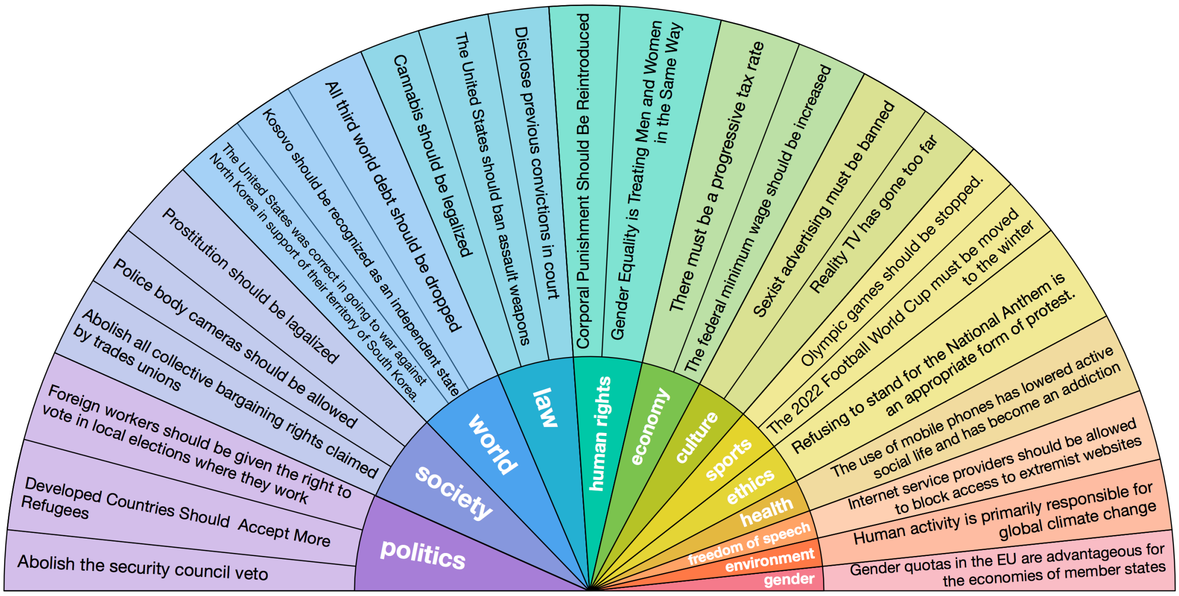

Figure 4: Visualization of the major topics and sample claims in each category.

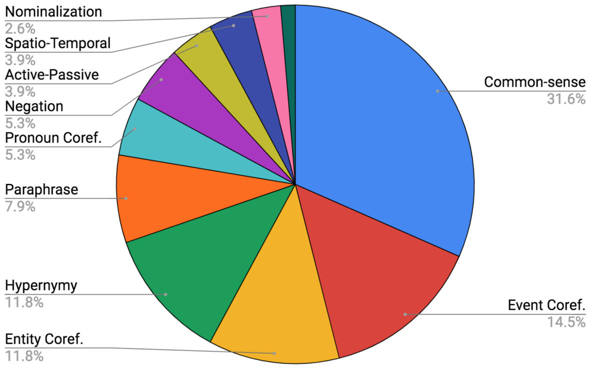

Figure 5: The set of reasoning abilities required to solve the stance classification task.

T2: Perspective stance classification. Given a claim, a system is expected to label every perspective in $P(c)$ with one of two labels *support* or *oppose*. We use the well-established definitions of precision-recall for this binary classification task.

T3: Perspective equivalence. A system is expected to decide whether two given perspectives are equivalent or not, with respect to a given claim. We evaluate this task in a way similar to a clustering problem. For a pair of perspectives $p_1, p_2 \in P(c)$, a system predicts whether the two are in the same cluster or not. The ground-truth is whether there is a cluster which contains both of the perspectives or not: $\exists \tilde{p} \ s.t. \ \tilde{p} \in P(c) \wedge p_1, p_2 \in \llbracket \tilde{p} \rrbracket$. We use this pairwise definition for all the pairs in $P(c) \times P(c)$, for any claim c in the test set.

T4: Extraction of supporting evidences. Given a perspective p, we expect a system to return all the evidence $\{e_i\}$ from the pool of evidence $\mathcal{U}^e$. Let $\hat{E}(p)$ and $E(p)$ be the predicted and gold evidence for a perspective p. Define macro-precision and macro-recall as $\text{Pre}(p) = \frac{|\hat{E}(p) \cap E(p)|}{|\hat{E}(p)|}$ and $\text{Rec}(p) = \frac{|\hat{E}(p) \cap E(p)|}{|E(p)|}$, respectively. The metrics are averaged across all the perspectives p participating in the test set.

T5: Overall performance. The goal is to get estimates of the overall performance of the systems. Instead of creating a complex measure that would take all the aspects into account, we approximate the overall performance by multiplying the disjoint measures in $T1$, $T2$ and $T4$. While this gives an estimate on the overall quality, it ignores the pipeline structure of the task (e.g., the propagation of the errors throughout the pipeline). We note that the task of $T3$ (perspective equivalence) is indirectly being measured within $T1$. Furthermore, since we do not report an IR performance on $T2$, we use the "always supp" baseline instead to estimate an overall performance for IR.

5.3 Results

5.3.1 Minimal perspective extraction (T1)

Table 3 shows a summary of the experimental results. To measure the performance of the IR system, we use the index containing $\mathcal{U}^p$. Given each claim, we query the top k perspectives, ranked according to their retrieval scores. We tune k on our development set and report the results on the test section according to the tuned parameter. We use IR results as candidates for other solvers (including humans). For this task, IR with top-15 candidates yields $>90\%$ recall (for the PR-curve, see Figure 6 in the Appendix). In order to train BERT on this task, we use the IR candidates as the training instances. We then tune a threshold on the dev data to select the top relevant perspectives. In order to measure human performance, we create an interface where two human annotators see IR top-k and select a *minimal* set of perspectives (i.e., no two equivalent perspectives).

5.3.2 Perspective stance classification (T2)

We measure the quality of perspective stance classification, where the input is a claim-perspective pair, mapped to {support, oppose}. The candidate inputs are generated on the collection of perspectives $P(c)$ relevant to a claim c. To have an understanding of a lower bound for the metric, we measure the quality of an always-support baseline. We measure the performance of BERT on this task as well, which is about 20% below human performance. This might be because this task requires a deep understanding of *commonsense* knowledge/reasoning (as indicated earlier in Section 5). Since a retrieval system is unlikely to distinguish perspectives with different stances, we do not report the IR performance for this task.

5.3.3 Perspective equivalence (T3)

We create instances in the form of (p_1, p_2, c) where $p_1, p_2 \in P(c)$. The expected label is whether the two perspectives belong to the same equivalence class or not. In the experiments, we observe that BERT has a significant performance gain of $\sim 36\%$ over the IR baseline. Meanwhile, this system is behind human performance by a margin of $\sim 20\%$.

5.3.4 Extraction of supporting evidence (T4)

We evaluate the systems on the extraction of items from the pool of evidences $\mathcal{U}^e$, given a *claim-perspective* pair. To measure the performance of the IR system working with the index containing $\mathcal{U}^e$ we issue a query containing the concatenation of a perspective-claim pair. Given the sorted results (according to their retrieval confidence score), we select the top candidates using a threshold parameter tuned on the dev set. We also use the IR system's candidates (top-60) for other baselines. This set of candidates yields a $>85\%$ recall (for the PR-curve, see Figure 6 in the Appendix). We train BERT system to map each (gold) *claim-perspective* pair to its corresponding *evidence* paragraph(s). Since each evidence paragraph could be long (hence hard to feed into BERT), we split each evidence paragraph into sliding windows of 3 sentences. For each *claim-perspective* pair, we use all 3-sentences windows of gold evidence paragraphs as positive examples, and rest of the IR candidates as negative examples. In the run-time, if a certain percentage (tuned on the dev set) of the sentences from a given evidence paragraph are predicted as positive by BERT, we consider the whole evidence as positive (i.e. it supports a given *perspective*).

Setting	Target set	System	*Pre.*	*Rec.*	$F1$
T1: Perspective relevance	$\mathcal{U}^p$	IR	46.8	34.9	40.0
		IR + BERT	47.3	54.8	**50.8**
		IR + Human	63.8	83.8	72.5
T2: Perspective stance	$P(c)$	Always "supp."	51.6	100.0	68.0
		BERT	70.5	71.1	**70.8**
		Human	91.3	90.6	90.9
T3: Perspective equivalence	$P(c)^2$	Always "¬equiv."	100.0	11.9	21.3
		Always "equiv."	20.3	100.0	33.7
		IR	36.5	36.5	36.5
		BERT	85.3	50.8	**63.7**
		Human	87.5	80.2	83.7
T4: Evidence extraction	$\mathcal{U}^e$	IR	42.2	52.5	46.8
		IR + BERT	69.7	46.3	**55.7**
		IR + Human	70.8	53.1	60.7
T5: Overall	$\mathcal{U}^p$,$\mathcal{U}^e$	IR	-	-	12.8
		IR + BERT	-	-	**17.5**
		IR + Human	-	-	40.0

Table 3: Quality of different baselines on different subtasks (Section 5). All the numbers are in percentage. Top machine baselines are in **bold**.

Overall, the performances on this task are lower, which could probably be expected, considering the length of the evidence paragraphs. Similar to the previous scenarios, the BERT solver has a significant gain over a trivial baseline, while standing behind human with a significant margin.

6 Discussion

As one of the key consequences of the information revolution, *information pollution* and *over-personalization* have already had detrimental effects on our life. In this work, we attempt to facilitate the development of systems that aid in better organization and access to information, with the hope that the access to more diverse information can address over-personalization too (Vydiswaran et al., 2014).

The dataset presented here is not intended to be *exhaustive*, nor does it attempt to reflect a true distribution of the important claims and perspectives in the world, or to associate any of the perspective and identified evidence with levels of expertise and trustworthiness. Moreover, it is important to note that when we ask crowd-workers to evaluate the validity of perspectives and evidence, their judgement process can potentially be influenced by their prior beliefs (Markovits and Nantel, 1989). To avoid additional biases introduced in the process of dataset construction, we try to take the least restrictive approach in filtering dataset content beyond the necessary quality assurances. For this reason, we choose not to explicitly ask annotators to filter contents based on the intention of their creators (e.g. offensive content).

A few algorithmic components were not addressed in this work, although they are important to the complete *perspective discovery and presentation* pipeline. For instance, one has to first verify that the input to the system is a reasonably well-phrased and an argue-worthy claim. And, to construct the pool of perspectives, one has to extract relevant arguments (Levy et al., 2014). In a similar vein, since our main focus is the study of the relations between *claim*s, *perspective*s, and *evidence*, we leave out important issues such as their degree of factuality (Vlachos and Riedel, 2014) or trustworthiness (Pasternack and Roth, 2014, 2010) as separate aspects of problem.

We hope that some of these challenges and limitations will be addressed in future work.

7 Conclusion

The importance of this work is three-fold; we define the problem of *substantiated perspective discovery* and characterize language understanding tasks necessary to address this problem. We combine online resources, web data and crowdsourcing and create a high-quality dataset, in order to drive research on this problem. Finally, we build and evaluate strong baseline supervised systems for this problem. Our hope is that this dataset would bring more attention to this important problem and would speed up the progress in this direction.

There are two aspects that we defer to future work. First, the systems designed here assumed that the input are valid claim sentences. To make use of such systems, one needs to develop mechanisms to recognize valid argumentative structures. In addition, we ignore trustworthiness and credibility issues, important research issues that are addressed in other works.

A Supplemental Material

A.1 Statistics

We provide brief statistics on the sources of different content in our dataset in Table 4. In particular, this table shows:

1. the size of the data collected from online debate websites (step 1).
2. the size of the data filtered out (step 2a).
3. the size of the perspectives added by paraphrases (step 2b).
4. the size of the perspective candidates added by web (step 2c).

	Website	# of claims	# of perspectives	# of evidences
after step 1	`idebate`	561	4136	4133
	`procon`	50	960	953
	`debatewise`	395	3039	3036
	total	1006	8135	8122
after step 2a	`idebate`	537	2571	–
	`procon`	49	619	–
	`debatewise`	361	1462	–
	total	947	4652	–
step 2b	paraphrases	–	4507	–
step 2c	web perspectives	–	2427	–

Table 4: The dataset statistics (See section 4.1).

A.2 Measure of agreement

We use the following definition formula in calculation of our measure of agreement. For a fixed subject (problem instance), let n_j represent the number of raters who assigned the given subject to the j-th category. The measure of agreement is defined as

$$\rho \triangleq \frac{1}{n(n-1)} \sum_{j=1}^{k} n_j(n_j - 1)$$

where for $n = \sum_{j=1}^{k} n_j$. Intuitively, this function measure concentration of values the vector $(n_1, ..., n_k)$. Take the edge cases:

- Values concentrated: $\exists j, n_j = n$ (in other words $\forall i \neq j, n_i = 0$) $\Rightarrow P = 1.0$.
- Least concentration (uniformly distribution): $n_1 = n_2 = ... = n_k \Rightarrow \rho = 0.0$.

This definition is used in calculation of more extensive agreement measures (e.g, Fleiss' kappa (Fleiss and Cohen, 1973)). There multiple ways of interpreting this formula:

- It indicates how many rater–rater pairs are in agreement, relative to the number of all possible rater–rater pairs.
- One can interpret this measure by a simple combinatorial notions. Suppose we have sets $A_1, ...A_k$ which are pairwise disjunct and for each j let $n_j = |A_j|$. We choose randomly two elements from $A = A_1 \cup A_2 \cup ... \cup A_k$. Then the probability that they are from the same set is the expressed by ρ.
- We can write ρ in terms of $\sum_{i=1}^{k}(n_i - n/k)^2/(n/k)$ which is the conventional *Chi-Square statistic* for testing if the vector of n_i values comes from the all-categories-equally-likely flat multinomial model.

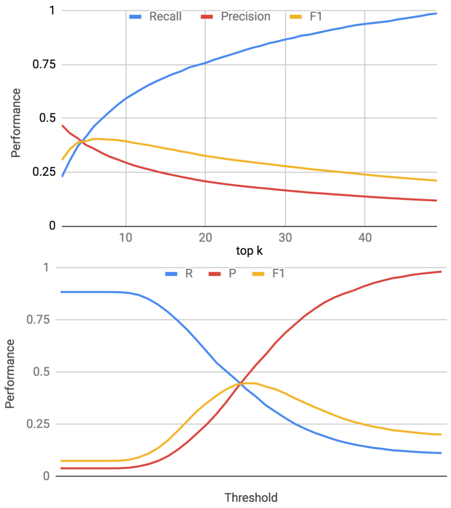

Figure 6: Candidates retrieved from IR baselines vs Precision, Recall, F1, for T1 and T4 respectively.

A.3 crowdsourcing interfaces

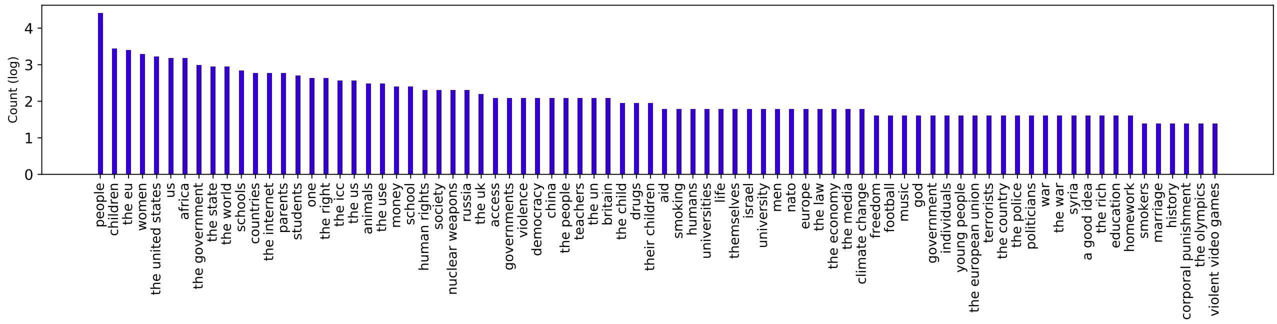

Figure 7: Histogram of popular noun-phrases in our dataset. The y-axis shows count in logarithmic scale.

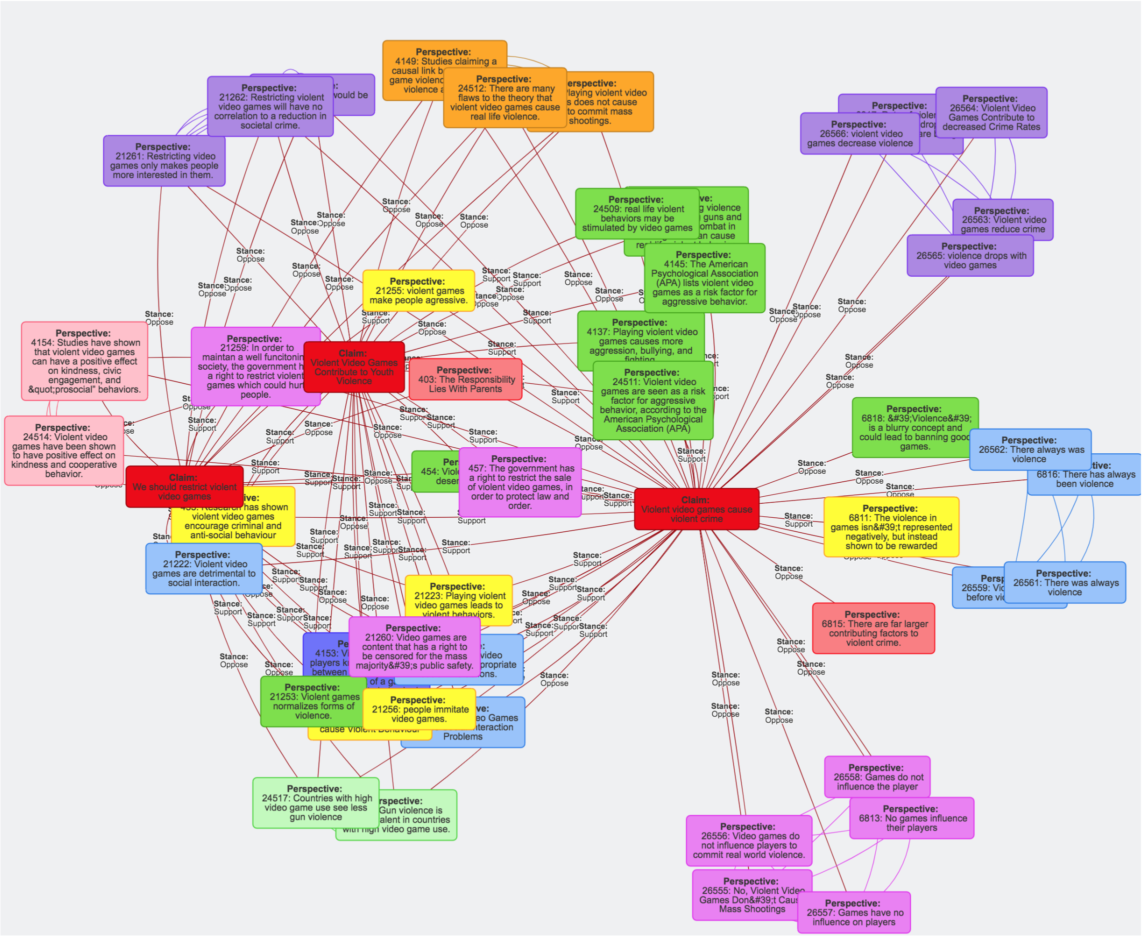

Figure 8: Graph visualization of three related example *claims* (colored in red) in our dataset with their *perspectives*. Each edge indicates a supporting/opposing relation between a perspective and a claim.

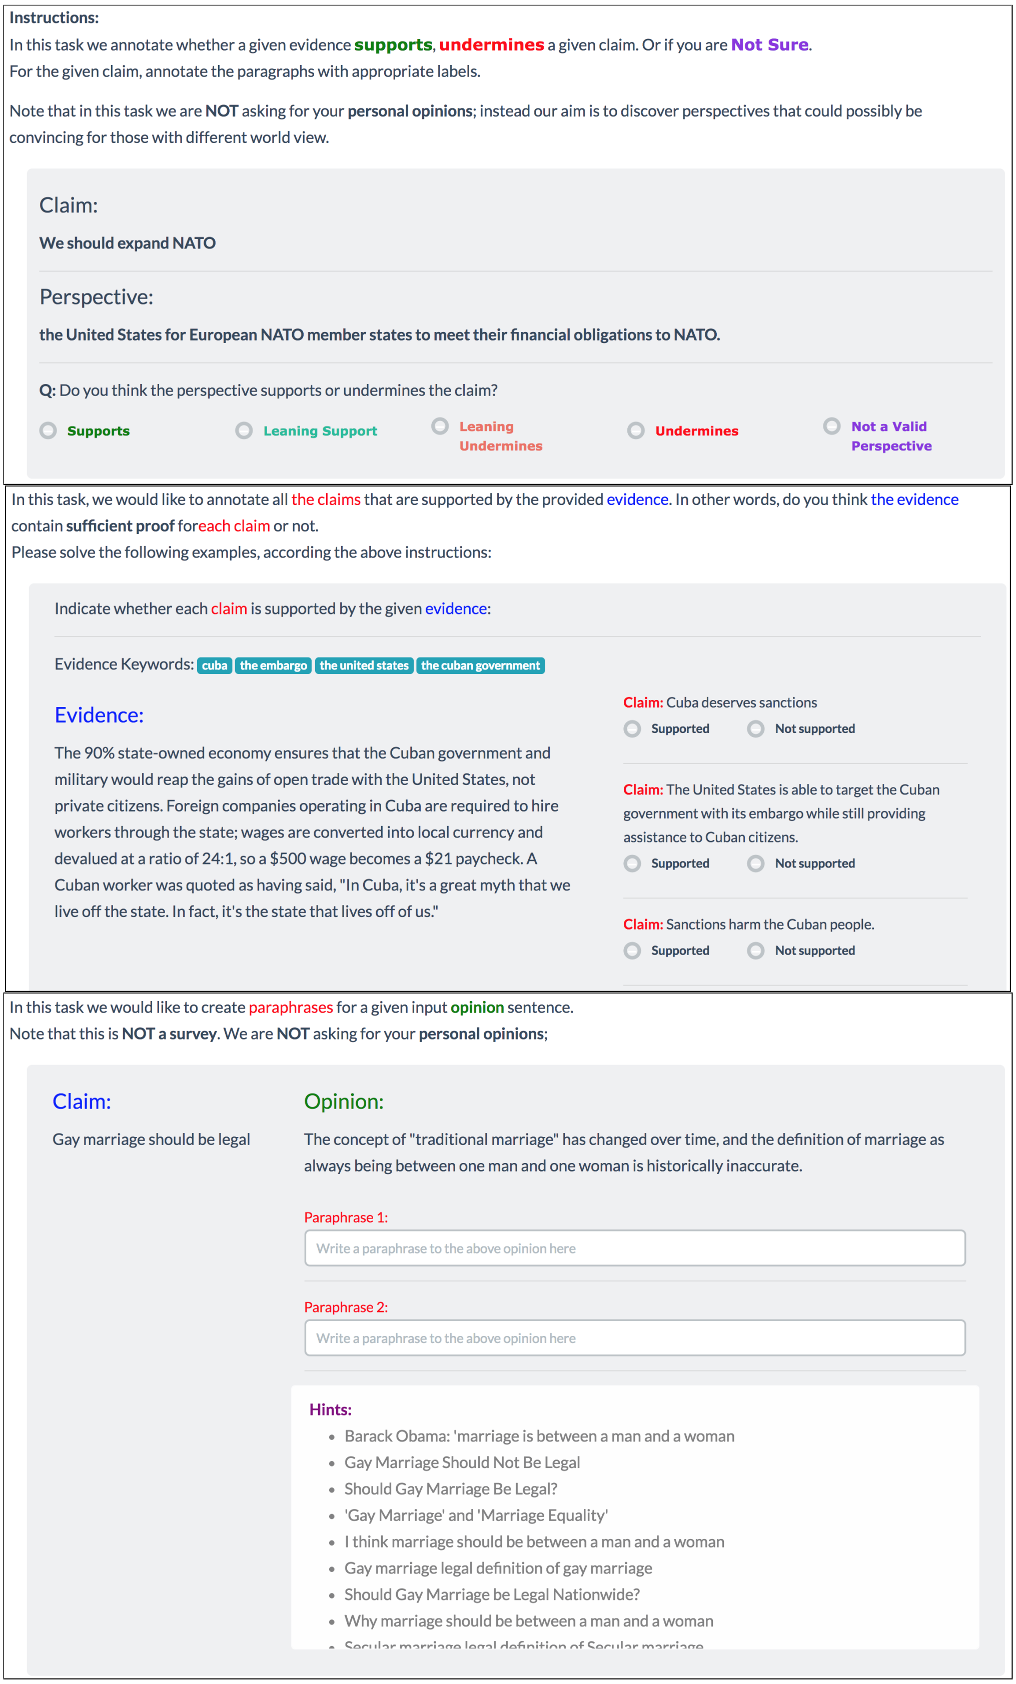


Instructions:
In this task we annotate whether a given evidence **supports**, **undermines** a given claim. Or if you are **Not Sure**.
For the given claim, annotate the paragraphs with appropriate labels.

Note that in this task we are **NOT** asking for your **personal opinions**; instead our aim is to discover perspectives that could possibly be convincing for those with different world view.

Claim:

We should expand NATO

Perspective:

the United States for European NATO member states to meet their financial obligations to NATO.

Q: Do you think the perspective supports or undermines the claim?

○ **Supports** ○ **Leaning Support** ○ **Leaning Undermines** ○ **Undermines** ○ **Not a Valid Perspective**

In this task, we would like to annotate all the claims that are supported by the provided evidence. In other words, do you think the evidence contain **sufficient proof** foreach claim or not.
Please solve the following examples, according the above instructions:

Indicate whether each claim is supported by the given evidence:

Evidence Keywords: cuba the embargo the united states the cuban government

Evidence:

The 90% state-owned economy ensures that the Cuban government and military would reap the gains of open trade with the United States, not private citizens. Foreign companies operating in Cuba are required to hire workers through the state; wages are converted into local currency and devalued at a ratio of 24:1, so a $500 wage becomes a $21 paycheck. A Cuban worker was quoted as having said, "In Cuba, it's a great myth that we live off the state. In fact, it's the state that lives off of us."

Claim: Cuba deserves sanctions
○ **Supported** ○ **Not supported**

Claim: The United States is able to target the Cuban government with its embargo while still providing assistance to Cuban citizens.
○ **Supported** ○ **Not supported**

Claim: Sanctions harm the Cuban people.
○ **Supported** ○ **Not supported**

In this task we would like to create paraphrases for a given input opinion sentence.
Note that this is **NOT a survey**. We are **NOT** asking for your **personal opinions**;

Claim:

Gay marriage should be legal

Opinion:

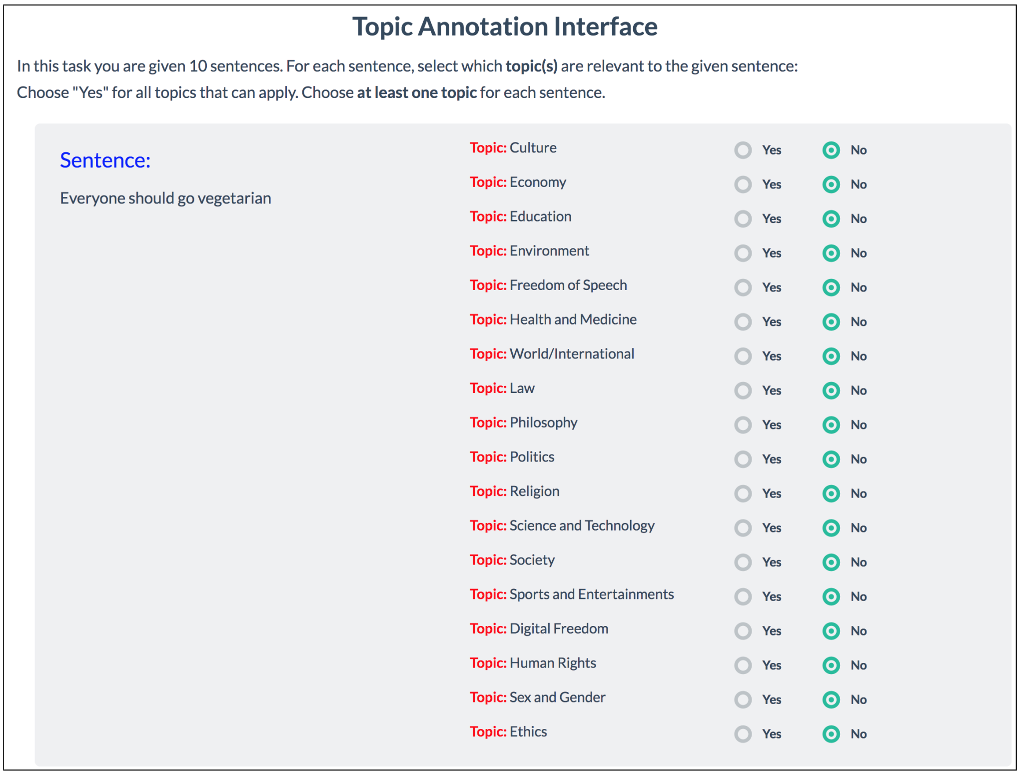
The concept of "traditional marriage" has changed over time, and the definition of marriage as always being between one man and one woman is historically inaccurate.

Paraphrase 1:
Write a paraphrase to the above opinion here

Paraphrase 2:
Write a paraphrase to the above opinion here

Hints:
- Barack Obama: 'marriage is between a man and a woman
- Gay Marriage Should Not Be Legal
- Should Gay Marriage Be Legal?
- 'Gay Marriage' and 'Marriage Equality'
- I think marriage should be between a man and a woman
- Gay marriage legal definition of gay marriage
- Should Gay Marriage be Legal Nationwide?
- Why marriage should be between a man and a woman
- Secular marriage legal definition of Secular marriage

Figure 9: Interfaces shown to the human annotators. Top: the interface for verification of perspectives (step 2a). Middle: the interface for annotation of evidences (step 3a). Bottom: the interface for generation of perspective paraphrases (step 2b).



Topic Annotation Interface

In this task you are given 10 sentences. For each sentence, select which **topic(s)** are relevant to the given sentence:
Choose "Yes" for all topics that can apply. Choose **at least one topic** for each sentence.

Sentence:

Everyone should go vegetarian

Topic: Culture ○ Yes ● No
Topic: Economy ○ Yes ● No
Topic: Education ○ Yes ● No
Topic: Environment ○ Yes ● No
Topic: Freedom of Speech ○ Yes ● No
Topic: Health and Medicine ○ Yes ● No
Topic: World/International ○ Yes ● No
Topic: Law ○ Yes ● No
Topic: Philosophy ○ Yes ● No
Topic: Politics ○ Yes ● No
Topic: Religion ○ Yes ● No
Topic: Science and Technology ○ Yes ● No
Topic: Society ○ Yes ● No
Topic: Sports and Entertainments ○ Yes ● No
Topic: Digital Freedom ○ Yes ● No
Topic: Human Rights ○ Yes ● No
Topic: Sex and Gender ○ Yes ● No
Topic: Ethics ○ Yes ● No

Abstract

Claims are the central component of an argument. Detecting claims across different domains or data sets can often be challenging due to their varying conceptualization. We propose to alleviate this problem by fine tuning a language model using a Reddit corpus of 5.5 million opinionated claims. These claims are self-labeled by their authors using the internet acronyms IMO/IMHO (in my (humble) opinion). Empirical results show that using this approach improves the state of art performance across four benchmark argumentation data sets by an average of 4 absolute F1 points in claim detection. As these data sets include diverse domains such as social media and student essays this improvement demonstrates the robustness of fine-tuning on this novel corpus.

1 Introduction

Toulmin's influential work on argumentation (2003) introduced a claim as an *assertion that deserves our attention*. More recent work describes a claim as *a statement that is in dispute and that we are trying to support with reasons* (Govier, 2010). While some traits of claims are defined by their context, such as that claims usually need some support to make up a 'complete' argument (e.g., premises, evidence, or justifications), the exact definition of a claim may vary depending on the domain, register, or task. Daxenberger et al. (2017) try to solve the problem of claim conceptualization by training models across one data set and testing on others, but their cross-domain claim detection experiments mostly led to decreased results over in-domain experiments.

To demonstrate that some properties of claims are shared across domains, we create a diverse and rich corpus mined from Reddit and evaluate on held out datasets from different sources. We use Universal Language Model Fine-Tuning (ULMFiT) (Howard and Ruder, 2018), which pre-trains a language model (LM) on a large general-domain corpus and fine-tunes it on our Reddit corpus before training a final classifier to identify claims on various data sets.

We make the following contributions:

- We release a dataset of 5.5 million opinionated claims from Reddit,[1] which we hope will be useful for computational argumentation.
- We show transfer learning helps in the detection of claims with varying definitions and conceptualizations across data sets from diverse domains such as social media and student essays.
- Empirical results show that using the Reddit corpus for language model fine-tuning improves the state-of-the-art performance across four benchmark argumentation data sets by an average of 4 absolute F1 points in claim detection.

2 Related Work

Argumentation mining (AM) is a research field within the growing area of computational argumentation. The tasks pursued within this field are highly challenging and include segmenting argumentative and non-argumentative text units, parsing argument structures, and recognizing argumentative components such as claims- the main focus of this work. On the modeling side, Stab and Gurevych (2017) and Persing and Ng (2016) used pipeline approaches for AM, combining parts of the pipeline using integer linear programming (ILP). Eger et al. (2017) proposed state-of-art sequence tagging neural end-to-end models for AM. Schulz et al. (2018) used multi-task learning (MTL) to identify argumentative components,

Minneapolis, Minnesota, June 2 - June 7, 2019.

challenging assumptions that conceptualizations across AM data sets are divergent and that MTL is difficult for semantic or higher-level tasks.

Rosenthal and McKeown (2012) were among the first to conduct cross-domain experiments for claim detection. However they focused on relatively similar data sets like blog articles from LiveJournal and Wikipedia discussions. Al-Khatib et al. (2016), on the other hand, wanted to identify argumentative sentences through cross-domain experiments. Their goal was, however, to improve argumentation mining via distant supervision rather than detecting differences in the notions of a claim. Daxenberger et al. (2017) showed that while the divergent conceptualization of claims in different data sets is indeed harmful to cross-domain classification, there are shared properties on the lexical level as well as system configurations that can help to overcome these gaps. To this end they carried out experiments using models with engineered features and deep learning to identify claims in a cross-domain fashion.

Pre-trained language models have been recently used to achieve state-of-the-art results on a wide range of NLP tasks (e.g., sequence labeling and sentence classification). Some of the recent works that have employed pre-trained language models include ULMFiT (Howard and Ruder, 2018), ELMo (Peters et al., 2018), GLoMo (Yang et al., 2018), BERT (Devlin et al., 2019) and OpenAI transformer (Radford et al., 2018). While these models have demonstrated success on a variety of tasks, they have yet to be widely used in argumentation mining.

3 Data

As the goal of our experiments is to develop models that generalize across domains, we collect a large, diverse dataset from social media and fine-tune and evaluate on held out data sets.

3.1 Self-labeled Opinion Data Collection

In order to obtain a data set representative of claims, we need a method of automatic data collection that introduces minimal linguistic bias. We thus mine comments containing the acronyms IMO (in my opinion) or IMHO (in my humble opinion) from the social media site Reddit. IM(H)O is a commonly used acronym[2] with the only purpose of identifying one's own comment as a personal opinion. We provide some examples[3] below:

> That's virtually the same as neglect right there **IMHO**.
>
> **IMO**, Lakers are in big trouble next couple years

To use these examples for pre-training, we need only to remove the acronym (and any resulting unnecessary punctuation).

We collect Reddit comments from December 2008 to August 2017 through the pushshift.io API, resulting in 5,569,962 comments. We perform sentence and word tokenization using Spacy. We then extract only the sentence containing IMO or IMHO and discarded the surrounding text. We refer to the resulting collection of comments as the **IMHO** dataset.

3.2 Labeled Claim Data

The IMHO dataset contains no negative examples, only labeled opinions. Furthermore, opinions in this dataset may be only a claim or both a claim and a premise. As our goal is to identify claims, we thus consider four data sets from argumentation mining. As argumentation appears in both monologue and dialogue data, we choose two datasets created from student essays and two from social media. Peldszus and Stede (2016) created a corpus of German microtexts (**MT**) of controlled linguistic and rhetorical complexity. Each document includes a single argument and does not exceed five argumentative components. This corpus was translated to English, which we use for our experiments. The persuasive essay (**PE**) corpus (Stab and Gurevych, 2017) includes 402 student essays. The scheme comprises major claims, claims, and premises at the clause level. This corpus has been used extensively in the argumentation mining community. The corpus from Habernal and Gurevych (2017) includes user-generated web discourse (**WD**) such as blog posts, or user comments annotated with claims and premises as well as backings, rebuttals and refutations. Finally, Hidey et al. (2017) propose a two-tiered annotation scheme to label claims and premises and their semantic types in an online persuasive forum (**CMV**) using a sample of 78 threads from the sub-reddit Change My View, with the long-term goal

[3] Examples have been modified to protect user privacy

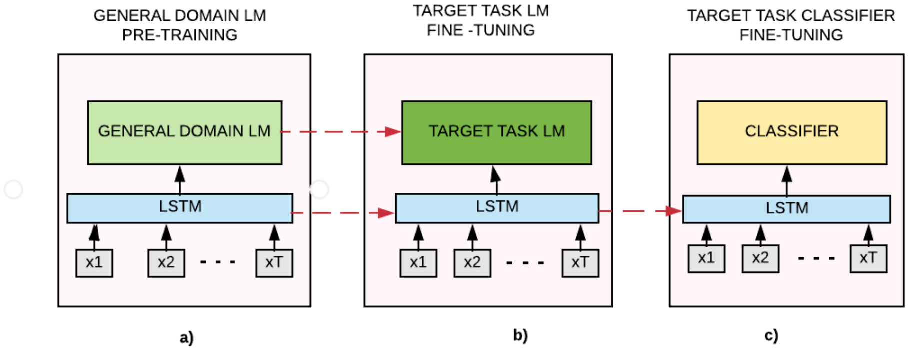

Figure 1: Schematic of ULMFiT, showing three stages. The dashed arrows indicate that the parameters from the previous stage were used to initialize the next stage.

	#Claims	#Sentences	%Claims
MT	112	449	24.94
PE	2108	7116	29.62
WD	211	3899	5.41
CMV	1206	3541	34.0

Table 1: Table showing number of claims and total number of sentences in the data sets along with the percentage of claims in them

of understanding what makes a message persuasive. As with Daxenberger et al. (2017), we model claim detection at the sentence level, as this is the only way to make all data sets compatible to each other. Table 1 gives an overview of the data.

4 Model

As the IMHO dataset is only self-labeled with claim data but does not contain non-claims, we need a method of incorporating this dataset into a claim detection model. We thus use a language model fine-tuning approach, which requires only data similar to the task of interest.

The Universal Language Model Fine-Tuning method (ULMFiT) (Howard and Ruder, 2018) consists of the following steps: a) General-domain LM pre-training b) Task-specific LM fine-tuning and c) Task-specific classifier fine-tuning. In step (a), the language model is trained on Wikitext-103 (Merity et al., 2017) consisting of 28,595 preprocessed Wikipedia articles and 103 million words capturing general properties of language. Step (b) fine-tunes the LM on task-specific data, as no matter how diverse the general-domain data used for pre-training is, the data of the target task will likely come from a different distribution. In step (c), a classifier is then trained on the target task, fine-tuning the pre-trained LM but with an additional layer for class prediction. The models all use a stacked LSTM to represent each sentence. For stages (a) and (b), the output of the LSTM is used to make a prediction of the next token and the parameters from stage (a) are used to initialize stage (b). For stage (c), the model is initialized with the same LSTM but with a new classifier layer given the output of the LSTM.

This process is illustrated in Figure 1. We refer the reader to Howard and Ruder (2018) for further details.

In our work, we maintain steps (a) and (c) but modify step (b) so that we fine-tune the language model on our IMHO dataset rather than the task-specific data. The goal of ULMFiT is to allow training on small datasets of only a few hundred examples, but our experiments will show that fine-tuning the language model on opinionated claims improves over only task-specific LM fine-tuning.

5 Results and Experiments

Table 2 show the results on the four data sets. We compare to two baselines. The numbers in the **CNN** column are taken directly from the results of the deep learning experiments mentioned in the work of Daxenberger et al. (2017). Their deep learning experiments consisted of 4 different models: a) bidirectional LSTM b) LSTM c) CNN initialized with random word embeddings and d) CNN initialized with word2vec. In their experiments for MT and PE, a CNN initialized with random word embeddings gave the best results and for WD a CNN with word2vec gave the best results. As CMV is a new data set we experimented with all four models and obtained the best result using a CNN with random initialization. The **Task-Specific LM Fine-Tuning** column

	Metric	CNN		Task-Specific LM Fine-Tuning		IMHO LM Fine-Tuning	
		Claim	Macro	Claim	Macro	Claim	Macro
WD	P	50.0	72.5	50.0	72.5	**54.0**	**75.9**
	R	20.4	59.2	20.0	59.8	**24.0**	**61.7**
	F	28.9	62.6	28.5	62.7	**33.3**	**65.2**
MT	P	66.5	79.0	66.2	78.5	**71.0**	**80.9**
	R	68.2	78.5	68.0	77.8	**71.8**	**81.4**
	F	67.3	78.6	67.0	78.1	**71.2**	**81.1**
PE	P	60.9	73.2	62.3	73.2	**62.6**	**74.4**
	R	61.2	74.0	65.8	75.1	**66.0**	**75.0**
	F	61.1	73.6	64.0	74.1	**64.3**	**74.8**
CMV	P	54.0	65.1	55.0	68.0	**55.7**	**69.5**
	R	53.0	62.5	59.0	65.0	**60.0**	**65.3**
	F	53.5	63.8	57.0	66.4	**57.8**	**67.3**

Table 2: Table showing the results on four data sets. Each cell contains the Precision (P), Recall (R) and F-score (F) for Claims as well as the Macro Precision, Recall and F-score for the binary classification.

contains the results obtained by fine-tuning the language model on each respective dataset while the **IMHO LM Fine-Tuning** column contains the results from fine-tuning the language model on IMHO. As in previous work, we report both Claim F1 and Macro F1.

The experiments were carried out in a 10-fold cross-validation setup with fixed splits into training and test data and the F1 scores are averaged over each of the folds. Each model was run 10 times to account for variance and the results reported in the table are an average of 10 runs. We use the same hyper-parameters as Howard and Ruder (2018) except for a batch size of 32 for MT and 64 for the remaining data sets. The learning rate for classifier fine-tuning is set to 0.0001. We train our classifier for 5 epochs on each data set.

We obtain statistically significant results ($p < 0.05$ using Chi Squared Test) over all CNN models trained only on the task-specific datasets. We also find that for all models, IMHO LM Fine-Tuning even performs better than Task-Specific LM Fine-Tuning, and is significantly better for the MT and WD datasets (which both contain very few claims). For the MT and WD datasets, Task-Specific LM Fine-Tuning actually performs worse than the CNN models.

6 Qualitative Analysis

To understand how using the IMHO dataset improved over the CNN and Task-Specific Fine-Tuning settings, we show examples that were incorrectly classified by the two baseline models but correctly classified by the IMHO Fine-Tuning. We retrieve the most similar example in the IMHO dataset to these misclassified samples according to TF-IDF over unigrams and bigrams. Table 3 presents the examples labeled by their dataset and the corresponding IMHO example. We find that the IMHO dataset contains n-grams indicative of claims, e.g. *can be very rewarding*, *should be taken off the market*, and *should intervene*, demonstrating that the IMHO LM Fine-Tuning learns representations of claims based on discriminatory phrases. In fact, the CMV example is almost an exact paraphrase of the IMHO example, differing only in the phrase *anecdotal evidence* compared to *my anecdotal experience*. At the same time, we find that many of the topics in these datasets occur in the IMHO dataset as well, such as *public schooling* and *licence fees*, suggesting that the language model learns a bias towards topics as well.

While empirical results indicate that IMHO Fine-Tuning helps in claim detection, we also investigated whether the language model introduces any bias towards types of claims. To this end, we also evaluated examples classified incorrectly by the model. Table 4 shows sentences that are predicted to be opinionated claims by our model but are actually non-claims. We note that a portion of these misclassified examples were premises used to back a claim which could be classified correctly given additional context. For instance, the second example from the MT data set in the table backs

Dataset	Sentence
MT	If there must be rent increases , there should also be a cap to avoid nasty surprises
MT	Video games namely FIFA in my case , can fascinate young people for hours more intensively and emotionally than any sport in the world !
PE	Last but not the least , using public transportation is much safer than using private transportation
PE	In a positive point of view , when people without jobs have hand phones that have access to the internet , they will be able to browse the net for more job opportunities
CMV	Cheating is evidence , that *something* must be wrong

Table 4: Sentences which are actually non-claims but predicted as claims by IMHO Fine-Tuning

Dataset	Sentence
WD	I send my daughter to public school but if I could afford to I would definitely send her to a nearby private school and not have to deal with lots of the problems in public schools.
IMHO	There is no telling that a private school will be better than public, that 's a parents choice, I pulled my kid from private school and went to public school that choice was made because the school we had access to was new and he excellent ratings and it was superior to the private school.
MT	That's why they should be taken off the market, unless they're unbreakable .
IMHO	Should be taken off the market.
MT	The Tv/Radio licence fee can only be required of all citizens/households equally.
IMHO	Radio 4 and Radio 6 music are pretty much worth the licence fee.
MT	Since, however, in Russia besides gas and oil only propaganda and corruption rule, the EU should intervene right away.
IMHO	Neither Russia or the EU should intervene in this case
CMV	Other than anecdotal evidence, I haven't seen anything to support this claim.
IMHO	I have personally seen no evidence to support this claim, but that's just my anecdotal experience .
PE	However, flourishing tourism in a place can be very rewarding in terms of local economy.
IMHO	It can be very rewarding.

Table 3: Sentences from each dataset and their nearest neighbor in the IMHO dataset

the claim *It would be fair to make them into an Olympic event* while the first example from the PE data set backs the claim *There is no reason that governments should hesitate to invest in public transportation, a healthy, safe and economical way of transporting*. While discriminatory phrases like *should* or *must be* and comparative statements like *much safer than* or *more ... than any* are often indicative of claims, the lack of context may lead to incorrect classifications. Language modeling with additional context sentences or jointly modeling context (e.g. by predicting relations between claims and premises) may address these errors.

7 Conclusion

We have collected a large dataset of over 5 million self-labeled opinionated claims and validated their utility on a variety of claim detection domains. Second, we demonstrate that by fine-tuning the language model on our IMHO dataset rather than each individual claim dataset, we obtain statistically significant improvement over previous state-of-the-art performance on each of these datasets on claim detection. Finally, our empirical results and error analysis show that there are features indicative of claims that transfer across data-sets.

In the future, we plan to expand this work beyond single sentences as the data-set for LM Fine-Tuning used in our experiments consists of sentences containing IM(H)O without additional context. We plan to experiment with modeling the context sentences from Reddit as well by using models such as BERT (Devlin et al., 2019), which perform well on pair classification tasks, as the fine-tuning step rather than ULMFiT. As BERT pre-training includes a next-sentence prediction task, we expect this model to be effective for modeling argumentative context and to be beneficial for predicting premise or justifications for these claims and the relations between these argumentative components.

Abstract

Neural network models have recently gained traction for sentence-level intent classification and token-based slot-label identification. In many real-world scenarios, users have multiple intents in the same utterance, and a token-level slot label can belong to more than one intent. We investigate an attention-based neural network model that performs multi-label classification for identifying multiple intents and produces labels for both intents and slot-labels at the token-level. We show state-of-the-art performance for both intent detection and slot-label identification by comparing against strong, recently proposed models. Our model provides a small but statistically significant improvement of 0.2% on the predominantly single-intent ATIS public data set, and 55% intent accuracy improvement on an internal multi-intent dataset.

1 Introduction

In dialog systems, the natural language understanding component (NLU) is responsible for identifying the user's request and creating a semantic frame that succinctly summarizes the user's needs. These semantic frames are typically constructed using *intents* and *slot-labels* (Tür et al., 2010). As the names imply, an intent captures the intention of the user and slot-labels capture any additional information or constraints the user provides. These constraints must be satisfied in order to fulfill the user's request. The example below shows a user's request, *"how is the weather in Dallas ?"*. We need to identify the intent (*"GetWeatherInfo"*) as well as the values for the slot-labels (SL), here, *"City"* (value=*"Dallas"*). It is crucial that intents and slot-labels are identified with high accuracy as an error made by the NLU component propagates through downstream components such as the dialog state tracker, the dialog policy and the natural language generator components, leading to a substantial degradation of the performance of the entire dialog system.

NLU Semantic Frame

	how	is	the	weather	in	Dallas	?
	↕	↕	↕	↕	↕	↕	↕
SL:	O	O	O	O	O	City	O

Intent: GetWeatherInfo

Intent detection has been modeled as a sentence classification task where an intent (y^I) is assigned to the user's utterance. Slot labeling is typically modeled as a sequential labeling problem, where a user's sentence, $x_1, x_2, ...x_N$, is labeled with $y_1^S, y_2^S, ..y_N^S$, and y_i^S is the slot label assigned to the token at position i (x_i). In the example above, the sequence of slot labels would be, *"O O O O O City O"*, where, *"O"* stands for *"Other"*.

Sequential models such as Maximum Entropy Markov models (Toutanova and Manning, 2000; McCallum et al., 2000; Berger et al., 1996) and Conditional Random Fields, CRFs (Lafferty et al., 2001; Jeong and Geunbae Lee, 2008) are popular approaches for slot-labeling while intent prediction is often performed using standard classification approaches such as Support Vector Machines (Cortes and Vapnik, 1995) or logistic regression (Bishop, 2006). More recently, neural network-based models (Mesnil et al., 2015; Kurata et al., 2016; Goo et al., 2018; Liu and Lane, 2016) have been shown to significantly outperform previous approaches. These models are also appealing since a single model is trained end-to-end to perform both intent detection and slot label identification. Jointly modeling intent and slot label identification (Liu and Lane, 2016; Goo et al., 2018) has been shown to significantly outperform other neural network-based approaches. This is intuitive since slot labels could depend on the intent.

Proceedings of NAACL-HLT 2019, pages 564–569

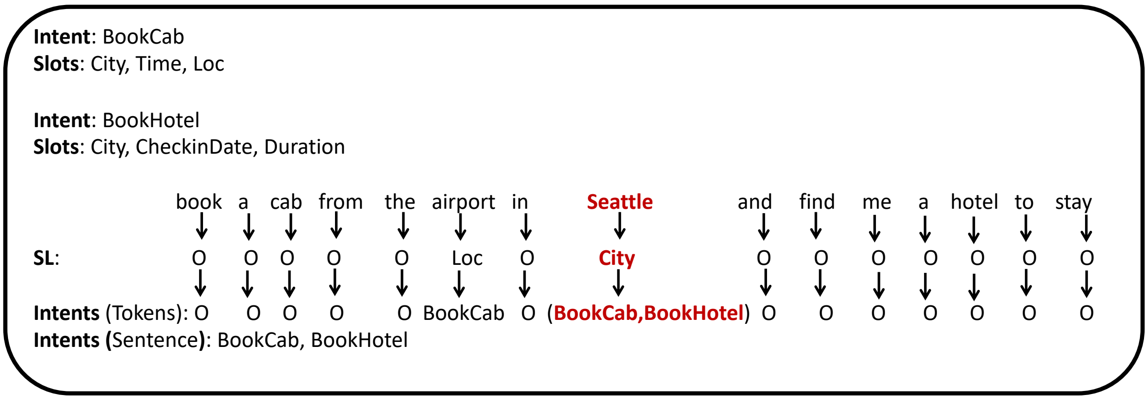

Figure 1: An example showing slot values belonging to multiple intents. Here, *Seattle* belongs to two of the intents in the user's utterance, *BookHotel* and *BookCab*.

Most neural network-based approaches (Mesnil et al., 2015; Kurata et al., 2016; Goo et al., 2018; Liu and Lane, 2016), with the exception of (Xu and Sarikaya, 2013a), predict a single intent for a user's utterance. In real-world scenarios, users indicate multiple intents in the same utterance. For example, a user's utterance such as, *"show me flights from Dallas to New York and the cost"*, clearly has two intents, one for obtaining the price of the flights (*"GetFlightCost"*) and another for the flight information. It is critical to understand and model such scenarios to allow more natural interaction with users. In this paper, we treat the intent detection task as a multi-label classification problem and suggest various neural network models to obtain multiple intents.

Our work is related to Xu et al.,(2013b) and Kim et al.,(2017), where multiple intents are assigned to a user's utterance. Xu et al., (2013b) use log-linear models to achieve this, while we use neural network models. Both Xu et al., (2013b) and Kim et al., (2017) only consider intents and do not handle slot labels. In this paper, we jointly perform multi-label intent classification and slot-label identification.

In contrast with all prior work, we investigate and study the problem of assigning slot labels (or constraints) provided by a user to multiple intents. Consider the example in Figure 1 with two intents in the same domain, *"BookCab"* and *"BookHotel"*. Suppose *"BookCab"* has three possible slot labels, *"City"*, *"Time"* and pick up location (*"Loc"*), and suppose that *"BookHotel"* has slot labels *"City"*, *"CheckinDate"*, and *"Duration"*. Consider a user's utterance, *"book a cab from the airport in Seattle and find me a hotel to stay"*. Here, the user wants to book a cab (*"BookCab"* intent) as well book a hotel (*"BookHotel"*). The slot label *"Seattle"* should be assigned to both intents to accurately capture the user's request. Hence, we study a model that predicts multiple intents both at the token level as well as at the sentence-level.

We model token-level multi-intent classification using Long Short Term Memory (LSTMs) units to capture dependencies that may exist between intents. For example, a user who wants to book a cab is also likely to make a request for a hotel in the same utterance but probably not order food i.e., intents such as *"BookCab"* and *"BookHotel"* are more likely to occur together when compared to *"BookCab"* and *"OrderFood"*. To summarize, the contributions of this paper are:

- We investigate approaches to the problem of multi-intent classification. We perform joint multi-intent classification both at sentence-level and at token-level. We see that,
  - the token-level multi-intents help assign user constraints to the intents.
  - sentence-level multi-intent classification captures dependencies between intents.
- We compare the performance of the approach with recently proposed state-of-the-art approaches and show significant improvement.

The paper is organized as follows. Section 2 describes the proposed approach. Section 3 describes the experimental setup, including, data sets and metrics used to evaluate the approaches followed by the results in Section 3.2. Finally, we conclude and suggest possible future directions and extensions in Section 4.

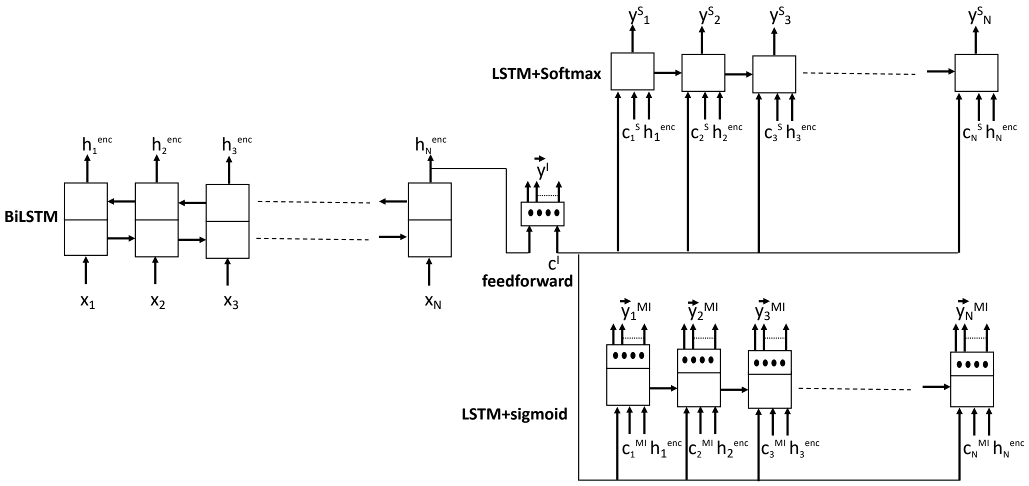

Figure 2: Proposed Approach. A bidirectional LSTM is used for the encoder layer. Multiple intents are predicted both at the sentence level (y^I) and at the token level (y^{MI}). y^I uses a feedforward network. Slot labels (y^S) and token level intent prediction (y^{MI}) both use LSTM layers, which have skip connections to the encoder states.

2 Proposed Approaches

LSTM-based RNN models have become popular for sequential labeling, especially in natural language processing tasks, due to their ability to model long-term dependencies. We extend encoder-decoder architectures from Liu et al., (2016) and Gangadharaiah et al., (2018), which showed superior performance when compared to Convolutional neural network based CRFs (Xu and Sarikaya, 2013a) and other RNN-based architectures (Mesnil et al., 2015; Kurata et al., 2016) for intent detect and slot label identification.

We use a bidirectional LSTM encoder to encode the input word sequence. The encoder hidden state, h_i^{enc}, at each word position is a concatenation of the forward state (fh_i) and backward state (bh_i), $h_i^{enc} = [fh_i, bh_i]$.

For intent detection at the sentence-level, a context vector c^I is computed using the encoder's final hidden state. The vectors, c^I and the final encoder's hidden state vector are sent to a dense layer of sigmoid units to predict the probabilities for every intent. This produces multiple intents ($\vec{y}^I$) as opposed to previous approaches that produce a single intent.

For slot labeling, the decoder also uses LSTMs. At each decoding step i, the decoder state ($h_i^{S,dec}$) is a function of the previous decoder state ($h_{i-1}^{S,dec}$), the previously emitted label (y_{i-1}^S), the encoder's state ($h_i^{S,enc}$), the context vectors, (c_i^S) and c^I, as shown in Figure 2. The context vector c_i^S is a weighted combination of the encoder's states ($h_1^{enc}, h_2^{enc}, ...h_N^{enc}$) with weights, $\alpha_{i,j}^S$, as shown in eqn. 1. g is a feed forward network.

$$c_i^S = \sum_{j=1}^{N} \alpha_{i,j}^S h_j^{enc} \tag{1}$$

$$\alpha_{i,j}^S = \frac{exp(e_{i,j})}{\sum_{k=1}^{N} exp(e_{i,k})}$$

$$e_{i,k} = g(h_{i-1}^{S,dec}, h_k^{enc})$$

The output of the LSTM layer is then sent to a softmax layer to predict the slot labels. We also experimented with a CRF layer as the decoder. In our preliminary experiments, the LSTM decoder was faster to train and also showed better performance when compared to the CRF layer and hence we use LSTMs in the experiments below. We also apply a slot-gated mechanism similar to Goo et al., (2018). The idea is to leverage the intent's context vector for modeling slot-intent relationships, thereby improving the performance of slot labeling. The slot gate is computed as a function of both the slot context vector (c_i^S) and the intent context vector (c^I), where, v and W are both trainable. In Goo et al., (2018), a similar model showed at-par or better performance over Liu et al. (2016) and Tür et. al. (2016). The slot gate gS is defined as,

$$gS = \sum v \cdot tanh(c_i^S + W \cdot c^I) \tag{2}$$

where, gS is used to weight h_i^{enc} and c_i^S to obtain y_i^S, i.e., $h_i^{enc} + c_i^S \cdot gS$ is sent to the feed forward network to compute y_i^S.

Since a slot label can belong to multiple intents, we also perform multi-label intent detection at the token level. We again use an LSTM decoder, where each decoder state, $h_i^{MI,dec}$, is a function of c^I, previous decoder state ($h_{i-1}^{MI,dec}$), the encoder's state (h_i^{enc}) and the context vector (c_i^{MI}), as shown in Figure 2. c_i^{MI} is computed in the same manner as c_i^S. The output of the decoder is sent to a dense layer with sigmoid units. Thus at each word position, we predict multiple intents.

3 Experiments

In all our experiments, we set the hidden vectors to a dimension of 64 and use the adam optimizer with an early stopping strategy. We use a drop-out rate of 0.5 for regularization and the maximum norm for gradient clipping is set to 5. The results are obtained by averaging the performance of the models over 10 runs. To do a fair comparison against existing models, we do not pre-train our word embeddings (Devlin et al., 2018; Pennington et al., 2014; Mikolov et al., 2013), instead we use an embedding layer in the model which is trained along with the rest of the model's parameters.

As done in the NLU community, we report F1 scores for slot labeling. We use F1 scores for intent detection at the token-level and accuracy for sentence-level intent detection.

3.1 Datasets

We use two widely used public datasets, ATIS (Airline Travel Information System) (Tür et al., 2010) and SNIPS [1]. The ATIS dataset contains audio recordings of people requesting flight reservations, with 21 intent types and 120 slot labels. There are 4,478 utterances in the training set, 893 in the test set and 500 utterances in the development set. The SNIPS data was collected from the SNIPS personal voice assistant, with 7 intent types and 72 slot labels. The training set contains 13,084 utterances, the test set contains 700 utterances and the development set also contains 700 utterances. The ATIS dataset contains utterances with multi intents, while the SNIPS is only single intent. In order to demonstrate that our approach does not degrade performance on single intent datasets, we also perform evaluations on the SNIPS dataset.

We also test the performance of the models on an internal dataset. In this dataset, about 52% of examples are multi-intent compared to ATIS which has ≈2% of test examples with multi-intents. The average number of intents per utterance in the internal dataset is 1.6.

3.2 Results

We compare our approach against two of the state of the art approaches that have shown the best performance in previous work. We will use **Model 1** to refer to the model proposed by Liu et al., (2016). **Model 2** refers to the more recent model proposed by Goo et al., (2018). Table **??** shows results obtained by the model investigated in this paper when compared with Model 1 and Model 2.

As mentioned earlier, both Models 1 and 2 only handle single intents per user utterance. For these two models, we insert a # between the multiple intents and treat it as one single intent, i.e., when an example such as, *"please give me a list of all the flights between dallas and baltimore and their cost"*, contains multiple intents, *"atis_flight"* and *"atis_airfare"*, we use *"atis_flight#atis_airfare"* instead. When evaluating the baselines, the ordering of intents does not matter, and so we replace the # with spaces once we have the predictions.

To allow comparison across approaches, both ATIS and SNIPS were modified to include token-level intents as follows. For utterances that had only a single intent, we assigned this intent to all tokens that had a slot label (i.e., to slot labels that do not correspond to O). For utterances that had more than one intent, we assigned all intents to all tokens that had slot labels. After this process, if an utterance had two intents, $intent_1$ and $intent_2$, and if a token i had a slot label, the token would end up with targets of the form,

$$(slot^i, intent_1^i, intent_2^i)$$

The proposed model shows a statistically significant improvement in sentence-level intent prediction (S-level) on ATIS when compared to the two baselines. Any improvement in slot labeling is unclear, since this could be attributed to the architecture changes which involved additional penalty terms on the intent (since we use both token-level and sentence-level intent loss). We also notice that the performance on SNIPS (a single intent dataset) does not degrade. We see a larger performance boost in both token-level (T-level) and sentence-level (S-level) intent detection on the internal dataset due to the large percentage of examples with multi-intents. Wilcoxon signed-rank test

Table 1: Performance of the model against Model 1 and Model 2. We report F1 scores for slot labeling. For intent detection, we use F1 scores for intent detection at the token-level (T-level) and accuracies (acc) for sentence-level (S-level) intent detection. N/A: as Models 1 and 2 perform single intent detection only at S-level.

(Wilcoxon, 1945) was used to find statistical significance.

4 Conclusion and Future Work

The paper investigated an approach for multi-intent classification. We perform multi-intent classification both at sentence-level and at token-level. The token-level multi-label classification helped assign common constraints (or slot labels) to multiple intents, improving accuracy. The sentence-level multi-intent classification captured dependencies between intents. We compared the performance of our approach with previously proposed state-of-the-art approaches for single intent classification and showed significant improvements in performance on all the datasets.

As future work, we would like to explore other architectures to directly model dependencies between slot labels and intents. This is useful since only a subset of slot labels occur with certain intents. We will also test the proposed approaches against real-world scenarios to understand their generality across various domains.

Abstract

This paper presents a novel crowd-sourced resource for multimodal discourse: our resource characterizes inferences in image–text contexts in the domain of cooking recipes in the form of coherence relations. Like previous corpora annotating discourse structure between text arguments, such as the Penn Discourse Treebank, our new corpus aids in establishing a better understanding of natural communication and common-sense reasoning, while our findings have implications for a wide range of applications, such as understanding and generation of multimodal documents.

1 Introduction

"*Sometimes a picture is worth the proverbial thousand words; sometimes a few well-chosen words are far more effective than a picture*" – Feiner and McKeown (1991). Modeling how visual and linguistic information can jointly contribute to coherent and effective communication is a longstanding open problem with implications across cognitive science. As Feiner and McKeown (1991) already observe, it is particularly important for automating the understanding and generation of text–image presentations. Theoretical models have suggested that images and text fit together into integrated presentations via *coherence relations* that are analogous to those that connect text spans in discourse; see Alikhani and Stone (2018a) and Section 2. This paper follows up this theoretical perspective through systematic corpus investigation.

We are inspired by research on text discourse, which has led to large-scale corpora with information about discourse structure and discourse semantics. The Penn Discourse Treebank (PDTB) is one of the most well-known examples (Miltsakaki et al., 2004; Prasad et al., 2008). However, although multimodal corpora increasingly include discourse relations between linguistic and nonlinguistic contributions, particularly for utterances and other events in dialogue (Cuayáhuitl et al., 2015; Hunter et al., 2015), to date there has existed no dataset describing the coherence of text–image presentations. In this paper, we describe the construction of an annotated corpus that fills this gap, and report initial analyses of the communicative inferences that connect text and accompanying images in this corpus.

As we describe in Section 2, our approach asks annotators to identify the presence of specific inferences linking text and images, rather than to use a taxonomy of coherence relations. This enables us to deal with the distinctive discourse contributions of photographic imagery. We describe our data collection process in Section 3, showing that our annotation scheme allows us to get reliable labels by crowdsourcing. We present analyses in Section 4 that show that our annotation highlights a range of cases where text and images work together in distinctive and theoretically challenging ways, and discuss the implications of our work for the understanding and generation of multimodal documents. We conclude in Section 5 with a number of problems for future research.

2 Discourse Coherence and Text–Image Presentations

We begin with an example to motivate our approach and clarify its relationship to previous work. Figure 1 shows two steps in an online recipe for a ravioli casserole from the RecipeQA data set (Yagcioglu et al., 2018). The image of Figure 1a shows a moment towards the end of carrying out the "covering" action of the accompanying text; that of Figure 1b shows one instance of the result of the "spooning" actions of the text. Cognitive scientists have argued that such images are

much like text contributions in the way their interpretation connects to the broader discourse. In particular, inferences analogous to those used to interpret text seem to be necessary with such images to recognize their spatio-temporal perspective (Cumming et al., 2017), the objects they depict (Abusch, 2013), and their place in the arc of narrative progression (McCloud, 1993; Cohn, 2013). In fact, such inferences seem to be a general feature of multimodal communication, applying also in the coherent relationships of utterance to co-speech gesture (Lascarides and Stone, 2009) or the coherent relationships of elements in diagrams (Alikhani and Stone, 2018b; Hiippala and Orekhova, 2018).

In empirical analyses of text corpora, researchers in projects such as the Penn Discourse Treebank (Miltsakaki et al., 2004; Prasad et al., 2008) have been successful at documenting such effects by annotating discourse structure and discourse semantics via coherence relations. We would like to apply a similar strategy to text–image documents like that shown in Figure 1. However, existing discourse annotation guidelines depend on the distinctive ways that coherence is signaled in text. In text, we find syntactic devices such as structural parallelism, semantic devices such as negation, and pragmatic elements such as discourse connectives, all of which can help annotators to recognize coherence relations in text. Images lack such features. At the same time, characterizing the communicative role of imagery, particularly photographic imagery, involves a special problem: distinguishing the content that the author specifically aimed to depict from merely incidental details that happen to appear in the scene (Stone and Stojnic, 2015).

Thus, rather than start from a taxonomy of discourse relations like that used in PDTB, we characterize the different kinds of inferential relationships involved in interpreting imagery separately.

- To characterize temporal relationships between imagery and text, we ask if the image gives information about the preparation, execution or results of the accompanying step.
- To characterize the logical relationship of imagery to text, we ask if the image shows one of several actions described in the text, and if it depicts an action that needs to be repeated.
- To characterize the significance of incidental detail, we ask a range of further questions (some relevant specifically to our domain of instructions), asking about what the image depicts from the text, what it leaves out from the text, and what it adds to the text.

Our approach is designed to elicit judgments that crowd workers can provide quickly and reliably.

This approach allows us to highlight a number of common patterns that we can think of as prototypical coherence relations between images and text. Figure 1a, for example, instantiates a natural **Depiction** relation: the image shows the action described in the text in progress; the mechanics of the action are fully visible in the image, but the significant details in the imagery are all reported in the text as well. Our approach also lets us recognize more sophisticated inferential relationships, like the fact that Figure 1b shows an **Example:Result** of the accompanying instruction. Many of the relationships that emerge from our annotation effort involve newly-identified features of text–image presentations that deserve further investigation: particularly, the use of loosely-related imagery to provide background and motivation for a multimodal presentation as a whole, and depictions of action that seem simultaneously to give key information about the context, manner and result of an action.

3 Annotation Effort[1]

Work on text has found that text genre heavily influences both the kinds of discourse relations one finds in a corpus and the way those relations are signalled (Webber, 2009). Since our focus is on developing methodology for consistent annotation, we therefore choose to work within a single genre. We selected instructional text because of its concrete, practical subject matter and because of its step-by-step organization, which makes it possible to automatically group together short segments of related text and imagery.

Text–Image Pairs. We base our data collection on an existing instructional dataset, RecipeQA (Yagcioglu et al., 2018). This is the only publicly available large-scale dataset of multimodal instructions. It consists of multimodal recipes—textual instructions accompanied by one or more images.

We excluded documents that either have multiple steps without images or that have multiple images per set. This was so that we could more easily study the direct relationship between an image and the associated text. There are 1,690 documents with this characteristic in the RecipeQA train set. To avoid overwhelming crowd workers, we further filtered those to retain only recipes with 70 or fewer words per step, for a final count of 516 documents (2,047 image–text pairs).

Protocol. We recruit participants through Amazon Mechanical Turk. All subjects were US citizens, agreed to a consent form approved by Rutgers's institutional review board, and were compensated at an estimated rate of USD 15 an hour.

Experiment Interface. Given an image and the corresponding textual instruction from the dataset, participants were requested to answer the following 10 questions.

For Question 1, participants were asked to highlight the relevant part of the text. For the others, we solicited True/False responses.

1. Highlight the part of the text that is most related to the image.
2. The image gives visual information about the step described in the text.
3. You need to see the image in order to be able to carry out the step properly.
4. The text provides specific quantities (amounts, measurements, etc.) that you would not know just by looking at the picture.
5. The image shows a tool used in the step but *not* mentioned in the text.
6. The image shows how to prepare before carrying out the step.
7. The image shows the results of the action that is described in the text.
8. The image depicts an action in progress that is described in the text.
9. The text describes several different actions but the image only depicts one.
10. One would have to repeat the action shown in the image many times in order to complete this step.

The interface is designed such that if the answer to Question 8 is TRUE, the subject will be prompted with Question 9 and 10. Otherwise, Question 8 is the last question in the list.

Agreement. To assess the inter-rater agreement, we determine Cohen's κ and Fleiss's κ values. For Cohen's κ, we randomly selected 150 image–text pairs and assigned each to two participants, obtaining a Cohen's κ of 0.844, which indicates almost perfect agreement. For Fleiss's κ (Fleiss and Cohen, 1973; Cocos et al., 2015; Banerjee et al., 1999), we randomly selected 50 text–image pairs, assigned them to five subjects, and computed the average κ. We obtain a score of 0.736, which indicates substantial agreement (Viera et al., 2005).

4 Analysis

Overall Statistics. Table 1 shows the rates of true answers for questions Q2–Q10. Subjects reported that in 17% of cases the images did not give any information about the step described in the accompanying text. Such images deserve further investigation to characterize their interpretive relationship to the document as a whole. Our anecdotal experience is that such images sometimes provide context for the recipe, which may suggest that imagery, like real-world events (Hunter et al., 2015), creates more flexible discourse structures than linguistic segments on their own.

Subjects reported that the image was required in order to carry out the instruction only for 6%

Table 1: Rate of true answers for annotation questions Q2–Q10 across the corpus.

	Q1	Q2**	Q3**	Q4**	Q5	Q6**	Q7**	Q8**	Q9*	Q10**
F1	0.74	0.86	0.76	0.85	0.88	0.92	0.64	0.83	0.77	0.92

Table 2: SVM classification accuracy: bag-of-words features; 80-20 train-test split; 5-fold cross validation. For the first question, this distinguishes highlighted text vs. its complement (excluded vs. included). For the rest of the questions, this distinguishes text of true instances from text of false instances, and is different from majority class baseline * at $p < 0.04, t = -3.5$ and ** at $p < 0.01, t > |2.49|$.

of cases. This suggests that subjects construe imagery as backgrounded or peripheral to the document, much as speakers regard co-speech iconic gesture as peripheral to speech (Schlenker and Chemla, 2017). Note, by contrast, that subjects characterized 12.7% of images as introducing a new tool: this includes many cases where the same subjects say the image is not required. In other words, subjects' intuitions suggest that coherent imagery typically does not contribute instruction content, but rather serves as a visual signal that facilitates inferences that have to be made to carry out the instruction regardless. Our annotated examples, where imagery is linked to specific kinds of inferences, provide materials to test this idea.

TEXT: Top with another layer of ravioli and the remaining sauce not all the ravioli may be needed. Sprinkle with the Parmesan.

Figure 2: The image depicts both the action and the result of the action. The recipe is from Autodesk Inc. www.instructables.com and was contributed by www.RealSimple.com.

The Complex Coherence of Imagery. Our annotation reveals cases where a single image does include more information than could be packaged into a single textual discourse unit (the proverbial thousand words). In particular, such imagery participates in more complex coherence relationships than we find between text segments. Multiple temporal relationships show this most clearly: 12% of images that have any temporal relation have more than one. For example, many images depict the action that is described in the text, while also showing preparations that have already been made by displaying the scene in which the action is performed. Figure 2 depicts the action and the result of the action. It also shows how to prepare before carrying out the action. Other images show an action in progress but nearing completion and thereby depict the result. For instance, the image that accompanies "mix well until blended" can show both late-stage mixing and the blended result. Looking at a few such cases closely, the circumstances and composition of the photos seem staged to invite such overlapping inferences.

Such cases testify to the richness of multimodal discourse, and help to justify our research methodology. The True/False questions characterize the relevant features of interpretation without necessarily mapping to single discourse relations. For instance, Q4 and Q5 indicate inferences in line with an **Elaboration** relation; Q9 and Q10 indicate inferences in line with an **Exemplification** relation, as information presented in images show just one case of a generalization presented in accompanying text. However, our data shows that these inferences can be combined in productive ways, in keeping with the potentially complex relevant content of images.

Information across modalities. We carried out machine learning experiments to assess what information images provide and what textual cues can guide image interpretation. We use SVM classifiers for performance, and Multinomial Naive Bayes classifiers to explain classifier decision making, both with bag-of-words features.

Table 2 reports the F1 measure for instance classification with SVMs (with 5-fold cross validation). In many cases, machine learning is able to find cues that reliably help guess inferential pat-

Q4. Text has quantities not in image

bread	-5.5	160	-5.1
make	-5.6	put	-5.2

Table 3: Top five features of Multimodal Naive Bayes classifier for two classification problems and their corresponding log–probability estimates.

terns. Table 3 looks at two effective Naive Bayes classifiers, for Q4 (text has quantities) and Q8 (image depicts action in progress). It shows the features most correlated with the classification decision and their log probability estimates. For Q4, not surprisingly, numbers and units are positive instances.

More interestingly, verbs of movement and combination are negative instances, perhaps because such steps normally involve material that has already been measured. For Q8, a range of physical action verbs are associated with actions in progress; negative features correlate with steps involved in actions that don't require ongoing attention (e.g., baking). Table 4 reports top SVM with NB (NBSVM) (Wang and Manning, 2012) features for Q1 that asks subjects to highlight the part of the text that is most related to the image. Action verbs are part of highlighted text, whereas adverbs and quantitative information that cannot be easily depicted in images are part of the remaining segments of the text. Such correlations set a direction for designing or learning strategies to select when to include imagery.

5 Conclusions

In this paper, we have presented the first dataset describing discourse relations across text and imagery. This data affords theoretical insights into the connection between images and instructional text, and can be used to train classifiers to support automated discourse analysis. Another important contribution of this study is that it presents a discourse annotation scheme for cross-modal data, and establishes that annotations for this scheme can be procured from non-expert contributors via crowd-sourcing.

Q1. Information in text		
1	do it clearly	on which
2	let cool for	favorite toppings
3	recipe with directions	after an
4	how slowly the	lightly season
5	7 minutes on	the 2

Table 4: Top five bigram and trigram features of NB-SVM for the first question. The highlighted text that is most relevant to the image describes depicted actions, while the complement descriptions describe quantities or modifications of the actions that are described in the highlighted segments.

Our paper sets the agenda for a range of future research. One obvious example is to extend the approach to other genres of communication with other coherence relations, such as the distinctive coherence of images and caption text (Alikhani and Stone, 2019). Another is to link coherence relations to the structure of multimodal discourse. For example, our methods have not yet addressed whether image–text relations have the same kinds of subordinating or coordinating roles that comparable relations have in structuring text discourse (Asher and Lascarides, 2003). Ultimately, of course, we hope to leverage such corpora to build and apply better models of multimodal communication.

Improving Dialogue State Tracking by Discerning the Relevant Context

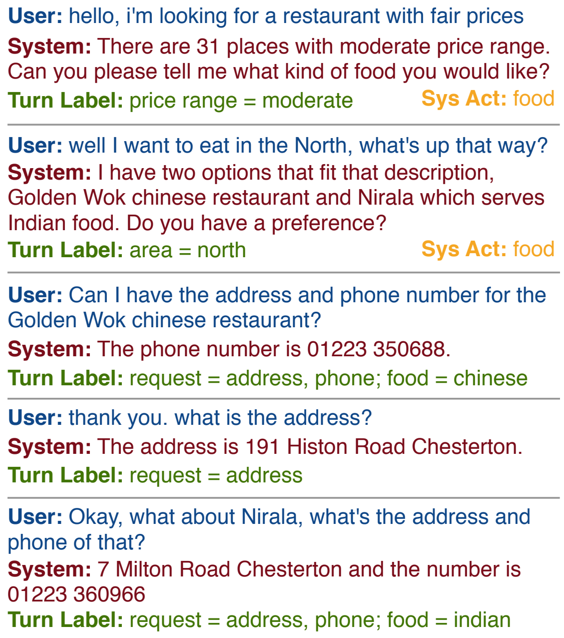
Sanuj Sharma, Prafulla Kumar Choubey, Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
`(sanuj, prafulla.choubey, huangrh)@tamu.edu`

Abstract

A typical conversation comprises of multiple turns between participants where they go back-and-forth between different topics. At each user turn, dialogue state tracking (DST) aims to estimate user's goal by processing the current utterance. However, in many turns, users implicitly refer to the previous goal, necessitating the use of relevant dialogue history. Nonetheless, distinguishing relevant history is challenging and a popular method of using dialogue recency for that is inefficient. We, therefore, propose a novel framework for DST that identifies relevant historical context by referring to the past utterances where a particular slot-value changes and uses that together with weighted system utterance to identify the relevant context. Specifically, we use the current user utterance and the most recent system utterance to determine the relevance of a system utterance. Empirical analyses show that our method improves joint goal accuracy by 2.75% and 2.36% on WoZ 2.0 and MultiWoZ 2.0 restaurant domain datasets respectively over the previous state-of-the-art GLAD model.

1 Introduction

Dialog state tracking (DST) is a vital component in the task-oriented dialog systems which is used to estimate user's goals and requests in order to plan next action and respond accordingly. At each turn, DST aims to identify the set of goals that a user aims to achieve and requests that are represented as slot-value pairs. Typically, this decision is made by considering user utterance in the current turn or system actions in the previous turn. However, in many cases, the considered user utterance or system actions do not present enough information and refers to a previous utterance.



User: hello, i'm looking for a restaurant with fair prices
System: There are 31 places with moderate price range. Can you please tell me what kind of food you would like?
Turn Label: price range = moderate **Sys Act:** food

User: well I want to eat in the North, what's up that way?
System: I have two options that fit that description, Golden Wok chinese restaurant and Nirala which serves Indian food. Do you have a preference?
Turn Label: area = north **Sys Act:** food

User: Can I have the address and phone number for the Golden Wok chinese restaurant?
System: The phone number is 01223 350688.
Turn Label: request = address, phone; food = chinese

User: thank you. what is the address?
System: The address is 191 Histon Road Chesterton.
Turn Label: request = address

User: Okay, what about Nirala, what's the address and phone of that?
System: 7 Milton Road Chesterton and the number is 01223 360966
Turn Label: request = address, phone; food = indian

Figure 1: An example dialog from WoZ 2.0 dataset. A turn contains user utterance (blue), system utterance (red), system actions (yellow) and turn label (green). Each turn is separated by a line.

As shown through an example in Figure 1, while exploring different available options, user can go back-and-forth between the currently and previously discussed facts. For instance, when offered with two different restaurant options namely *Nirala* `(food=indian)` and *Golden Wok* `(food=chinese)` in the second turn, user first inquires about the details of *Golden Wok*. And after getting relevant details about the *Golden Wok* in the following two turns, user refers back to the second option provided in second turn and asks about *Nirala* restaurant. To predict the correct slot-value pair `food=indian` in the dialog state of the fifth turn, the system is required to refer back to the second turn again to find information about *Nirala*, as the context obtained from the current dialog turn is insufficient.

Identifying such implicitly referenced historical turns is challenging since implicit references are

Proceedings of NAACL-HLT 2019, pages 576–581
Minneapolis, Minnesota, June 2 - June 7, 2019.

not local and most recent turns are often not informative. Therefore, the traditional approach of modeling dialogue recency (El Asri et al., 2017) may not suffice. Instead, we propose to model implicit references by storing links to the past turn where each of the slots was modified. Then at each turn, we look up though the stored links to find the previous turn which may provide additional cues for predicting the appropriate slot-value.

Moreover, the dialogue system often asks polar questions with yes-no answers. For instance, the DST system should update the dialogue state with `food=indian` when a user replies *Yes* to a system utterance *Do you want Indian food?*. In such cases, neither the user utterance nor system acts (*food* in this example) contain any information about the actual slot-value. This makes utilization of both system and user utterance eminent for dialog state tracking. However, utilizing the previous system utterance together with the current user utterance always at each turn may add noise. Therefore, we use a gating mechanism based on both utterances to determine the relevance of the previous system utterance in the current turn.

The evaluation shows that identifying the relevant context is essential for dialogue state tracking. Our novel model that discerns important details in non-adjacent dialogue turns and the previous system utterance from a dialog history is able to improve the previous state-of-the-art GLAD (Zhong et al., 2018) model on all evaluation metrics for both WoZ and MultiWoZ (restaurant) datasets. Furthermore, we empirically show that a simple self-attention based biLSTM model, using only one-third of the number of parameters as GLAD, outperforms GLAD by identifying and incorporating the relevant context.

2 Related Work

Early work for DST relied on separate Spoken Language Understanding (SLU) module (Henderson et al., 2012) to extract relevant information from user utterances in a pipelined approach. Such systems are prone to error accumulation from a separate SLU module, in absence of necessary dialog context required to interpret the user utterance. Thus, later work on DST moved away from separate SLU modules and inferred the dialog state directly from user utterance and dialog history (Henderson et al., 2014b,c; Zilka and Jurcicek, 2015). These models depend on delexicalization, using generic tags to replace specific slot types and values, and handcrafted semantic dictionaries. In practice, it is difficult to scale these models for every slot type and recent state-of-the-art models for DST use deep learning based methods to learn general representations for user and system utterances and previous system actions, and predict the turn state (Henderson et al., 2013, 2014b; Mrkšić et al., 2015, 2017; Hori et al., 2016; Liu and Lane, 2017; Dernoncourt et al., 2017; Chen et al., 2016). However, these systems are found to perform poorly on rare and unknown slot-value pairs which was recently addressed through local slot-specific encoders (Zhong et al., 2018) and pointer network (Xu and Hu, 2018).

A crucial limitation to all these approaches lies in the modeling of appropriate historical context, which is simply ignored in most of the works. Since user's goal may change back-and-forth between previous values, incorporating relevant historical context is useful in monitoring implicit goal references. In a recent work, El Asri et al. (2017) discussed on similar limitations of current DST task and introduced a new task of frame tracking that explicitly tracks every slot-values that were introduced during the dialogue. However, that significantly complicates the task by maintaining multiple redundant frames that are often left unreferenced. Our proposed model, that explicitly track relevant historical user and system utterances, can be easily incorporated into any known DST or frame tracking systems such as Schulz et al. (2017) to replace the recency encoding.

3 Discerning Relevant Context for DST

Similar to previous works, we decompose the multi-label classification problem to binary classification where we score each slot-value pair and select the ones that receive a score above a threshold to be included in the current dialog state. To predict the score for a candidate slot-value pair, the model uses the relevant past user utterance (referential utterance), a fused utterance composed using the current user utterance and the system utterance of the previous turn, as well as previous system actions as evidence. Shown in Figure 2, our model comprises of:

Lookup module: retrieves a link to the turn where each of the slots changes. At each step, our system refers to the lookup module that returns the past user utterance (the "*antecedent user utterance*")

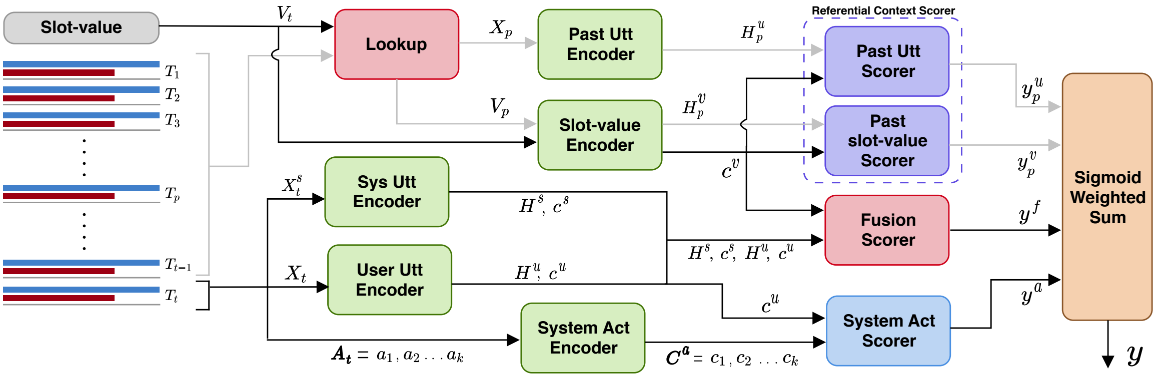


Figure 2: The Architecture of Context Aware Dialogue State Tracker.

where the candidate slot-type was modified as well as outputs the previous slot-value.

GLE modules: Each of the five green modules in Figure 2 is a global-locally self-attentive encoder (GLE module) (Zhong et al., 2018) that encodes each type of evidence into a vector representation (c). Each input is represented as a sequence of words which is encoded to a vector representation via global-local self-attentive encoder (GLE) module (Zhong et al., 2018). Specifically, GLE employs local slot-specific bidirectional LSTMs and a global bidirectional LSTM (Hochreiter and Schmidhuber, 1997) that is shared across all slots for encoding the input sequence into a sequence of hidden states (H), followed by a self-attention layer (Lin et al., 2016) to obtain a fixed dimension vector representation (c).

The GLE modules are used to encode the antecedent user utterance (H_p^u, c_p^u), the current user utterance (H^u, c^u), the previous system utterance (H^s, c^s), each of the system acts (H^{a_i}, c^{a_i}), as well as the previous slot-value (H_p^v, c_p^v) and the candidate (H^v, c^v) slot-value.

Referential Context Scorer: uses the candidate slot value (c^v), the antecedent user utterance as well as the previous slot-value to determine if the candidate slot value was referenced in the antecedent utterance. Specifically, the scorer uses the representation of the candidate slot value c^v to attend over hidden states of the antecedent user utterance and the previous slot-value, H_p^u and H_p^v, and then computes attention weights for each of the hidden states. Next, the scorer sums up the hidden states weighed with the calculated attentions to get the summary context (Equation 1). Finally, the scorer applies a linear neural layer to calculate the scores y_p^v and y_p^u representing the likelihoods that the candidate slot-value is different from the previous slot-value and the candidate slot-value was unreferenced in the antecedent utterance (Equation 2).

$$Q(H,c): \ a_j = (H_j)^\top c \, ; \ p = softmax(a) \qquad Q(H,c) = \sum_i p_i H_i \tag{1}$$

$$y_p^u = W_p^u \, Q(H_p^u, c^v) + b_p^u \qquad y_p^v = W_p^v \, Q(H_p^v, c^v) + b_p^v \tag{2}$$

Fusion Scorer: leverages necessary details in the previous system utterance to enrich the current user utterance. First, we use a gating mechanism based on c^s and c^u that determines the relevance of the previous system utterance in the current turn. We concatenate c^s and c^u and use a linear layer with sigmoid activation to calculate the score α (Equation 3). Then, we use attention from c^v over H^s and H^u to calculate context summaries (l^s, l^u), and combine the summary vectors by taking their normalized weighted sum based on α. We finally apply a single linear layer to calculate the score y^f that determines the likelihood of the candidate slot-value based on both the current user utterance and the previous system utterance (Equation 4).

$$f_c = W_{fc}(c^s \oplus c^u) + b_{fc} \qquad \alpha = \sigma(W_\alpha tanh(f_c) + b_\alpha) \tag{3}$$

$$l^s = Q(H^s, c^v) \, ; \ l^u = Q(H^u, c^v) \qquad l^f = \alpha l^s + (1-\alpha) l^u \, ; \ y^f = W_{lf} l^f + b_{lf} \tag{4}$$

System Act Scorer: is the same as the action scorer proposed by (Zhong et al., 2018). Specifically, The scorer uses attention from c^u over C^a to calculate action summary followed by a linear layer with sigmoid activation to calculate the score y^a that determines the relevance of the candidate slot-value based on the previous system actions (Equation 5).

$$l^a = Q(C^a, c^u)\ ; \quad y^a = (l^a)^\top c^v \qquad (5)$$

It then calculates the final score of the candidate slot-value by taking weighted sum of the four scores (y_p^u, y_p^v, y^f, y^a) followed by a sigmoid layer, where weights are learned in the network.

4 Evaluations

4.1 Experimental Setup

We primarily use WoZ 2.0 (Wen et al., 2017) restaurant reservation task dataset that consists of 1200 dialogues for training and evaluation. Each dialogue has an average of eight turns, where each turn contains *system utterance transcript*, *user utterance transcript*, *turn label* and *belief state*. All the dialogue states and actions are based on a task ontology that supports three different informable slot-types namely *price range* with 4 values, *food* with 72 values, *area* with 7 values, and *requests* of 7 different types like *address* and *phone*. Following the standard settings, we use 600 dialogues for training, 200 for validation and the remaining 400 for testing.

We also use dialogues from restaurant domain in MultiWoZ 2.0 dataset (Budzianowski et al., 2018) for secondary evaluation. It banks on a significantly complex ontology covering seven informable slot types with 276 different values (*food, price range, restaurant name, area, book time, book day* and *book people* with 97, 6, 105, 8, 43, 8 and 9 values respectively). We use standard training, validation and test splits of 1199, 50 and 61 dialogues respectively.

All the models on WoZ 2.0 are evaluated on the two standard metrics introduced in Henderson et al. (2014a). First, **Joint Goal Accuracy** is the percentage of turns in a dialogue where the user's informed joint goals are identified correctly. Joint goals are accumulated turn goals up to the current dialog turn. Second, **Turn Request Accuracy** calculates the percentage of turns in a dialogue where the user's requests were correctly identified. Models on MultiWoZ 2.0 dataset are evaluated using joint goal and turn inform accuracies, as used by Nouri and Hosseini-Asl (2018).

4.2 Implementation Details

We use pretrained GloVe word embeddings (Pennington et al., 2014) concatenated with character n-gram embeddings (Hashimoto et al., 2017) which are kept fixed during the training. Each of bi-LSTMs use 200 hidden dimensions. All the models are trained using ADAM optimizer (Kingma and Ba, 2014) with the initial learning rate of 0.001. Dropout rate (Srivastava et al., 2014) is set to 0.2 for all biLSTM modules and the embedding layer. The models are trained for a maximum of 100 epochs with a batch size of 50. The validation data was used for early stopping and hyperparameter tuning.

Model	WoZ 2.0 Joint Goal	 Turn Request
Delexalisation-Based Model + SD	83.7%	87.6%
NBT - DNN	84.4%	91.2%
NBT - CNN	84.2%	91.6%
GLAD †	**86.4%**	**97.1%**
Global biLSTM based GLE	85.0%	96.8%
Global biLSTM based GLE + RC	87.4%	**97.0%**
Global biLSTM based GLE + RC + FS	**88.4%**	**97.0%**
GLAD + RC + FS	**89.2%**	**97.4%**

Table 1: Test accuracy of baselines and proposed models on WoZ 2.0 restaurant reservation dataset. †Retrained using docker container provided by the authors with exactly same hyper-parameters. We also experimented with different versions of PyTorch and cuDNN and found that results had high variance. Therefore, we report the average performance over 5 runs with different initializations for GLAD and all our models.

Model	MultiWoZ 2.0 (Restaurant) Joint Goal	 Turn Inform
GLAD	43.95%	76.99%
GLAD + RC	**45.72%**	**77.87%**
GLAD + RC + FS	**46.31%**	**78.76%**

Table 2: Test accuracy of GLAD and proposed models on MultiWoZ 2.0 restaurant domain dataset. Note that we considered all 276 slot-values for evaluating models. Budzianowski et al. (2018) reported joint goal accuracy of 80.9 on MultiWoZ 2.0 (restaurant) dataset. We believe they didn't include *restaurant name* slot in their evaluation and only considered presence of three slot-types—*book time, book day* and *book people*—and not their values.

4.3 Results

Table 1 compares the performance of our proposed models with different baselines, including **delexalisation-based model + SD** (Wen et al., 2017), DNN and CNN variants of **neural belief tracker** (Mrkšić et al., 2017) and the previous state-of-the-art GLAD systems (Zhong et al., 2018) on WoZ 2.0 dataset. We also implement a simplified variant of GLAD, **Global BiLSTM**

Model	Approx. # of parameters
Global biLSTM based GLE	1.2 million
Global biLSTM based GLE + RC + FS	**6 million**
GLAD	17 million
GLAD + RC + FS	28 million

Table 3: Number of learnable parameters for different models on WoZ 2.0 dataset

based GLE, by removing slot-specific local biLSTMs from the GLE encoder. We then successively combine it with referential context (**Global biLSTM based GLE + RC**) and the fused previous system utterance (**Global biLSTM based GLE + RC + FS**). Finally, we directly incorporate the referential context and gate selected system utterance into the GLAD system (**GLAD + RC + FS**).

Irrespective of the underlying system, utilizing appropriate context from the previous turns improves the overall performance of a dialogue state tracker on both joint goal and turn request accuracies on WoZ 2.0 dataset. First, incorporating relevant referential utterances to identify implicitly mentioned slot-value improves the accuracy of global biLSTM based GLE model on joint goal task by 2.4%. Then, gating based mechanism to augment user utterance with relevant information from the previous system utterance further improves the joint goal accuracy by 1.0%. Together, they improve joint goal and request accuracy of the global biLSTM based GLE model by 3.4% and 0.2% respectively. Furthermore, as evident from the results in Table 2, both referential context and fused system utterance proportionally improve performance on MultiWoZ 2.0 dataset as well with overall improvement of 2.36% and 1.77% on joint goal and turn inform accuracies respectively. Performances of all models on MultiWoZ 2.0 are significantly inferior compared to WoZ 2.0 owing to higher complexity, with richer and longer utterances and considerably more slot-values in the former dataset.

5 Analysis

The utilization of relevant context results in significant reduction in the number of learnable parameters in the model as shown in Table 3. Relevant context with the baseline model is able to outperform GLAD while using only one third of the number of learnable parameters. The parameters added due to using relevant context are the parameters for encoding the antecedent referential user utterance and the previous system utterance as well as the past utterance and past slot-value scorers. However, we also observe high variance in the joint goal accuracy. Since joint goal is calculated by accumulating turn goals, an error in predicting a turn goal is propagated to all the downstream turns.

6 Conclusion

We have presented a novel method for identifying the relevant historical user utterance as well as determining the relevance of the system utterance from the last turn to enrich the current user utterance and improve goal tracking in dialogue systems. The experimental results show that discerning relevant context from the dialog history is crucial for tracking dialog states.

CLEVR-Dialog:
A Diagnostic Dataset for Multi-Round Reasoning in Visual Dialog

Abstract

Visual Dialog is a multimodal task of answering a sequence of questions grounded in an image (using the conversation history as context). It entails challenges in vision, language, reasoning, and grounding. However, studying these subtasks in isolation on large, real datasets is infeasible as it requires prohibitively-expensive complete annotation of the 'state' of all images and dialogs.

We develop CLEVR-Dialog, a large diagnostic dataset for studying multi-round reasoning in visual dialog. Specifically, we construct a *dialog grammar* that is grounded in the scene graphs of the images from the CLEVR dataset. This combination results in a dataset where all aspects of the visual dialog are fully annotated. In total, CLEVR-Dialog contains 5 instances of 10-round dialogs for about $85k$ CLEVR images, totaling to $4.25M$ question-answer pairs.

We use CLEVR-Dialog to benchmark performance of standard visual dialog models; in particular, on *visual coreference resolution* (as a function of the coreference distance). This is the first analysis of its kind for visual dialog models that was not possible without this dataset. We hope the findings from CLEVR-Dialog will help inform the development of future models for visual dialog. Our code and dataset are publicly available[1].

1 Introduction

The focus of this work is on intelligent systems that can *see* (perceive their surroundings through vision), *talk* (hold a visually grounded dialog), and *reason* (store entities in memory as a dialog progresses, refer back to them as appropriate, count, compare, *etc*.). Recent works have begun studying such systems under the umbrella of *Visual Dialog* (Das et al., 2017a; de Vries et al., 2017), where an agent must answer a *sequence* of questions grounded in an image. As seen in Fig. 1, this entails challenges in – vision (*e.g*., identifying objects and their attributes in the image), language/reasoning (*e.g*., keeping track of and referencing previous conversation via memory), and grounding (*e.g*., grounding textual entities in the image).

In order to train and evaluate agents for Visual Dialog, Das et al. (2017a) collected a large dataset of human-human dialog on real images collected between pairs of workers on Amazon Mechanical Turk (AMT). While such large-scale realistic datasets enable new lines of research, it is difficult to study the different challenges (vision, language, reasoning, grounding) in isolation or to break down the performance of systems over different challenges to identify bottlenecks, because that would require prohibitively-expensive complete annotation of the 'state' of all images and dialogs (all entities, coreferences, *etc*.).

In this work, we draw inspiration from Johnson et al. (2017), and develop a large diagnostic dataset—CLEVR-Dialog—for studying and benchmarking multi-round reasoning in visually-grounded dialog. Each CLEVR image is synthetically rendered by a particular scene graph (Johnson et al., 2017) and thus, is by construction exhaustively annotated. We construct a *dialog grammar* that is grounded in these scene graphs. Specifically, similar to Das et al. (2017b), we view dialog generation as communication between an Answerer (A-er) who can 'see' the image and has the complete scene graph (say S_a), and a Questioner (Q-er), who does not 'see' the image and is trying to reconstruct the scene graph over rounds of dialog (say S_q^t). As illustrated in Fig. 1, the dialog begins by A-er providing a grounded caption for the image, which conveys some but not all information about S_a. The Q-er builds a partial scene graph S_q^0 based on the caption, and follows up by asking questions

Proceedings of NAACL-HLT 2019, pages 582–595
Minneapolis, Minnesota, June 2 - June 7, 2019.

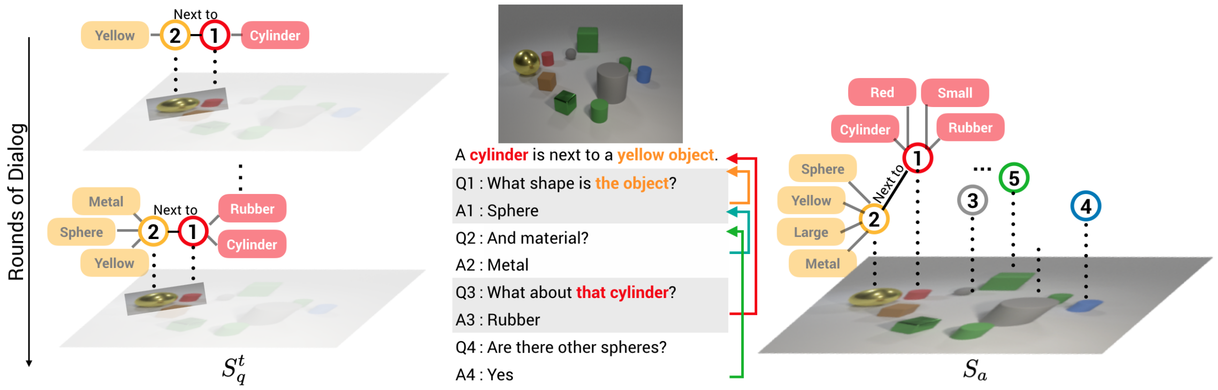

Figure 1: CLEVR-Dialog: we view dialog generation as communication between an Answerer (A-er) who can 'see' the image I and has the complete scene graph S_a (far right), and a Questioner (Q-er), who does not 'see' the image. A-er begins the dialog with a grounded caption (*'A cylinder is next to a yellow object'*). The Q-er converts this caption into a partial scene graph S_q^0 (far left, top), follows up with a question grounded in S_q^0 (*'What shape is the object?'*), which the A-er answers, and the dialog progresses. Questions at round t are generated based solely on S_q^t, *i.e.*, without looking at I or S_a, which mimics real-life scenarios of visual dialog. Note that while studying visual dialog on CLEVR-Dialog, models are forced to answer questions with just the image and dialog history as additional inputs, and do not have access to S_a.

grounded in S_q^0, which the A-er answers, and the dialog progresses. Our dialog grammar defines rules and templates for constructing this grounded dialog. Note that A-er with access to S_a (perfect vision) exists **only** during dialog generation to obtain ground truth answers. While studying visual dialog on CLEVR-Dialog, models are forced to answer questions with just the image and dialog history as additional inputs.

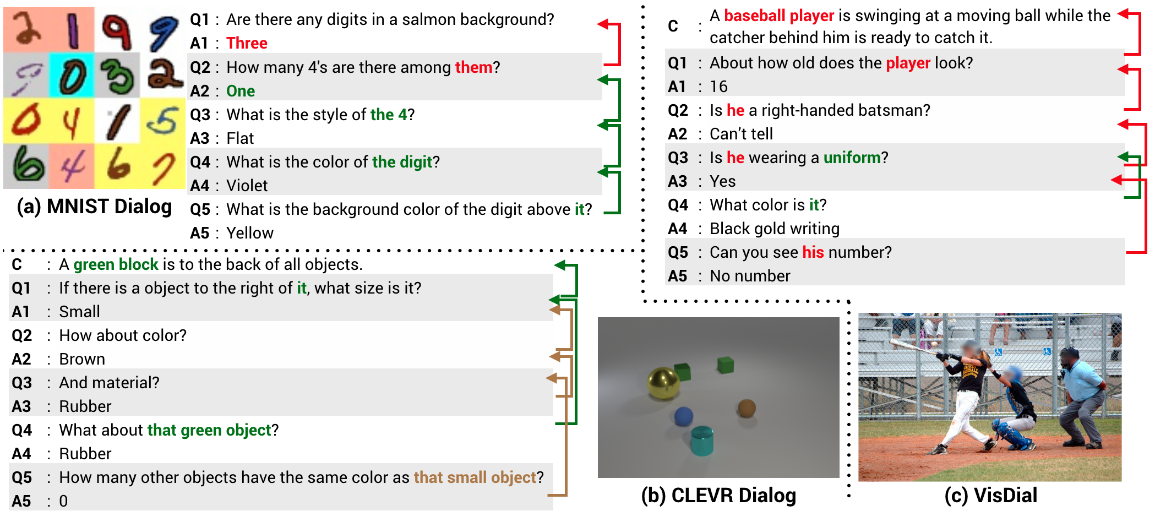
In total, CLEVR-Dialog contains 5 instances of 10-round dialogs for each of 70k (train) and 15k (val) CLEVR images, totaling to 3.5M (train) and 0.75M (val) question-answer pairs. We benchmark several visual dialog models on CLEVR-Dialog as strong baselines for future work.

The combination of CLEVR images (with full scene graph annotations) and our dialog grammar results in a dataset where all aspects of the visual dialog are fully annotated. We use this to study one particularly difficult challenge in multi-dialog visual reasoning – of *visual coreference resolution*. A coreference arises when two or more phrases (*coreferring phrases*) in the conversation refer to the same entity (*referent*) in the image. For instance, in the question *'What about that cylinder?'* (Q3) from Fig. 1, the referent for the phrase *'that cylinder'* can be inferred only after resolving the phrase correctly based on the dialog history, as there are multiple cylinders in the image. We use CLEVR-Dialog to diagnose performance of different methods as a function of the history dependency (*e.g.*, coreference distance—the number of rounds between successive mentions of the same object) and find that the performance of a state-of-art model (CorefNMN) is at least 30 points inferior for questions involving coreference resolution compared to those which do not (Fig. 5), highlighting the challenging nature of our dataset. This is the first analysis of its kind for visual dialog that was simply not possible without this dataset. We hope the findings from CLEVR-Dialog will help inform the development of future models for visual dialog.

2 Related Work

Coreference Resolution is a well studied problem in the NLP community (Ng, 2010; Wiseman et al., 2016; Lee et al., 2017; Clark and Manning, 2016a,b). Our work focuses on *visual* coreference resolution – the referent is now a visual entity to be grounded in visual data. Several works have tackled visual coreference resolution in videos (Ramanathan et al., 2014; Rohrbach et al., 2017) and 3D data (Kong et al., 2014), and have introduced real image datasets for the same (Hodosh et al., 2014).

Visual Dialog and Synthetic Datasets. We contrast CLEVR-Dialog against four existing datasets: (1) **CLEVR** (Johnson et al., 2017) is a diagnostic dataset for visual question answering (VQA) (Antol et al., 2015) on rendered images that contain objects like cylinders, cubes, *etc.*, against a plain background (Fig. 1). While CLEVR-Dialog uses the same set of images, the key difference is that of focus and emphasis – the objective of CLEVR-



Q1 : Are there any digits in a salmon background?
A1 : Three
Q2 : How many 4's are there among them?
A2 : One
Q3 : What is the style of the 4?
A3 : Flat
Q4 : What is the color of the digit?
A4 : Violet
Q5 : What is the background color of the digit above it?
A5 : Yellow

(a) MNIST Dialog

C : A baseball player is swinging at a moving ball while the catcher behind him is ready to catch it.
Q1 : About how old does the player look?
A1 : 16
Q2 : Is he a right-handed batsman?
A2 : Can't tell
Q3 : Is he wearing a uniform?
A3 : Yes
Q4 : What color is it?
A4 : Black gold writing
Q5 : Can you see his number?
A5 : No number

C : A green block is to the back of all objects.
Q1 : If there is a object to the right of it, what size is it?
A1 : Small
Q2 : How about color?
A2 : Brown
Q3 : And material?
A3 : Rubber
Q4 : What about that green object?
A4 : Rubber
Q5 : How many other objects have the same color as that small object?
A5 : 0

(b) CLEVR Dialog

(c) VisDial

Figure 2: Example dialogs from MNIST Dialog, CLEVR-Dialog, and VisDial, with coreference chains manually marked for VisDial and automatically extracted for MNIST Dialog and CLEVR-Dialog.

VQA questions is to stress-test spatial reasoning in independent single-shot question answering; the objective of CLEVR-Dialog is to stress-test temporal or multi-round reasoning over the dialog history. (2) **CLEVR-Ref+** (Liu et al., 2019) is a diagnostic dataset based on CLEVR images for visual reasoning in referring expressions. CLEVR-Dialog goes beyond CLEVR-Ref+, which focuses on grounding objects given a natural language expression, and deals with additional visual and linguistic challenges that require multi-round reasoning in visual dialog. (3) **MNIST-Dialog** (Seo et al., 2017) is a synthetic dialog dataset on a grid of 4×4 stylized MNIST digits (Fig. 2). While MNIST-Dialog is similar in spirit to CLEVR-Dialog, key difference is complexity – the distance between a coreferring phrase and its antecedent is always 1 in MNIST-Dialog; in contrast, CLEVR-Dialog has a distribution ranging from 1 to 10. (4) **VisDial** (Das et al., 2017a) is a large scale visual dialog dataset collected by pairing two human annotators (a Q-er and an A-er) on AMT, built on COCO (Lin et al., 2014) images. VisDial being a large open-ended real dataset encompasses all the challenges of visual dialog, making it difficult to study and benchmark progress on individual challenges in isolation. Fig. 2 qualitatively compares MNIST-Dialog, CLEVR-Dialog, and VisDial, and shows coreference chains (manually annotated for this VisDial example, and automatically computed for MNIST-Dialog and CLEVR-Dialog). We can see that the chains in MNIST-Dialog are the simplest (distance always 1). While coreferences in VisDial can be on a similar level of difficulty than CLEVR-Dialog, the difficult cases are rarer in VisDial.

Name	CLEVR Dialog (ours)	MNIST Dialog	VisDial
# Images	85k	50k	123k
# Dialogs	425k	150k	123k
# Questions	4.25M	1.5M	1.2M
# Unique Q	73k	355	380k
# Unique A	29	38	340k
Vocab. Size	125	54	7.k
Mean Q Len.	10.6	8.9	5.1
Mean Coref Dist.	3.2	1.0	-

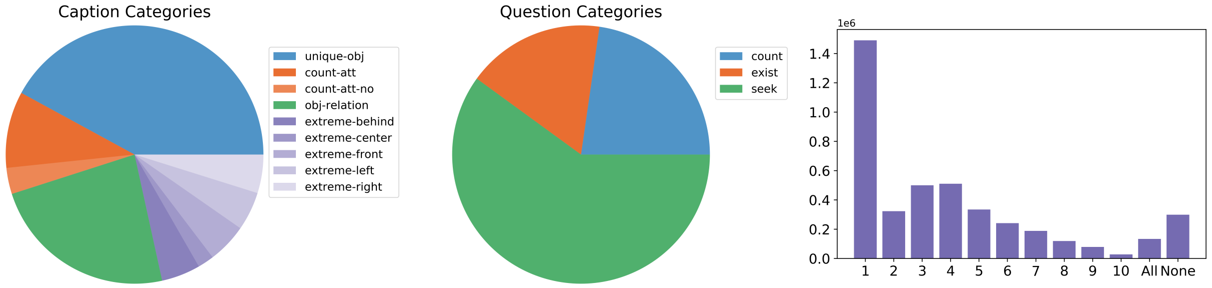
Table 1: Dataset statistics comparing CLEVR-Dialog to MNIST Dialog (Seo et al., 2017). Our dataset has 3× the questions (larger), 206× the unique number of questions (more diverse), 3.2× the mean coreference distance (more complex), and longer question lengths. Similar stats for VisDial are also shown. Coreference distance can not be computed for VisDial due to lack of annotations.

3 CLEVR-Dialog Dataset

In this section, we describe the existing annotation for CLEVR images, then detail the generation process for CLEVR-Dialog, and present the dataset statistics in comparison to existing datasets.

Setup. Every CLEVR image I has a full scene graph annotation, S_a. This contains information about all the objects in the scene, including four major attributes $\{$*color, shape, material, size*$\}$, 2D image and 3D world positions, and relationships $\{$*front, back, right, left*$\}$ between these objects. We only use objects, attributes, and relationships.

Dialog Grammar. An important characteristic of visual dialog that makes it suitable for practical applications is that the questioner does not 'see'



(a) Distribution of caption (left) and question (right) categories.

(b) Distribution of coreference distances.

Figure 3: Distribution of caption and question categories, and history dependency in CLEVR-Dialog dataset.

the image (because if it did, it would not *need* to ask questions). To mimic this setup, we condition our question generation at round t only on the partial scene graph S_q^t that accumulates information received so far from the dialog history (and not on S_a). Specifically, we use a set of caption $\{T_i^C\}$ and question $\{T_i^Q\}$ templates, which serve as the structural units of our dialog grammar. The role of the caption is to *seed* the dialog and initialize S_q^0. Each of the question templates is accompanied by a set of constraints on S_q^t, which decide if a particular template can be selected at the current round. For instance, a question *'What shape is the blue object?'* can be only be asked (generated) if the dialog so far has already *mentioned* a 'blue object', *i.e.*, only if S_q^t contains a (unique) 'blue object'. The nature and difficulty of the dataset is highly dependent on these templates, thus making their selection crucial.

To this end, we carefully design four categories of caption templates: (a) `Obj-unique` mentions an object with unique set of attributes in the image, (b) `Obj-count` specifies the presence of a group of objects with common attributes, (c) `Obj-extreme` describes an object at one of the positional extremes of the image (right, left, fore, rear, center), (d) `Obj-relation` talks about the relationship between two objects along with their attributes in a way that allows them to be uniquely identified in the complete scene graph S_a.

For the questions, we experiment with three different categories: (a) **Count** questions ask for a count of objects in the image satisfying specific conditions, *e.g.*, *'How many objects share the same color as this one?'*, (b) **Existence** questions are yes/no binary questions that verify conditions in the image, *e.g.*, *'Are there any other cubes?'*, and (c) **Seek** questions query attributes of objects, *e.g.*, *'What color is that cylinder?'*. Note that CLEVR-Dialog represents not just a static dataset but also a recipe for constructing increasingly challenging grounded dialog by expanding this grammar. Refer to the appendix for further details.

Dialog Generation. At a high level, dialog generation now 'simply' involves selecting a sequence of templates such that the accompanying constraints are satisfied by S_q^t at all t. As a tractable approximation to this exponentially-large constraint satisfaction problem, we use beam search that finds a valid solution *and* enforces additional conditions to make the dialog *interesting* (see Fig. 4). At every round of the dialog (after 3 rounds), we ensure that each of the question template types—count, existence, and seek—falls within a range ($10\% - 20\%$ for count/existence each, and $30\% - 60\%$ for seek). In addition, we identify *independent* questions that do not need history to answer them, *e.g.*, *'How many objects are present in the image?'*, and limit their number to under 10%. We found this to be effective both in terms of speed and dialog diversity. Fig. 4 illustrates the diverse set of candidate questions generated at each round for a given image.

Dataset Statistics. We compare CLEVR-Dialog to MNIST-Dialog and VisDial in Tab. 1, but the key measure of coreference distance cannot be reported for VisDial as it is not annotated. Overall, CLEVR-Dialog has 3× the questions and a striking 206× the unique number of questions than MNIST-Dialog , indicating higher linguistic diversity. CLEVR-Dialog questions are longer with a mean length of 10.6 compared to 8.9 for MNIST-Dialog. Crucially, supporting our motivation, the mean distance (in terms of rounds) between the coreferring expressions in CLEVR-Dialog is 3.2× compared to 1.0 in MNIST-Dialog. Moreover, the distances (see Fig. 3b) in CLEVR-Dialog vary (min of 1, max of 10), while it is constant (at 1) in MNIST-Dialog, making it easy for models to pick

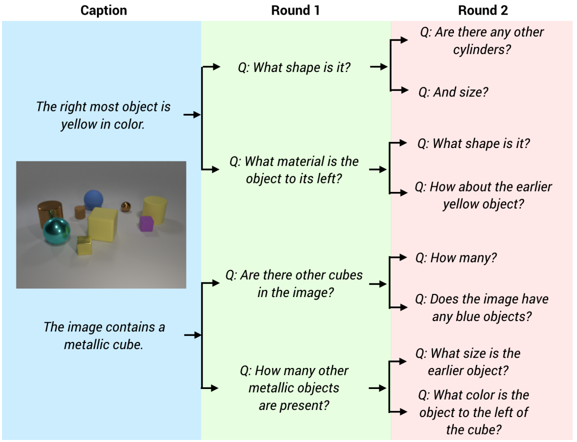


Figure 4: Dialog generation in CLEVR-Dialog. At each round, all valid question templates are used to generate candidates for the next question. However, only a few *interesting* candidates (beams) are retained for further generation, thus avoiding an exploding number of possibilities as rounds of dialog progress.

up on this bias. The distribution of caption and question templates is given in Fig. 3a. See appendix for further analysis.

4 Experiments

Baselines. To benchmark performance, we evaluate several models on CLEVR-Dialog. **Random** picks an answer at random. **Random-Q** picks an answer at random among valid answers for a given question type (*e.g.*, name of a color for color questions). Further, we adapt the discriminative visual dialog models from Das et al. (2017a): (a) **L**ate **F**usion (**LF**) that models separately encode each of question (Q), history (H), and image (I); and then fuse them by concatenation. (b) **H**ierarchical **R**ecurrent **E**ncoder (**HRE**) that models dialog via both dialog-level and sentence-level recurrent neural networks. (c) **M**emory **N**etwork (**MN**) that stores history as memory units and retrieves them based on the current question. We also consider neural modular architectures: (a) **CorefNMN** (Kottur et al., 2018) that explicitly models coreferences in visual dialog by identifying the reference in the question (textual grounding) and then localizing the referent in the image (visual grounding), (b) **NMN** (Hu et al., 2017), which is a history-agnostic ablation of CorefNMN.

Results. We use multi-class classification accuracy for evaluation since CLEVR-Dialog has one-word answers. Tab. 2 shows the performance of different models. The key observations are: (a) Neural models outperform random baselines by a large margin. The best performing model, CorefNMN, outperforms Random-Q by 35%. (b) History-agnostic models (LF-Q, LF-QI, NMN) also suffer in performance, highlighting the importance of history. (c) Finally, we break down the performance of top-3 models on questions which depend on entire history (*All*), require coreference resolution (*Coref*), and are history-independent (*None*), in Fig. 5. We find that CorefNMN is 30% worse on *Coref* than *None* questions, signifying the complexity of CLEVR-Dialog as the former are qualitatively harder to answer than the latter. (d) More interestingly, HRE-QIH, though inferior to CorefNMN on *Coref*, outperforms the latter on *All* questions (*'How many other objects?'*) by around 20%. A possible explanation is that the former, owing to its dialog-level RNN, captures global summaries more efficiently than the latter. This is the first analysis of its kind for visual dialog that was simply not possible without this dataset. Appendix provides a further analysis of model performances.

Conclusion. We proposed a large, synthetic dataset called CLEVR-Dialog, to study multi-round reasoning in visual dialog, and in particular the challenge of visual coreference resolution. We benchmarked several qualitatively different models from prior work on this dataset, which act as baselines for future work. Our dataset opens the door to evaluate how well models do on visual coreference resolution, without the need to collect expensive annotations on real datasets.

Appendix

The appendix is organized as follows:

- We begin with the description of CLEVR images in Sec. A,
- Sec. B describes further details of the dialog generation,
- Sec. C provides additional statistical analysis for CLEVR-Dialog,
- Diagnostic model performance analysis in given in Sec. D, and finally
- Implementation details can be found in Sec. E.

A CLEVR Images

First introduced by Johnson et al. (2017), CLEVR images are synthetically rendered, and contain several objects spatial located on a plain background. These objects have four different attributes: (a) *Shape*—cylinder, cube, sphere; (b) *Color*—blue, brown, cyan, gray, green, purple, red, yellow; (c) *Size*—large and small; and finally (d) *Material*—metal and rubber.

B Generating CLEVR-Dialog Dataset

As noted in the main paper, an important characteristic of visual dialog that makes it suitable for practical applications is that the questioner does not 'see' the image (because if it did, it would not *need* to ask questions). To mimic this setup, we condition our question generation at round t only on the partial scene graph S_q^t that accumulates information received so far from the dialog history (and not on S_a). Specifically, we use a set of caption $\{T_i^C\}$ and question $\{T_i^Q\}$ templates (enumerated in Tab. 3), which serve as the basis for our dialog generation. Each of these templates in turn consists of primitives, composed together according to a generation grammar. In what follows, we will first describe these primitives, discuss how they are used to generate a caption or a question at each round, and tie everything together to explain dialog generation in CLEVR-Dialog.

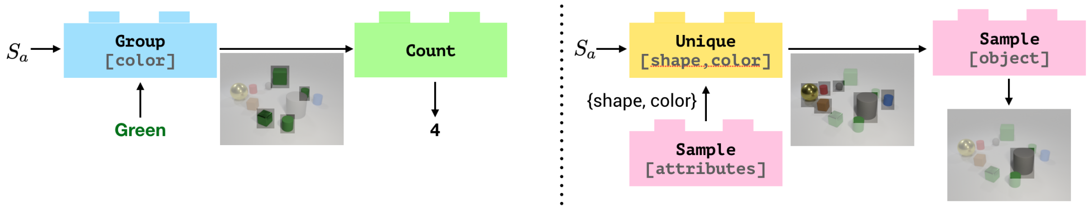
Grammar Primitives. The templates used to generate captions and questions are composed of intuitive and atomic operations called primitives. Each of these primitives can have different instantiations depending on a parameter, and also take input arguments. For example, all `Filter` primitives filter out objects from an input set of objects according to certain constraints. In particular, `Filter[color](blue)` filters out blue objects from a given set of objects, while `Filter[shape](sphere)` filters out all spheres. In our work, we use the following primitives:

- `Sample`: sample an object/attribute,
- `Unique`: identify unique objects/attributes,
- `Count`: count the number of input objects,
- `Group`: group objects based on attribute(s),
- `Filter`: filter inputs according to a constraint,
- `Exist`: check for existence of objects,
- `Relate`: apply a relation (*e.g.*, *right of*).

Note that each of these primitives inherently denotes a set of constraints, which when failed leads to a reset of the generation process for the current caption/question in the dialog. For example, if the output of `Filter[color](blue)` is empty due to an absence of blue objects in the input, we abort generation for the current template and move on to the next template.

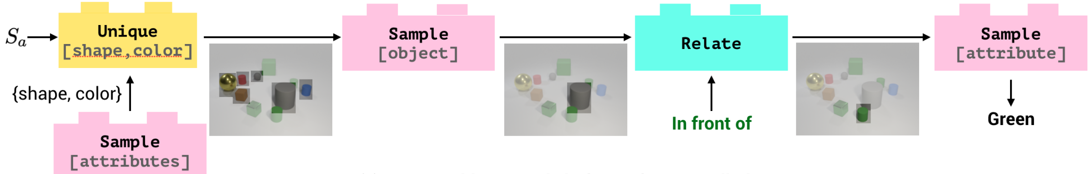
Caption Generation. The role of the caption is to *seed* the dialog and initialize S_q^0. In other words, caption gives Q-er partial information about the image so that asking follow-up questions is possible. Because A-er generates the caption, it uses the full scene graph S_a. Fig. 6 shows the caption grammar in action, producing three different captions for a given image. Consider the grammar for Fig. 6(c). First, `Sample[attribute]` produces {*shape, color*} used by `Unique` to select objects from S_a with unique shape and color attributes. An object (gray cylinder) is then sampled from these using `Sample[object]`. Next, a relation (*in front of*) is enforced via a `Relate` primitive leading to the green cylinder in front of the gray cylinder. Finally, `Sample[attribute]` samples one of the attributes to give us the caption, *'A green object stands in front of a gray cylinder.'*

Question Generation. Unlike the caption, the questions are generated by the Q-er, having access only to a partial scene graph S_q^t at round t. This S_q^t is an assimilation of information from the previous rounds of the dialog. The primitives in the question template therefore take S_q^t as the input scene graph, and the generation proceeds in a manner similar to that of the caption explained above. As the dialog is driven by Q-er based on partial scene information, only a few questions are non-redundant (or even plausible) at a given round of the dialog. To this



(a) There are four green objects in the scene.

(b) The image contains a gray cylinder.



(c) A green object stands in front of a gray cylinder.

Figure 6: Usage of dialog grammar in caption generation. See text for details.

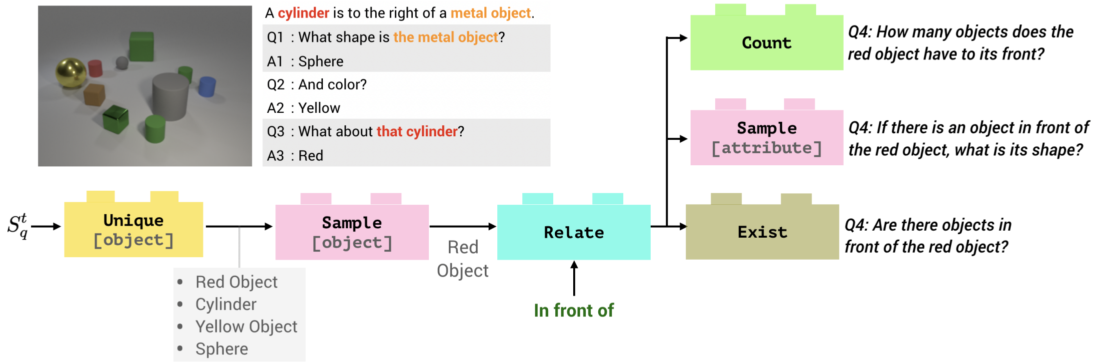


Figure 7: Usage of dialog grammar in question generation. See text for details.

end, the inherent constraints associated with the primitives now play a bigger role in the template selection.

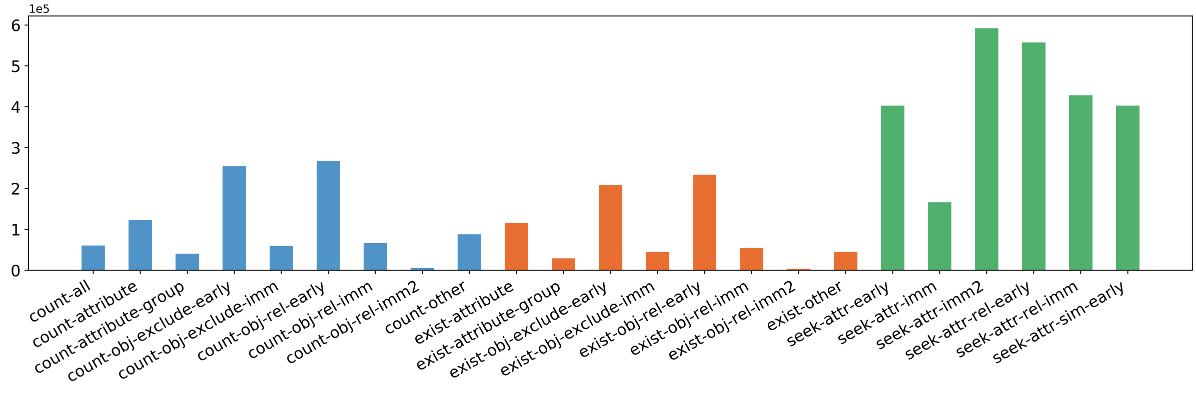
Consider Fig. 7 that shows how the current question is generated using the primitives and grammar, given the caption and dialog history (question-answer pair for the first three rounds). For the current round, the question *'What material is the green object at the back?'* is clearly implausible (Q-er is unaware of the existence of a green object), while the question *'What shape is the red object?'* is redundant. For the templates visualized, `Unique[object]` returns a list of unique known object-attribute pairs (using S_q^t). A candidate is sampled by `Sample[object]` and a relation is applied through `Relate(in front of)`. There are multiple choices at this junction: (a) The use of `Count` leads to a counting question (`count-obj-rel-early`), (b) Invoking `Sample[attribute]` results in a seek question (`seek-attr-rel-early`), and finally, (c) `Exist` primitive generates an exist question of type `exist-obj-rel-early`.

Dialog Generation. As specified in the main paper, we use beam search as a more tractable alternative to search through the exponential space of possible dialogs, by using additional constrains to retain only *interesting* dialogs. At every round of the dialog (after 3 rounds), we ensure that each of the question template types—count, existence, and seek—falls within a range (10% – 20% for count/existence each, and 30% – 60% for seek). In addition, we identify *independent* questions that do not need history to answer them, *e.g.*, *'How many objects are present in the image?'*, and limit their number to under 10%. Finally, to encourage questions that require reasoning over the history, *e.g.*, `seek-attr-sim-early` and `count-obj-excl-imm`, we tailor our beam search objective so that dialogs containing such questions have a higher value. We use a beam search with 100 beams for each dialog. Fig. 4 illustrates the diverse set of candidate questions generated at each round for a given image.

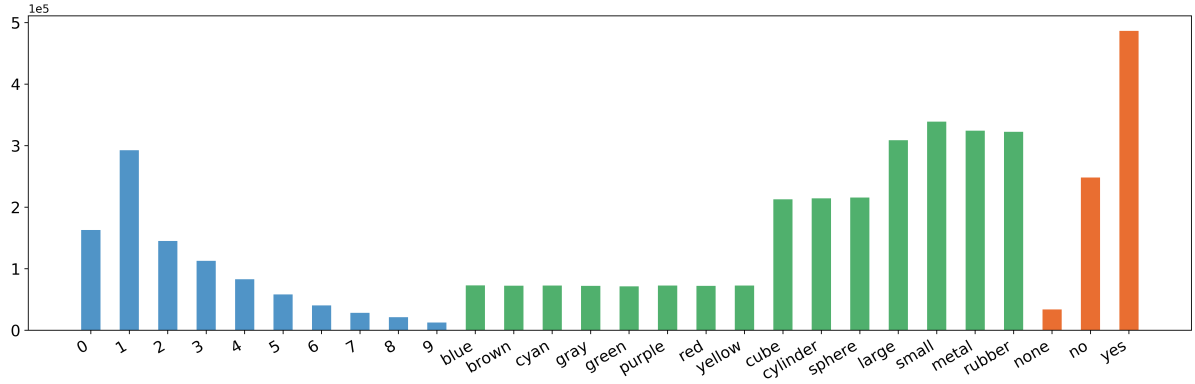
To summarize, the usage of primitives and a dialog grammar makes our generation procedure: (a) modular: each primitive has an intuitive meaning,

Captions	
`obj-relation`	*‘A [Z] [C] [M] [S] stands [R] a [Z1] [C1] [M1] [S1].’* *‘A gray sphere stands to the right of a red object.’*
`obj-unique`	*’A [Z] [C] [M] [S] is present in the image.’* *‘A red object is present in the image’*
`obj-extreme`	*‘The rightmost thing in the view is a [Z] [C] [M] [S].’* *‘The rightmost thing in the view is a cylinder.’*
`obj-count`	*‘The image has [X] [Z] [C] [M] [S].’* *‘The image has four cylinders.’*
Count/Exist Question Type	
`count-all`	*‘How many objects in the image?’*
`count/exist-excl`	*‘[How many | Are there] other [Z] [C] [M] [S] in the picture?’* *‘[How many | Are there] other cubes in the picture?’*
`count/exist-attr`	*‘[If present, how many | Are there] [Z] [C] [M] [S] objects?’* *‘[If present, how many | Are there] metallic objects?’*
`count/exist-attr-group`	*‘[How many | Are there] [Z] [C] [M] [S] among them?’* *‘[How many | Are there] blue cylinders among them?’*
`count/exist-obj-rel-imm`	*‘[How many | Are there] things to its [R]?’* *‘[How many | Are there] things to its right?’*
`count/exist-obj-rel-imm2`	*‘How about to its [R]?’* *‘How about to its left?’*
`count/exist-obj-rel-early`	*‘[How many | Are there] things [R] that [Z] [C] [M] [S]?’* *‘[How many | Are there] things in front of that shiny object?’*
`count/exist-obj-excl-imm`	*‘[How many | Are there] things that share its [A]?’* *‘[How many | Are there] things that share its color?’*
`count/exist-obj-excl-early`	*‘[How many | Are there] things that are the same [A] as that [Z] [C] [M] [S]?’* *‘[How many | Are there] things that are the same size as that round object?’*
Seek Question Type	
`seek-attr-imm`	*‘What is its [A]?’* *‘What is its shape?’*
`seek-attr-imm2`	*‘How about [A]?’* *‘How about color?’*
`seek-attr-early`	*‘What is the [A] of that [Z] [C] [M] [S]?’* *‘What is the shape of that shiny thing?’*
`seek-attr-sim-early`	*‘What about the earlier [Z] [C] [M] [S]?’* *‘What about the earlier box?’*
`seek-attr-rel-imm`	*‘If there is a thing to its [R], what [A] is it?’* *‘If there is a thing to its right, what color is it?’*
`seek-attr-rel-early`	*‘If there is a thing [R] that [Z] [C] [M] [S], what [A] is it made of?’* *‘If there is a thing in front of that shiny object, what material is it made of?’*

Table 3: Example templates for all the caption and question types used to generate CLEVR-Dialog dataset. For each type, we show both: (a) a sample template with placeholders (Z=size, C=color, M=material, S=shape, A=attribute, X=count, R=relation), and (b) a realization with placeholders filled with random values.



(a) Distribution of questions according to the template labels.



(b) Distribution of answers.

Figure 8: Visualization of distributions for question types and answers in our CLEVR-Dialog dataset. See Sec. C for more details.

(b) expressive: complex templates can be broken down into these primitives, (c) computationally efficient: outputs can reused for templates sharing similar primitive structures (as seen in Fig. 7), thus allowing an easy extension to new primitives and templates. We believe that CLEVR-Dialog represents not just a static dataset but also a recipe for constructing increasingly challenging grounded dialog by expanding this grammar.

C Additional Datasets Analysis

Fig. 8 visualizes the distribution of caption templates, question templates, answers, and the history dependency of questions in CLEVR-Dialog.

Caption Categories. As the dialog between Q-er and A-er is initiated by the caption, care must be taken to ensure it is *interesting enough* to spawn clarifying questions from the Q-er. To this end, we carefully design four different categories of caption templates (Fig. 3a): (a) `Obj-unique` mentions an object with unique set of attributes in the image, (b) `Obj-count` specifies the presence of a group of objects with common attributes, (c) `Obj-extreme` describes an object at one of the positional extremes of the image (right, left, fore, rear, center), (d) `Obj-relation` talks about the relationship between two objects along with their attributes in a way that allows them to be uniquely identified in the complete scene graph S_a. Example captions are given in Tab. 3. In contrast, MNIST Dialog does not have captions.

Question Categories and Types. CLEVR-Dialog contains three broad question categories—count, exist, and seek—with each further containing variants totaling up to 23 different types of questions. In comparison, MNIST-Dialog only has 5 types of questions and is less diverse. The distributions for the question categories and question types are shown in Fig. 3a and Fig. 8a, respectively. Our questions are 60% seek as they open up more interesting follow-up questions, 23% count, and 17% exist.

History Dependency. Recall that our motivation for CLEVR-Dialog to create a diagnostic dataset

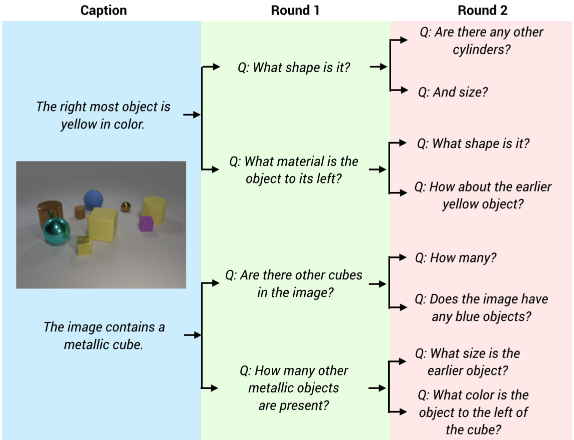


Figure 9: Dialog generation in CLEVR-Dialog. At each round, all valid question templates are used to generate candidates for the next question. However, only a few *interesting* candidates (beams) are retained for further generation, thus avoiding an exploding number of possibilities as rounds of dialog progress.

	1	2	3	4	5	6	7	8	9	10	All	None
LF-Q	40	43	37	34	36	42	41	41	36	42	40	50

CorefNMN	73	63	58	54	57	68	68	70	70	62	59	94

Figure 10: Accuracy breakdown of models according to the history dependency type. While CorefNMN outperforms all methods on questions (average) containing references ($1-10$), it performs poorly on questions that depend on the entire history ('All').

for multi-round reasoning in visual dialog. As a result, a majority of questions in our dataset depend on the dialog history. We identify three major kinds of history dependency for the questions: (a) **Coreference** occurs when a phrase within the current question refers to a earlier mentioned object (referent). We characterize coreferences by measuring the distance between the current and the earlier mention, in terms of dialog rounds. This can range from 1 (*e.g.*, *'What is its color?'*) to 10 (a question in round 10 referring to an entity in the caption). (b) **All**: When the question depends on the entire dialog history, *e.g.*, *'How many other objects are present in the image?'*, (c) **None**: When the question is stand-alone and does not depend on the history, *e.g.*, *'How many spheres does the scene have?'* The distribution of questions characterized according to the history dependency is shown in Fig. 3b. Unlike MNIST Dialog, CLEVR-Dialog contains a good distribution of reference distances beyond just 1, leading to a mean distance of 3.2. Thus, the models will need to reason through different rounds of dialog history in order to succeed.

D Additional Model Analysis

In this section, we diagnose performance of all the models by breaking it down according to question type and history dependency. We then focus on the best performing model, CorefNMN (Kottur et al., 2018), which explicitly models coreferences in visual dialog by identifying the *reference* in the question (textual grounding) and then localizing the *referent* in the image (visual grounding). We study the behavior of CorefNMN on CLEVR-Dialog both qualitatively and quantitatively. Specifically, we visualize qualitative examples and develop metrics to quantitatively evaluate the textual and visual grounding. Note that such a diagnostic analysis is first of its kind which would not be possible without our CLEVR-Dialog.

D.1 Accuracy vs History Dependency

The breakdown of model performances based on this history dependency is presented in Fig. 10. The following are the key observations:

- The best performing model, CorefNMN, has a superior performance (on an average) on all question with coreference ($1-10$) compared to all other models. As CorefNMN is designed specifically to handle coreferences in visual dialog, this is not surprising.
- Interestingly, the second best model HRE-QIH has the best accuracy on 'All' questions, even beating CorefNMN by a margin of 20%. In other words, HRE-QIH (and even MN-QIH) is able to answer 'All' questions significantly better than CorefNMN perhaps due to the ability of its dialog-level RNN to summarize information as the dialog progresses.
- Both NMN and CorefNMN perform similarly on the 'None' questions. This observation is intuitive as NMN is a history-agnostic version of CorefNMN by construction. However, the difference becomes evident as CorefNMN outperforms NMN by about 12% overall.

CorefNMN	86	93	80	59	39	51	43	32	52	99	83	87	80	84	79	64	73	73	68	79	61	75	29

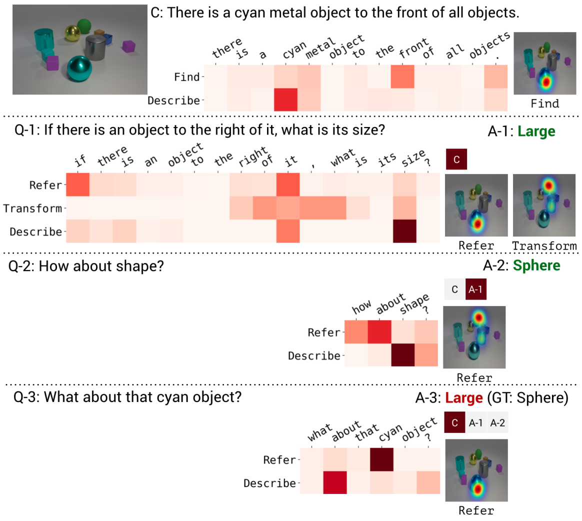
Figure 11: Accuracy breakdown of models according to the question type.

D.2 Accuracy vs Question Type

Fig. 11 breaks down the performance of all the models according to the question types. An obvious observation is that performance on counting and seek questions is worse than that on exist questions. While this is in part because of the binary nature of exist questions, they are also easier to answer than counting or extracting attributes that need complicated visual understanding.

D.3 Qualitative Anaylsis for CorefNMN

We now qualitatively visualize (Fig. 12) the best performing model, CorefNMN. In the example shown, CorefNMN first parses the caption *'There is a cyan metal object to the front of all the objects.'* and localizes the right cyan object. While answering Q-1, CorefNMN rightly instantiates the `Refer` module and applies the desired transformation (see module outputs on the right). For Q-2, it accurately identifies the object as the previous one, and extracts the attributes. Finally, the question *'What about that cyan object?'* cannot be answered in isolation as: (a) there are multiple cyan objects, (b) the meaning of the question is incomplete without Q-2. It is interesting to note that even though CorefNMN overcomes (a) by correctly resolving the reference *that cyan object* (in the image), it is unable to circumvent (b) due to its specialization in visual coreferences.



C: There is a cyan metal object to the front of all objects.

Q-1: If there is an object to the right of it, what is its size?

A-1: Large

Q-2: How about shape?

A-2: Sphere

Q-3: What about that cyan object?

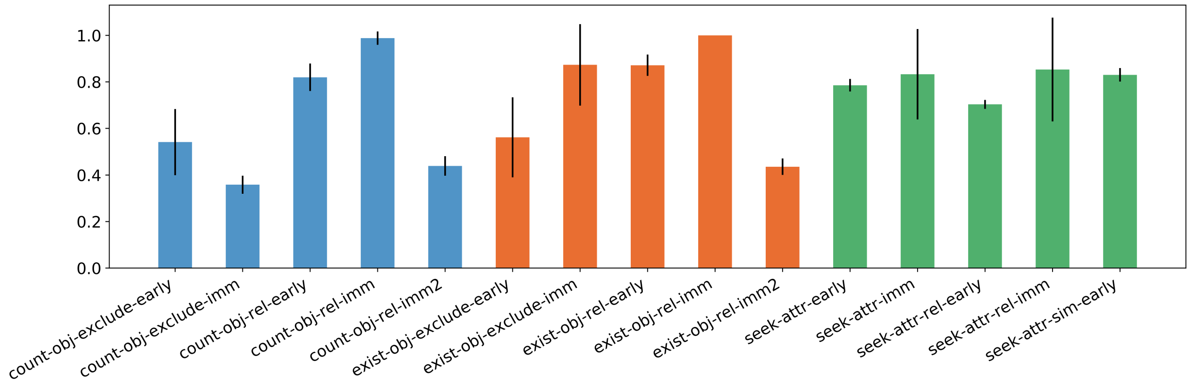
A-3: Large (GT: Sphere)

Figure 12: Qualitative visualization of CorefNMN on CLEVR-Dialog.

D.4 Grounding Analysis for CorefNMN

As shown in Fig. 12, CorefNMN identifies a reference phrase in the current question and proceeds to visually ground the corresponding referent in the image. Such explicit textual and visual grounding at each round allows for an interesting quantitative analysis for CorefNMN, with the help of annotations in our CLEVR-Dialog. To elaborate, CLEVR-Dialog provides coreference annotations for each question, if any, in the form of a reference phrase and its bounding box localization in the image. By comparing these grounding annotations with the output from the model, we can quantitatively assess grounding (both textual and visual) by CorefNMN. In what follows, we first describe the ground annotations, detail the evaluation procedure and then present our observations.

(a) NDCG value for text grounding for various question types.



(b) NDCG value for visual grounding for various question types.

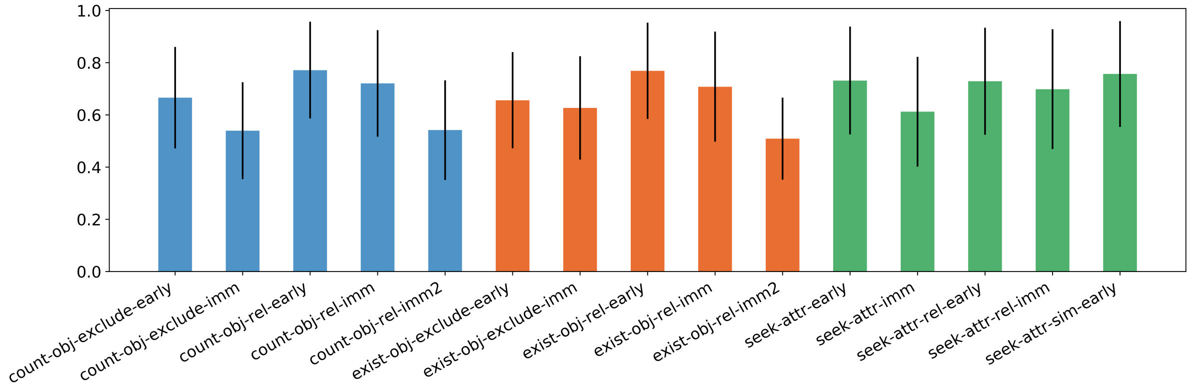


Figure 13: Evaluating the textual (above) and visual (below) grounding of CorefNMN on CLEVR-Dialog, using Normalized Discounted Cumulative Gain (NDCG) for various question types. Higher is better.

Annotations. While the original CLEVR dataset (Johnson et al., 2017) does not contain bounding box annotations for the objects in the scene, Krishna et al. (2018) later added these in their work on referring expressions. We leverage these annotations to obtain the ground truth visual groundings (A_V) for the referents in our questions. On the other hand, each of the caption and question templates has referring phrase annotations in them, thus giving the ground truth textual groundings (A_T). We use the above two groundings for evaluation.

Evaluation. For every coreference resolution, CorefNMN produces an visual attention map of size 14×14 ($\widehat{A}_V$) and a textual attention over the question words ($\widehat{A}_T$). We rank all the $14^2 = 196$ cells in $\widehat{A}_V$ according to their attention values. Next, we obtain the relevant cells among them from an appropriately scaled down (14×14) version of A_V and Next, we appropriately scaled down A_V (14×14) and consider the cells spanning the bounding box as relevant. To evaluate grounding, we measure the retrieval performance of the relevant cells in the sorted $\widehat{A}_V$ through the widely used Normalized Discounted Cumulative Gain (NDCG)[2]. It is a measure of how highly the relevant cells were ranked in the sorted $\widehat{A}_V$, with a logarithmic weighting scheme to higher ranks, thus higher is better. For the textual grounding, we perform a similar computation between $\widehat{A}_T$ and A_T and report NDCG.

Observations. The NDCG values to evalute both textual and visual groundings for CorefNMN are shown in Fig. 13. An important takeaway being that the model is able to accurately ground the references in the question (Fig. 13a) consistently for several question types, as reflected in an higher average NDCG. On the other hand, the visual grounding in Fig. 13b is inferior compared to the ground truth annotations with a mean of around 0.3 and a high variance. This trend remains the same across all the question types. A possible hypothesis is that while the model is able to identify the references

---

[2] `https://en.wikipedia.org/wiki/Discounted_cumulative_gain`

in text, it is unable to resolve and ground the referent accurately in the image–an area of potential improvement.

E Implementation details

Dataset generation was done entirely in Python, without any significant additional package dependencies. To evaluate the models from Das et al. (2017a), we use their open source implementation[3] based on Lua Torch[4]. For the neural module architectures (Hu et al., 2017; Kottur et al., 2018), we use the authors' Python-based, publicly available implementations—NMN[5] and CorefNMN[6]. Questions are encoded by first learning a 128-dimensional embedding for the words, which are then fed into a single layer LSTM of hidden size 128. We use a pretrained convolution neural network, ResNet-101 (He et al., 2016), to extract features for the images. Adam (Kingma and Ba, 2014) steps with a learning rate of 0.0001 are employed to maximize the loglikelihood of the ground truth answer, while training. A small portion (500 images) from the training set is set aside to pick the best performing model via early stopping. Our code and dataset are publicly available[7].

Learning Outside the Box:
Discourse-level Features Improve Metaphor Identification

Jesse Mu[1,3], **Helen Yannakoudakis**[2], **Ekaterina Shutova**[4]

Abstract

Most current approaches to metaphor identification use restricted linguistic contexts, e.g. by considering only a verb's arguments or the sentence containing a phrase. Inspired by pragmatic accounts of metaphor, we argue that broader discourse features are crucial for better metaphor identification. We train simple gradient boosting classifiers on representations of an utterance and its surrounding discourse learned with a variety of document embedding methods, obtaining near state-of-the-art results on the 2018 VU Amsterdam metaphor identification task without the complex metaphor-specific features or deep neural architectures employed by other systems. A qualitative analysis further confirms the need for broader context in metaphor processing.

1 Introduction

From *bottled up anger* to *the world is your oyster*, metaphor is a defining component of language, adding poetry and humor to communication (Glucksberg and McGlone, 2001) and serving as a tool for reasoning about relations between concepts (Lakoff and Johnson, 1980). Designing metaphor processing systems has thus seen significant interest in the NLP community, with applications from information retrieval (Korkontzelos et al., 2013) to machine translation (Saygin, 2001).

An important first step in any metaphor processing pipeline is metaphor *identification*. To date, most approaches to its identification operate in restricted contexts, for instance, by only considering isolated verb–argument pairs (e.g. *deflate economy*) (Rei et al., 2017) or the sentence containing an utterance (Gao et al., 2018). However, wider context is crucial for understanding metaphor: for instance, the phrase *drowning students* can be interpreted as literal (in the context of *water*) or metaphorical (in the context of *homework*). Often the context required extends beyond the immediate sentence; in Table 1, coreferences (*them*) must be resolved to understand the arguments of a verb, and a *game* is metaphorical in a political context. Indeed, a rich linguistic tradition (Grice, 1975; Searle, 1979; Sperber and Wilson, 1986) explains metaphor as arising from violations of expectations in a conversational context.

"You can't steal their ideas." "No, idiot—not so I can **steal** them."
Britain still can't decide when to **play** the mandarinate game of of silence [. . .] interests and concern of the Chinese government.

Table 1: Metaphorical examples from the VUA dataset in context. Verb is bolded, arguments underlined. Immediate sentence in black, with further context in gray.

Following these theories, in this paper we argue that metaphor processing models should expand beyond restricted contexts to use representations of wider discourse. We support this claim with two contributions: (1) we develop metaphor identification models which take as input an utterance, its immediate lexico–syntactic context, and broader discourse representations, and demonstrate that incorporating discourse features improves performance; (2) we perform a qualitative analysis and show that broader context is often required to correctly interpret metaphors. To the best of our knowledge, this is the first work to investigate the effects of broader discourse on metaphor identification.[1]

2 Related work

Metaphor identification is typically framed as a binary classification task, either with (1) word tu-

Minneapolis, Minnesota, June 2 - June 7, 2019.

ples such as SVO triples (car *drinks* gasoline) or (2) whole sentences as input, where the goal is to predict the metaphoricity of a token in the sentence. Recent work has used a variety of features extracted from these two types of contexts, including selectional preferences (Shutova, 2013; Beigman Klebanov et al., 2016), concreteness/imageability (Turney et al., 2011; Tsvetkov et al., 2014), multi-modal (Tekiroglu et al., 2015; Shutova et al., 2016) and neural features (Do Dinh and Gurevych, 2016; Rei et al., 2017).

At the recent VU Amsterdam (VUA) metaphor identification shared task (Leong et al., 2018), neural approaches dominated, with most teams using LSTMs trained on word embeddings and additional linguistic features, such as semantic classes and part of speech tags (Wu et al., 2018; Stemle and Onysko, 2018; Mykowiecka et al., 2018; Swarnkar and Singh, 2018). Most recently, Gao et al. (2018) revisited this task, reporting state-of-the-art results with BiLSTMs and contextualized word embeddings (Peters et al., 2018). To the best of our knowledge, none of the existing approaches have utilized information from wider discourse context in metaphor identification, nor investigated its effects.

3 Data

Following past work, we use the *Verbs* subset of the VUA metaphor corpus (Steen et al., 2010) used in the above shared task. The data consists of 17240 training and 5873 test examples, equally distributed across 4 genres of the British National Corpus: Academic, Conversation, News, and Fiction. All verbs are annotated as metaphorical or literal in these texts. We sample 500 examples randomly from the training set as a development set.

4 Models

For each utterance, our models learn generic representations of a *verb lemma*,[2] its syntactic *arguments*, and its broader discourse *context*. We concatenate these features into a single feature vector and feed them into a gradient boosting decision tree classifier (Chen and Guestrin, 2016).[3] By observing performance differences when using the lemma only (L), lemma + arguments (LA), or lemma + arguments + context (LAC), we can investigate the effects of including broader context.

To obtain arguments for verbs, we extract subjects and direct objects with Stanford CoreNLP (Manning et al., 2014). 67.4% of verb usages in the dataset have at least one argument; absent arguments are represented as zero vectors. To obtain the broader *context* of a verb, we take its surrounding paragraph as defined by the BNC; the average number of tokens in a context is 97.3. Figure 1 depicts the feature extraction and classification pipeline of our approach.

To learn representations, we use several widely-used embedding methods:[4]

GloVe We use 300-dimensional pre-trained GloVe embeddings (Pennington et al., 2014) trained on the Common Crawl corpus as representations of a lemma and its arguments. To learn a context embedding, we simply average the vectors of the tokens in the context. Out-of-vocabulary words are represented as a mean across all vectors.

doc2vec We use pretrained 300-dimensional paragraph vectors learned with the distributed bag-of-words method of Le and Mikolov (2014) (colloquially, doc2vec), trained on Wikipedia (Lau and Baldwin, 2016). Here, paragraph vectors are learned to predict randomly sampled words from the paragraph, ignoring word order. To extract representations for verbs and arguments, we embed one-word "documents" consisting of only the word itself.[5] We use a learning rate $\alpha = 0.01$ and 1000 epochs to infer vectors.

Skip-thought We use pretrained skip-thought vectors (Kiros et al., 2015) learned from training an encoder–decoder model to reconstruct the surrounding sentences of an input sentence from the Toronto BooksCorpus (Zhu et al., 2015). From this model, we extract 4800-dimensional representations for verb lemma, arguments, and contexts.

ELMo Finally, we use ELMo, a model of deep contextualized word embeddings (Peters et al., 2018). We extract 1024-dimensional representations from the last layer of a stacked BiLSTM

---

[2] The lemmatized form of the verb has improved generalization in other systems (Beigman Klebanov et al., 2016).

[3] We use the default parameters of the XGBoost package: a maximum tree depth of 3, 100 trees, and $\eta = 0.1$.

[4] These methods differ significantly in dimensionality and training data. Our intent is not to exhaustively compare these methods, but rather claim generally that many embeddings give good performance on this task.

[5] Since some methods provide only document embeddings and not word embeddings, for consistency, in all methods we use the same embedding process even for single-word verbs and arguments.

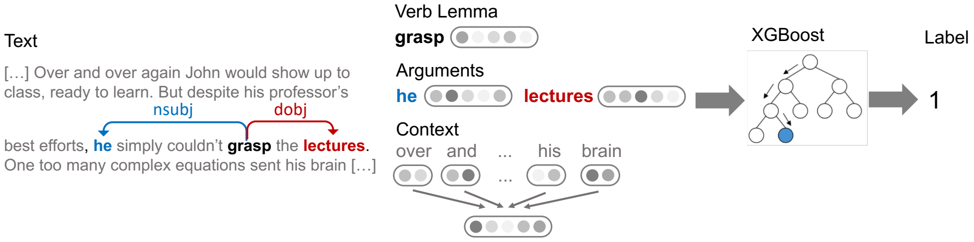

Figure 1: The general feature extraction and classification pipeline of our approach.

trained on Wikipedia and monolingual news data from WMT 2008–2012. To learn embeddings for verbs and arguments, we extract representations for sentences containing only the word itself. To learn context embeddings, we again average the constituent word embeddings.

5 Evaluation

For each embedding method, we evaluate the three configurations of features—L, LA, and LAC—on the VUA shared task train/test split, reporting precision, recall and F1 score. Since we are interested in whether incorporating broader context significantly improves identification performance, we compare successive model predictions (LAC vs. LA; LA vs. L) using the *mid-p* variant of McNemar's test for paired binary data (Fagerland et al., 2013).

5.1 Comparison Systems

We first compare our models to the baselines of the VUA shared task (Leong et al., 2018): *Baseline 1*, a logistic regression classifier trained only on one-hot encodings of verb lemmas; and *Baseline 2*, the same classifier with additional WordNet class and concreteness features. We also compare to the best systems submitted to the VUA shared task: Wu et al. (2018), an ensemble of 20 CNN-BiLSTMs trained on word2vec embeddings, part-of-speech tags, and word embedding clusters; and Stemle and Onysko (2018), a BiLSTM trained on embeddings from English language learner corpora.

5.2 Results

Results for our models are presented in Table 2. Interestingly, most of the simple lemma models (L) already perform at Baseline 2 level, obtaining F1 scores in the range 60–62. This is likely due to the generalization made possible by dense representations of lemmas (vs. one-hot encodings) and the more powerful statistical classifier used. As expected, the addition of argument information consistently enhances performance.

Model		P	R	F1
Baseline 1 (lemma)		51.0	65.4	57.3
Baseline 2 (+WN, concrete)		52.7	69.8	60.0
Stemle and Onysko (2018)		54.7	**77.9**	64.2
Wu et al. (2018)		**60.0**	76.3	**67.2**
GloVe	L (lemma)	51.6	74.1	60.8
	LA (+ args)	54.0	74.4	62.6^{***}
	LAC (+ ctx)	56.7	76.8	65.2^{***}
doc2vec	L	48.8	72.1	58.2
	LA	50.5	71.4	59.1^{**}
	LAC	52.7	72.2	60.9^{***}
skip-thought	L	53.5	76.1	62.8
	LA	57.0	74.0	64.3^{***}
	LAC	59.5	75.4	66.5^{***}
ELMo	L	51.3	74.9	60.9
	LA	56.0	73.5	63.6^{***}
	LAC	58.9	77.1	66.8^{***}

**,*** Significant improvement over previous model ($p < 0.01, 0.001$).

Table 2: Metaphor identification results.

Crucially, the addition of broader discourse context improves performance for all embedding methods. In general, we observe consistent, statistically significant increases of 2-3 F1 points for incorporating discourse. Overall, all LAC models except doc2vec exhibit high performance, and would have achieved second place in the VUA shared task. These results show a clear trend: the incorporation of discourse information leads to improvement of metaphor identification performance across models.

Table 3 displays the performance breakdown by genre in the VUA test set for our best performing model (ELMo LAC) and selected comparison systems. Echoing Leong et al. (2018), we observe that the *Conversation* and *Fiction* genres are consistently more difficult than the *Academic* and *News* genres across all models. This is partially because in this dataset, metaphors in these genres are rarer, occuring 35% of the time in *Academic* and 43% in *News*, but only 15% in *Conversation* and 24% in *Fiction*. In addition, for our model specifically, Conversation genre contexts are much

Genre	Model	P	R	F1
Academic	Baseline 2	70.7	83.6	**76.6**
	Wu et al. (2018)	**74.6**	76.3	75.5
	ELMo LAC	65.4	**86.8**	74.6
Conversation	Baseline 2	30.1	82.1	44.1
	Wu et al. (2018)	40.3	65.6	**50.3**
	ELMo LAC	**42.6**	56.0	48.4
Fiction	Baseline 2	40.7	66.7	50.6
	Wu et al. (2018)	**54.5**	**78.4**	**57.6**
	ELMo LAC	48.2	63.0	54.6
News	Baseline 2	67.7	68.9	68.3
	Wu et al. (2018)	**69.4**	74.4	71.8
	ELMo LAC	65.2	**80.0**	**71.8**

Table 3: Performance breakdown by genre for ELMo LAC model and comparison systems.

	Args	Sentence	Paragraph
Overall	40	49	11
Model errors			
ELMo L	37	50	13
ELMo LA	36	49	15
ELMo LAC	39	53	8

Table 4: Types of context required to interpret metaphors in the development set, both overall (first row) and for model errors. Each row is a separate (but overlapping) sample from the development set.

shorter on average (23.8 vs. 97.3).

Our best performing model (ELMo LAC) is within 0.4 F1 score of the first-place model in the VUA shared task (Wu et al., 2018). The GloVe LAC model would also have obtained second place at 65.2 F1, yet is considerably simpler than the systems used in the shared task, which employed ensembles of deep neural architectures and hand-engineered, metaphor-specific features.

6 Qualitative analysis

To better understand the ways in which discourse information plays a role in metaphor processing, we randomly sample 100 examples from our development set and manually categorize them by the amount of context required for their interpretation. For instance, a verb may be interpretable when given just its arguments (direct subject/object), it may require context from the enclosing sentence, or it may require paragraph-level context (or beyond). We also similarly analyze 100 sampled errors made on the development set by the ELMo L, LA, and LAC models, to examine whether error types vary between models.

Our analysis in Table 4 shows that 11% of examples in the development set require paragraph-level context for correct interpretation. Indeed, while such examples are frequently misclassified by the L and LA models (13%, 15%), the error rate is halved when context is included (8%).

Table 5 further presents examples requiring at least paragraph-level context, along with gold label and model predictions. Out of the 31 unique such examples identified in the above analyses, we found 11 (35%) requiring explicit coreference resolution of a pronoun or otherwise underspecified noun (e.g. Table 5 row 1) and 5 (16%) which reference an entity or event implicitly (*ellipsis*; e.g. Table 5 row 2). However, we also observed 4 errors (13%) due to examples with non-verbs and incomplete sentences and 11 examples (35%) where not even paragraph-level context was sufficient for interpretation, mostly in the *Conversation* genre, demonstrating the subjective and borderline nature of many of the annotations.

This analysis shows *a priori* the need for broader context beyond sentence-level for robust metaphor processing. Yet this is not an upper bound on performance gains; the general improvement of the LAC models over LA shows that even when context is not strictly necessary, it can still be a useful signal for identification.

7 Conclusion

We presented the first models which leverage representations of discourse for metaphor identification. The performance gains of these models demonstrate that incorporating broader discourse information is a powerful feature for metaphor identification systems, aligning with our qualitative analysis and the theoretical and empirical evidence suggesting metaphor comprehension is heavily influenced by wider context.

Given the simplicity of our representations of context in these models, we are interested in future models which (1) use discourse in more sophisticated ways, e.g. by modeling discourse relations or dialog state tracking (Henderson, 2015), and (2) leverage more sophisticated neural architectures (Gao et al., 2018).

Detection of Abusive Language: the Problem of Biased Datasets

Michael Wiegand[*0], **Josef Ruppenhofer**[†‡], **Thomas Kleinbauer**[*]

Abstract

We discuss the impact of data bias on abusive language detection. We show that classification scores on popular datasets reported in previous work are much lower under realistic settings in which this bias is reduced. Such biases are most notably observed on datasets that are created by focused sampling instead of random sampling. Datasets with a higher proportion of implicit abuse are more affected than datasets with a lower proportion.

1 Introduction

Abusive or offensive language is commonly defined as hurtful, derogatory or obscene utterances made by one person to another person.[1] Examples are (1)-(3). In the literature, closely related terms include *hate speech* (Waseem and Hovy, 2016) or *cyber bullying* (Zhong et al., 2016). While there may be nuanced differences in meaning, they are all compatible with the general definition above.

(1) stop editing this, you **dumbass**.
(2) Just want to slap the **stupid** out of these **bimbos**!!!
(3) Go lick a pig you arab muslim piece of **scum**.

Due to the rise of user-generated web content, in particular on social media networks, the amount of abusive language is also steadily growing. NLP methods are required to focus human review efforts towards the most relevant microposts.

In this paper, we examine the issue of data bias. For the creation of manually annotated datasets, randomly sampling microposts from large social media platforms typically results in a too small proportion of abusive comments (Wulczyn et al., 2017; Founta et al., 2018). Therefore, more focused sampling strategies have to be applied which cause biases in the resulting datasets. We show what implications this has on classifiers trained on these datasets: Previous evaluations reported high classification performance on datasets with difficult cases of abusive language, e.g. implicit abuse (§2). Contrarily, we find that the high classification scores are likely to be the result of modeling the bias in those datasets.

Although we will explicitly name shortcomings of existing individual datasets, our paper is not intended as a reproach of those who created them. On the contrary, we acknowledge the great efforts the researchers have taken to provide these resources. Without them, much existing research would not have been possible. However, we also noticed a lack of awareness of the special properties of those datasets among researchers using them. As we will illustrate with specific examples, this may result in unforeseen results of particular classification approaches.

2 Explicit and Implicit Abuse

One major distinction that has been proposed in the literature is the division into **explicitly** and **implicitly** abusive language (Waseem et al., 2017). The former are microposts that employ some abusive words (1)-(3) (e.g. *dumbass* or *scum*), while the latter represents the more difficult case in which the abusive nature is conveyed by other means, such as sarcasm, jokes, and particularly the usage of negative stereotypes etc. (4)-(5).

(4) i havent had an intelligent conversation with a woman.
(5) Jews don't marry children. Muslims do. All the time.

To determine which of the datasets that we consider in this work contain which type of abusive language, we proceeded as follows. On the set of abusive microposts of each dataset, we computed the proportion of microposts that include at least

Minneapolis, Minnesota, June 2 - June 7, 2019.

one abusive word according to the lexicon of abusive words from Wiegand et al. (2018a). Datasets with a high proportion of abusive words typically contain a high amount of explicitly abusive microposts, whereas datasets with a low proportion contain a higher amount of implicitly abusive language. The resulting figures, of course, are only a lower bound estimate for explicit language abuse. There will also be microposts containing abusive words that are missing from the lexicon. However, after manual inspection of a sample of microposts, we are fairly confident that this does not significantly change the *relative* order of datasets when ranked according to their degree of explicit language abuse.

3 Datasets and Their Properties

Due to the limited space of this paper, we restrict our discussion to frequently cited (publicly available) datasets and datasets from shared tasks. Substantial interannotation agreement has also been reported with these datasets.

As we focus on the detection of abusive language in general, for those datasets containing more fine-grained class inventories describing subtypes of abusive language[2], we conflate the categories to one general category. As a result, there are always only two categories: *abuse* and *no-abuse*. This merging removes differences between the individual annotation schemes that would otherwise impede a meaningful comparison.

Table 1 shows a brief summary of the different datasets. Among the properties, we list the performance of a text classifier in the right-most column. Since in previous work performance on the different datasets was reported on the basis of different types of classifiers and also varying evaluation metrics, we ran the same classifier on all datasets in order to ensure a meaningful comparison. We chose FastText, which is an efficient supervised classifier known to produce state-of-the-art performance on many text classification tasks[3] (Joulin et al., 2017) and whose results are easy to reproduce. Performance is evaluated in a 10-fold crossvalidation setting using the macro-average F1-score.

Table 1 also describes the way the datasets were sampled. Not a single dataset has been produced by *pure* random sampling. This would always result in tiny proportions of abusive language. For example, Founta et al. (2018) estimate that on Twitter, there are only between 0.1% up to at most 3% abusive tweets. What comes closest to random sampling is the procedure followed by Founta et al. (2018), Razavi et al. (2010) and the Kaggle-challenge.[4] They took a random sample and applied some heuristics in order to boost the proportion of abusive microposts. For instance, in the Kaggle-challenge, further microposts from users were added who had been blocked due to being reported to post personal attacks.

The procedures applied by other researchers are more drastic because, as we show in §4 and §5, they affect more heavily the topic distribution of the dataset. These approaches do not even start with a random sample. The topic distribution is mostly determined by the creators of the dataset themselves. For example, Waseem and Hovy (2016) extract tweets matching query words likely to co-occur with abusive content. Kumar et al. (2018) choose Facebook-pages covering topics that similarly coincide with abusive language. The resulting datasets are far from representing a natural sample of the underlying social-media sites.

Table 1 shows that datasets that apply biased sampling (*Warner*, *Waseem*, *Kumar*) contain a high degree of implicit abuse. Boosted random sampling, which provides a more realistic cross section of microposts, on the other hand, captures a larger amount of explicit abuse. Future work should explore whether this is due to the predominance of explicit abuse on social media or some other reason, for example, the fact that human annotators more readily detect explicit abuse.

Intuitively, one would expect that the lower the proportion of explicit abuse is on the set of abusive microposts of a dataset, the lower the F1-score becomes because implicit abuse is not conveyed by lexical cues that are easy to learn. Table 1 confirms this notion, yet *Waseem* is the notable exception. We need to find an explanation for this deviation since *Waseem* is by far the most frequently used dataset for detecting abusive language (Badjatiya et al., 2017; Bourgonje et al., 2017; Pitsilis et al., 2018; Agrawal and Awekar, 2018; Karan and Snajder, 2018; Kshirsagar et al.,

---

[2] For example, Waseem and Hovy (2016) distinguish between *sexism* and *racism*.

[3] More involved classifiers achieve better performance, however, the relative differences between the datasets remain.

Table 1: Properties of the different datasets. (**: proportion of explicitly abusive microposts among abusive microposts.* †*: This is an extension of the dataset presented in* Wulczyn et al. (2017)*. Details on the corpus creation about* Kaggle *can therefore be found in that publication.*)

2018; Mishra et al., 2018a,b; Park et al., 2018; Qian et al., 2018; Sahlgren et al., 2018; Sharifirad et al., 2018; Unsvåg and Gambäck, 2018; Wiegand et al., 2018a). This investigation is only possible since, fortunately, *Waseem* is one of the datasets whose creation process has been meticulously documented.

4 Topic Bias

The *Waseem*-dataset has been sampled in such a way that it contains a high proportion of microposts discussing the role of women in sports, particularly their suitability as football commentators. Such microposts also very often coincide with sexist remarks. However, the authors did not make any attempt to *debias* their dataset. As a consequence, domain-specific expressions such as *announcer*, *commentator*, *football* or *sport* occur very frequently and almost exclusively in abusive tweets. Yet intuitively these words should not be representative of abusive language. There are many texts on the web including Twitter that contain mentions of these expressions but that are not abusive. The current dataset, however, does not reflect that.

Table 2 illustrates this bias by listing the words with the highest Pointwise Mutual Information (PMI) towards abusive microposts. It compares the *Founta*-dataset (a dataset representing almost random sampling) with the *Waseem*-dataset (a dataset produced by biased sampling). We deliberately chose two datasets sampled from the *same* social-media site, namely Twitter, as otherwise the difference we report could be ascribed to differences in the underlying text sources. Table 2 shows that on the *Founta*-dataset, abusive words occupy the high ranks. Most of the highly ranked words of the *Waseem*-dataset, however, are not abusive. Similar observations can be made on the other datasets produced by biased sampling (i.e. *Warner* and *Kumar*). In the *Warner*-dataset, the words *CBS* and *Hollywood* are two of the most predictive words. They refer to the anti-semitic prejudice that Jews are supposed to control most of the US media. On that dataset, the bias of identity terms is also extreme: Almost 80% of the 256 mentions of the identity term *Jew* occur in abusive microposts. On the *Kumar*-dataset, even common Arabic person names, such as *Azan* or *Nahid*, strongly correlate with abusive language.

rank	Founta	Waseem
1	bitch	**commentator**
2	niggas	comedian
3	motherfucker	**football**
4	fucking	**announcer**
5	nigga	pedophile
6	idiot	mankind
7	asshole	sexist
8	fuck	**sport**
9	fuckin	outlaw
10	pussy	driver

Table 2: Top 10 words having strongest correlation with abusive microposts according to PMI on *Founta* (dataset representing almost random sample) and *Waseem* (dataset produced by biased sampling).

Feature Set	Prec	Rec	F1
all words	80.91	80.08	80.49
(ii) query words removed	76.65	76.02	76.33
(i) topic words removed	75.07	74.41	74.72

Table 3: Impact of removing specific words from classifier trained and tested on *Waseem*.

In order to demonstrate the detrimental effects such biases have, we now report the performance of further classifiers trained on the *Wassem*-dataset. Similar results could be obtained on the *Warner*- and *Kumar*-dataset. Yet they are most pronounced on the *Waseem*-dataset, which is also the dataset on which unexpectedly high classification performance has been observed in Table 1. Presumably, it is also the most biased dataset.

In our first experiment, we tested a FastText-classifier (§3) trained on the *Waseem*-dataset on a random sample of 500 additional tweets that include mentions of the topic words *football* and

racist		sexist	
author name	**freq**	**author name**	**freq**
Vile_Islam	1915	Yes You're Sexist	1320
Yes You're Sexist	8	Male Tears #4648	948
Standing Up 4 Trump	5	Vile_Islam	50
YESMarriageEquality	1	LilBeasy91	10
LilBeasy91	1	N!ck	9

Table 4: The 5 most sexist and racist authors on the *Waseem*-dataset and the number of their microposts.

sport. One would expect a low proportion of these particular tweets to be predicted as abusive. However, due to the fact that the abusive training data have such a large topic bias towards sports, the proportion of tweets predicted to be abusive is unreasonably high (i.e. 70%). Manual inspection confirmed that only a small proportion (up to 5%) was actually abusive. This result shows us that classifiers trained on the *Waseem*-dataset hardly generalize to the concept of abusive language. Difficult tweets on that dataset, e.g. instances of implicit abuse, may be classified correctly just because biased words such as *football* or *sport* occur in them.

In our second experiment, we train and test a classifier on the original *Waseem*-dataset in 10-fold crossvalidation. However, we remove either of the two types of biased words from the dataset:

(i) We remove 25 topic words from the 100 most correlating words that we thought bear no relation towards abusive language (e.g. *announcer*, *commentator*, *football* or *sport*).

(ii) We remove the 17 words that were used as a query by Waseem and Hovy (2016) to produce the dataset.

With (i) we want to show how good classifiers are that do not have access to biased words. This would be a realistic setting since words, such as *football* or *sport*, only have this bias towards abusive language on the *Waseem*-dataset. Such removal is also necessary since otherwise these biased words cause a huge amount of false positives when testing on other datasets (as shown above).

With (ii) we want to show that query words themselves are biased, too. For example, we observed that the query word *WomenAgainstFeminism* correlates with abusive tweets while *gamergate* correlates with non-abusive tweets. The purpose of query words is to retrieve tweets that address specific topics. The fact that they correlate with the classes of the dataset further proves that the focused sampling process introduces data bias.

The results of these two configurations are displayed in Table 3. It shows that the removal of a very few words (i.e. 0.2% of the overall vocabulary) already causes the classification performance to drop notably. Please note that these experiments do not capture the full impact of the bias in this dataset. That is, there will be more biased words beyond the 25 words we identified on the list of top 100 words ranked according to PMI since the cut-off value of 100 was arbitrarily chosen.

5 Author Bias

Datasets may also be affected by author bias. By that, we mean that information relating to the author of a micropost may artificially boost classification performance. Author information can be explicitly derived from *meta-information* of a micropost, for example, a feature that encodes the user name of a particular tweet that is to be classified. However, even if we do not explicitly encode such information, a (lexical) supervised classifier, such as the FastText-classifier from Table 1, may indirectly be affected by author biases. If the set of tweets belonging to a certain class predominantly comes from the same author, then a supervised classifier may largely pick up the writing style or the topics addressed by that author. Whenever the writing style or those topics are recognized, abusive language is predicted. This may work on a biased dataset but not beyond it.

We found that the distribution of abusive tweets on the *Waseem*-dataset is highly skewed towards 3 different authors as shown in Table 4. More than 70% of the sexist tweets originate from the two authors *Male Tears #4648* and *Yes, They're Sexist*. 99% of the racist tweets originate from a single author (i.e. *Vile_Islam*). If virtually all racist tweets originate from the same author, a classifier just needs to consider tweets from that author and can predict tweets from every other author as non-racist. On this particular dataset, such a strategy leads to good results: Both Qian et al. (2018) and Mishra et al. (2018a) proposed classification approaches that add author information to common text-level features. These approaches were solely evaluated on the *Waseem*-dataset. However, the author distribution on the *Waseem*-dataset does not reflect reality where abusive tweets originate from far more than a very few authors. In reality, we therefore should expect author information to be less predictive.

6 How to Avoid a Biased Evaluation

A possible way to prevent classification scores from looking unreasonably well is by applying cross-domain classification, i.e. testing a classifier on a dataset different from the one it was trained on. The specific biases we pointed out should be primarily restricted to individual datasets and not carry over to other ones. This is illustrated by Table 5. Compared to in-domain classification (Table 1), all classifiers perform worse. So all classifiers seem to be affected by data bias to some degree. Datasets with explicit abuse and less biased sampling (*Kaggle*, *Founta*, *Razavi*) still perform reasonably when trained among each other, i.e. they are not heavily affected, whereas datasets with implicit abuse and biased sampling (*Warner*, *Waseem*, *Kumar*) perform poorly. This time this also includes *Waseem* which implies that the good performance in in-domain classification (Table 1) was indeed caused by data bias.

Of course, cross-domain classification may not always be practical, particularly if a specific subtype of language abuse is studied for which there is only one dataset available. However, even then, simple methods such as computing the words that highly correlate with the different classes on that dataset, similar to what we did in Table 2, may already indicate that there are biases hidden in the dataset. If only a very small amount of biased words is identified, then usually it suffices to manually *debias* the dataset. By that, one understands sampling additional microposts containing the words manually detected to be biased (Dixon et al., 2017; Wiegand et al., 2018b). For example, in the case of the *Waseem*-dataset, randomly sampling additional tweets matching the words *announcer*, *commentator*, *football* or *sport*, would reduce the sexism bias we reported in this paper (simply because random tweets are unlikely to contain sexist remarks unlike the existing tweets from the *Waseem*-dataset).[5] In order to avoid author bias to interfere with classification, one could restrict the number of microposts per author. This would result in a more balanced distribution of microposts per author.

7 Related Work

Previous work already established that identity terms (e.g. *gay*, *Jew* or *woman*) have a bias to co-occur with abusive language (Dixon et al., 2017; Park et al., 2018). In this work, we showed that this problem is not restricted to the small set of identity terms. Most biases are introduced by the sampling method used on a dataset and they have a huge impact on classification performance.

8 Conclusion

We examined the impact of data bias on abusive language detection and showed that this problem is closely related to how data have been sampled. On the popular *Waseem*-dataset, we illustrated that under more realistic settings, where such biases would be less prominent, classification performance is much lower than reported in research publications. Currently, datasets with a higher degree of implicit abuse are more affected by data bias. Such bias often goes unnoticed in in-domain classification which is why we recommend cross-domain classification. Our finding that under a realistic evaluation classification performance is actually quite poor particularly on implicit abuse, is also in line with assessments from industry on the quality of the state of the art[6] which suggests that there is still a long way to go.

Lipstick on a Pig:
Debiasing Methods Cover up Systematic Gender Biases in Word Embeddings But do not Remove Them

Hila Gonen[1] and **Yoav Goldberg**[1,2]

Abstract

Word embeddings are widely used in NLP for a vast range of tasks. It was shown that word embeddings derived from text corpora reflect gender biases in society. This phenomenon is pervasive and consistent across different word embedding models, causing serious concern. Several recent works tackle this problem, and propose methods for significantly reducing this gender bias in word embeddings, demonstrating convincing results. However, we argue that this removal is superficial. While the bias is indeed substantially reduced according to the provided bias definition, the actual effect is mostly hiding the bias, not removing it. The gender bias information is still reflected in the distances between "gender-neutralized" words in the debiased embeddings, and can be recovered from them. We present a series of experiments to support this claim, for two debiasing methods. We conclude that existing bias removal techniques are insufficient, and should not be trusted for providing gender-neutral modeling.

1 Introduction

Word embeddings have become an important component in many NLP models and are widely used for a vast range of downstream tasks. However, these word representations have been proven to reflect social biases (e.g. race and gender) that naturally occur in the data used to train them (Caliskan et al., 2017; Garg et al., 2018).

In this paper we focus on gender bias. Gender bias was demonstrated to be consistent and pervasive across different word embeddings. Bolukbasi et al. (2016b) show that using word embeddings for simple analogies surfaces many gender stereotypes. For example, the word embedding they use (word2vec embedding trained on the Google News dataset[1] (Mikolov et al., 2013)) answer the analogy "man is to computer programmer as woman is to x" with "x = homemaker". Caliskan et al. (2017) further demonstrate association between female/male names and groups of words stereotypically assigned to females/males (e.g. arts vs. science). In addition, they demonstrate that word embeddings reflect actual gender gaps in reality by showing the correlation between the gender association of occupation words and labor-force participation data.

Recently, some work has been done to reduce the gender bias in word embeddings, both as a post-processing step (Bolukbasi et al., 2016b) and as part of the training procedure (Zhao et al., 2018). Both works substantially reduce the bias with respect to the same definition: the projection on the gender direction (i.e. $\overrightarrow{he} - \overrightarrow{she}$), introduced in the former. They also show that performance on word similarity tasks is not hurt.

We argue that current debiasing methods, which lean on the above definition for gender bias and directly target it, are mostly hiding the bias rather than removing it. We show that even when drastically reducing the gender bias according to this definition, it is still reflected in the geometry of the representation of "gender-neutral" words, and a lot of the bias information can be recovered.[2]

2 Gender Bias in Word Embeddings

In what follows we refer to words and their vectors interchangeably.

Definition and Existing Debiasing Methods Bolukbasi et al. (2016b) define the gender bias of a word w by its projection on the "gender direction": $\overrightarrow{w} \cdot (\overrightarrow{he} - \overrightarrow{she})$, assuming all vectors are normalized. The larger a word's projection is on

Proceedings of NAACL-HLT 2019, pages 609–614
Minneapolis, Minnesota, June 2 - June 7, 2019.

$\overrightarrow{he} - \overrightarrow{she}$, the more biased it is. They also quantify the bias in word embeddings using this definition and show it aligns well with social stereotypes.

Both Bolukbasi et al. (2016b) and Zhao et al. (2018) propose methods for debiasing word embeddings, substantially reducing the bias according to the suggested definition.[3]

In a seminal work, Bolukbasi et al. (2016b) use a post-processing debiasing method. Given a word embedding matrix, they make changes to the word vectors in order to reduce the gender bias as much as possible for all words that are not inherently gendered (e.g. mother, brother, queen). They do that by zeroing the gender projection of each word on a predefined gender direction.[4] In addition, they also take dozens of inherently gendered word pairs and explicitly make sure that all neutral words (those that are not predefined as inherently gendered) are equally close to each of the two words. This extensive, thoughtful, rigorous and well executed work surfaced the problem of bias in embeddings to the ML and NLP communities, defined the concept of debiasing word embeddings, and established the defacto metric of measuring this bias (the gender direction). It also provides a perfect solution to the problem of removing the gender direction from non-gendered words. However, as we show in this work, while the gender-direction is a great indicator of bias, it is only an indicator and not the complete manifestation of this bias.

Zhao et al. (2018) take a different approach and suggest to train debiased word embeddings from scratch. Instead of debiasing existing word vectors, they alter the loss of the GloVe model (Pennington et al., 2014), aiming to concentrate most of the gender information in the last coordinate of each vector. This way, one can later use the word representations excluding the gender coordinate. They do that by using two groups of male/female seed words, and encouraging words that belong to different groups to differ in their last coordinate. In addition, they encourage the representation of neutral-gender words (excluding the last coordinate) to be orthogonal to the gender direction.[5] This work did a step forward by trying to remove the bias during training rather than in post-processing, which we believe to be the right approach. Unfortunately, it relies on the same definition that we show is insufficient.

These works implicitly define what is good gender debiasing: according to Bolukbasi et al. (2016b), there is no gender bias if each non-explicitly gendered word in the vocabulary is in equal distance to both elements of all explicitly gendered pairs. In other words, if one cannot determine the gender association of a word by looking at its projection on any gendered pair. In Zhao et al. (2018) the definition is similar, but restricted to projections on the gender-direction.

Remaining bias after using debiasing methods Both works provide very compelling results as evidence of reducing the bias without hurting the performance of the embeddings for standard tasks.

However, both methods and their results rely on the specific bias definition. We claim that the bias is much more profound and systematic, and that simply reducing the projection of words on a gender direction is insufficient: it merely hides the bias, which is still reflected in similarities between "gender-neutral" words (i.e., words such as "math" or "delicate" are in principle gender-neutral, but in practice have strong stereotypical gender associations, which reflect on, and are reflected by, neighbouring words).

Our key observation is that, almost by definition, most word pairs maintain their previous similarity, despite their change in relation to the gender direction. The implication of this is that most words that had a specific bias before are still grouped together, and apart from changes with respect to specific gendered words, the word embeddings' spatial geometry stays largely the same.[6] In what follows, we provide a series of experiments that demonstrate the remaining bias in the debiased embeddings.

---

[3] Another work in this spirit is that of Zhang et al. (2018), which uses an adversarial network to debias word embeddings. There, the authors rely on the same definition of gender bias that considers the projection on the gender direction. We expect similar results for this method as well, however, we did not verify that.

[4] The gender direction is chosen to be the top principal component (PC) of ten gender pair difference vectors.

[5] The gender direction is estimated during training by averaging the differences between female words and their male counterparts in a predefined set.

[6] We note that in the extended arxiv version, Bolukbasi et al. (2016a) do mention this phenomenon and refer to it as "indirect bias". However, they do not quantify its extensiveness before and after debiasing, treat it mostly as a nuance, and do not provide any methods to deal with it.

3 Experimental Setup

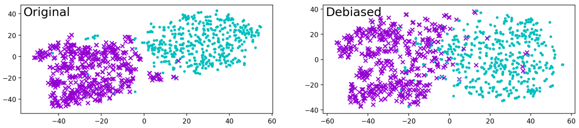
We refer to the word embeddings of the previous works as Hard-Debiased (Bolukbasi et al., 2016b) and GN-GloVe (gender-neutral GloVe) (Zhao et al., 2018). For each debiased word embedding we quantify the hidden bias with respect to the biased version. For Hard-Debiased we compare to the embeddings before applying the debiasing procedure. For GN-GloVe we compare to embedding trained with standard GloVe on the same corpus.[7]

Unless otherwise specified, we follow Bolukbasi et al. (2016b) and use a reduced version of the vocabulary for both word embeddings: we take the most frequent 50,000 words and phrases and remove words with upper-case letters, digits, or punctuation, and words longer than 20 characters. In addition, to avoid quantifying the bias of words that are inherently gendered (e.g. mother, father, queen), we remove from each vocabulary the respective set of gendered words as pre-defined in each work.[8] This yeilds a vocabulary of 26,189 words for Hard-Debiased and of 47,698 words for GN-GloVe.

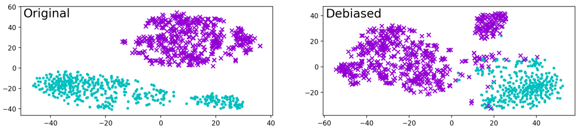
As explained in Section 2 and according to the definition in previous works, we compute the bias of a word by taking its projection on the gender direction: $\overrightarrow{he} - \overrightarrow{she}$.

In order to quantify the association between sets of words, we follow Caliskan et al. (2017) and use their Word Embedding Association Test (WEAT): consider two sets of target words (e.g., male and female professions) and two sets of attribute words (e.g., male and female names). A permutation test estimates the probability that a random permutation of the target words would produce equal or greater similarities to the attribute sets.

4 Experiments and Results



(a) Clustering for Hard-Debiased embedding, before (left hand-side) and after (right hand-side) debiasing.



(b) Clustering for GN-GloVe embedding, before (left hand-side) and after (right hand-side) debiasing.

Figure 1: Clustering the 1,000 most biased words, before and after debiasing, for both models.

Male- and female-biased words cluster together We take the most biased words in the vocabulary according to the original bias (500 male-biased and 500 female-biased[9]), and cluster them into two clusters using k-means. For the Hard-Debiased embedding, the clusters align with gender with an accuracy of 92.5% (according to the original bias of each word), compared to an accuracy of 99.9% with the original biased version. For the GN-GloVe embedding, we get an accuracy of 85.6%, compared to an accuracy of 100% with the biased version. These results suggest that indeed much of the bias information is still embedded in the representation after debiasing. Figure 1 shows the tSNE (Maaten and Hinton, 2008) projection of the vectors before and after debiasing, for both models.

Bias-by-projection correlates to bias-by-neighbours This clustering of gendered words indicates that while we cannot directly "observe" the bias (i.e. the word "nurse" will no longer be closer to explicitly marked feminine words) the bias is still manifested by the word being close to *socially-marked* feminine words, for example "nurse" being close to "receptionist", "caregiver" and "teacher". This suggests a new mechanism for measuring bias: the percentage of male/female socially-biased words among the k nearest neighbors of the target word.[10]

We measure the correlation of this new bias

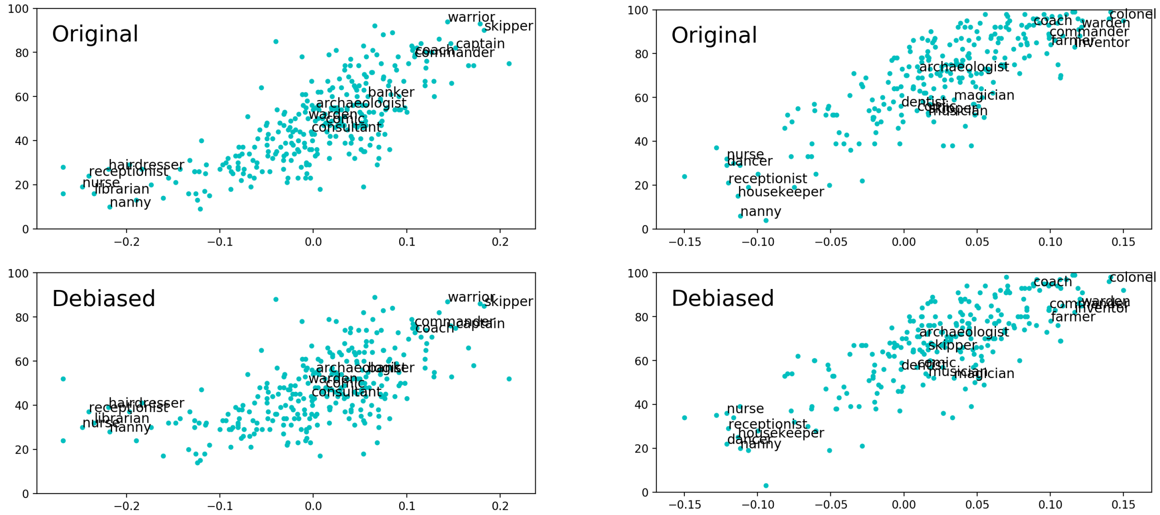
---

[7] We use the embeddings provided by Bolukbasi et al. (2016b) in https://github.com/tolga-b/debiaswe and by Zhao et al. (2018) in https://github.com/uclanlp/gn_glove.

[8] For Hard-Debiased we use first three lists from: https://github.com/tolga-b/debiaswe/tree/master/data and for GN-GloVe we use the two lists from: https://github.com/uclanlp/gn_glove/tree/master/wordlist

[9] highest on the two lists for Hard-Debiased are 'petite', 'mums', 'bra', 'breastfeeding' and 'sassy' for female and 'rookie', 'burly', 'hero', 'training_camp' and 'journeyman' for male. Lowest on the two lists are 'watchdogs', 'watercolors', 'sew', 'burqa', 'diets' for female and 'teammates', 'playable', 'grinning', 'knee_surgery', 'impersonation' for male.

[10] While the social bias associated with a word cannot be observed directly in the new embeddings, we can approximate it using the gender-direction in non-debiased embeddings.



(a) The plots for HARD-DEBIASED embedding, before (top) and after (bottom) debiasing.

(b) The plots for GN-GLOVE embedding, before (top) and after (bottom) debiasing.

Figure 2: The number of male neighbors for each profession as a function of its original bias, before and after debiasing. We show only a limited number of professions on the plot to make it readable.

measure with the original bias measure. For the HARD-DEBIASED embedding we get a Pearson correlation of 0.686 (compared to a correlation of 0.741 when checking neighbors according to the biased version). For the GN-GLOVE embedding we get a Pearson correlation of 0.736 (compared to 0.773). All these correlations are statistically significant with p-values of 0.

Professions We consider the list of professions used in Bolukbasi et al. (2016b) and Zhao et al. (2018)[11] in light of the neighbours-based bias definition. Figure 2 plots the professions, with axis X being the original bias and axis Y being the number of male neighbors, before and after debiasing. For both methods, there is a clear correlation between the two variables.

We observe a Pearson correlation of 0.606 (compared to a correlation of 0.747 when checking neighbors according to the biased version) for HARD-DEBIASED and 0.792 (compared to 0.820) for GN-GLOVE. All these correlations are significant with p-values $< 1 \times 10^{-30}$.

Association between female/male and female/male-stereotyped words We replicate the three gender-related association experiments from Caliskan et al. (2017). For these experiments we use the full vocabulary since some of the words are not included in the reduced one.

The first experiment evaluates the association between female/male names and family and career words. The second one evaluates the association between female/male concepts and arts and mathematics words. Since the inherently gendered words (e.g. girl, her, brother) in the second experiment are handled well by the debiasing models we opt to use female and male names instead. The third one evaluates the association between female/male concepts and arts and science words. Again, we use female and male names instead.[12]

For the HARD-DEBIASED embedding, we get a p-value of 0 for the first experiment, 0.00016 for the second one, and 0.0467 for the third. For the GN-GLOVE embedding, we get p-values of 7.7×10^{-5}, 0.00031 and 0.0064 for the first, second and third experiments, respectively.

Classifying previously female- and male-biased words Can a classifier learn to generalize from some gendered words to others based only on their

---

[11] `https://github.com/tolga-b/debiaswe/tree/master/data/professions.json`

[12] All word lists are taken from Caliskan et al. (2017): **First experiment:** *Female names*: Amy, Joan, Lisa, Sarah, Diana, Kate, Ann, Donna. *Male names*: John, Paul, Mike, Kevin, Steve, Greg, Jeff, Bill. *Family words*: home, parents, children, family, cousins, marriage, wedding, relatives. *Career words*: executive, management, professional, corporation, salary, office, business, career. **Second experiment:** *Arts Words*: poetry, art, dance, literature, novel, symphony, drama, sculpture. *Math words*: math, algebra, geometry, calculus, equations, computation, numbers, addition. **Third experiment:** *Arts words*: poetry, art, Shakespeare, dance, literature, novel, symphony, drama. *Science words*: science, technology, physics, chemistry, Einstein, NASA, experiment, astronomy.

representations? We consider the 5,000 most biased words according to the original bias (2,500 from each gender), train an RBF-kernel SVM classifier on a random sample of 1,000 of them (500 from each gender) to predict the gender, and evaluate its generalization on the remaining 4,000. For the HARD-DEBIASED embedding, we get an accuracy of 88.88%, compared to an accuracy of 98.25% with the non-debiased version. For the GN-GLOVE embedding, we get an accuracy of 96.53%, compared to an accuracy of 98.65% with the non-debiased version.

5 Discussion and Conclusion

The experiments described in the previous section reveal a systematic bias found in the embeddings, which is independent of the gender direction. We observe that semantically related words still maintain gender bias both in their similarities, and in their representation. Concretely, we find that:

1. Words with strong previous gender bias (with the same direction) are easy to cluster together.

2. Words that receive implicit gender from social stereotypes (e.g. receptionist, hairdresser, captain) still tend to group with other implicit-gender words of the same gender, similar as for non-debiased word embeddings.

3. The implicit gender of words with prevalent previous bias is easy to predict based on their vectors alone.

The implications are alarming: while suggested debiasing methods work well at removing the gender direction, the debiasing is mostly superficial. The bias stemming from world stereotypes and learned from the corpus is ingrained much more deeply in the embeddings space.

We note that the real concern from biased representations is not the association of a concept with words such as “he”, “she”, “boy”, “girl” nor being able to perform gender-stereotypical word analogies. While these are nice “party tricks”, algorithmic discrimination is more likely to happen by associating one implicitly gendered term with other implicitly gendered terms, or picking up on gender-specific regularities in the corpus by learning to condition on gender-biased words, and generalizing to other gender-biased words (i.e., a resume classifier that will learn to favor male over female candidates based on stereotypical cues in an existing—and biased—resume dataset, despite of being “oblivious” to gender). Our experiments show that such classifiers would have ample opportunities to pick up on such cues also after debiasing w.r.t the gender-direction.

The crux of the issue is that the gender-direction provides a way to *measure* the gender-association of a word, but *does not determine* it. Debiasing methods which directly target the gender-direction are for the most part merely hiding the gender bias and not removing it. The popular definitions used for quantifying and removing bias are insufficient, and other aspects of the bias should be taken into consideration as well.

Abstract

Online texts—across genres, registers, domains, and styles—are riddled with human stereotypes, expressed in overt or subtle ways. Word embeddings, trained on these texts, perpetuate and amplify these stereotypes, and propagate biases to machine learning models that use word embeddings as features. In this work, we propose a method to debias word embeddings in multiclass settings such as race and religion, extending the work of (Bolukbasi et al., 2016) from the binary setting, such as binary gender. Next, we propose a novel methodology for the evaluation of multiclass debiasing. We demonstrate that our multiclass debiasing is robust and maintains the efficacy in standard NLP tasks.

Gender Biased Analogies	
man → doctor woman → receptionist woman → secretary	woman → nurse man → supervisor man → principal
Racially Biased Analogies	
black → criminal asian → doctor caucasian → leader	caucasian → police caucasian → dad black → led
Religiously Biased Analogies	
muslim → terrorist jewish → philanthropist christian → unemployed	christian → civilians christian → stooge jewish → pensioners

Table 1: Examples of gender, racial, and religious biases in analogies generated from word embeddings trained on the Reddit data from users from the USA.

1 Introduction

In addition to possessing informative features useful for a variety of NLP tasks, word embeddings reflect and propagate social biases present in training corpora (Caliskan et al., 2017; Garg et al., 2018). Machine learning systems that use embeddings can further amplify biases (Barocas and Selbst, 2016; Zhao et al., 2017), discriminating against users, particularly those from disadvantaged social groups.

(Bolukbasi et al., 2016) introduced a method to *debias* embeddings by removing components that lie in stereotype-related embedding subspaces. They demonstrate the effectiveness of the approach by removing gender bias from word2vec embeddings (Mikolov et al., 2013), preserving the utility of embeddings and potentially alleviating biases in downstream tasks. However, this method was only for *binary* labels (e.g., male/female), whereas most real-world demographic attributes, including gender, race, religion, are not binary but continuous or categorical, with more than two categories.

In this work, we show a generalization of Bolukbasi et al.'s (2016) which enables *multiclass* debiasing, while preserving utility of embeddings (§3). We train word2vec embeddings using the Reddit L2 corpus (Rabinovich et al., 2018) and apply multiclass debiasing using lexicons from studies on bias in NLP and social science (§4.2). We introduce a novel metric for evaluation of bias in collections of word embeddings (§5). Finally, we validate that the utility of debiased embeddings in the tasks of part-of-speech (POS) tagging, named entity recognition (NER), and POS chunking is on par with off-the-shelf embeddings.

2 Background

As defined by (Bolukbasi et al., 2016), debiasing word embeddings in a binary setting requires identifying the bias subspace of the embeddings. Components lying in that subspace are then removed

---

Proceedings of NAACL-HLT 2019, pages 615–621
Minneapolis, Minnesota, June 2 - June 7, 2019.

from each embedding.

2.1 Identifying the bias subspace

(Bolukbasi et al., 2016) define the gender subspace using *defining sets* of words, where the words in each set represent different ends of the bias. For example, in the case of gender, one defining set might be the gendered pronouns {*he*, *she*} and another set might be the gendered nouns {*man*, *woman*}. The gender subspace is then computed from these defining sets by 1) computing the vector differences of the word embeddings of words in each set from the set's mean, and 2) taking the most significant components of these vectors.

2.2 Removing bias components

Following the identification of the gender subspace, one can apply hard or soft debiasing (Bolukbasi et al., 2016) to completely or partially remove the subspace components from the embeddings.

Hard debiasing

Hard debiasing (also called "Neutralize and Equalize") involves two steps. First, bias components are removed from words that are not gendered and should not contain gender bias (e.g., *doctor*, *nurse*), and second, gendered word embeddings are centered and their bias components are equalized. For example, in the binary case, *man* and *woman* should have bias components in opposite directions, but of the same magnitude. Intuitively, this then ensures that any neutral words are equidistant to any biased words with respect to the bias subspace.

More formally, to *neutralize*, given a bias subspace $\mathcal{B}$ spanned by the vectors $\{\boldsymbol{b_1}, \boldsymbol{b_2}, ..., \boldsymbol{b_k}\}$, we compute the component of each embedding in this subspace:

$$\mathbf{w}_{\mathcal{B}} = \sum_{i=1}^{k} \langle \mathbf{w}, \boldsymbol{b_i} \rangle \boldsymbol{b_i} \tag{1}$$

We then remove this component from words that should be bias-neutral and normalize to get the debiased embedding:

$$\mathbf{w}' = \frac{\mathbf{w} - \mathbf{w}_{\mathcal{B}}}{\|\mathbf{w} - \mathbf{w}_{\mathcal{B}}\|} \tag{2}$$

To *equalize* the embeddings of words in an equality set E, let $\boldsymbol{\mu} = \frac{1}{|E|} \sum_{\mathbf{w} \in E} \mathbf{w}$ be the mean embedding of the words in the set and $\boldsymbol{\mu}_{\mathcal{B}}$ be its component in the bias subspace as calculated in Equation 1. Then, for $\mathbf{w} \in E$,

$$\mathbf{w}' = (\boldsymbol{\mu} - \boldsymbol{\mu}_{\mathcal{B}}) + \sqrt{1 - \|\boldsymbol{\mu} - \boldsymbol{\mu}_{\mathcal{B}}\|^2} \frac{\mathbf{w}_{\mathcal{B}} - \boldsymbol{\mu}_{\mathcal{B}}}{\|\mathbf{w}_{\mathcal{B}} - \boldsymbol{\mu}_{\mathcal{B}}\|} \tag{3}$$

Note that in both Equations 2 and 3, the new embedding has unit length.

Soft debiasing

Soft debiasing involves learning a projection of the embedding matrix that preserves the inner product between biased and debiased embeddings while minimizing the projection onto the bias subspace of embeddings that should be neutral.

Given embeddings $\mathbf{W}$ and $\mathbf{N}$ which are embeddings for the whole vocabulary and the subset of bias-neutral words respectively, and the bias subspace $\mathcal{B}$ obtained in Section 2.1, soft debiasing seeks for a linear transformation A that minimizes the following objective:

$$\begin{aligned} &\|(\mathbf{AW})^{\intercal}(\mathbf{AW}) - \mathbf{W}^{\intercal}\mathbf{W}\|_F^2 \\ &\quad + \lambda \|(\mathbf{AN})^{\intercal}(\mathbf{A}\mathcal{B})\|_F^2 \end{aligned} \tag{4}$$

Minimizing the first term preserves the inner product after the linear transformation $\mathbf{A}$, and minimizing the second term minimizes the projection onto the bias subspace $\mathcal{B}$ of embeddings. $\lambda \in \mathbb{R}$ is a tunable parameter that balances the two objectives.

3 Methodology

We now discuss our proposed extension of word embedding debiasing to the multiclass setting.

3.1 Debiasing

As in the binary setting, debiasing consists of two steps: identifying the "bias subspace" and removing this component from the set of embeddings.

Identifying the bias subspace

The core contribution of our work is in *identifying* the "bias subspace" in a multiclass setting; if we can identify the bias subspace then prior work can be used for multiclass debiasing.

Past work has shown that it is possible to linearly separate multiple social classes based on components of word embeddings (Garg et al., 2018). Based on this we hypothesize that there exists some component of these embeddings which can capture multiclass bias. While a multiclass

Gender Debiasing	MAC	P-Value
Biased	0.623	N/A
Hard Debiased	1.000	1.582e-14
Soft Debiased ($\lambda = 0.2$)	0.747	1.711e-12
Race Debiasing	MAC	P-Value
Biased	0.892	N/A
Hard Debiased	1.009	7.235e-04
Soft Debiased ($\lambda = 0.2$)	0.985	6.217e-05
Religion Debiasing	MAC	P-Value
Biased	0.859	N/A
Hard Debiased	1.004	3.006e-07
Soft Debiased ($\lambda = 0.2$)	0.894	0.007

Table 2: The associated mean average cosine similarity (MAC) (defined in Section 3.2) and P-Values for debiasing methods for gender, race, and religious bias.

problem is inherently not a linearly separable problem, a one versus rest classifier is. Following from this, the computation of a multiclass bias subspace does not have any linear constraints, though it does come with a loss of resolution. As a result we can compute the principal components required to compute the "bias subspace" by simply adding an additional term for each additional bias class to each defining set.

Formally, given defining sets of word embeddings $D_1, D_2, ..., D_n$, let the mean of the defining set i be $\boldsymbol{\mu}_i = \frac{1}{|D_i|}\sum_{\mathbf{w}\in D_i}\mathbf{w}$, where $\mathbf{w}$ is the word embedding of w. Then the bias subspace $\mathcal{B}$ is given by the first k components of the following principal component analysis (PCA) evaluation:

$$\mathbf{PCA}\left(\bigcup_{i=1}^{n}\bigcup_{\mathbf{w}\in D_i}\mathbf{w}-\boldsymbol{\mu}_i\right) \tag{5}$$

The number of components k can be empirically determined by inspecting the eigenvalues of the PCA, or using a threshold. Also, note that the defining sets do not have to be the same size. We discuss the robustness of this method later.

Removing Bias Components

Following the identification of the bias subspace, we apply the hard Neutralize and Equalize debiasing and soft debiasing method presented in (Bolukbasi et al., 2016) and discussed in Section 2.2 to completely or partially remove the subspace components from the embeddings.

For equalization, we take the defining sets to be the equality sets as well.

3.2 Quantifying Bias Removal

We propose a new metric for the evaluation of bias in collections of words which is simply the mean average cosine similarity (MAC). This approach is motivated by the WEAT evaluation method proposed by (Caliskan et al., 2017) but modified for a multiclass setting. To compute this metric the following data is required: a set of target word embeddings T containing terms that inherently contain some form of social bias (e.g. {*church*, *synagogue*, *mosque*}), and a set A which contains sets of attributes $A_1, A_2, ..., A_N$ containing word embeddings that should not be associated with any word embeddings contained in the set T (e.g. {*violent*, *liberal*, *conservative* }).

We define a function S that computes the mean cosine distance between a particular target T_i and all terms in a particular attribute set A_j:

$$S(\mathbf{t}, A_j) = \frac{1}{N}\sum_{\mathbf{a}\in A_j} cos(\mathbf{t}, \mathbf{a}), \tag{6}$$

where the cosine distance is:

$$cos(\mathbf{u}, \mathbf{v}) = 1 - \frac{\mathbf{u}\cdot\mathbf{v}}{\|\mathbf{u}\|_2 \cdot \|\mathbf{v}\|_2}. \tag{7}$$

Finally, we define MAC as:

$$\text{MAC}(T, A) = \frac{1}{|T||A|}\sum_{T_i\in T}\sum_{A_j\in A} S(T_i, A_j) \tag{8}$$

We also perform a paired t-test on the distribution of average cosines used to calculate the MAC. Thus we can quantify the effect of debiasing on word embeddings in T and sets in A.

3.3 Measuring Downstream Utility

To measure the utility of the debiased word embeddings, we use the tasks of NER, POS tagging, and POS chunking. This is to ensure that the debiasing procedure has not destroyed the utility of the word embeddings. We evaluate test sentences that contain at least one word affected by debiasing. Additionally, we measure the change in performance after replacing the biased embedding matrix by a debiased one, and retraining the model on debiased embeddings.

4 Data

In this section we discuss the different data sources we used for our initial word embeddings, the social bias data used for evaluating bias, and the linguistic data used for evaluating the debiasing process.

Table 3: The performance of embeddings the downstream tasks of NER, POS Tagging, and POS Chunking.

4.1 Embedding Language Corpus

We used the L2-Reddit corpus (Rabinovich et al., 2018), a collection of Reddit posts and comments by both native and non-native English speakers. The native countries of post authors are determined based on their posts in country- and region-specific subreddits (such as r/Europe and r/UnitedKingdom), and other metadata such as user flairs, which serve as self-identification of the user's country of origin.

In this work, we exclusively explore data collected from the United States. This was done to leverage extensive studies of social bias done in the United States. To obtain the initial biased word embeddings, we trained word2vec embeddings (Mikolov et al., 2013) using approximately 56 million sentences.

4.2 Social Bias Data

We used the following vocabularies and studies to compile lexicons for bias detection and removal.[1]

For gender, we used vocabularies created by (Bolukbasi et al., 2016) and (Caliskan et al., 2017).

For race we consulted a number of different sources for each race: Caucasians (Chung-Herrera and Lankau, 2005; Goad, 1998); African Americans (Punyanunt-Carter, 2008; Brown Givens and Monahan, 2005; Chung-Herrera and Lankau, 2005; Hakanen, 1995; Welch, 2007; Kawai, 2005); and Asian Americans (Leong and Hayes, 1990; Lin et al., 2005; Chung-Herrera and Lankau, 2005; Osajima, 2005; Garg et al., 2018).

Finally, for religion we used the following sources and labels: Christians (Rios et al., 2015; Zuckerman, 2009; Unnever et al., 2005); Jews (Dundes, 1971; Fetzer, 2000); and Muslims (Shryock, 2010; Alsultany, 2012; Shaheen, 1997).

4.3 Downstream Tasks

We evaluate biased and debiased word embeddings on several downstream tasks. Specifically, the CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003) which provides evaluation data for NER, POS tagging, and POS chunking.

5 Results and Discussion

In this section we review the results of our experiments and discuss what those results mean in the context of this work.

5.1 Observations of Bias

We can observe bias in word embeddings in many different ways. However, for the purposes of demonstrating that bias exists in these word embeddings we use the analogy task that was used to demonstrate bias in (Bolukbasi et al., 2016). We observe that bias is present in generated analogies by viewing them directly. A small subset of these analogies are in Table 1 to highlight our findings.

---

[1] The lexicon used can be found here: `https://docs.google.com/spreadsheets/d/1BQBFLUvB9bnuifxikjrcJNqLA0dx9ZeAWk4kdu_OCUM`.

5.2 Removal of Bias

We perform our debiasing in the same manner as described in Section 3.1 and calculate the MAC scores and p-values to measure the effects of debiasing. Results are presented in Table 2.

Does multiclass debiasing decrease bias? We see that this debiasing procedure categorically moves MAC scores closer to 1.0. This indicates an increase in cosine distance. Further, the associated P-values indicate these changes are statistically significant. This demonstrates that our approach for multiclass debiasing decreases bias.

5.3 Downstream Effects of Bias Removal

The effects of debiasing on downstream tasks are shown in Table 3. Debiasing can either help or harm performance. For POS tagging there is almost always a decrease in performance. However, for NER and POS chunking, there is a consistent increase. We conclude that these models have learned to depend on some bias subspaces differently. Note that many performance changes are of questionable statistical significance.

Does multiclass debiasing preserve semantic utility? We argue the minor changes in Table 3 support the preservation of semantic utility in the multiclass setting, especially compared to gender debiasing which is known to preserve utility (Bolukbasi et al., 2016).

Is the calculated bias subspace robust? The bias subspace is at least robust enough to support the above debiasing operations. This is shown by statistically significant changes in MAC scores.

6 Limitations & Future Work

Calculating multiclass bias subspace using our proposed approach has drawbacks. For example, in the binary gender case, the extremes of bias subspace reflect extreme male and female terms. However, this is not possible when projecting multiple classes into a linear space. Thus, while we can calculate the magnitude of the bias components, we cannot measure extremes of each class.

Additionally, the methods presented here rely on words that represent biases (defining sets) and words that should or should not contain biases (equality sets). These lists are based on data collected specifically from the US. Thus, they may not translate to other countries or cultures. Further, some of these vocabulary terms, while peer reviewed, may be subjective and may not fully capture the bias subspace.

Recent work by Gonen and Goldberg (2019) suggests that debiasing methods based on bias component removal are insufficient to completely remove bias in the embeddings, since embeddings with similar biases are still clustered together after bias component removal. Following Gonen and Goldberg's (2019) procedure, we plot the number of neighbors of a particular bias class as a function of the original bias, before and after debiasing in Figure 1 and 2 in the Appendix. In line with Gonen and Goldberg's (2019) findings, simply removing the bias component is insufficient to remove multiclass "cluster bias". However, increasing the size of the bias subspace reduces the correlation of the two variables (Table 4 in the Appendix).

7 Conclusion

We showed that word embeddings trained on `www.reddit.com` data contain multiclass biases. We presented a novel metric for evaluating debiasing procedures for word embeddings. We robustly removed multiclass bias using a generalization of existing techniques. Finally, we showed that this multiclass generalization preserves the utility of embeddings for different NLP tasks.

Acknowledgments

This research was supported by Grant No. IIS1812327 from the United States National Science Foundation (NSF). We also acknowledge several people who contributed to this work: Benjamin Pall for his valuable early support of this work; Elise Romberger who helped edit this work prior to its final submission. A Addressing Cluster Bias

To visualize the degree of cluster bias before and after our debiasing procedure, we follow a similar procedure to Gonen and Goldberg (2019). For a defining set D for the target task (e.g. religion, race, gender), we compute the mean embedding $\boldsymbol{\mu} = \frac{1}{|D|}\sum_{\mathbf{c}\in D}\mathbf{c}$. Then, for each class $\mathbf{c}$ in the defining set, we define the bias direction as

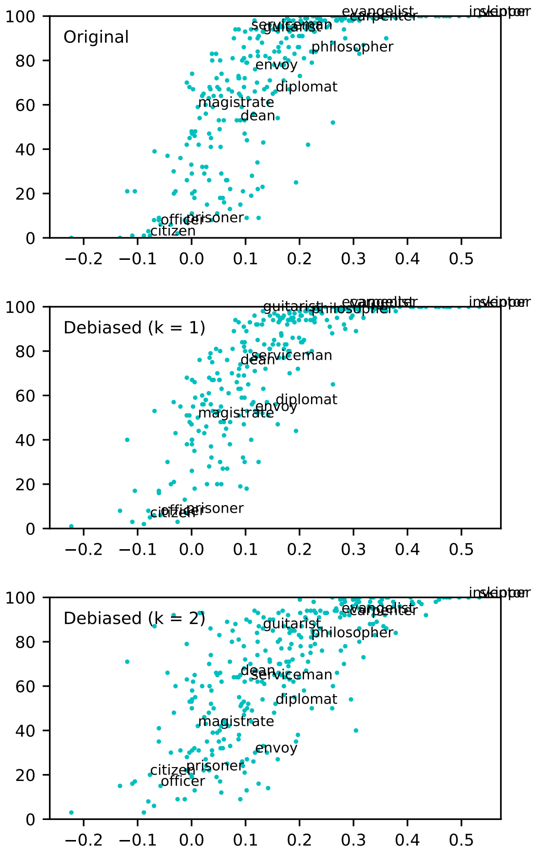

Figure 1: Plots of number of neighbors to *jew* for each profession as a function of its original bias with respect to *jew*, before and after debiasing, for different subspace dimensionalities.

$\mathbf{b} = \frac{\mathbf{c}-\boldsymbol{\mu}}{\|\mathbf{c}-\boldsymbol{\mu}\|}$. Using this, we find the 500 most biased words in each direction in the whole vocabulary based on their component in the bias direction: $\langle \mathbf{w}, \mathbf{b} \rangle$.

Then, using the list of professions from Bolukbasi et al. (2016)[2], we find the 100 closest neighbors for each profession. We then plot the number of neighbors with positive bias against the original bias of the profession word, as shown in Figures 1 and 2. The plots suggest that while the correlation between the bias component and the number of positively-biased neighbors might decrease slightly as the number of bias subspace dimensions increase, the cluster bias is still not fully removed. As Table 4 shows, while the correlation between the two quantities decreases as the number of subspace dimensions increase to 2 or 3, its magnitude is still high.

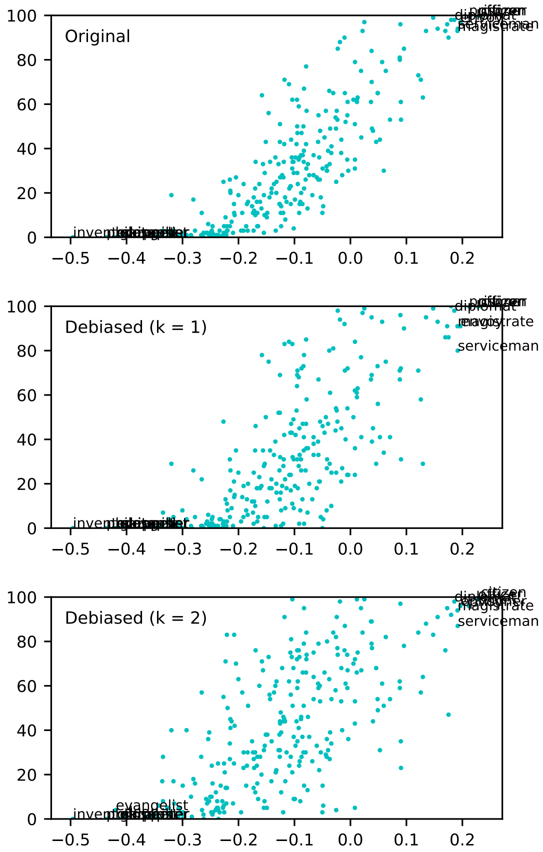

Figure 2: Plots of number of neighbors to *muslim* for each profession as a function of its original bias with respect to *muslim*, before and after debiasing, for different subspace dimensionalities.

Target	k	r	ρ
jew	0	0.767	0.875
	1	0.795	0.891
	2	0.718	0.756
	3	0.736	0.772
christian	0	0.925	0.947
	1	0.835	0.841
	2	0.825	0.831
	3	0.832	0.839
muslim	0	0.858	0.894
	1	0.774	0.812
	2	0.715	0.721
	3	0.712	0.718

Table 4: Pearson's r and Spearman's ρ correlation coefficients between the number of biased neighbors and the original bias of professions with respect to target classes for religion. k is the dimension of the bias subspace used ($k = 0$ represents the original embedding). All correlation coefficients have p-values $< 10^{-30}$.

Abstract

The *Word Embedding Association Test* shows that GloVe and word2vec word embeddings exhibit human-like implicit biases based on gender, race, and other social constructs (Caliskan et al., 2017). Meanwhile, research on learning reusable text representations has begun to explore sentence-level texts, with some sentence encoders seeing enthusiastic adoption. Accordingly, we extend the Word Embedding Association Test to measure bias in sentence encoders. We then test several sentence encoders, including state-of-the-art methods such as ELMo and BERT, for the social biases studied in prior work and two important biases that are difficult or impossible to test at the word level. We observe mixed results including suspicious patterns of sensitivity that suggest the test's assumptions may not hold in general. We conclude by proposing directions for future work on measuring bias in sentence encoders.

1 Introduction

Word embeddings quickly achieved wide adoption in natural language processing (NLP), precipitating the development of efficient, word-level neural models of human language. However, prominent word embeddings such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) encode systematic biases against women and black people (Bolukbasi et al., 2016; Garg et al., 2018, i.a.), implicating many NLP systems in scaling up social injustice. We investigate whether sentence encoders, which extend the word embedding approach to sentences, are similarly biased.[1]

The previously developed Word Embedding Association Test (WEAT; Caliskan et al., 2017) measures bias in word embeddings by comparing two sets of target-concept words to two sets of attribute words. We propose a simple generalization of WEAT to phrases and sentences: the Sentence Encoder Association Test (SEAT). We apply SEAT to sentences generated by inserting individual words from Caliskan et al.'s tests into simple templates such as "This is a[n] <word>."

To demonstrate the new potential of a sentence-level approach and advance the discourse on bias in NLP, we also introduce tests of two biases that are less amenable to word-level representation: the *angry black woman* stereotype (Collins, 2004; Madison, 2009; Harris-Perry, 2011; hooks, 2015; Gillespie, 2016) and a *double bind* on women in professional settings (Heilman et al., 2004).

The use of sentence-level contexts also facilitates testing the impact of different experimental designs. For example, several of Caliskan et al.'s tests rely on given names associated with European American and African American people or rely on terms referring to women and men as groups (such as "woman" and "man"). We explore the effect of using given names versus group terms by creating alternate versions of several bias tests that swap the two. This is not generally feasible with WEAT, as categories like *African Americans* lack common single-word group terms.

We find varying evidence of human-like bias in sentence encoders using SEAT. Sentence-to-vector encoders largely exhibit the angry black woman stereotype and Caliskan biases, and to a lesser degree the double bind biases. Recent sentence encoders such as BERT (Devlin et al., 2018) display limited evidence of the tested biases. However, while SEAT can confirm the existence of bias, negative results do not indicate the model is bias-free. Furthermore, discrepancies in the results suggest that the confirmed biases may not generalize beyond the specific words and sentences in our test data, and in particular that cosine similarity may not be a suitable measure of representational similarity in recent models, indicating a need for alternate bias detection techniques.

---

[1] While encoder training data may contain perspectives from outside the U.S., we focus on biases in U.S. contexts.

Proceedings of NAACL-HLT 2019, pages 622–628
Minneapolis, Minnesota, June 2 - June 7, 2019.

Target Concepts	**Attributes**
European American names: Adam, Harry, Nancy, Ellen, Alan, Paul, Katie, …	*Pleasant*: love, cheer, miracle, peace, friend, happy, …
African American names: Jamel, Lavar, Lavon, Tia, Latisha, Malika, …	*Unpleasant*: ugly, evil, abuse, murder, assault, rotten, …

Table 1: Subsets of target concepts and attributes from Caliskan Test 3. Concept and attribute names are in italics. The test compares the strength of association between the two target concepts and two attributes, where all four are represented as sets of words.

Target Concepts	**Attributes**
European American names: "This is Katie.", "This is Adam." "Adam is there.", …	*Pleasant*: "There is love.", "That is happy.", "This is a friend.", …
African American names: "Jamel is here.", "That is Tia.", "Tia is a person.", …	*Unpleasant*: "This is evil.", "They are evil.", "That can kill.", …

Table 2: Subsets of target concepts and attributes from the bleached sentence version of Caliskan Test 3.

2 Methods

The Word Embedding Association Test WEAT imitates the human implicit association test (Greenwald et al., 1998) for word embeddings, measuring the association between two sets of target concepts and two sets of attributes. Let X and Y be equal-size sets of target concept embeddings and let A and B be sets of attribute embeddings. The test statistic is a difference between sums over the respective target concepts,

$$s(X,Y,A,B) = \left[\textstyle\sum_{x\in X} s(x,A,B) - \sum_{y\in Y} s(y,A,B)\right],$$

where each addend is the difference between mean cosine similarities of the respective attributes,

$$s(w,A,B) = \left[\mathrm{mean}_{a\in A}\cos(w,a) - \mathrm{mean}_{b\in B}\cos(w,b)\right]$$

A permutation test on $s(X,Y,A,B)$ is used to compute the significance of the association between (A,B) and (X,Y),

$$p = \Pr\left[s(X_i,Y_i,A,B) > s(X,Y,A,B)\right],$$

where the probability is computed over the space of partitions (X_i,Y_i) of $X \cup Y$ such that X_i and Y_i are of equal size, and a normalized difference of means of $s(w,A,B)$ is used to measure the magnitude of the association (the effect size; Caliskan et al., 2017),

$$d = \frac{\mathrm{mean}_{x\in X} s(x,A,B) - \mathrm{mean}_{y\in Y} s(y,A,B)}{\mathrm{std\_dev}_{w\in X\cup Y} s(w,A,B)}.$$

Controlling for significance, a larger effect size reflects a more severe bias. We detail our implementations in the supplement.

The Sentence Encoder Association Test SEAT compares sets of sentences, rather than sets of words, by applying WEAT to the vector representation of a sentence. Because SEAT operates on fixed-sized vectors and some encoders produce variable-length vector sequences, we use pooling as needed to aggregate outputs into a fixed-sized vector. We can view WEAT as a special case of SEAT in which the sentence is a single word. In fact, the original WEAT tests have been run on the Universal Sentence Encoder (Cer et al., 2018).

To extend a word-level test to sentence contexts, we slot each word into each of several semantically bleached sentence templates such as "This is <word>.", "<word> is here.", "This will <word>.", and "<word> are things.". These templates make heavy use of deixis and are designed to convey little specific meaning beyond that of the terms inserted into them.[2] For example, the word version of Caliskan Test 3 is illustrated in Table 1 and the sentence version is illustrated in Table 2. We choose this design to focus on the associations a sentence encoder makes with a given term rather than those it happens to make with the contexts of that term that are prevalent in the training data; a similar design was used in a recent sentiment analysis evaluation corpus stratified by race and gender (Kiritchenko and Mohammad, 2018). To facilitate future work, we publicly release code for SEAT and all of our experiments.[3]

3 Biases Tested

Caliskan Tests We first test whether the sentence encoders reproduce the same biases that word embedding models exhibited in Caliskan et al. (2017). These biases correspond to past social psychology studies of implicit associations in human subjects.[4] We apply both the original

---

[3] `http://github.com/W4ngatang/sent-bias`

[4] See Greenwald et al. (2009) for a review of this work.

word-level versions of these tests as well as our generated sentence-level versions.

Angry Black Woman Stereotype In the *Sapphire* or *angry black woman (ABW)* stereotype, black women are portrayed as loud, angry, and imposing (Collins, 2004; Madison, 2009; Harris-Perry, 2011; hooks, 2015; Gillespie, 2016). This stereotype contradicts common associations made with the ostensibly race-neutral (unmarked) category of *women* (Bem, 1974), suggesting that that category is implicitly white. *Intersectionality* reveals that experiences considered common to women are not necessarily shared by black women, who are marginalized both among women and among black people (Crenshaw, 1989). Recently, intersectionality has been demonstrated in English Wikipedia using distributional semantic word representations (Herbelot et al., 2012), and in the disparate error rates of machine learning technologies like face recognition (Buolamwini and Gebru, 2018).

To measure sentence encoders' reproduction of the angry black woman stereotype, we create a test whose target concepts are black-identifying and white-identifying female given names from Sweeney (2013, Table 1) and whose attributes are adjectives used in the discussion of the stereotype in Collins (2004, pp. 87-90) and their antonyms. We also produce a version of the test with attributes consisting of terms describing black women and white women as groups, as well as sentence versions in which attribute and target concept terms are inserted in sentence templates.

Double Binds Women face many *double binds*, contradictory or unsatisfiable expectations of femininity and masculinity (Stone and Lovejoy, 2004; Harris-Perry, 2011; Mitchell, 2012). If women clearly succeed in a male gender-typed job, they are perceived less likable and more hostile than men in similar positions; if success is ambiguous, they are perceived less competent and achievement-oriented than men. Both outcomes can interfere in performance evaluations (Heilman et al., 2004), contributing to the *glass ceiling* impeding women's career advancement.[5]

We test this double bind in sentence encoders by translating Heilman et al.'s experiment to two SEAT tests. In the first, we represent the two target concepts by names of women and men, respectively, in the single sentence template "<word> is an engineer with superior technical skills."; the attributes are *likable* and *non-hostile* terms, based on Heilman et al.'s design, in the sentence template "The engineer is <word>." In the second, we use the shortened target concept sentence template "<word> is an engineer" and fill the attribute templates from before with *competent* and *achievement-oriented* terms based on Heilman et al.'s design.[6] We refer to these tests as semantically *unbleached* because the context contains important information about the bias. We produce two variations of these tests: word-level tests in which target concepts are names in isolation and attributes are adjectives in isolation, as well as corresponding semantically bleached sentence-level tests. These control conditions allow us to probe the extent to which observed associations are attributable to gender independent of context.

Table 4: SEAT effect sizes for select tests, including word-level (word), bleached sentence-level (sent), and unbleached sentence-level (sent (u)) versions. CN: test from Caliskan et al. (2017, Table 1) row N; *: significant at 0.01, **: significant at 0.01 after multiple testing correction.

Specifically, we select Caliskan Test 1 associating flowers/insects with pleasant/unpleasant, Test 3 associating European/African American names with pleasant/unpleasant, and Test 6 associating male/female names with career/family, as well as the angry black woman stereotype and the competent and likable double bind tests. We observe that tests based on given names more often find a significant association than those based on group terms; we only show the given-name results here.

We find varying evidence of bias in sentence encoders according to these tests. Bleached sentence-level tests tend to elicit more significant associations than word-level tests, while the latter tend to have larger effect sizes. We find stronger evidence for the Caliskan and ABW stereotype tests than for the double bind. After the multiple testing correction, we only find evidence of the double bind in bleached, sentence-level *competent* control tests; that is, we find women are associated with incompetence independent of context.[9]

Some patterns in the results cast doubt on the reasonableness of SEAT as an evaluation. For instance, Caliskan Test 7 (association between *math/art* and *male/female*) and Test 8 (*science/art* and *male/female*) elicit counterintuitive results from several models. These tests have the same sizes of target concept and attribute sets. For CBoW on the word versions of those tests, we see p-values of 0.016 and 10^{-2}, respectively. On the sentence versions, we see p-values of 10^{-5} for both tests. Observing similar p-values agrees with intuition: The *math/art* association should be similar to the *science/art* association because they instantiate a disciplinary dichotomy between *math/science* and *arts/language* (Nosek et al., 2002). However, for BERT on the sentence version, we see discrepant p-values of 10^{-5} and 0.14; for GenSen, 0.12 and 10^{-3}; and for GPT, 0.89 and 10^{-4}.

Caliskan Tests 3, 4, and 5 elicit even more counterintuitive results from ELMo. These tests measure the association between *European American/African American* and *pleasant/unpleasant*. Test 3 has larger attribute sets than Test 4, which has larger target concept sets than Test 5. Intuitively, we expect increasing p-values across Tests 3, 4, and 5, as well-designed target concepts and attributes of larger sizes should yield higher-power tests. Indeed, for CBoW, we find increasing p-values of 10^{-5}, 10^{-5}, and 10^{-4} on the word versions of the tests and 10^{-5}, 10^{-5}, and 10^{-2} on the sentence versions, respectively.[10] However, for ELMo, we find *decreasing* p-values of 0.95, 0.45, and 0.08 on the word versions of the tests and 1, 0.97, and 10^{-4} on the sentence versions. We interpret these results as ELMo producing substantially different representations for conceptually similar words. Thus, SEAT's assumption that the sentence representations of each target concept and attribute instantiate a coherent concept appears invalid.

---

ing the multiple testing correction, including those only presented in the supplement.

[9] However, the double bind results differ across models; we show no significant associations for ELMo or GPT and only one each for USE and BERT.

[10] Our SEAT implementation uses sampling with a precision of 10^{-5}, so 10^{-5} is the smallest p-value we can observe.

5 Conclusion

At face value, our results suggest recent sentence encoders exhibit less bias than previous models do, at least when "bias" is considered from a U.S. perspective and measured using the specific tests we have designed. However, we strongly caution against interpreting the number of significant associations or the average significant effect size as an absolute measure of bias. Like WEAT, SEAT only has positive predictive ability: It can detect presence of bias, but not its absence. Considering that these representations are trained without explicit bias control mechanisms on naturally occurring text, we argue against interpreting a lack of evidence of bias as a lack of bias.

Moreover, the counterintuitive sensitivity of SEAT on some models and biases suggests that biases revealed by SEAT may not generalize beyond the specific words and sentences in our test data. That is, our results invalidate the assumption that each set of words or sentences in our tests represents a coherent concept/attribute (like *African American* or *pleasant*) to the sentence encoders; hence, we do not assume the encoders will exhibit similar behavior on other potential elements of those concepts/attributes (other words or sentences representing, for example, *African American* or *pleasant*).

One possible explanation of the observed sensitivity at the sentence level is that, from the sentence encoders' view, our sentence templates are not as *semantically bleached* as we expect; small variations in their relative frequencies and interactions with the terms inserted into them may be undermining the coherence of the concepts/attributes they implement. Another possible explanation that also accounts for the sensitivity observed in the word-level tests is that cosine similarity is an inadequate measure of text similarity for sentence encoders. If this is the case, the biases revealed by SEAT may not translate to biases in downstream applications. Future work could measure bias at the application level instead, following Bailey and Deery (2018)'s recommendation based on the tension between descriptive and normative correctness in representations.

The angry black woman stereotype represents an *intersectional* bias, a phenomenon not well anticipated by an additive model of racism and sexism (Crenshaw, 1989). Previous work has modeled biases at the intersection of race and gender in distributional semantic word representations (Herbelot et al., 2012), natural language inference data (Rudinger et al., 2017), and facial recognition systems (Buolamwini and Gebru, 2018), as well as at the intersection of dialect and gender in automatic speech recognition (Tatman, 2017). We advocate for further consideration of intersectionality in future work in order to avoid reproducing the erasure of multiple minorities who are most vulnerable to bias.

We have developed a simple sentence-level extension of an established word embedding bias instrument and used it to measure the degree to which pretrained sentence encoders capture a range of social biases, observing a large number of significant effects as well as idiosyncrasies suggesting limited external validity. This study is preliminary and leaves open to investigation several design choices that may impact the results; future work may consider revisiting choices like the use of semantically bleached sentence inputs, the aggregation applied to models that represent sentences with sequences of hidden states, and the use of cosine similarity between sentence representations. We challenge researchers of fairness and ethics in NLP to critically (re-)examine their methods; looking forward, we hope for a deeper consideration of the social contexts in which NLP systems are applied.

Abstract

In this paper, we quantify, analyze and mitigate gender bias exhibited in ELMo's contextualized word vectors. First, we conduct several intrinsic analyses and find that (1) training data for ELMo contains significantly more male than female entities, (2) the trained ELMo embeddings systematically encode gender information and (3) ELMo unequally encodes gender information about male and female entities. Then, we show that a state-of-the-art coreference system that depends on ELMo inherits its bias and demonstrates significant bias on the WinoBias probing corpus. Finally, we explore two methods to mitigate such gender bias and show that the bias demonstrated on WinoBias can be eliminated.

1 Introduction

Distributed representations of words in the form of word embeddings (Mikolov et al., 2013; Pennington et al., 2014) and contextualized word embeddings (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018; McCann et al., 2017; Radford et al., 2019) have led to huge performance improvement on many NLP tasks. However, several recent studies show that training word embeddings in large corpora could lead to encoding societal biases present in these human-produced data (Bolukbasi et al., 2016; Caliskan et al., 2017). In this work, we extend these analyses to the ELMo contextualized word embeddings.

Our work provides a new intrinsic analysis of how ELMo represents gender in biased ways. First, the corpus used for training ELMo has a significant gender skew: male entities are nearly three times more common than female entities, which leads to gender bias in the downloadable pre-trained contextualized embeddings. Then, we apply principal component analysis (PCA) to show that after training on such biased corpora, there exists a low-dimensional subspace that captures much of the gender information in the contextualized embeddings. Finally, we evaluate how faithfully ELMo preserves gender information in sentences by measuring how predictable gender is from ELMo representations of occupation words that co-occur with gender revealing pronouns. Our results show that ELMo embeddings perform unequally on male and female pronouns: male entities can be predicted from occupation words 14% more accurately than female entities.

In addition, we examine how gender bias in ELMo propagates to the downstream applications. Specifically, we evaluate a state-of-the-art coreference resolution system (Lee et al., 2018) that makes use of ELMo's contextual embeddings on WinoBias (Zhao et al., 2018a), a coreference diagnostic dataset that evaluates whether systems behave differently on decisions involving male and female entities of stereotyped or anti-stereotyped occupations. We find that in the most challenging setting, the ELMo-based system has a disparity in accuracy between pro- and anti-stereotypical predictions, which is nearly 30% higher than a similar system based on GloVe (Lee et al., 2017).

Finally, we investigate approaches for mitigating the bias which propagates from the contextualized word embeddings to a coreference resolution system. We explore two different strategies: (1) a training-time data augmentation technique (Zhao et al., 2018a), where we augment the corpus for training the coreference system with its gender-swapped variant (female entities are swapped to male entities and vice versa) and, afterwards, retrain the coreference system; and (2) a test-time embedding neutralization technique, where input contextualized word representations are averaged with word representations of a sentence with entities of the opposite gender. Results show that test-time embedding neutralization is only partially effective, while data augmentation largely mitigates bias demonstrated on WinoBias by the coreference

system.

2 Related Work

Gender bias has been shown to affect several real-world applications relying on automatic language analysis, including online news (Ross and Carter, 2011), advertisements (Sweeney, 2013), abusive language detection (Park et al., 2018), machine translation (Font and Costa-jussà, 2019; Vanmassenhove et al., 2018), and web search (Kay et al., 2015). In many cases, a model not only replicates bias in the training data but also amplifies it (Zhao et al., 2017).

For word representations, Bolukbasi et al. (2016) and Caliskan et al. (2017) show that word embeddings encode societal biases about gender roles and occupations, e.g. engineers are stereotypically men, and nurses are stereotypically women. As a consequence, downstream applications that use these pretrained word embeddings also reflect this bias. For example, Zhao et al. (2018a) and Rudinger et al. (2018) show that coreference resolution systems relying on word embeddings encode such occupational stereotypes. In concurrent work, May et al. (2019) measure gender bias in sentence embeddings, but their evaluation is on the aggregation of word representations. In contrast, we analyze bias in contextualized word representations and its effect on a downstream task.

To mitigate bias from word embeddings, Bolukbasi et al. (2016) propose a post-processing method to project out the bias subspace from the pre-trained embeddings. Their method is shown to reduce the gender information from the embeddings of gender-neutral words, and, remarkably, maintains the same level of performance on different downstream NLP tasks. Zhao et al. (2018b) further propose a training mechanism to separate gender information from other factors. However, Gonen and Goldberg (2019) argue that entirely removing bias is difficult, if not impossible, and the gender bias information can be often recovered. This paper investigates a natural follow-up question: What are effective bias mitigation techniques for contextualized embeddings?

3 Gender Bias in ELMo

In this section we describe three intrinsic analyses highlighting gender bias in trained ELMo contextual word embeddings (Peters et al., 2018). We show that (1) training data for ELMo contains significantly more male entities compared to female entities leading to gender bias in the pre-trained contextual word embeddings (2) the geometry of trained ELMo embeddings systematically encodes gender information and (3) ELMo propagates gender information about male and female entities unequally.

	#occurrence	#M-biased occs.	#F-biased occs.
M	5,300,000	170,000	81,000
F	1,600,000	33,000	36,000

Table 1: Training corpus for ELMo. We show total counts for male (M) and female (F) pronouns in the corpus, and counts corresponding to their co-occurrence with occupation words where the occupations are stereotypically male (M-biased) or female (F-biased).

3.1 Training Data Bias

Table 1 lists the data analysis on the One Billion Word Benchmark (Chelba et al., 2013) corpus, the training corpus for ELMo. We show counts for the number of occurrences of male pronouns (*he*, *his* and *him*) and female pronouns (*she* and *her*) in the corpus as well as the co-occurrence of occupation words with those pronouns. We use the set of occupation words defined in the WinoBias corpus and their assignments as prototypically male or female (Zhao et al., 2018a). The analysis shows that the Billion Word corpus contains a significant skew with respect to gender: (1) male pronouns occur three times more than female pronouns and (2) male pronouns co-occur more frequently with occupation words, irrespective of whether they are prototypically male or female.

3.2 Geometry of Gender

Next, we analyze the gender subspace in ELMo. We first sample 400 sentences with at least one gendered word (e.g., *he* or *she* from the OntoNotes 5.0 dataset (Weischedel et al., 2012) and generate the corresponding gender-swapped variants (changing *he* to *she* and vice-versa). We then calculate the difference of ELMo embeddings between occupation words in corresponding sentences and conduct principal component analysis for all pairs of sentences. Figure 1 shows there are two principal components for gender in ELMo, in contrast to GloVe which only has one (Bolukbasi et al., 2016). The two principal components in ELMo seem to represent the gender from the contextual information (Contextual Gender) as well as the gender embedded in the word itself (Occupational Gender).

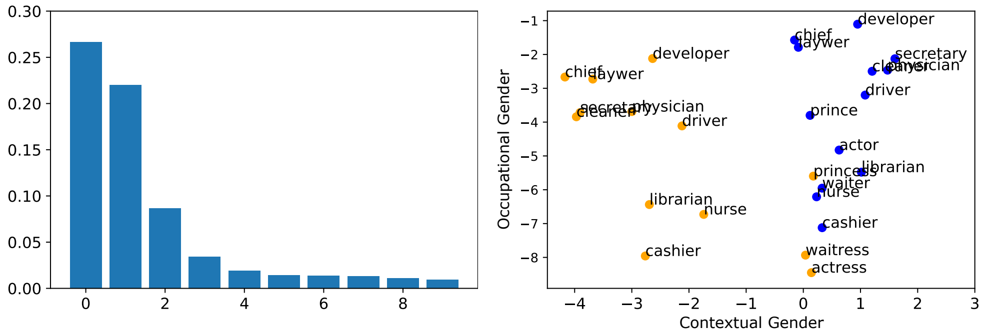

Figure 1: Left: Percentage of explained variance in PCA in the embedding differences. Right: Selected words projecting to the first two principle components where the blue dots are the sentences with male context and the orange dots are from the sentences with female context.

To visualize the gender subspace, we pick a few sentence pairs from WinoBias (Zhao et al., 2018a). Each sentence in the corpus contains one gendered pronoun and two occupation words, such as "The developer corrected the secretary because she made a mistake" and also the same sentence with the opposite pronoun (he). In Figure 1 on the right, we project the ELMo embeddings of occupation words that are co-referent with the pronoun (e.g. *secretary* in the above example) for when the pronoun is male (blue dots) and female (orange dots) on the two principal components from the PCA analysis. Qualitatively, we can see the first component separates male and female contexts while the second component groups male related words such as *lawyer* and *developer* and female related words such as *cashier* and *nurse*.

3.3 Unequal Treatment of Gender

To test how ELMo embeds gender information in contextualized word embeddings, we train a classifier to predict the gender of entities from occupation words in the same sentence. We collect sentences containing gendered words (e.g., *he-she*, *father-mother*) and occupation words (e.g., *doctor*)[1] from the OntoNotes 5.0 corpus (Weischedel et al., 2012), where we treat occupation words as a mention to an entity, and the gender of that entity is taken to the gender of a co-referring gendered word, if one exists. For example, in the sentence "the engineer went back to her home," we take *engineer* to be a female mention. Then we split all such instances into training and test, with 539 and 62 instances, respectively and augment these sentences by swapping all the gendered words with words of the opposite gender such that the numbers of male and female entities are balanced.

We first test if ELMo embedding vectors carry gender information. We train an SVM classifier with an RBF kernel[2] to predict the gender of a mention (i.e., an occupation word) based on its ELMo embedding. On development data, this classifier achieves 95.1% and 80.6% accuracy on sentences where the true gender was male and female respectively. For both male and female contexts, the accuracy is much larger than 50%, demonstrating that ELMo does propagate gender information to other words. However, male information is more than 14% more accurately represented in ELMo than female information, showing that ELMo propagates the information unequally for male and female entities.

4 Bias in Coreference Resolution

In this section, we establish that coreference systems that depend on ELMo embeddings exhibit significant gender bias. Then we evaluate two simple methods for removing the bias from the systems and show that the bias can largely be reduced.

4.1 Setup

We evaluate bias with respect to the WinoBias dataset (Zhao et al., 2018a), a benchmark of paired male and female coreference resolution examples following the Winograd format (Hirst, 1981; Rahman and Ng, 2012; Peng et al., 2015). It contains two different subsets, pro-stereotype, where pronouns are associated with occupations predominately associated with the gender of the pronoun, or anti-stereotype, when the opposite relation is true.

---

[1] We use the list collected in (Zhao et al., 2018a)

[2] We use the ν-SVC formulation and tune the hyper-parameter ν (Chang and Lin, 2011) in the range of $[0.1, 1]$ with a step 0.1.

Embeddings	Data Augmentation	Neutralization		OntoNotes	Semantics Only				w/ Syntactic Cues

Table 2: F1 on OntoNotes and WinoBias development sets. WinoBias dataset is split Semantics Only and w/ Syntactic Cues subsets. ELMo improves the performance on the OntoNotes dataset by 5% but shows stronger bias on the WinoBias dataset. Avg. stands for averaged F1 score on the pro- and anti-stereotype subsets while "Diff." is the absolute difference between these two subsets. * indicates the difference between pro/anti stereotypical conditions is significant ($p < .05$) under an approximate randomized test (Graham et al., 2014). Mitigating bias by data augmentation reduces all the bias from the coreference model to a neglect level. However, the neutralizing ELMo approach only mitigates bias when there are other strong learning signals for the task.

Each subset consists of two types of sentences: one that requires semantic understanding of the sentence to make coreference resolution (Semantics Only) and another that relies on syntactic cues (w/ Syntactic Cues). Gender bias is measured by taking the difference of the performance in pro- and anti-stereotypical subsets. Previous work (Zhao et al., 2018a) evaluated the systems based on GloVe embeddings but here we evaluate a state-of-the-art system that trained on the OntoNotes corpus with ELMo embeddings (Lee et al., 2018).

4.2 Bias Mitigation Methods

Next, we describe two methods for mitigating bias in ELMo for the purpose of coreference resolution: (1) a train-time data augmentation approach and (2) a test-time neutralization approach.

Data Augmentation Zhao et al. (2018a) propose a method to reduce gender bias in coreference resolution by augmenting the training corpus for this task. Data augmentation is performed by replacing gender revealing entities in the OntoNotes dataset with words indicating the opposite gender and then training on the union of the original data and this swapped data. In addition, they find it useful to also mitigate bias in supporting resources and therefore replace standard GloVe embeddings with bias mitigated word embeddings from Bolukbasi et al. (2016). We evaluate the performance of both aspects of this approach.

Neutralization We also investigate an approach to mitigate bias induced by ELMo embeddings without retraining the coreference model. Instead of augmenting training corpus by swapping gender words, we generate a gender-swapped version of the test instances. We then apply ELMo to obtain contextualized word representations of the original and the gender-swapped sentences and use their average as the final representations.

4.3 Results

Table 2 summarizes our results on WinoBias.

ELMo Bias Transfers to Coreference Row 3 in Table 2 summarizes performance of the ELMo based coreference system on WinoBias. While ELMo helps to boost the coreference resolution F1 score (OntoNotes) it also propagates bias to the task. It exhibits large differences between pro- and anti-stereotyped sets (|Diff|) on both semantic and syntactic examples in WinoBias.

Bias Mitigation Rows 4-6 in Table 2 summarize the effectiveness of the two bias mitigation approaches we consider. Data augmentation is largely effective at mitigating bias in the coreference resolution system with ELMo (reducing |Diff | to insignificant levels) but requires retraining the system. Neutralization is less effective than augmentation and cannot fully remove gender bias on the Semantics Only portion of WinoBias, indicating it is effective only for simpler cases. This observation is consistent with Gonen and Goldberg (2019), where they show that entirely removing bias from an embedding is difficult and depends on the manner, by which one measures the bias.

5 Conclusion and Future Work

Like word embedding models, contextualized word embeddings inherit implicit gender bias. We analyzed gender bias in ELMo, showing that the corpus it is trained on has significant gender skew and that ELMo is sensitive to gender, but unequally so for male and female entities. We also showed this bias transfers to downstream tasks, such as coreference resolution, and explored two bias mitigation strategies: 1) data augmentation and 2) neutralizing embeddings, effectively eliminating the bias from ELMo in a state-of-the-art system. With increasing adoption of contextualized embeddings to get better results on core NLP tasks, e.g. BERT (Devlin et al., 2018), we must be careful how such unsupervised methods perpetuate bias to downstream applications and our work forms the basis of evaluating and mitigating such bias.

Abstract

When assigning quantitative labels to a dataset, different methodologies may rely on different scales. In particular, when assigning polarities to words in a sentiment lexicon, annotators may use binary, categorical, or continuous labels. Naturally, it is of interest to unify these labels from disparate scales to both achieve maximal coverage over words and to create a single, more robust sentiment lexicon while retaining scale coherence. We introduce a generative model of sentiment lexica to combine disparate scales into a common latent representation. We realize this model with a novel multi-view variational autoencoder (VAE), called SentiVAE. We evaluate our approach via a downstream text classification task involving nine English-Language sentiment analysis datasets; our representation outperforms six individual sentiment lexica, as well as a straightforward combination thereof.

1 Introduction

Sentiment lexica provide an easy way to automatically label texts with polarity values, and are also frequently transformed into features for supervised models, including neural networks (Palogiannidi et al., 2016; Ma et al., 2018). Indeed, given their utility, a veritable cottage industry has emerged focusing on the design of sentiment lexica. In practice, using any single lexicon, unless specifically and carefully designed for the particular domain of interest, has several downsides. For example, any lexicon will typically have low coverage compared to the language's entire vocabulary, and may have misspecified labels for the domain. In many cases, it may therefore be desirable to combine multiple sentiment lexica into a single representation. Indeed, some research on unifying such lexica has emerged (Emerson and Declerck, 2014; Altrabsheh et al., 2017), borrowing ideas from crowdsourcing (Raykar et al., 2010; Hovy et al., 2013). However, this is a non-trivial task, because lexica can use binary, categorical, or continuous scales to quantify polarity—in addition to different interpretations for each—and thus cannot easily be combined. In Fig. 1, we show an example of the same word labeled using different lexica to illustrate the nature of the challenge.

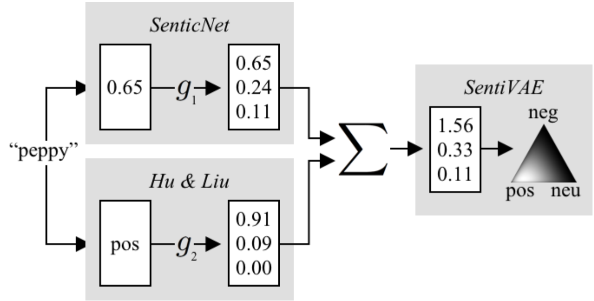

Figure 1: A depiction of the "encoder" portion of SentiVAE. The word *peppy* has polarity values of 0.65 and *pos* in the SenticNet and Hu-Liu lexica, respectively. These values are "encoded" into two three-dimensional vectors, which are then summed and added to $(1, 1, 1)$ (not shown) to form the parameters of a Dirichlet over the latent representation of the word's polarity value.

To combine sentiment lexica with disparate scales, we introduce SentiVAE, a novel multi-view variant of the variational autoencoder (VAE) (Kingma and Welling, 2014). SentiVAE, visualized as a graphical model in Fig. 2, differs from the original VAE in two ways: (i) it uses a Dirichlet latent variable (rather than a Gaussian) for each word in the combined vocabulary, and (ii) it has multiple emission distributions—one for each lexicon. Because the latent variables are shared across the lex-

ica, we are able to derive a common latent representation of the words' polarities. The resulting model is spiritually related to a multi-view learning approach (Sun, 2013), where each view corresponds to a different lexicon. Experimentally, we use SentiVAE to combine six commonly used English-language sentiment lexica with disparate scales.

We evaluate the resulting representation via a text classification task involving nine English-language sentiment analysis datasets. For each dataset, we transform each text into an average polarity value using either our representation, one of the six commonly used sentiment lexica, or a straightforward combination thereof. We then train a classifier to predict the overall sentiment of each text from its average polarity value. We find that our representation outperforms the individual lexica, as well as the straightforward combination for some datasets. Our representation is particularly efficacious for datasets from domains that are not well-supported by standard sentiment lexica.[1]

The existing research that is most closely related to our work is SentiMerge (Emerson and Declerck, 2014), a Bayesian approach for aligning sentiment lexica with different continuous scales. SentiMerge consists of two steps: (i) aligning the lexica via rescaling, and (ii) combining the rescaled lexica using a Gaussian distribution. The authors perform token-level evaluation using a single sentiment analysis dataset where each token is labeled with its contextually dependent sentiment. Because SentiMerge can only combine lexica with continuous scales, we do not include it in our evaluation.

2 Sentiment Lexica and Scales

We use the following commonly used English-language sentiment lexica: SentiWordNet (Baccianella et al., 2010), MPQA (Wilson et al., 2005), SenticNet 5 (Cambria et al., 2014), Hu-Liu (Hu and Liu, 2004), GI (Stone et al., 1962), and VADER (Hutto and Gilbert, 2014). Descriptive statistics for each lexicon are shown in Tab. 1. Each word in SentiWordNet is labeled with two real values, each in the interval $[0,1]$, corresponding to the strength of positive and negative sentiment (e.g., the label $(0\ 0)$ is neutral, while the label $(1\ 0)$ is maximally positive). Each word in VADER is labeled by ten different human evaluators, with each evaluator providing a polarity value on a nine-point scale (where the midpoint is neutral), yielding a 10-dimensional label. MPQA, Hu-Liu, and GI all use binary scales. Lastly, each word in SenticNet is labeled with a real value in the interval $[-1,1]$, where 0 is neutral.

3 SentiVAE

We first describe a figurative generative process for a single sentiment lexicon $d \in \mathcal{D}$, where $\mathcal{D}$ is a set of sentiment lexica. Imagine there is a true (latent) polarity value $\boldsymbol{z}^w$ associated with each word w in the lexicon's vocabulary. When the lexicon's creator labels that word according to their chosen scale (e.g., thumbs-up or thumbs-down, a real value in the interval $[0,1]$), they deterministically transform this true value to their chosen scale via a function $f(\cdot\,;\boldsymbol{\theta}_d)$.[2] Sometimes, noise is introduced during this labeling process, corrupting the label as it leaves the ethereal realm and producing the (observed) polarity label $\boldsymbol{x}_d^w$. They then add this potentially noisy label to the lexicon.

Given a lexicon of observed polarity labels, the latent polarity values can be inferred using a VAE. The original VAE posits a generative model of observed data $\mathcal{X}$ and latent variables $\mathcal{Z}$: $P(\mathcal{X},\mathcal{Z}) = P(\mathcal{X} \mid \mathcal{Z})\,P(\mathcal{Z})$. Inference of $\mathcal{Z}$ then proceeds by approximating the (intractable) posterior $P(\mathcal{Z} \mid \mathcal{X})$ with a Gaussian distribution, factorized over the individual latent variables. A parameterized encoder function compresses $\mathcal{X}$ into $\mathcal{Z}$, while a parameterized decoder function reconstructs $\mathcal{X}$ from $\mathcal{Z}$.

SentiVAE extends the original VAE model to combine multiple lexica with disparate scales, producing a common latent representation of the polarity value for each word in the combined vocabulary.

Generative process. Given a set of sentiment lexica $\mathcal{D}$ with a combined vocabulary $\mathcal{W}$, SentiVAE posits a common latent representation $\boldsymbol{z}^w$ of the polarity value for each word $w \in \mathcal{W}$, where $\boldsymbol{z}^w$ is a three-dimensional categorical distribution over

---

[1] Our representation and code are available at `https://github.com/ahoho/SentiVAE`.

[2] Parameterized by lexicon-specific weights $\boldsymbol{\theta}_d$.

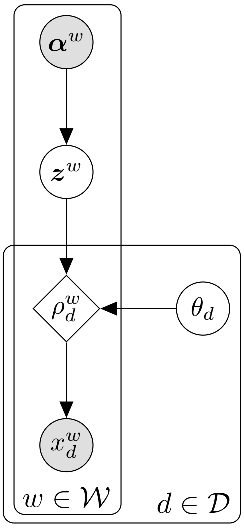

Figure 2: Generative model for SentiVAE.

the sentiments *positive*, *negative*, and *neutral*.

The generative process starts by drawing each latent polarity value $\boldsymbol{z}^w$ from a three-dimensional Dirichlet prior, parameterized by $\boldsymbol{\alpha}^w = (1, 1, 1)$:

$$\boldsymbol{z}^w \sim \text{Dir}(\boldsymbol{\alpha}^w). \tag{1}$$

If the word is uncontroversial,[3] we spur this prior somewhat using the number of lexica in which the word appears $c(w)$. Specifically, we add $c(w)$ to the parameter for the sentiment associated with that word in the lexica, e.g., $\boldsymbol{\alpha}^{\text{SUPERB}} = (1 + c(\text{SUPERB}), 1, 1)$. This has the effect of regularizing the inferred latent polarity value toward the desired distribution over sentiments.

Having generated $\boldsymbol{z}^w$, the process proceeds by "decoding" $\boldsymbol{z}^w$ into each lexicon's chosen scale. First, for each lexicon $d \in \mathcal{D}$, $\boldsymbol{z}^w$ is deterministically transformed via neural network $f(\,\cdot\,; \boldsymbol{\theta}_d)$ with a single 32-dimensional hidden layer, parameterized by lexicon-specific weights $\boldsymbol{\theta}_d$:

$$\boldsymbol{\rho}_d^w = f(\boldsymbol{z}^w; \boldsymbol{\theta}_d). \tag{2}$$

The transformed value $\boldsymbol{\rho}_d^w$ is then used to generate the (observed) polarity label $\boldsymbol{x}_d^w$ for that lexicon:

$$\boldsymbol{x}_d^w \sim P_d(\boldsymbol{x}_d^w \mid \boldsymbol{\rho}_d^w). \tag{3}$$

The dimensionality of $\boldsymbol{\rho}_d^w$ and the emission distribution P_d are lexicon-specific. For SentiWordNet, P_d is a two-dimensional Gaussian with mean $\boldsymbol{\rho}_d^w$ and a diagonal covariance matrix equal to $0.01\boldsymbol{I}$; for VADER, P_d consists of ten nine-dimensional categorical distributions, collectively parameterized by $\boldsymbol{\rho}_d^w$; for MPQA, Hu-Liu, and GI, P_d is a Bernoulli distribution, parameterized by $\boldsymbol{\rho}_d^w$; and for SenticNet, P_d is a univariate Gaussian with mean and variance each an element in a two-dimensional $\boldsymbol{\rho}_d^w$.

Table 2: Descriptive statistics for the training portions of the sentiment analysis datasets. N: number of texts.

Inference. Inference involves forming the posterior distribution over the latent polarity values $\mathcal{Z}$ given the observed polarity labels $\mathcal{X}$. Because computing the normalizing constant $P(\mathcal{X})$ is intractable, we instead approximate the posterior with a family of distributions $Q_{\boldsymbol{\lambda}}(\mathcal{Z})$, indexed by variational parameters $\boldsymbol{\lambda}$. Specifically, we use

$$Q_{\boldsymbol{\lambda}}(\mathcal{Z}) = \prod_{w \in \mathcal{W}} Q_{\boldsymbol{\beta}^w}(\boldsymbol{z}^w) = \prod_{w \in \mathcal{W}} \text{Dir}(\boldsymbol{\beta}^w). \tag{4}$$

To construct $\boldsymbol{\beta}^w$, we first define a neural network $g(\cdot; \boldsymbol{\phi}_d)$, with a single 32-dimensional hidden layer, which "encodes" $\boldsymbol{x}_d^w$ into a three-dimensional vector. The output of this neural network is then transformed via a softmax as follows:

$$\boldsymbol{\omega}_d^w = \text{softmax}\big(g(\boldsymbol{x}_d^w; \phi_d)\big) \tag{5}$$

$$\boldsymbol{\beta}^w = 1 + \sum_{d \in \mathcal{D}} \boldsymbol{\omega}_d^w. \tag{6}$$

The intuition behind $\boldsymbol{\beta}_w$ can be understood by appealing to the "pseudocount" interpretation of Dirichlet parameters. Each lexicon contributes exactly one pseudocount, divided among *positive*, *negative*, and *neutral*, to what would otherwise be a symmetric, uniform Dirichlet distribution. As a consequence of this construction, words that appear in more lexica will have more concentrated Dirichlets. Intuitively, this property is appealing.

We optimize the resulting ELBO objective (Blei et al., 2017) with respect to the variational parameters via stochastic variational inference (Hoffman

---

[3] We say that a word is uncontroversial if there is strong agreement across the sentiment lexica in which it appears. Even without this spurring, the inferred latent representation typically separates into the three sentiment classes, but performance on our text classification task is somewhat diminished.

et al., 2013) using Adam (Kingma and Ba, 2015) in the Pyro framework (Bingham et al., 2018). The standard reparameterization trick used in the original VAE does not apply to models with Dirichlet-distributed latent variables, so we use the generalized reparameterization trick of Ruiz et al. (2016).

4 Experiments and Results

To evaluate our approach, we first use SentiVAE to combine the six lexica described in §2. For each word w in the combined vocabulary, we obtain an estimate of $\boldsymbol{z}^w$ by taking the mean of $Q_{\boldsymbol{\beta}^w}(\boldsymbol{z}^w) = \mathrm{Dir}(\boldsymbol{\beta}^w)$—i.e., by normalizing $\boldsymbol{\beta}^w$. We compare this representation to using $\boldsymbol{\beta}^w$ directly, because $\boldsymbol{\beta}^w$ contains information about SentiVAE's certainty about the word's latent polarity value. We evaluate our common latent representation via a text classification task involving nine English-language sentiment analysis datasets: IMDB (Maas et al., 2011), Yelp (Zhang et al., 2015), SemEval 2017 Task 4 (SemEval, Rosenthal et al. (2017)), multi-domain sentiment analysis (MultiDom, Blitzer et al. (2007)), and PeerRead (Kang et al., 2018) with splits ACL 2017 and ICLR 2017 (Kang et al., 2018). Each dataset consists of multiple texts (e.g., tweets, articles), each labeled with an overall sentiment (e.g., *positive*). Descriptive statistics for each dataset are shown in Tab. 2. For the datasets with more than three sentiment labels, we consider two versions—the original and a version with only three (bucketed) sentiment labels.

For each dataset, we transform each text into an average polarity value using either our representation, one of the six lexica,[4] or a straightforward combination thereof, where the polarity value for each word in the (combined) vocabulary is a 16-dimensional vector that consists of a concatenation of polarity values. (Unlike SentiVAE, this concatenation does not yield a single sentiment lexicon that retains scale coherence, while achieving maximal coverage over words.) Specifically, we replace each token with its corresponding polarity value, and then average the these values (Go et al., 2009; Özdemir and Bergler, 2015; Kiritchenko et al., 2014). We then use the training portion of the dataset to learn a logistic regression classifier to predict the overall sentiment of each text from its average polarity value. Finally, we use the testing portion to compute the accuracy of the classifier.

Results. The results in Tab. 3 show that our representation using $\boldsymbol{\beta}^w$ outperforms the individual lexica for all but one dataset, and that our representation using the mean of $Q_{\boldsymbol{\beta}^w}(\boldsymbol{z}^w)$ outperforms them for six datasets. This is likely because SentiVAE has a richer representation of sentiment than any individual lexicon, and it has greater coverage over words (see Tab. 4). The results in Tab. 5 support the former reason: even when we limit the words in our representation to match those in an individual lexicon, our representation still outperforms the individual lexicon. Unsurprisingly, our representation especially outperforms lexica with unidimensional scales. We also find that our representation outperforms the straightforward combination for datasets from domains that are not well supported by the individual lexica (see Tabs. 1 and 2 for lexicon and dataset sources, respectively). By combining lexica from different domains, our representation captures a general notion of sentiment that is not tailored to any specific domain.

5 Conclusion

We introduced a generative model of sentiment lexica to combine disparate scales into a common

---

[4] We bucket the upper four and lower four points of VADER's nine-point scale, to yield a three-point scale. Without this bucketing, our representation outperforms VADER on four of the nine datasets. We do not bucket VADER when using it in SentiVAE or in the straightforward combination.

latent representation, and realized this model with a novel multi-view variational autoencoder, called SentiVAE. We then used SentiVAE to combine six commonly used English-language sentiment lexica with binary, categorical, and continuous scales. Via a downstream text classification task involving nine English-language sentiment analysis datasets, we found that our representation outperforms the individual lexica, as well as a straightforward combination thereof. We also found that our representation is particularly efficacious for datasets from domains that are not well-supported by standard sentiment lexica. Finally, we note that our approach is more general than SentiMerge (Emerson and Declerck, 2014). While SentiMerge can only combine sentiment lexica with continuous scales, SentiVAE is designed to combine lexica with disparate scales.

Abstract

Opinion role labeling (ORL) is an important task for fine-grained opinion mining, which identifies important opinion arguments such as holder and target for a given opinion trigger. The task is highly correlative with semantic role labeling (SRL), which identifies important semantic arguments such as agent and patient for a given predicate. As predicate agents and patients usually correspond to opinion holders and targets respectively, SRL could be valuable for ORL. In this work, we propose a simple and novel method to enhance ORL by utilizing SRL, presenting semantic-aware word representations which are learned from SRL. The representations are then fed into a baseline neural ORL model as basic inputs. We verify the proposed method on a benchmark MPQA corpus. Experimental results show that the proposed method is highly effective. In addition, we compare the method with two representative methods of SRL integration as well, finding that our method can outperform the two methods significantly, achieving 1.47% higher F-scores than the better one.

1 Introduction

Fine-grained opinion mining aims to detect structured user opinions in text, which has drawn much attention in the natural language processing (NLP) community (Kim and Hovy, 2006; Breck et al., 2007; Ruppenhofer et al., 2008; Wilson et al., 2009; Qiu et al., 2011; Irsoy and Cardie, 2013, 2014; Liu et al., 2015; Wiegand et al., 2016). A structured opinion includes the key arguments of one opinion, such as expressions, holders and targets (Breck et al., 2007; Yang and Cardie, 2012, 2013; Katiyar and Cardie, 2016). Here we focus on opinion role labeling (ORL) (Marasović and Frank, 2018), which identifies opinion holders and targets assuming that the opinion expressions are given. Figure 1 shows an example of the task.

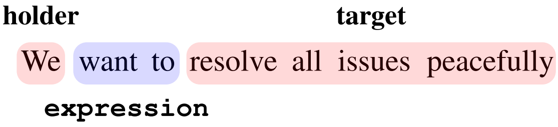

Figure 1: Examples of fine-grained opinion mining.

The focused task behaves very similar with semantic role labeling (SRL) which identifies the core semantic roles for given predicates. Earlier work attempts to exploit a well-trained SRL model to recognize possible semantic roles for a given opinion expression, and then map the semantic roles into opinion roles (Kim and Hovy, 2006; Ruppenhofer et al., 2008). The heuristic approach is unable to obtain high performance for ORL because there are large mismatches between SRL and ORL. For example, opinion expressions are different from verb/noun predicates in SRL, and meanwhile, opinion holders and targets may not always correspond to semantic agents (ARG0) and patients (ARG1), respectively.

We can exploit machine learning based method to solve the mismatching problem between ORL and SRL. With a small number of annotated ORL corpus, we can feed the SRL outputs as inputs to build a statistical model for ORL. By this way, the model can learn the consistencies and inconsistencies between SRL and ORL, arriving at a full exploration of SRL. The method is essentially a feature-based method, treating SRL outputs as a source of features for ORL. The main drawback of the method is that direct exploration of SRL outputs may lead to the error propagation problem. SRL errors can be further propagated into ORL outputs, resulting in degraded ORL performance.

In this work, we propose a simple and novel

Proceedings of NAACL-HLT 2019, pages 641–646
Minneapolis, Minnesota, June 2 - June 7, 2019.

method by using implicit semantic-aware word representations from SRL to enhance ORL. The method is referred to as **SRL-SAWR** for brief. Thanks to the recent advances of encoder-decoder neural SRL models (Zhou and Xu, 2015; He et al., 2017), we can extract implicit vectorized features from the intermediate encoder module instead, avoiding the direct exploration of the final one-best SRL outputs. The vectorized features from the encoder part are implicit semantic-aware representations for input sentences. By taking the semantic-aware representations from SRL as ORL inputs, we are able to make use of SRL information and meanwhile alleviate the error propagation problem.

Here we exploit a neural conditional random field (CRF) model with deep bi-directional long short-term memory networks (Bi-LSTMs) as a baseline, most of which is borrowed from Katiyar and Cardie (2016) and Marasović and Frank (2018). Our preliminary experiments show that the model is able to achieve state-of-the-art performances for both ORL and SRL. Based on this model, we study the proposed implicit semantic-aware word representations for ORL. In addition, we compare this method with two other representative methods of SRL integration as well: one uses discrete SRL outputs as features directly for ORL and the other one exploits a multi-task-learning (MTL) framework to benefit ORL by SRL information.

Experiments are conducted on the MPQA 2.0 dataset, which is a standard benchmark for opinion mining. Results show that SRL is highly effective for ORL, which is consistent with previous findings (Kim and Hovy, 2006; Ruppenhofer et al., 2008; Marasović and Frank, 2018). Meanwhile, our implicit SRL-SAWR method can achieve the best ORL performance, 2.23% higher F-scores than the second best method. All the codes and datasets are released publicly available for research purpose under Apache Licence 2.0 at https://github.com/zhangmeishan/SRL4ORL.

2 Method

2.1 Baseline

ORL aims to identify important opinion arguments for a given opinion expression. The task can be modeled as a sequence labeling problem, similar to SRL (Zhou and Xu, 2015; He et al., 2017). We adopt the {BMESO} schema to convert opinion arguments into a sequence of boundary tags for each word, where B, M and E denote the beginning, middle and ending words of an argument, S denotes a single-word argument, and O denotes the other words. Formally, given a sentence $w_1 \cdots w_n$ and a span of opinion expression $w_s \cdots w_e (1 \leq s \leq e \leq n)$, we aim to assign each word in the sentence by a tag, outputting $t_1 \cdots t_n$.

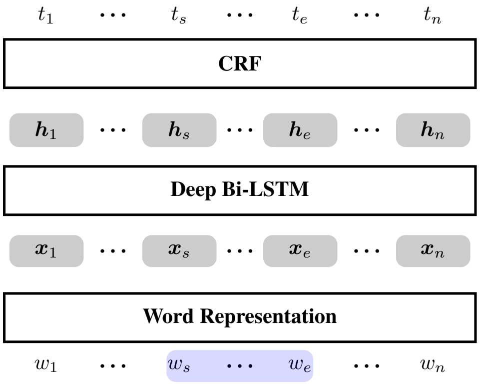

Figure 2: The overall architecture of the baseline.

Inspired by Katiyar and Cardie (2016) and Marasović and Frank (2018), we exploit a deep Bi-LSTM CRF model as the baseline. Figure 2 shows the overall architecture of the baseline model. This model can achieve state-of-the-art performances for both ORL and SRL, which facilitates our study. The key components of the baseline model include three parts: word representation, the deep Bi-LSTM encoder and the CRF decoder. The word representation takes sequential words and opinion expressions as input, mapping them into dense-valued feature vectors $\boldsymbol{x}_1 \cdots \boldsymbol{x}_n$. Following we extract high-level neural features based on the vectors by deep Bi-LSTM, arriving at $\boldsymbol{h}_1 \cdots \boldsymbol{h}_n$. And finally a CRF decoder is applied to output the ORL results $t_1 \cdots t_n$.

2.2 SRL Integration

SRL aims to find the core semantic arguments for a given predicate, which is highly correlative with the ORL task. The semantic roles agent (ARG0) and patient (ARG1) are often corresponding to the opinion holder and target, respectively. Several works even directly transfer semantic roles into opinion roles for ORL (Kim and Hovy, 2006; Ruppenhofer et al., 2008), treating opinion expressions as the major predicates. These systems can achieve good performances, indicating that SRL information can be greatly useful for ORL.

Here we propose a novel method to encode

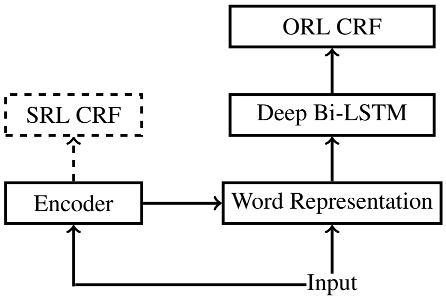

Figure 3: SRL integration methods for ORL.

the SRL information implicitly, enhancing ORL model with semantic-aware word representations from a neural SRL model (SRL-SAWR). Figure 3 shows the overall architectures of our SRL integration method. Instead of using the discrete outputs from the SRL model, the SRL-SAWR method exploits the intermediate encoder outputs as inputs for ORL, which can alleviate the problems in the above two methods. On the one hand, we do not rely on the discrete outputs of a well-trained SRL, reducing the error prorogation problem. And on the other hand, we handle ORL and SRL separately, avoiding the model structure dependencies between the two tasks.

We assume that the external SRL system is a neural-based encoder-decoder model. For fair comparisons with FS-MTL, here we use the same deep Bi-LSTM CRF model for SRL as well. Thus the encoder outputs are the hidden vectors from deep Bi-LSTMs. Assuming that the dumped hidden vector sequence from the SRL encoder is $\boldsymbol{h}_1^{\text{SRL}} \cdots \boldsymbol{h}_n^{\text{SRL}}$, we integrate it into the ORL model by the following equation:

$$\boldsymbol{x}_i^* = \boldsymbol{x}_i \oplus \boldsymbol{W}_{\text{SRL}} \boldsymbol{h}_i^{\text{SRL}}, \qquad (1)$$

where $\boldsymbol{W}_{\text{SRL}}$ is a projection matrix which is a model parameter, $\boldsymbol{x}_i$ is the baseline word representation of word w_i, and $\boldsymbol{x}_i^*$ is the new word representation, which will be further fed into the deep Bi-LSTM layer of the ORL model. Noticeably, the model parameters of the SRL encoder are also fine tuned according to the ORL objective, as the preliminary results indicate that fine-tuning can bring better performance.

3 Experiments

3.1 ORL Data

We exploit the MPQA version 2.0 corpus (Wiebe et al., 2005; Wilson, 2008) to evaluate our models,[1] which has been widely adopted as a benchmark dataset for opinion mining (Yang and Cardie, 2013; Katiyar and Cardie, 2016; Marasović and Frank, 2018). There are 482 documents in the dataset. Following these work, we set aside 132 documents as the development set, and the remaining 350 documents are used as the test set in our experiments. We conduct experiments using five-fold cross-validation (CV) on the test set at the document level. Following Marasović and Frank (2018), we focus on opinion holders and targets only. The gold standard opinion expressions, holders and targets correspond to the direct subjective annotations, agent annotations and target annotations, respectively.

3.2 Evaluation Metrics

We use recall (R), precision (P) and their F1-measure value to measure our proposed models. The average values of the five-fold CV results are reported in this work. We exploit exact matching as the major metric. Following Marasović and Frank (2018), two kinds of soft evaluation methods are also adopted for evaluation, namely binary and proportional overlapping, Binary overlap treats an entity as correct if it contains an overlapped region with the gold-standard entity, and the proportional overlap assigns a partial score proportional to the ratio of the overlapped region.

3.3 Setting

There are several hyper-parameters to define our neural network structures. We simply set their values according to previous work (He et al., 2017; Marasović and Frank, 2018), without much tuning work. Concretely, we set the dimension size of all embeddings to 100, the output hidden size of LSTMs to 200 and the layer number of Bi-LSTM to 3. For external word embeddings, we use the pretrained 100-dimensional glove embeddings (Pennington et al., 2014).

We exploit online training to learn model parameters, and train on the entire training instances for 40 epochs, choosing the best-epoch model according to the performance on the development corpus. We use Adam (Kingma and Ba, 2014) with a learning rate 10^{-3} to update model parameters, and use gradient clipping by a max norm 1.0 and l_2-regularization by a parameter 10^{-8}. We apply dropout with a ratio of 0.2 over word represen-

---

[1] Available at http://www.cs.pitt.edu/mpqa.

tations, output layers of Bi-LSTMs to avoid overfitting (Srivastava et al., 2014).

3.4 SRL

For SRL, we use the large-scale dataset of CoNLL-2012 shared task, which is extracted from OntoNotes v5.0 corpus. The description and separation of train, development and test data set can be found in Pradhan et al. (2013). The training corpus contains over 250K predicates, which is much larger than the number of opinion expressions in the ORL training corpus (averaged 3.6K).

We exploit the same neural network model as the ORL for SRL, in order to make fair comparisons between our proposed model with FS-MTL. According to the preliminary experiments, the SRL model can reach an F-measure of 81.8%, which is comparable to the reported result (81.7%) in He et al. (2017).

3.5 Results

Table 1 shows the final results on the test dataset. We report the overall as well as the fine-grained performance in term of opinion arguments (i.e., holder and target). Compared with the baseline system, our final SRL-SAWR model can bring significantly better results ($p < 10^{-5}$ under pairwise t-test). For fine-grained evaluations, the final model outperforms the baseline model consistently on opinion holders and targets. The tendencies are similar by exploiting the binary and proportional matching methods. The results show that SRL information is very helpful for ORL, which is consistent with previous studies (Kim and Hovy, 2006; Ruppenhofer et al., 2008; Marasović and Frank, 2018). The implicit SRL-SAWR method is highly effective to integrate SRL information into the ORL model.

Further, we compare the SRL-SAWR method with two other methods as well, namely SRL-TE and FS-MTL, respectively. The SRL-TE approach simply exploits the output SRL tags as inputs for ORL, embedding them as an additional source of word representations. The FS-MTL approach is exactly the proposed model by Marasović and Frank (2018). As shown in Table 1, all three methods can bring improved performance by integrating SRL, further demonstrating that SRL is indeed valuable for ORL. In addition, the SRL-SAWR method can achieve the best performance among the three methods, obtaining further significant improvements by at least $63.74 - 61.51 = 2.23$ points on overall F1-measure with exact matching ($p < 10^{-4}$). For fine-grained evaluations, the SRL-SAWR method can also give the best performance. The results demonstrate that SRL-SAWR is most effective to integrate the SRL information into a neural ORL model. The two methods, SRL-TE and FS-MTL, are comparable by evaluations based on the exact matching.

Model	Holder	Target	Overall
Exact F1			
Baseline	73.07	42.70	58.30

(a) Holder (b) Target

Figure 4: Percentages with respect to semantic roles.

3.6 Analysis

In this section, we conduct several experimental analysis on the test dataset to deeply understand the effectiveness of SRL information.

First, we examine the relationship between SRL and ORL. SRL identifies the semantic arguments for predicates, and ORL recognizes the opinion arguments for opinion expressions. Intuitively, in most cases, the opinion holders are corresponding to semantic agents/ARG0 of opinion triggers/expressions, and similarly, the opinion targets are usually corresponding to patients/ARG1. Figure 4 shows the percentages of opinion hold-

Model	Holder	Target	Overall
Baseline	**73.07**	**42.70**	**58.30**
SRL Mapping	68.56	25.33	46.29

Table 2: The performance of the SRL mapping method.

Model	Holder	Target	Overall
Consistent arguments			
Baseline	87.63	61.67	80.87

SRL-SAWR	**49.09**	**44.24**	**44.65**
SRL Mapping	0.00	0.00	0.00
SRL-TE	42.30	39.23	40.14
FS-MTL	43.47	39.04	40.25

Table 3: Comparisons in terms of the consistent/inconsistent arguments between SRL and ORL.

ers/targets being corresponding to semantic roles, which are calculated according to the word-level mapping over the 1-best SRL outputs and the gold-standard ORL tags. We list only the five semantic roles with highest mapping percentages. As shown, the results are consistent with our intuition. Thus SRL and ORL are highly correlative. Considering the much larger scale of annotated SRL corpora, SRL can benefit ORL potentially.

According to the above findings, we design a simple system by mapping SRL outputs into ORL directly (Kim and Hovy, 2006; Ruppenhofer et al., 2008). We simply convert the semantic role ARG0 into holder, and ARG1 into target. Table 2 shows the performance. The results of the baseline system are shown for comparison. We can see that the simple mapping method is also one feasible alternative as a whole.

Further, we compare the SRL utilization capabilities of our proposed method and the other SRL-enhanced ORL systems, including the above SRL Mapping method. We categorize the opinion arguments by whether they can be directly mapped from the SRL outputs. The opinion arguments which can be directly mapped from SRL, referred to as consistent arguments, should be more easily identified by SRL enhanced models than the remaining inconsistent arguments. Table 3 shows the comparison results. We can see that all SRL-enhanced supervised models can achieve better performances for consistent arguments. For the inconsistent arguments, the tendency is similar, except the holder performance of SRL-TE. In addition, our method can gain much larger improvements, which indicates that our method can better handle the inconsistencies between SRL and ORL.

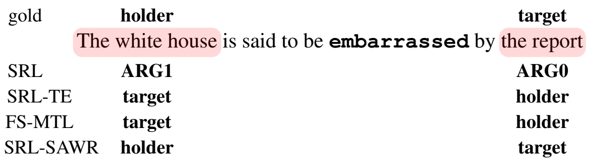

Figure 5: One example for case study.

Finally, we show one case study to illustrate the advantage of our SRL-SAWR method. Figure 5 shows one example. As shown, the SRL argument ARG0, which is more probably mapped onto holder, is annotated by target in the example. The SRL argument ARG1 is labeled as opinion holder, which is also one inconsistent case. Compared with SRL-TE and FS-MTL, our model can better handle these inconsistent cases. The observation further confirms our results in Table 3.

4 Conclusion

We proposed a simple and novel method (SRL-SAWR) to enhance ORL with SRL information by exploiting implicit semantic-aware word representations from SRL. The main idea is to export intermediate SRL encoder outputs as inputs to better word representations of an ORL model. This method does not impose any extra requirement for ORL, and meanwhile avoids the error proropagation problem from discrete SRL outputs. We conducted experiments to verify our method on a benchmark MPQA dataset. The results showed that our method can exploit SRL information effectively. We compared the proposed method with SRL-TE and FS-MTL, which are two representative approaches to enhance ORL by SRL. The results demonstrated our method can bring the best performance among the three approaches.

Abstract

The development of a fictional plot is centered around characters who closely interact with each other forming dynamic social networks. In literature analysis, such networks have mostly been analyzed without particular relation types or focusing on roles which the characters take with respect to each other. We argue that an important aspect for the analysis of stories and their development is the emotion between characters. In this paper, we combine these aspects into a unified framework to classify emotional relationships of fictional characters. We formalize it as a new task and describe the annotation of a corpus, based on fan-fiction short stories. The extraction pipeline which we propose consists of character identification (which we treat as given by an oracle here) and the relation classification. For the latter, we provide results using several approaches previously proposed for relation identification with neural methods. The best result of 0.45 F_1 is achieved with a GRU with character position indicators on the task of predicting undirected emotion relations in the associated social network graph.

1 Introduction

Every fictional story is centered around characters in conflict (Ingermanson and Economy, 2009) which interact, grow closer or apart, as each of them has ambitions and concrete goals (Ackerman and Puglisi, 2012, p. 9). Previous work on computational literary studies includes two tasks, namely social network analysis and sentiment/emotion analysis, both contributing to a computational understanding of narrative structures. We argue that joining these two tasks leverages simplifications that each approach makes when considered independently. We are not aware of any such attempt and therefore propose the task of emotional character network extraction from fictional texts, in which, given a text, a network is to be generated, whose nodes correspond to characters and edges to emotions between characters. One of the characters is part of a trigger/cause for the emotion experienced by the other. Figure 1 depicts two examples for emotional character interactions at the text level. Such relation extraction is the basis for generating social networks of emotional interactions.

Dynamic social networks of characters are analyzed in previous work with different goals, *e.g.*, to test the differences in interactions between various adaptations of a book (Agarwal et al., 2013); to understand the correlation between dialogue and setting (Elson et al., 2010); to test whether social networks derived from Shakespeare's plays can be explained by a general sociological model (Nalisnick and Baird, 2013); in the task of narrative generation (Sack, 2013); to better understand the nature of character interactions (Piper et al., 2017). Further, previous work analyses personality traits of characters (mostly) independently of each other (Massey et al., 2015; Barth et al., 2018; Bamman et al., 2014).

Emotion analysis in literature has focused on the development of emotions over time, abstracting away who experiences an emotion (Reagan et al., 2016; Elsner, 2015; Kim et al., 2017; Piper and Jean So, 2015, *i.a.*). Fewer works have ad-

dressed the annotation of emotion causes, *e.g.*, Neviarouskaya and Aono (2013), Ghazi et al. (2015), Saurí and Pustejovsky (2009), and Kim and Klinger (2018). To the best of our knowledge, there is no previous research that deals with emotional relationships of literary characters. The works that are conceptually the closest to our paper are Chaturvedi et al. (2017) and Massey et al. (2015), who use a more general set of relationship categories.

Most approaches to emotion classification from text build on the classes proposed by Plutchik (2001) and Ekman (1992). Here, we use a discrete emotion categorization scheme based on fundamental emotions as proposed by Plutchik. This model has previously been used in computational analysis of literature (Mohammad, 2012, *i.a.*). We refer the reader to social psychology literature for more details on the emotional relationship between people (Burkitt, 1997; Gaelick et al., 1985).

The main contributions of this paper are (1) to propose the new task of emotional relationship classification of fictional characters, (2) to provide a fan-fiction short story corpus annotated with characters and their emotional relationships, and (3) to provide results for relation extraction models for the task. We evaluate our models on the textual and the social network graph level and show that a neural model with positional indicators for character roles performs the best. An additional analysis shows that the task of character relationship detection leads to higher performance scores for polarity detection than for more fine-grained emotion classes. Differences between models are minimal when the task is cast as a polarity classification but are striking for emotion classification.

This work has potential to support a literary scholar in analyzing differences and commonalities across texts. As an example, one may consider Goethe's *The Sorrows of Young Werther* (Goethe, 1774), a book that gave rise to a plethora of imitations by other writers, who attempted to depict a similar love triangle between main characters found in the original book. The results of our study can potentially be used to compare the derivative works with the original (see also Barth et al., 2018).

2 Corpus

Data Collection and Annotation. Each emotion relation is characterized by a triple $(C_{\text{exp}}, e, C_{\text{cause}})$, in which the character C_{exp} feels the emotion e (mentioned in text explicitly or implicitly). The character C_{cause} is part of an event which triggers the emotion e. We consider the eight fundamental emotions defined by Plutchik (2001) (anger, fear, joy, anticipation, trust, surprise, disgust, sadness). Each character corresponds to a token sequence for the relation extraction task and to a normalized entity in the graph depiction.

Using WebAnno (Yimam et al., 2013), we annotate a sample of 19 complete English fan-fiction short stories, retrieved from the Archive of Our Own project[1] (due to availability, the legal possibility to process the texts and a modern language), and a single short story by Joyce (1914) (Counterparts) being an exception from this genre in our corpus. All fan-fiction stories were marked by the respective author as complete, are shorter than 1500 words, and depict at least four different characters. They are tagged with the keywords "emotion" and "relationships".

The annotators were instructed to mark every character mention with a canonical name and to decide if there is an emotional relationship between the character and another character. If so, they marked the corresponding emotion phrase with the emotion labels (as well as indicating if the emotion is amplified, downtoned or negated). Based on this phrase annotation, they marked two relations: from the emotion phrase to the experiencing character and from the emotion phrase to the causing character (if available, *i.e.*, C_{cause} can be empty). One character may be described as experiencing multiple emotions.

We generate a "consensus" annotation by keeping all emotion labels by all annotators. This is motivated by the finding by Schuff et al. (2017) that such high-recall aggregation is better modelled in an emotion prediction task. The data is available at http://www.ims.uni-stuttgart.de/data/relationalemotions.

Inter-Annotator Agreement We calculate the agreement along two dimensions, namely unlabelled vs. labeled and instance vs. graph-level. Table 1 reports the pairwise results for three annotators. In the *Inst. labelled* setting, we accept an instance being labeled as true positive if both annotators marked the same characters as experiencer and cause of an emotion and classified their in-

---

[1] https://archiveofourown.org

	a1–a2	a1–a3	a2–a3
Inst. labelled	24	19	24
Inst. unlab.	33	27	29
Graph labelled	66	69	66
Graph unlabelled	90	93	92

Table 1: F_1 scores in % for agreement between annotators on different levels. a1, a2, and a3 are different annotators.

teraction with the same emotion. In the *Inst. unlabelled* case, the emotion label is allowed to be different. On the graph level (*Graph labelled* and *Graph unlabelled*), the evaluation is performed on an aggregated graph of interacting characters, *i.e.*, a relation is accepted by one annotator if the other annotator marked the same interaction somewhere in the text. We use the F_1 score to be able to measure the agreement between two annotators on the span levels. For that, we treat the annotations from one annotator in the pair as correct and the annotations from the other as predicted.

As Table 1 shows, agreement on the textual level is the lowest with values between 19 and 33 % (depending on the annotator pair), which also motivated our aggregation strategy mentioned before. The values for graph-labelled agreement are more relevant for our use-case of network generation. The values are higher (66–93 %), showing that annotators agree when it comes to detecting relationships regardless of where exactly in the text they appear.

Statistics. Table 2 summarizes the aggregated results of the annotation. The column "All" lists the number of experiencer annotations (with an emotion), the column "Rel." refers to the counts of emotion annotations with both experiencer and cause.

Joy has the highest number of annotated instances and the highest number of relationship instances (413 and 308 respectively). In contrast, *sadness* has the lowest number of annotations with a total count of instances and relations being 97 and 64 respectively. Overall, we obtain 1335 annotated instances, which we use to build and test our models.

3 Methods

Figure 2 depicts the process flow for each of the models. We distinguish between *directed* and *undirected* relation prediction. In the directed scenario, we classify which character is the experiencer and which character is the cause, as well as what is the emotion between two characters. For the undirected scenario, we only classify the emotion relation between two characters. We do not tackle character name recognition here: our models build on top of gold character annotations.

Emotion	All	Rel.
anger	258	197
anticipation	307	239
disgust	163	122
fear	182	120
joy	413	308
sadness	97	64
surprise	143	129
trust	179	156
total	**1742**	**1335**

Table 2: Statistics of emotion and relation annotation. "All" indicates the total number of emotion annotations. "Rel." indicates total number of emotional relationships (including a causing character) instantiated with the given emotion.

Indicator	Implementation example
No-Ind.	Alice is angry with Bob
Role	`<e>`Alice`</e>`...`<c>`Bob`</c>`
MRole	`<e>`...`<c>`
Entity	`<et>`Alice`</et>`...`<et>`Bob`</et>`
MEntity	`<et>`...`</et>`

Table 3: Different indicators applied to the same instance. *No-Ind.* means no positional indicators are added. *M* in *MRole* and *MEntity* means that the name of the character is masked. Tag `<e>` indicates the experiencer. Tag `<c>` indicates the cause. Tag `<et>` indicates an entity.

The *baseline* model predicts the emotion for a character pair based on the NRC dictionary (Mohammad and Turney, 2013). It accepts the emotion associated with the words occurring in a window of n tokens around the two characters, with n being a parameter set based on results on a development set for each model (see supplementary material for more details).

Further we cast the relation detection as a machine learning-based classification task, in which each classification instance consists of two character mentions with up to n tokens context to the

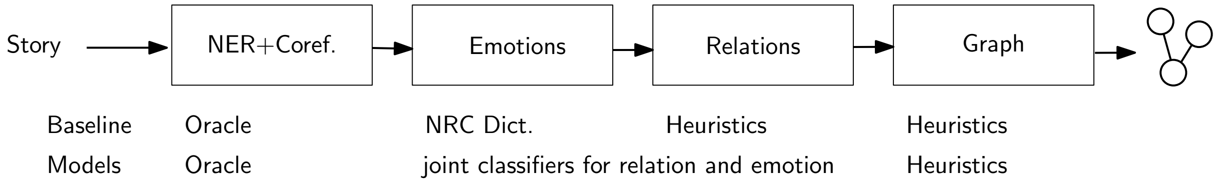

Figure 2: Models for the emotional relationship prediction. Oracle: a set of character pairs from the gold data.

left and to the right of the character mentions. We compare an extremely randomized tree classifier with bag-of-words features (Geurts et al., 2006) (*BOW-RF*) with a two-layer GRU neural network (Chung et al., 2014) with max and averaged pooling. In the latter, we use different variations of encoding the character positions with indicators (inspired by Zhou et al. (2016), who propose the use of positional indicators for relation detection). Our variations are exemplified in Table 3. Note that the case of predicting directed relations is simplified in the "Role" and "MRole" cases in contrast to "Entity" and "MEntity", as the model has access to gold information about the relation direction.

We obtain word vectors for the embedding layer from GloVe (pre-trained on Common Crawl, $d = 300$, Pennington et al., 2014) and initialize out-of-vocabulary terms with zeros (including the position indicators).

4 Experiments

Experimental Setting. In the classification experiments, we compare the performance of our models on different label sets. Namely, we compare the complete emotion set with 8 classes to a 5 class scenario where we join *anger* and *disgust*, *trust* and *joy*, as well as *anticipation* and *surprise* (based on preliminary experiments and inspection of confusion matrices). The 2-class scenario consists of positive (*anticipation, joy, trust, surprise*) and negative relations (*anger, fear, sadness, disgust*). For each set of classes, we consider a setting where directed relations are predicted with one where the direction is ignored. Therefore, in the *directed* prediction scenario, each emotion constitutes two classes to be predicted for both possible directions (therefore, 16, 10, and 4 labels exist).

The evaluation is performed with precision, recall and F_1 in a cross-story validation setting, in which each story is used as one separate test/validation source. For model selection and meta-parameter optimization, we use 50 % randomly sampled annotations from this respective test/validation instance as a validation set and the remainder as test data.

Further, we evaluate on three different levels of granularity: Given two character mentions, in the instance-level evaluation, we only accept the prediction to be correct if exactly the same mention has the according emotion annotation. We then aggregate the different true positive, false positive and false negative values across all stories before averaging to an aggregated score (similar to micro-averaging). On the story-level, we also accept a prediction to be a true positive the same way, but first calculate the result P/R/F_1 for the whole story before averaging (similar to macro-averaging). On the graph-level, we accept a prediction for a character pair to be correct without considering the exact position.

Results. Table 4 shows the results (precision and recall shown in supplementary material) on development data and independent test data for the best models. The GRU+MRole model achieves the highest performance with improvement over BOW-RF on the instance and story levels, and shows a clear improvement over the GRU+NoInd. model in the directed 8-class setting. GRU+Role achieves the highest performance on the graph level in the directed 8-class setting. In the undirected prediction setting, all models perform better in the 5-class experiment and 2-class experiment than in 8-class experiment. This is not always the case for the directed prediction, where some models perform better in 8-class experiment (GRU+NoInd., GRU+Entity, BOW-RF).

We observe that the difference in F_1 score between the baseline, bag-of-words model and our GRU models in a 2-class experiment is marginal. This may be an indicator that the binary representation harms the classification of emotional relations between characters, as they can be nuanced and do not always perfectly map to either positive and negative classes. On the other side, a more sophisticated classification approach is necessary to capture these nuanced differences.

		Undir.			Directed		
	Model	8c	5c	2c	8c	5c	2c
Dev Instance level	Baseline	24	30	56	–	–	–

Dev Story level	Baseline	24	31	56	–	–	–
	BOW-RF	21	35	58	22	20	38
	GRU+NoInd.	33	41	66	25	23	38
	GRU+Role	19	34	55	33	35	56
	GRU+MRole	32	44	67	39	44	65
	GRU+Entity	21	31	57	22	18	30
	GRU+MEntity	33	46	65	28	30	39
Dev Graph-level	Baseline	31	46	65	–	–	–
	BOW-RF	27	36	71	34	34	54
	GRU+NoInd.	44	55	73	35	33	54
	GRU+Role	35	49	65	41	43	57
	GRU+MRole	45	58	73	40	48	65
	GRU+Entity	37	50	68	39	29	49
	GRU+MEntity	47	63	73	39	39	52
Test	GRU+MRole Inst.	30	44	64	38	43	65
	GRU+MRole Story	33	45	65	39	43	66
	GRU+MRole Graph	45	59	71	42	49	66

Table 4: Cross-validated results in % F_1 score, average of four runs. Inst. level: aggregated over all instances in the dataset. Story level: averaged performance on all stories. Graph-level: averaged performance on graph level on all stories. Test results are reported for the best indicator type. See Table 3 for the examples of the indicator implementation.

As expected, we observe a better performance on a graph level for all models, with the highest performance of 47 % F_1 (GRU+MEntity), 63 % F_1 (GRU+MEntity), and 73 % F_1 (GRU+MRole, GRU+MEntity, GRU+NoInd.) in undirected 8-, 5-, and 2-class experiments, respectively, on the development set. In the directed scenario, the highest performances are 41 % F_1 (GRU+Role), 48 % F_1 (GRU+MRole), and 65 % F_1 (GRU+MRole).

The results show that the sequential and embedding information captured by a GRU as well as additional positional information are all relevant for a substantial performance, at least on the fine-grained emotion prediction task.

5 Conclusion & Future Work

In this paper, we formulated the new task of emotional character network extraction from fictional texts. We argued that joining social network analysis of fiction with emotion analysis leverages simplifications that each approach makes when considered independently. We presented a publicly available corpus of fan-fiction short stories annotated with character relations and proposed several relation classification models. We showed that a recurrent neural architecture with positional indicators leads to the best results of relation classification. We also showed that differences between different machine learning models with binary mapping of emotion relation is almost leveled. This may suggest that emotion relation classification is best modeled in a multi-class setting, as emotional interactions of fictional characters are nuanced and do not simply map to either a positive or a negative class.

For future work we propose to develop a real-world application pipeline in which character pairs are not given by an oracle, but rather extracted from text automatically using named entity recognition. To better understand the relation between instance and graph levels, we propose to explore the best strategy for edge labeling either by a majority vote or accepting the edges with the highest confidence scores. Further, modeling the task in an end-to-end learning setting from text to directly predict the graph, in the spirit of multi-instance learning, is one of the next steps. To that end, we suggest obtaining more gold data with character relations and optimize the pipeline towards the best performance on additional data.

Abstract

Authorship verification is the problem of inferring whether two texts were written by the same author. For this task, unmasking is one of the most robust approaches as of today with the major shortcoming of only being applicable to book-length texts. In this paper, we present a generalized unmasking approach which allows for authorship verification of texts as short as four printed pages with very high precision at an adjustable recall tradeoff. Our generalized approach therefore reduces the required material by orders of magnitude, making unmasking applicable to authorship cases of more practical proportions. The new approach is on par with other state-of-the-art techniques that are optimized for texts of this length: it achieves accuracies of 75–80 %, while also allowing for easy adjustment to forensic scenarios that require higher levels of confidence in the classification.

1 Introduction

With advances in computational stylometry, determining the original authorship of unknown literary publications can be accomplished with near certainty by state-of-the-art authorship verification. If the source material is abundant and sufficiently many known publications exist, linking them together is hardly a challenge. But the playing field changes entirely if only fragments are available for verification, either because few known works of an author exist or because the text to be verified is only a few pages long. With classification results significantly above chance, yet far below certainty, verification approaches struggle to produce reliable results in short-text scenarios and thus lack real-world practicality for material far below book length. Even the unmasking approach by Koppel and Schler (2004), which otherwise proved to be one of the most ingenious and robust verification approaches, fails in this setting and can only deliver below-average performance compared to more specialized verification systems, which still display high uncertainty themselves with an error of up to 25 % (Stamatatos et al., 2015). At PAN 2015, individual texts of the English-language dataset had an average size of about 1.5 kB (less than 400 words), so it does not come as a surprise that none of the participants employed unmasking.

To tackle the uncertainty problem of authorship verification on short texts, we propose a generalized unmasking approach which prioritizes precision so as to verify authorship with reliable results while rejecting cases of low certainty. We also present a new open-source general-purpose unmasking framework as a highly-customizable implementation of our approach.[1]

2 Related Work

Authorship analysis has been practiced since the late 19th century (Bourne, 1897). Although mostly the narrower task of authorship attribution has been considered, where texts are attributed to a set of given authors, recently, authorship verification has been proposed as a more fundamental task. For long texts, unmasking by Koppel and Schler (2004) has since been established as a gold standard. Sanderson and Guenter (2006) showed that its performance is far worse for short texts, though, whereas their own model produced acceptable results with a minimum of 5,000 words per training text. Newer research has emerged through a series of shared tasks at PAN (Juola and Stamatatos, 2013; Stamatatos et al., 2014, 2015), which focused on shorter texts and achieved higher scores than unmasking. In general, however, the verification problem could not be solved to a point where results are highly reliable. The winner of the shared task at PAN 2015 (Bagnall, 2015) achieved an accuracy of 76 %, thus delivering a false decision in one in four cases while being unclear about which 24 %

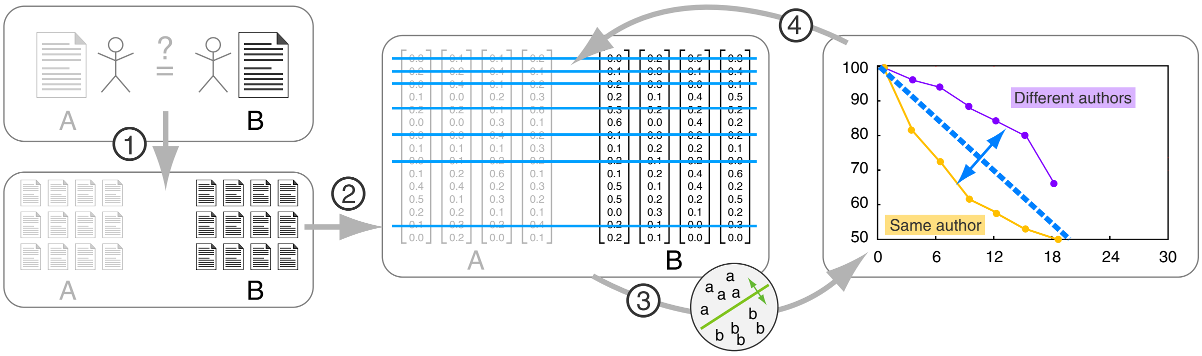

Figure 1: Schematic of the unmasking algorithm. Steps 1-4 are described in the text below. Dependent on whether the authors of texts A and B are the same or different, accuracy curves as exemplified can be expected.

are most likely to be incorrect. If applied in a real-world forensic scenario, such a verifier might give only hints as to whether two texts share authorship. Verification approaches based on text compression (Teahan and Harper, 2003; Khmelev and Teahan, 2003; Halvani et al., 2017) have been proposed, whose latest incarnations proved at least competitive to the approaches developed during the shared tasks; the state of the art in short-text authorship verification achieves around 75–80 % accuracy.

3 Unmasking for Short Texts

After reviewing the original unmasking algorithm, we introduce our generalization for short texts.

3.1 The Original Unmasking Algorithm

Unmasking as per Koppel and Schler (2004) is based on the idea that the style of texts from the same author differs only in a few superficial features. By iteratively removing these most discriminating style features, one can measure the "speed" at which cross-validation accuracy between sets of chunks of the two texts degrades. For texts written by the same author, the accuracy tends to decrease faster than otherwise. Combining the obtained accuracy values into curves for each pair, a meta classifier can be trained on the curves to determine the class of a pair (same / different author).

Koppel and Schler evaluated their approach on a corpus of 21 books (each at least 500 kB) by 10 different authors. The task was to verify for each book A whether it has been written by a given author, using all the latter's books B for an author profile, except book A, in case it was the same author. As described in their paper, the unmasking algorithm works as follows (see Figure 1):

1. From either text, create non-overlapping chunks of at least 500 words length without splitting paragraphs.
2. Use the 250 words with highest average frequency in A and B as features.
3. Obtain 10-fold cross-validation accuracy between A and B with a linear SVM kernel.
4. Eliminate the 3 highest positive and negative features for the model trained in each fold.
5. Go to Step 3 if there are features left.

The declining cross-validation accuracy values from curves on which a meta classifier is trained. Koppel and Schler used another SVM as the meta classifier, utilizing as features the curve points, the curves' point-wise first- and second-order derivatives, and the derivatives sorted by steepest point-wise drop. With this approach, they achieved a verification accuracy of over 95 %.

3.2 Generalization for Short Texts

While impressive as such, the performance of unmasking hinges on the availability of sufficiently many chunks per text, where each chunk has to be of at least the aforementioned 500 words length, or else the training data becomes too sparse and no descriptive curves can be generated. Short texts have the inherent problem that not many chunks can be extracted by cutting them into pieces.

To generate more training samples from short texts, one method would be to generate overlapping chunks, but this only ends in many almost identical chunks and provides only a marginal performance boost. Instead, we exploit the bag-of-words nature of the unmasking features and create the chunks by oversampling words in a bootstrap aggregating manner. We treat each text as a random pool of words from which we can draw without replacement to fill up a chunk. Once the pool is exhausted, we replenish it and draw again until we have generated a sufficient number of chunks. This is to guarantee that each word is drawn at least once.

Employing this bagging approach alone will not yield satisfying results, however. The curves will be quite random with high variance. To counteract this, we run unmasking on the generated chunks multiple times and average the curves to get smoother and more reproducible results. Our generalized unmasking algorithm works as follows:

1. From either text, create 30 chunks counting 700 words each by random chunk generation.
2. Use the 250 words with highest average frequency in A and B as features.
3. Obtain 10-fold cross-validation accuracy between A and B with a linear SVM kernel.
4. Eliminate the on average 5 most significant positive and negative features across folds (resulting in a total of 10 removals).
5. Go to Step 3 if there are still features left.

Another linear SVM classifier is trained on these training curves, their central-difference gradients (first- and second-order), as well as their gradients sorted by magnitude. This classifier is then used to classify curves generated in the same fashion from text pairs in the test set.

4 Evaluation

The data we use for our experiments is a collection of 180 text pairs (consisting of 90 *same-author* and 90 *different-authors* cases) for training and a similar set of 80 text pairs (consisting of 40 *same-author* and 40 *different-authors* cases) for testing. The texts were obtained from Project Gutenberg, comprise about 4,000 words each (23,000 characters), and were written by a total of 390 unique English-language authors. We took special care to select texts of similar genre and publication period to avoid accidental topic classification.

Since short-text authorship verification presents itself as such a difficult problem, it becomes all the more important to find a good measure for assessing the quality of a verifier. Due to the high uncertainty of many results, a standard two-class accuracy measure is not an optimal choice. Instead of trying to develop perfect verifiers, we can already build more useful tools today by optimizing for precision and sacrificing recall. Unfortunately, this approach—although more useful in general—does not perform well in a setting where accuracy is measured. In order to provide a more suitable evaluation quantity, PAN adopted the c@1 measure by Peñas and Rodrigo (2011):

$$\frac{1}{n} \cdot \left(n_{ac} + \frac{n_{ac}}{n} \cdot n_u \right) ,$$

where n denotes the number of problems, n_{ac} the number of correct answers and n_u the number of non-answers. The c@1 measure solves the uncertainty problem by rewarding non-answers in that it assigns them the same accuracy as the rest of the problems. All-correct answers still yield a score of 1, all-wrong or completely unanswered problem sets a score of 0. Hence, with this measure, a verifier is at liberty not to answer a given problem in case of doubt and still receive a reasonably good score, even if its overall sensitivity (or recall) is low. Most PAN participants did not exploit the c@1 measure to a larger extent, so c@1 scores of their submitted approaches are roughly the same as their accuracy (within margin of a few percent).

A problem with c@1 is that it is still designed for binary classification with equal weights for both classes. If we are primarily interested in whether two texts were written by the same author, but do not need a reliable decision in the other case, c@1 does not serve us well. For that reason, we propose as an alternative the $\mathrm{F}_{0.5}$ measure where we treat non-answers as false negatives:

$$\frac{(1 + 0.5^2) \cdot n_{tp}}{(1 + 0.5^2) \cdot n_{tp} + 0.5^2 \cdot (n_{fn} + n_u) + n_{fp}} ,$$

with n_{tp} denoting the number of true positives, n_{fn} the number of false negatives, and n_{fp} the number of false positives. As before, n_u is the number of unanswered problems. The parameter $\beta = 0.5$ of the F measure was chosen so as to weigh precision substantially higher than recall without diminishing its contribution entirely. Other values can be used depending on individual use cases. We call this specialized $\mathrm{F}_{0.5}$ measure $\mathrm{F}_{0.5\mathrm{u}}$.

4.1 Unmasking's Hyperparameters

The hyperparameters of unmasking have a direct and intuitive effect on its output. The most important hyperparameters are the number of chunks, the number of words per chunk, the size of the feature vectors, the number of feature removals per round, and the total number of averaged unmasking runs.

The degradation speed or curve slope is determined primarily by the number of chunks generated (more chunks result in generally shallower curves) and the amount of information lost in each round (shorter feature vectors or more removals cause the curves to plummet). Both parameters also control

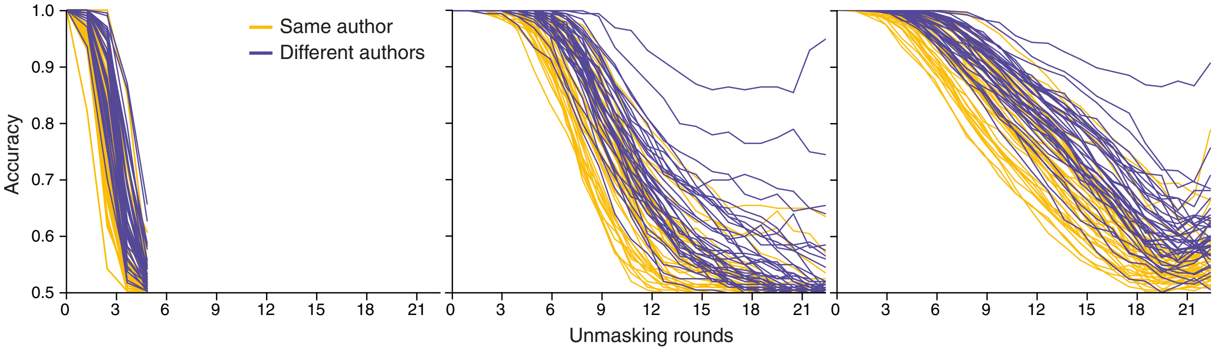

Figure 2: Unmasking curves on the test corpus with three different sets of hyperparameters. Each curve represents one text pair. *Left:* 100 features, 20 eliminations per round, 10 chunks of 1,000 words each. *Center:* 250 features, 10 eliminations, 10 chunks of 700 words each. *Right:* 250 features, 10 eliminations, 30 chunks of 700 words each. All curves are averages of 10 runs. Few features and chunks and many removals in a single round lead to curves dropping too quickly in straight lines. The center and right-hand configurations perform much better.

the granularity of the curves. Longer feature vectors and more chunks result in smoother curves, whereas very short vectors and very few chunks create larger straight-line segments. It is vital to find a good middle ground for both these parameters or else the curves will either altogether drop too quickly with all significant features eliminated in a single round, or runtime is wasted without benefit. Particularly removals and vector size need to be balanced so as to optimally capture enough of the highly significant features and not only the tail of the distribution. Furthermore, curves with insufficient granularity contain a lot less information and are often harder to distinguish, regardless of their slope. The number of words per chunk, on the other hand, appears to be mostly responsible for the slope of the first few initial rounds with larger chunks delaying the first major drop. Overall, this parameter's influence seems rather low, probably because we are only repeatedly sampling from an already small sample of the same distribution. Finally, the number of unmasking runs that are averaged smooths noisy curves and compensates for outliers. Here, more is generally better, but with diminishing returns beyond a certain point.

The hyperparameters given in Section 3 result from cross-validating several hundred configurations to find the most useful value ranges on our training data. Optimal choices can vary slightly between datasets, which leaves room for improvement. Figure 2 shows the differences between a select number of hyperparameter choices. We found that between 25 and 50 chunks, vector sizes of 250 to 400 features, and not fewer than 5, yet no more than 20 removals per round are necessary to achieve sufficient curve granularity and satisfying gradients. For chunk sizes, a large range between 300 and 1,000 words seems possible, though we found sizes of 500–700 words to work best without adding too much computational overhead. For stable classification, about 10 total runs need to be averaged, while 15–20 are still a sensible choice.

4.2 Verification Results

The overall performance of our approach is on par with other state-of-the-art verifiers, but we can improve our precision significantly by increasing the minimal distance a pair must have from the SVM hyperplane to be classified at all. We use this distance threshold as our confidence parameter c. Classification results at different values for c are shown in Table 1. At a threshold of 0.8, we can derive an answer for only 13.8 % of the cases, but are able to do so with a precision of 1.0, meaning all *same-author* classifications are correct. We can reduce the threshold down to a value of 0.4, at which we can classify about half the cases with a still all-correct answer set—but with lower confidence in the correctness. The actual numbers vary within a certain margin at low thresholds due to our random chunk generation. Thresholds below 0.4 will produce an increasing amount of false positives. The choice of c depends on the assurance level desired by the user. In medium- to high-assurance scenarios (where false positives are to be avoided, but not entirely critical), we recommend a threshold of 0.6 or higher. If false positives have to be entirely avoided, we recommend at least 0.7 or higher. On our dataset, results at $c \geq 0.8$ can be considered correct with near certainty. Cases which are not classifiable at the desired confidence threshold must be left undecided as "unknown authorship."

Hyperplane threshold c	**Classified cases [%]**	**Effectiveness**			
		Precision	Recall	$F_{0.5u}$	c@1
0.8	13.8	1.00	0.24	0.42	0.26
0.7	15.0	1.00	0.24	0.42	0.25
0.6	23.3	1.00	0.27	0.47	0.41
0.5	38.8	1.00	0.32	0.55	0.54
0.4	50.0	1.00	0.39	0.64	0.66
0.1	91.2	0.82	0.54	0.74	0.76
0.0	100.0	0.83	0.59	0.76	0.73

Table 1: Unmasking performance on our test data at various confidence thresholds. Recall was calculated after assigning all non-decisions the negative class. $F_{0.5u}$ and c@1 diverge significantly at high thresholds with an increasing class balance skew.

We compare the performance of our generalized unmasking approach to the two state-of-the-art short-text verification approaches by Bagnall (2015) and Halvani et al. (2017). Since no ready-to-use implementation of the latter approach is available, we reimplemented it using the PPMd compression algorithm and trained a random forest with 100 trees on the two suggested similarity measures Compression-based Cosine (CBC) and the Chen-Li metric (CLM). For a fairer comparison, we use a confidence threshold $c = 0.1$ for unmasking as this results in about the same amount of c@1 “optimization” as employed by Bagnall, although our $F_{0.5u}$ is higher at $c = 0$. The results of our performance comparison are shown in Table 2. The precision of our new generalized unmasking is the highest with slightly worse c@1 and $F_{0.5u}$ compared to Bagnall and CLM due to a lower recall. CBC appears to score the worst, although Halvani et al. found it to be best-performing. Overall, however, all approaches perform equally well and (treating non-answers as incorrect) no actual difference between their (binary) decision quality can be inferred from a McNemar test between unmasking and Bagnall ($\chi^2 = 0.35$, $p = 0.56$) or unmasking and Halvani et al. with CLM ($\chi^2 = 0.83$, $p = 0.36$).

In terms of runtime, compression performs best with under a minute on the whole corpus due to the optimized C implementation of the compressor, followed by our new generalized unmasking implementation with about 2–3 minutes. Bagnall runs the longest with 4:45 hours on all 80 cases in the corpus. It is worth noting that, unlike unmasking and compression models, Bagnall’s approach is not intrinsic and needs other texts from the input corpus to arrive at a decision for the single pair in question, which is a valid approach, but can effectively exploit potential biases in the corpus. We further noticed that compression appears to balance precision and recall more than the other approaches, whereas generalized unmasking heavily prioritizes precision, which is generally more preferable in a real-world scenario: here, false positives can have dire consequences, such as a wrong conviction. Another advantage of generalized unmasking is that it allows for easy optimization of all hyperparameters compared to the other approaches which are more of a blackbox. By building ensembles with other machine learning models, different features, chunk sizes, etc., we expect further improvements, but leave this for future work.

Approach	**Precision**	**Recall**	$\mathbf{F_{0.5u}}$	**c@1**
Generalized Unmasking	0.82	0.54	0.74	0.76
Bagnall	0.81	0.71	0.77	0.79
Halvani et al. (CLM)	0.78	0.78	0.78	0.78
Halvani et al. (CBC)	0.71	0.71	0.71	0.70

Table 2: Performance comparison with the state of the art in short-text authorship verification ($c = 0.1$ in generalized unmasking). Differences between the first three are non-significant.

4.3 Reproducibility

To enable our research on short-text unmasking, we developed an extensive general-purpose unmasking framework for running any kind of unmasking experiment with a plethora of different features, parameters, and aggregations for final or partial results from different runs. Each unmasking run comes with a detailed job configuration allowing for easy reproduction of previous experiments. We published the source code of our framework and all data used in our research under an open-source license alongside this paper.

5 Conclusion

We have successfully generalized and applied unmasking to short texts establishing another state-of-the-art verification approach for scenarios in which only little source material is available. This new unmasking approach prioritizes precision to deliver highly-reliable decisions even though short texts naturally show a high amount of uncertainty as a result of their low stylistic information content. We compared our approach to other state-of-the-art authorship verification systems specialized for short texts and can produce competitive results with low computational effort and high prospect of further optimization in the future.

Adversarial Training for Satire Detection: Controlling for Confounding Variables

Abstract

The automatic detection of satire vs. regular news is relevant for downstream applications (for instance, knowledge base population) and to improve the understanding of linguistic characteristics of satire. Recent approaches build upon corpora which have been labeled automatically based on article sources. We hypothesize that this encourages the models to learn characteristics for different publication sources (*e.g.*, "The Onion" vs. "The Guardian") rather than characteristics of satire, leading to poor generalization performance to unseen publication sources. We therefore propose a novel model for satire detection with an adversarial component to control for the confounding variable of publication source. On a large novel data set collected from German news (which we make available to the research community), we observe comparable satire classification performance and, as desired, a considerable drop in publication classification performance with adversarial training. Our analysis shows that the adversarial component is crucial for the model to learn to pay attention to linguistic properties of satire.

1 Introduction

Satire is a form of art used to criticize in an entertaining manner (*cf.* Sulzer, 1771, p. 995ff.). It makes use of different stylistic devices, *e.g.*, humor, irony, sarcasm, exaggerations, parody or caricature (Knoche, 1982; Colletta, 2009). The occurrence of harsh, offensive or banal and funny words is typical (Golbert, 1962; Brummack, 1971).

Satirical news are written with the aim of mimicking regular news in diction. In contrast to misinformation and disinformation (Thorne and Vlachos, 2018), it does not have the intention of fooling the readers into actually believing something wrong in order to manipulate their opinion.

The task of satire detection is to automatically distinguish satirical news from regular news. This is relevant, for instance, for downstream applications, such that satirical articles can be ignored in knowledge base population. Solving this problem computationally is challenging. Even human readers are sometimes not able to precisely recognize satire (Allcott and Gentzkow, 2017). Thus, an automatic system for satire detection is both relevant for downstream applications and could help humans to better understand the characteristics of satire.

Previous work mostly builds on top of corpora of news articles which have been labeled automatically based on the publication source (*e.g.*, "The New York Times" articles would be labeled as regular while "The Onion" articles as satire[1]). We hypothesize that such distant labeling approach leads to the model mostly representing characteristics of the publishers instead of actual satire. This has two main issues: First, interpretation of the model to obtain a better understanding of concepts of satire would be misleading, and second, generalization of the model to unseen publication sources would be harmed. We propose a new model with adversarial training to control for the confounding variable of publication sources, *i.e.*, we debias the model.

Our experiments and analysis show that (1) the satire detection performance stays comparable when the adversarial component is included, and (2) that adversarial training is crucial for the model to pay attention to satire instead of publication characteristics. (3), we publish a large German data set for satire detection which is a) the first data set in German, b) the first data set including publication sources, enabling the experiments at hand, and c) the largest resource for satire detection so far.[2]

2 Previous Work

Previous work tackled the task of automatic English satire detection with handcrafted features, for instance, the validity of the context of entity mentions (Burfoot and Baldwin, 2009), or the coherence of a story (Goldwasser and Zhang, 2016). Rubin et al. (2016) use distributions of parts-of-speech, sentiment, and exaggerations. In contrast to these approaches, our model uses only word embeddings as input representations. Our work is therefore similar to Yang et al. (2017) and De Sarkar et al. (2018) who also use artificial neural networks to predict if a given text is satirical or regular news. They develop a hierarchical model of convolutional and recurrent layers with attention over paragraphs or sentences. We follow this line of work but our model is not hierarchical and introduces less parameters. We apply attention to words instead of sentences or paragraphs, accounting for the fact that satire might be expressed on a sub-sentence level.

Adversarial training is popular to improve the robustness of models. Originally introduced by Goodfellow et al. (2014) as generative adversarial networks with a generative and a discriminative component, Ganin et al. (2016) show that a related concept can also be used for domain adaptation: A domain-adversarial neural network consists of a classifier for the actual class labels and a domain discriminator. The two components share the same feature extractor and are trained in a minimax optimization algorithm with gradient reversal: The sign of the gradient of the domain discriminator is flipped when backpropagating to the feature extractor. Building upon the idea of eliminating domain-specific input representations, Wadsworth et al. (2018) debias input representations for recidivism prediction, or income prediction (Edwards and Storkey, 2016; Beutel et al., 2017; Madras et al., 2018; Zhang et al., 2018).

Debiasing mainly focuses on word embeddings, *e.g.*, to remove gender bias from embeddings (Bolukbasi et al., 2016). Despite previous positive results with adversarial training, a recent study by Elazar and Goldberg (2018) calls for being cautious and not blindly trusting adversarial training for debiasing. We therefore analyze whether it is possible at all to use adversarial training in another setting, namely to control for the confounding variable of publication sources in satire detection (see Section 3.1).

3 Methods for Satire Classification

3.1 Limitations of Previous Methods

The data set used by Yang et al. (2017) and De Sarkar et al. (2018) consists of text from 14 satirical and 6 regular news websites. Although the satire sources in train, validation, and test sets did not overlap, the sources of regular news were not split up according to the different data sets (Yang et al., 2017). We hypothesize that this enables the classifier to learn which articles belong to which publication of regular news and classify everything else as satire, given that one of the most frequent words is the name of the website itself (see Section 4.1). Unfortunately, we cannot analyze this potential limitation since their data set does not contain any information on the publication source[3]. Therefore, we create a new corpus in German (see Section 4.1) including this information and investigate our hypothesis on it.

3.2 Model

Motivated by our hypothesis in Section 3.1, we propose to consider two different classification problems (satire detection and publication identification) with a shared feature extractor. Figure 1 provides an overview of our model. We propose to train the publication identifier as an adversary.

3.2.1 Feature Extractor

Following De Sarkar et al. (2018), we only use word embeddings and no further handcrafted features to represent the input. We pretrain word embeddings of 300 dimensions on the whole corpus using word2vec (Mikolov et al., 2013). The feature generator f takes the embeddings of the words of each article as input for a bidirectional LSTM (Hochreiter and Schmidhuber, 1997), followed by a self-attention layer as proposed by Lin et al. (2017). We refer to the union of all the parameters of the feature extractor as θ_f in the following.

3.2.2 Satire Detector

The gray part of Figure 1 shows the model part for our main task – satire detection. The satire detector feeds the representation from the feature extractor into a softmax layer and performs a binary classification task (satire: yes or no). Note that, in contrast to De Sarkar et al. (2018), we classify satire solely

[3] https://data.mendeley.com/datasets/hx3rzw5dwt/draft?a=377d5571-af17-4e61-bf77-1b77b88316de, v.1, 2017, accessed on 2018-11-23

on the document level, as this is sufficient to analyze the impact of the adversarial component and the influence of the publication source.

3.2.3 Publication Identifier

The second classification branch of our model aims at identifying the publication source of the input. Similar to the satire detector, the publication identifier consists of a single softmax layer which gets the extracted features as an input. It then performs a multi-class classification task since our dataset consists of 15 publication sources (see Table 1).

3.2.4 Adversarial Training

Let θ_f be the parameters of the feature extractors and θ_s and θ_p be the parameters of the satire detector and the publication identifier, respectively. The objective function for satire detection is

$$J_s = -\mathbb{E}_{(x,y_s)\sim p_{\text{data}}} \log P_{\theta_f \cup \theta_s}(y_s, x)\,, \quad (1)$$

while the objective for publication identification is

$$J_p = -\mathbb{E}_{(x,y_p)\sim p_{\text{data}}} \log P_{\theta_f \cup \theta_p}(y_p, x)\,. \quad (2)$$

Note that the parameters of the feature extractor θ_f are part of both model parts. Since our goal is to control for the confounding variable of publication sources, we train the publication identifier as an adversary: The parameters of the classification part θ_p are updated to optimize the publication identification while the parameters of the shared feature generator θ_f are updated to fool the publication identifier. This leads to the following update equations for the parameters

$$\theta_s := \theta_s - \eta \frac{\partial J_s}{\partial \theta_s} \quad (3)$$

$$\theta_p := \theta_p - \eta \frac{\partial J_p}{\partial \theta_p} \quad (4)$$

$$\theta_f := \theta_f - \eta \left(\frac{\partial J_s}{\partial \theta_f} - \lambda \frac{\partial J_p}{\partial \theta_f}\right) \quad (5)$$

with η being the learning rate and λ being a weight for the reversed gradient that is tuned on the development set. Figure 1 depicts the gradient flow.

4 Experiments

4.1 Experimental Setting

Dataset. We consider German regular news collected from 4 websites and German satirical news from 11 websites. Table 1 shows statistics and sources of the corpus, consisting of almost 330k articles. The corpus contains articles published between January 1st, 2000 and May 1st, 2018. Each publication has individual typical phrases and different most common words. Among the most common words is typically the name of each publication, *e.g.*, "Der Spiegel" has "SPIEGEL" as fifth and "Der Postillon" "Postillon" as third most common word. We did not delete those words to keep the dataset as realistic as possible. We randomly split the data set into training, development (dev) and test (80/10/10 %) with the same label distributions in all sets. Given the comparable large size of the corpus, we opt for using a well-defined test set for reproducability of our experiments in contrast to a crossvalidation setting.

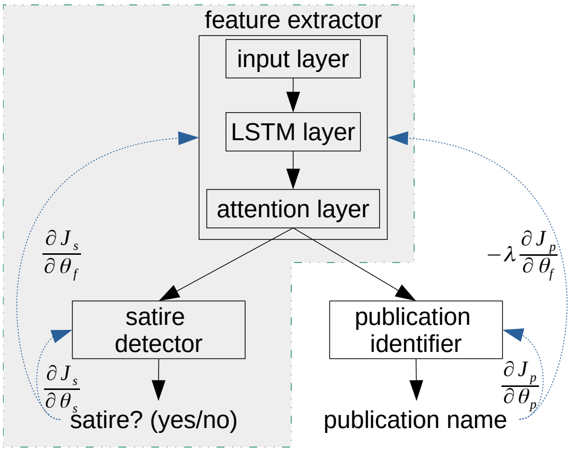

Figure 1: Architecture of the model. The gray area on the left shows the satire detector; the white area on the right is the adversary (publication identifier); the gradient flow with and without adversarial training is shown with blue arrows pointing upwards.

Research questions. We discuss two questions. RQ1: How does a decrease in publication classification performance through adversarial training affect the satire classification performance? RQ2: Is adversarial training effective for avoiding that the model pays most attention to the characteristics of publication source rather than actual satire?

Baseline. As a baseline model, we train the satire detector part (gray area in Figure 1) on the satire task. Then, we freeze the weights of the feature extractor and train the publication classifier on top of it. In addition, we use a majority baseline model which predicts the most common class.

Hyperparameters. We cut the input sentences to a maximum length of 500 words. This enables us to fully represent almost all satire articles and

	Publication	#Articles	Average Length		
			Article	Sent.	Title
Regular	Der Spiegel	31,180	556.74	19.04	7.47

Table 1: Corpus statistics (average length in words)

capture most of the content of the regular articles while keeping the training time low. As mentioned before, we represent the input words with 300 dimensional embeddings. The feature extractor consists of a biLSTM layer with 300 hidden units in each direction and a self-attention layer with an internal hidden representation of 600. For training, we use Adam (Kingma and Ba, 2014) with an initial learning rate of 0.0001 and a decay rate of 10^{-6}. We use mini-batch gradient descent training with a batch size of 32 and alternating batches of the two branches of our model. We avoid overfitting by early stopping based on the satire F1 score on the development set.

Evaluation. For evaluating satire detection, we use precision, recall and F1 score of the satire class. For publication identification, we calculate a weighted macro precision, recall and F1 score, *i.e.*, a weighted sum of class-specific scores with weights determined by the class distribution.

4.2 Selection of Hyperparameter λ

Table 2 (upper part) shows results for different values of λ, the hyperparameter of adversarial training, on dev. For $\lambda \in \{0.2, 0.3, 0.5\}$, the results are comparably, with $\lambda = 0.2$ performing best for satire detection. Setting $\lambda = 0.7$ leads to a performance drop for satire but also to $F_1 = 0$ for publication classification. Hence, we chose $\lambda = 0.2$ (the best performing model on satire classification) and $\lambda = 0.7$ (the worst performing model on publication identification) to investigate RQ1.

	Model	Satire			Publication		
		P	R	F1	P	R	F1
dev	majority class	0.0	0.0	0.0	29.5	54.3	38.3
	no adv	98.9	**52.6**	**68.7**	44.6	56.2	49.7
	adv, $\lambda = 0.2$	**99.3**	50.8	67.2	31.2	55.4	40.0
	adv, $\lambda = 0.3$	97.3	48.9	65.0	31.1	54.8	39.6
	adv, $\lambda = 0.5$	99.1	50.8	67.2	31.7	55.2	40.3
	adv, $\lambda = 0.7$	86.7	44.1	58.4	**26.9**	**0.0**	**0.0**
test	majority class	0.0	0.0	0.0	29.1	53.9	37.8
	no adv.	99.0	**50.1**	**66.5**	44.2	55.7	49.3
	adv, $\lambda = 0.2$	**99.4**	49.4	66.0	**30.8**	54.8	39.5
	adv, $\lambda = 0.7$	85.0	42.5	56.6	31.3	**0.0**	**0.0**

Table 2: Results on dev and independent test data.

5 Results (RQ1)

The bottom part of Table 2 shows the results on test data. The majority baseline fails since the corpus contains more regular than satirical news articles. In comparison to the baseline model without adversarial training (no adv), the model with $\lambda = 0.2$ achieves a comparable satire classification performance. As expected, the publication identification performance drops, especially the precision declines from 44.2 % to 30.8 %. Thus, a model which is punished for identifying publication sources can still learn to identify satire.

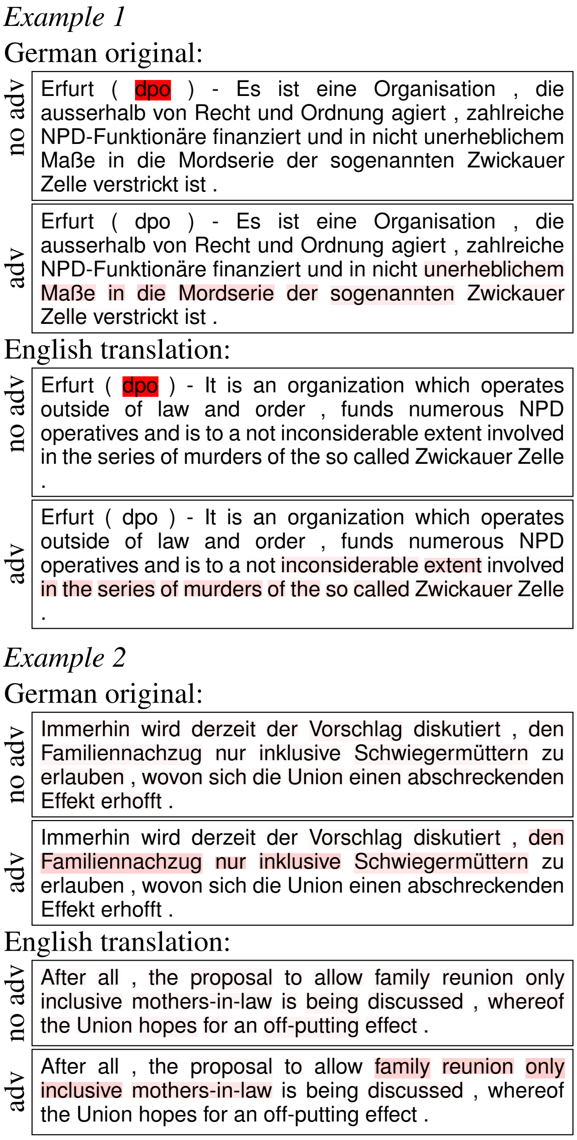
Similar to the results on dev, the recall of the model with $\lambda = 0.7$ drops to (nearly) 0 %. In this case, the satire classification performance also drops. This suggests that there are overlapping features (cues) for both satire and publication classification. This indicates that the two tasks cannot be entirely untangled.

6 Analysis (RQ2)

To address RQ2, we analyze the results and attention weights of the baseline model and our model with adversarial training.

6.1 Shift in Publication Identification

The baseline model (no adv) mostly predicts the correct publication for a given article (in 55.7 % of the cases). The model with $\lambda = 0.2$ mainly (in 98.2 % of the cases) predicts the most common publication in our corpus ("Süddeutsche Zeitung"). The model with $\lambda = 0.7$ shifts the majority of predictions (98.7 %) to a rare class (namely "Eine Zeitung"), leading to its bad performance.



Example 1

German original:

no adv: Erfurt (dpo) - Es ist eine Organisation , die ausserhalb von Recht und Ordnung agiert , zahlreiche NPD-Funktionäre finanziert und in nicht unerheblichem Maße in die Mordserie der sogenannten Zwickauer Zelle verstrickt ist .

adv: Erfurt (dpo) - Es ist eine Organisation , die ausserhalb von Recht und Ordnung agiert , zahlreiche NPD-Funktionäre finanziert und in nicht unerheblichem Maße in die Mordserie der sogenannten Zwickauer Zelle verstrickt ist .

English translation:

no adv: Erfurt (dpo) - It is an organization which operates outside of law and order , funds numerous NPD operatives and is to a not inconsiderable extent involved in the series of murders of the so called Zwickauer Zelle .

adv: Erfurt (dpo) - It is an organization which operates outside of law and order , funds numerous NPD operatives and is to a not inconsiderable extent involved in the series of murders of the so called Zwickauer Zelle .

Example 2

German original:

no adv: Immerhin wird derzeit der Vorschlag diskutiert , den Familiennachzug nur inklusive Schwiegermüttern zu erlauben , wovon sich die Union einen abschreckenden Effekt erhofft .

adv: Immerhin wird derzeit der Vorschlag diskutiert , den Familiennachzug nur inklusive Schwiegermüttern zu erlauben , wovon sich die Union einen abschreckenden Effekt erhofft .

English translation:

no adv: After all , the proposal to allow family reunion only inclusive mothers-in-law is being discussed , whereof the Union hopes for an off-putting effect .

adv: After all , the proposal to allow family reunion only inclusive mothers-in-law is being discussed , whereof the Union hopes for an off-putting effect .

Figure 2: Attention weight examples for satirical articles, with and without adversary.

6.2 Interpretation of Attention Weights

Figure 2 exemplifies the attention weights for a selection of satirical instances. In the first example the baseline model (no adv) focuses on a single word ("dpo" as a parody of the German newswire "dpa") which is unique to the publication the article was picked from ("Der Postillon"). In comparison the model using adversarial training ($\lambda = 0.2$) ignores this word completely and pays attention to "die Mordserie" ("series of murders") instead. In the second example, there are no words unique to a publication and the baseline spreads the attention evenly across all words. In contrast, the model with adversarial training is able to find cues for satire, being humor in this example ("family reunion [for refugees] is only allowed including mothers-in-law").

7 Conclusion and Future Work

We presented evidence that simple neural networks for satire detection learn to recognize characteristics of publication sources rather than satire and proposed a model that uses adversarial training to control for this effect. Our results show a considerable reduction of publication identification performance while the satire detection remains on comparable levels. The adversarial component enables the model to pay attention to linguistic characteristics of satire.

Future work could investigate the effect of other potential confounding variables in satire detection, such as the distribution of time and region of the articles. Further, we propose to perform more quantitative but also more qualitative analysis to better understand the behaviour of the two classifier configurations in comparison.

Abstract

Authors' keyphrases assigned to scientific articles are essential for recognizing content and topic aspects. Most of the proposed supervised and unsupervised methods for keyphrase generation are unable to produce terms that are valuable but do not appear in the text. In this paper, we explore the possibility of considering the keyphrase string as an abstractive summary of the title and the abstract. First, we collect, process and release a large dataset of scientific paper metadata that contains 2.2 million records. Then we experiment with popular text summarization neural architectures. Despite using advanced deep learning models, large quantities of data and many days of computation, our systematic evaluation on four test datasets reveals that the explored text summarization methods could not produce better keyphrases than the simpler unsupervised methods, or the existing supervised ones.

1 Introduction

A valuable concept for searching and categorizing scientific papers in digital libraries is the *keyphrase* (we use *keyphrase* and *keyword* interchangeably), a short set of one or few words that represent concepts. Scientific articles are commonly annotated with keyphrases based on taxonomies of concepts and the authors' judgment. Finding keyphrases that best describe the contents of a document is thus essential and rewarding.

Most of the proposed keyphrase extraction solutions tend to be unsupervised (Florescu and Caragea, 2017; Nguyen and Luong, 2010; Rose et al., 2010; Bougouin et al., 2013; Campos et al., 2018) and generate terms by selecting the most appropriate candidates, ranking the candidates based on several features and finally returning the top N. Another way is to utilize datasets of texts and keywords for training supervised models with linguistic or other features to predict if candidates are keywords or not (Witten et al., 1999; Turney, 2000; Medelyan, 2009; Hulth, 2003).

All above methods propose N keyphrases for each article which are joined together with "," (or other separator like ";") to form the *keyphrase string* of that article. They suffer from various problems or discrepancies. First, they are unable to find an optimal value for N and require it as a preset parameter. Furthermore, semantic and syntactic properties of article phrases are analyzed separately. The meaning of paragraphs, sections or entire document is thus missed. Lastly, only phrases that do appear in the article are returned. Meng et al. (2017) recently proposed a deep supervised keyphrase generation solution trained on a big dataset. It successfully solves the last two problems above, but not the first one.

Motivated by recent advances in neural machine translation and abstractive text summarization (Vaswani et al., 2017; Foster et al., 2018; Rush et al., 2015; See et al., 2017), in this paper, we explore the possibility of considering keyphrase generation as an abstractive text summarization task. Instead of generating keywords one by one and linking them to form the keyphrase string, we consider the later as an abstractive summary of the concatenated paper title and abstract. Different recently-proposed text summarization architectures are tried on four test datasets of article keyphrases (Tanti et al., 2017; Rush et al., 2015; See et al., 2017). We trained them with a newly created dataset of 2.2 million article titles, abstracts and keyphrase strings that we processed and released.[1]

The selected text summarization models are compared with popular unsupervised and supervised methods using ROUGE (Lin, 2004) and full-match F_1 metrics. The results show that though

Minneapolis, Minnesota, June 2 - June 7, 2019.

trained with large data quantities for many days, the tried text summarization methods could not produce better keywords than the existing supervised or deep supervised predictive models. In our opinion, a possible explanation for this is the fact that the title and the abstract may not carry sufficient topical information about the article, even when joined together. In contrast, when assigning keywords annotations of their paper, authors are highly influenced by the topic aspects of it.

This paper carries several contributions, despite the fact that no progressive result scores were reached. It is the first work that considers keyphrase generation as an abstractive text summarization task. We produced a large dataset of article titles, abstracts, and keywords that can be used for keyword generation, text summarization or similar purposes. Finally, we evaluated the performance of different neural network architectures on summarization of article keyword strings, comparing them with popular unsupervised methods.

2 Scientific Paper Datasets

Because of the open source and open data initiatives, many public datasets from various domains can be found online (Çano and Morisio, 2015). Among the several collections of scientific articles, some of them have gained considerable popularity in research literature. In Meng et al. (2017), we found a recent and big collection of 20K paper abstracts and keyphrases. These metadata belong to articles of computer science from ACM Digital Library, ScienceDirect, and Web of Science. In Hulth (2003), we found a collection of 2000 (1500 for train/val and 500 for testing) abstracts in English, together with titles and authors' keywords. The corresponding articles were published from 1998 to 2002 and belong to the discipline of *Information Technology*. Furthermore, Krapivin et al. (2010) released a dataset of 2000 (1600 for train/val and 400 for testing) full articles published by ACM from 2003 to 2005 in Computer Science domain. More information about similar keyphrase data collections or other available resources can be found in Hasan and Ng (2014) and in online repositories.[2]

Regarding text summarization, some of the most popular datasets are: DUC-2004 [3] mainly used for testing, English Gigaword (Napoles et al., 2012), CNN/Daily Mail described in Section 4.3 of (Nallapati et al., 2016) and Newsroom, a heterogeneous bundle of news articles described in Grusky et al. (2018). These datasets are frequently used for the task of predicting titles from abstracts or short stories. However, no keyphrases are provided; they do not serve to our purpose. ArnetMiner is a recent attempt to crawl scientific paper data from academic networks (Tang et al., 2008). The system extracts profiles of researchers from digital resources and integrates their data in a common network. A spin-off is the Open Academic Graph (OAG) data collection (Sinha et al., 2015).

Attribute	**Train**	**Val**	**Test**	**Fullset**
Records	2M	100K	100K	2.2M
Keyphrases	12M	575K	870K	13.4M
Title tokens	24M	1.3M	1.6M	27M
Abstract tokens	441M	21M	37M	499M
Av. Keyphrase	6	5.8	8.7	6.1
Av. Title	12.1	12.8	15.9	12.3
Av. Abstract	220	211	372	227

Table 1: Statistics of OAGK dataset

To produce a usable collection for our purpose, we started from OAG. We extracted *title*, *abstract* and *keywords*. The list of keywords was transformed into a comma-separated string and a language identifier was used to remove records that were not in English. Abstracts and titles were lowercased, and Stanford CoreNLP tokenizer was used for tokenizing. Short records of fewer than 20 tokens in the abstract, 2 tokens in the title and 2 tokens in the keywords were removed. For the test portion, we selected documents of at least 27, 3 and 2 tokens in each field. Data preprocessing stopped here for the release version (no symbol filtering), given that many researchers want to filter text in their own way. This new dataset named OAGK can be used for both text summarization (predicting title from abstract) and keyphrase extraction (unsupervised, supervised or deep supervised) tasks. Some rounded measures about each set of released data are presented in Table 1.

3 Keyphrase Extraction Strategies

3.1 Unsupervised and Supervised Methods

TOPICRANK is an extractive method that creates topic clusters using the graph of terms and phrases (Bougouin et al., 2013). Obtained topics are then ranked according to their importance in the document. Finally, keyphrases are extracted by pick-

---

[2] `https://github.com/LIAAD/KeywordExtractor-Datasets`

[3] `https://duc.nist.gov/duc2004/`

ing one candidate from each of the most important topics. A more recent, unsupervised and feature-based method for keyphrase extraction is YAKE! (Campos et al., 2018). It heuristically combines features like *casing*, *word position* or *word frequency* to generate an aggregate score for each phrase and uses it to select the best candidates.

One of the first supervised methods is KEA described by Witten et al. (1999). It extracts those candidate phrases from the document that have good chances to be keywords. Several features like *TF-IDF* are computed for each candidate phrase during training. In the end, Naïve Bayes algorithm is used to decide if a candidate is a keyword or not (binary classification). An improvement and generalization of KEA is MAUI (Medelyan, 2009). Additional features are computed, and bagged decision trees are used instead of Naïve Bayes. The author reports significant performance improvements in precision, recall and F_1 scores.

The above keyphrase extraction methods and others like Florescu and Caragea (2017) or Nguyen and Luong (2010) reveal various problems. First, they are not able to find an optimal value for N (number of keywords to generate for an article) based on article contents and require it as a preset parameter. Second, the semantic and syntactic properties of article phrases (considered as candidate keywords) are analyzed separately. The meaning of longer text units like paragraphs or entire abstract/paper is missed. Third, only phrases that do appear in the paper are returned. In practice, authors do often assign words that are not part of their article.

Meng et al. (2017) overcome the second and third problem using an encoder-decoder model (COPYRNN) with a bidirectional Gated Recurrent Unit (GRU) and a forward GRU with attention. They train it on a datasets of hundred thousands of samples, consisting of abstract-keyword (one keyword only) pairs. The model is entirely data-driven and can produce terms that may not appear in the document. It still produces one keyword at a time, requiring N (first problem) as parameter to create the full keyphrase string.

3.2 Text Summarization Methods

To overcome the three problems mentioned in Section 3.1, we explore abstractive text summarization models proposed in the literature, trained with article abstracts and titles as sources and keyword strings as targets. They are expected to learn and paraphrase over entire source text and produce a summary in the form of a keyphrase string with no need for extra parameters. They should also introduce new words that do not appear in the abstract. Two simple encoder-decoder variants based on LSTMs are described in Figure 3 of Tanti et al. (2017). MERGE (Figure 3.a) encodes input and the current summary independently and merges them in a joint representation which is later decoded to predict the next summary token. INJECT model (Figure 3.b) on the other hand injects the source document context representation to the encoding part of the current summary before the decoding operation is performed.

ABS is presented in Figure 3.a of Rush et al. (2015). The encoder (Figure 3.b) takes in the input text and a learned soft alignment between the input and the summary, producing the context vector. This soft alignment is the attention mechanism (Bahdanau et al., 2014). To generate the summary words, Rush et al. apply a beam-search decoder with a window of K candidate words in each position of the summary.

Pointer-Generator network (POINTCOV) depicted in Figure 3 of See et al. (2017) is similar to ABS. It is composed of an attention-based encoder that produces the context vector. The decoder is extended with a pointer-generator model that computes a probability p_{gen} from the context vector, the decoder states, and the decoder output. That probability is used as a switch to decide if the next word is to be generated or copied from the input. This model is thus a compromise between abstractive and extractive (copying words from input) models. Another extension is the coverage mechanism for avoiding word repetitions in the summary, a common problem of encoder-decoder summarizers (Tu et al., 2016).

4 Results

We performed experiments with the unsupervised and supervised methods of Section 3 on the first three datasets of Section 2 and on OAGK. All supervised methods were trained with the 2M records of OAGK train part. An exception was MAUI which could be trained on 25K records at most (memory limitation). In addition to the processing steps of Section 2, we further replaced digit symbols with # and limited source and tar-

get text lengths to 270 and 21 tokens, respectively. Vocabulary size was also limited to the 90K most frequent words.

The few parameters of the unsupervised methods (length and windows of candidate keyphrases for YAKE!, ranking strategy for TOPICRANK) were tuned using the validation part of each dataset. For the evaluation, we used F_1 score of full matches between predicted and authors' keywords. Given that the average number of keywords in the data is about 6, we computed F_1 scores on top 5 and top 7 returned keywords (**F_1@5, F_1@7**).

Before each comparison, both sets of terms were stemmed with Porter Stemmer and duplicates were removed. In the case of summarization models, keyphrases were extracted from their comma-separated summaries. We also computed ROUGE-1 and ROUGE-L F_1 scores (R_1F_1, R_LF_1) that are suitable for evaluating short summaries (Lin, 2004). The keywords obtained from the unsupervised methods were linked together to form the keyphrase string (assumed summary). This was later compared with the original keyphrase string of the authors.

Full-match results on each dataset are reported in Table 2. From the unsupervised models, we see that YAKE! is consistently better than TOPICRANK. The next two supervised models perform even better, with COPYRNN being discretely superior than MAUI.

Results of the four summarization models seem disappointing. MERGE and INJECT are the worst on every dataset, with highest score 13.39 %. Various predictions of these models are empty or very short, and some others contain long word repetitions which are discarded during evaluation. As a result, there are usually fewer than five predicted keyphrases. This explains why **F_1@5** and **F_1@7** scores are very close to each other.

ABS works slightly better reaching scores from 10.24 to 14.75 %. POINTCOV is the best of the text summarizers producing keyphrase predictions that are usually clean and concise with few repetitions. This is probably the merit of the coverage mechanism. There is still a considerable gap between POINTCOV and COPYRNN. Rouge-1 and Rouge-L F_1 scores are reported in Table 3. COPYRNN is still the best but POINTCOV is close. ABS scores are also comparable to those of MAUI and YAKE!. TOPICRANK, MERGE and INJECT are again the worst.

Regarding the test datasets, the highest result scores are achieved on Hulth and the lowest on Krapivin. We checked some samples of the later and observed that each of them contains separation tags (e.g., –T, –A, –B, Figure etc.) for indicating different parts of text in the original paper. A more intelligent text cleaning step may be required on those data.

5 Discussion

The results show that the tried text summarization models perform poorly on full-match keyword predictions. Their higher ROUGE scores further indicate that the problem is not entirely in the summarization process. Observing a few samples, we found differences between the two evaluation strategies. For example, suppose we have the predicted keyword *"intelligent system"* compared against authors' keyword *"system design"*. Full-match evaluation adds nothing to $\mathbf{F}_1\mathbf{@5}$ and $\mathbf{F}_1\mathbf{@7}$ scores. However, in the case of ROUGE evaluation, the prediction is partially right and a certain value is added to $\boldsymbol{R_1F_1}$ score. In follow up works, one solution to this discrepancy could be to try partial-match comparison scores like overlap coefficients.

Another detail that has some negative effect in full-match scores is keyword separation. The predicted string:

"health care,,,,immune system; human -;
metabolism, immunity,,,,"

produces ["health care", "immune system", "human", "metabolism", "immunity"] as the list of keywords after removing the extra separators. Instead, we expected ["health care", "immune system", "human metabolism", "immunity"]. This again penalizes full-match scores but not $\boldsymbol{R_1F_1}$ score. A more intelligent keyword separation mechanism could thus help for higher full-match result scores.

A third reason could be the fact that we used the title and abstract of papers only. This is actually what most researchers do, as it is hard to find high quantities of article full texts for free. Article body is usually restricted. Abstractive summarization methods could still benefit from longer source texts. Using default hyperparameters for the models may have also influenced the results. Some parameter tuning could be beneficial, though.

The main reason could be even more fundamental. We trained abstractive summarization models on abstracts and titles with authors' keyphrases considered as golden ones. There might be two issues here. First, when setting their keywords, authors mostly consider the topical aspects of their work rather than paraphrasing over the contents. Abstracts and titles we used may not carry enough topical information about the article, even when joined together. Second, considering authors' keywords as golden ones may not be reasonable. One solution is to employ human experts and ask them to annotate each article based on what they read. This is however prohibitive when hundred thousands of samples are required. Extensive experiments on this issue may provide different facts and change the picture. For the moment, a safe way to go seems developing deep supervised generative models like the one of Meng et al. (2017) that predict one keyphrase at each step independently.

6 Conclusions

In this paper, we experimented with various unsupervised, supervised, deep supervised and abstractive text summarization models for predicting keyphrases of scientific articles. To the best of our knowledge, this is the first attempt that explores the possibility of conceiving article string of keywords as an abstractive summary of title and abstract. We collected and produced a large dataset of 2.2 million abstracts, titles and keyphrase strings from scientific papers available online. It can be used for future text summarization and keyphrase generation experiments. Systematic evaluation on four test datasets shows that the used summarization models could not produce better keywords than the supervised predictive models. Extensive experiments with more advanced summarizaiton methods and better parameter optimization may still reveal a different view of the situation.

Abstract

Neural sequence-to-sequence models are currently the dominant approach in several natural language processing tasks, but require large parallel corpora. We present a sequence-to-sequence-to-sequence autoencoder (SEQ^3), consisting of two chained encoder-decoder pairs, with words used as a sequence of discrete latent variables. We apply the proposed model to unsupervised abstractive sentence compression, where the first and last sequences are the input and reconstructed sentences, respectively, while the middle sequence is the compressed sentence. Constraining the length of the latent word sequences forces the model to distill important information from the input. A pretrained language model, acting as a prior over the latent sequences, encourages the compressed sentences to be human-readable. Continuous relaxations enable us to sample from categorical distributions, allowing gradient-based optimization, unlike alternatives that rely on reinforcement learning. The proposed model does not require parallel text-summary pairs, achieving promising results in unsupervised sentence compression on benchmark datasets.

1 Introduction

Neural sequence-to-sequence models (SEQ2SEQ) perform impressively well in several natural language processing tasks, such as machine translation (Sutskever et al., 2014; Bahdanau et al., 2015) or syntactic constituency parsing (Vinyals et al., 2015). However, they require massive parallel training datasets (Koehn and Knowles, 2017). Consequently there has been extensive work on utilizing non-parallel corpora to boost the performance of SEQ2SEQ models (Sennrich et al., 2016; Gülçehre et al., 2015), mostly in neural machine translation where models that require absolutely no parallel corpora have also been proposed (Artetxe et al., 2018; Lample et al., 2018b).

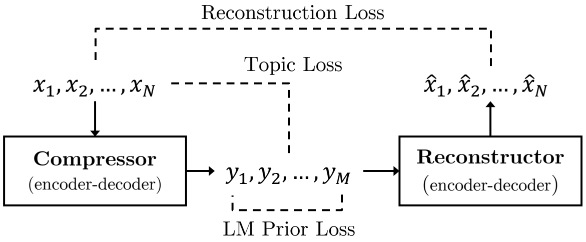

Figure 1: Overview of the proposed SEQ^3 autoencoder.

Unsupervised (or semi-supervised) SEQ2SEQ models have also been proposed for summarization tasks with no (or small) parallel text-summary sets, including unsupervised sentence compression. Current models, however, barely reach lead-N baselines (Fevry and Phang, 2018; Wang and Lee, 2018), and/or are non-differentiable (Wang and Lee, 2018; Miao and Blunsom, 2016), thus relying on reinforcement learning, which is unstable and inefficient. By contrast, we propose a sequence-to-sequence-to-sequence autoencoder, dubbed SEQ^3, that can be trained end-to-end via gradient-based optimization. SEQ^3 employs differentiable approximations for sampling from categorical distributions (Maddison et al., 2017; Jang et al., 2017), which have been shown to outperform reinforcement learning (Havrylov and Titov, 2017). Therefore it is a generic framework which can be easily extended to other tasks, e.g., machine translation and semantic parsing via task-specific losses. In this work, as a first step, we apply SEQ^3 to unsupervised abstractive sentence compression.

SEQ^3 (§2) comprises two attentional encoder-decoder (Bahdanau et al., 2015) pairs (Fig. 1): a compressor C and a reconstructor R. C (§2.1) receives an input text $\mathbf{x} = \langle x_1, \ldots, x_N \rangle$ of N words, and generates a summary $\mathbf{y} = \langle y_1, \ldots, y_M \rangle$ of M words ($M<N$), $\mathbf{y}$ being a latent variable. R and C communicate only through the discrete words of the summary $\mathbf{y}$ (§2.2). R (§2.3) produces a sequence $\hat{\mathbf{x}} = \langle \hat{x}_1, \ldots, \hat{x}_N \rangle$ of N words from $\mathbf{y}$, try-

Proceedings of NAACL-HLT 2019, pages 673–681
Minneapolis, Minnesota, June 2 - June 7, 2019.

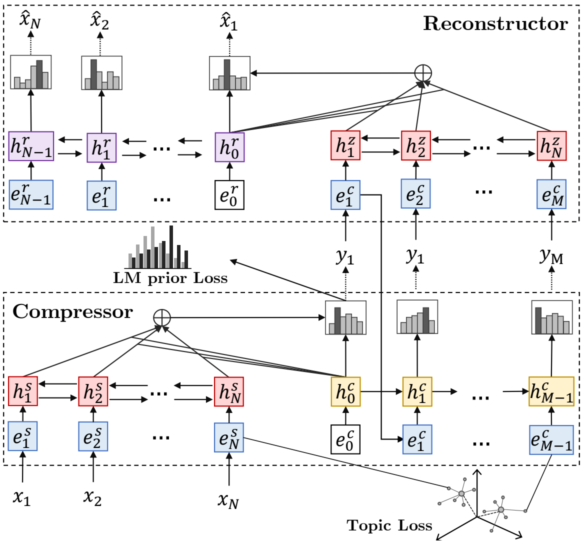

Figure 2: More detailed illustration of SEQ^3. The compressor (C) produces a summary from the input text, and the reconstructor (R) tries to reproduce the input from the summary. R and C comprise an attentional encoder-decoder each, and communicate only through the (discrete) words of the summary. The LM prior incentivizes C to produce human-readable summaries, while topic loss rewards summaries with similar topic-indicating words as the input text.

ing to minimize a reconstruction loss $L_R = (\mathbf{x}, \hat{\mathbf{x}})$ (§2.5). A pretrained language model acts as a prior on $\mathbf{y}$, introducing an additional loss $L_P(\mathbf{x}, \mathbf{y})$ that encourages SEQ^3 to produce human-readable summaries. A third loss $L_T(\mathbf{x}, \mathbf{y})$ rewards summaries $\mathbf{y}$ with similar topic-indicating words as $\mathbf{x}$. Experiments (§3) on the Gigaword sentence compression dataset (Rush et al., 2015) and the DUC-2003 and DUC-2004 shared tasks (Over et al., 2007) produce promising results.

Our contributions are: (1) a fully differentiable sequence-to-sequence-to-sequence (SEQ^3) autoencoder that can be trained without parallel data via gradient optimization; (2) an application of SEQ^3 to unsupervised abstractive sentence compression, with additional task-specific loss functions; (3) state of the art performance in unsupervised abstractive sentence compression. This work is a step towards exploring the potential of SEQ^3 in other tasks, such as machine translation.

2 Proposed Model

2.1 Compressor

The bottom left part of Fig. 2 illustrates the internals of the compressor C. An embedding layer projects the source sequence $\mathbf{x}$ to the word embeddings $\mathbf{e}^s = \langle e^s_1, \ldots, e^s_N \rangle$, which are then encoded by a bidirectional RNN, producing $\mathbf{h}^s = \langle h^s_1, \ldots, h^s_N \rangle$. Each h^s_t is the concatenation of the corresponding left-to-right and right-to-left states (outputs in LSTMs) of the bi-RNN.

$$h^s_t = [\overrightarrow{\text{RNN}}_s(e^s_t, \overrightarrow{h}^s_{t-1}); \overleftarrow{\text{RNN}}_s(e^s_t, \overleftarrow{h}^s_{t+1})]$$

To generate the summary $\mathbf{y}$, we employ the attentional RNN decoder of Luong et al. (2015), with their global attention and input feeding. Concretely, at each timestep ($t \in \{1, \ldots, M\}$) we compute a probability distribution a_i over all the states $h^s_1, \ldots, h^s_N$ of the source encoder conditioned on the current state h^c_t of the compressor's decoder to produce a context vector c_t.

$$a_i = \text{softmax}(h^{s\intercal}_i \, W_a \, h^c_t), \quad c_t = \sum_{i=1}^{N} a_i \, h^s_i$$

The matrix W_a is learned. We obtain a probability distribution for y_t over the vocabulary V by combining c_t and the current state h^c_t of the decoder.

$$o^c_t = \tanh(W_o \, [c_t; h^c_t] + b_o) \qquad (1)$$

$$u^c_t = W_v \, o^c_t + b_v \qquad (2)$$

$$p(y_t | y_{<t}, \mathbf{x}) = \text{softmax}(u^c_t) \qquad (3)$$

W_o, b_o, W_v, b_v are learned. c_t is also used when updating the state h^c_t of the decoder, along with the embedding e^c_t of y_t and a countdown argument $M - t$ (scaled by a learnable w_d) indicating the number of the remaining words of the summary (Fevry and Phang, 2018; Kikuchi et al., 2016).

$$h^c_{t+1} = \overrightarrow{\text{RNN}}_c(h^c_t, e^c_t, c_t, w_d \, (M - t)) \qquad (4)$$

For each input $\mathbf{x} = \langle x_1, \ldots, x_N \rangle$, we obtain a target length M for the summary $\mathbf{y} = \langle y_1, \ldots, y_M \rangle$ by sampling (and rounding) from a uniform distribution $U(\alpha N, \beta N)$; α, β are hyper-parameters ($\alpha < \beta < 1$); we set $M = 5$, if the sampled M is smaller. Sampling M, instead of using a static compression ratio, allows us to train a model capable of producing summaries with varying (e.g., user-specified) compression ratios. Controlling the output length in encoder-decoder architectures has been explored in machine translation (Kikuchi et al., 2016) and summarization (Fan et al., 2018).

2.2 Differentiable Word Sampling

To generate the summary, we need to sample its words y_t from the categorical distributions $p(y_t | y_{<t}, \mathbf{x})$, which is a non-differentiable process.

Soft-Argmax Instead of sampling y_t, a simple workaround during training is to pass as input to the next timestep of C's decoder and to the corresponding timestep of R's encoder a weighted sum of all the vocabulary's (V) word embeddings, using a peaked softmax function (Goyal et al., 2017):

$$\bar{e}_t^c = \sum_i^{|V|} e(w_i)\,\text{softmax}(u_t^c/\tau) \tag{5}$$

where u_t^c is the unnormalized score in Eq. 2 (i.e., the logit) of each word w_i and $\tau \in (0, \infty)$ is the temperature. As $\tau \to 0$ most of the probability mass in Eq. 5 goes to the most probable word, hence the operation approaches the $\arg\max$.

Gumbel-Softmax We still want to be able to perform sampling, though, as it has the benefit of adding stochasticity and facilitating exploration of the parameter space. Hence, we use the Gumbel-Softmax (GS) reparametrization trick (Maddison et al., 2017; Jang et al., 2017) as a low variance approximation of sampling from categorical distributions. Sampling a specific word y_t from the softmax (Eq. 3) is equivalent to adding (element-wise) to the logits an independent noise sample ξ from the Gumbel distribution[1] and taking the $\arg\max$:

$$y_t \sim \text{softmax}(u_t^c) \leftrightarrow y_t = \arg\max(u_t^c + \xi) \tag{6}$$

Therefore, using the GS trick, Eq. 5 becomes:

$$\tilde{e}_t^c = \sum_i^{|V|} e(w_i)\,\text{softmax}((u_t^c + \xi)/\tau) \tag{7}$$

Straight-Through Both relaxations lead to mixtures of embeddings, which do not correspond to actual words. Even though this enables the compressor to communicate with the reconstructor using continuous values, thus fully utilizing the available embedding space, ultimately our aim is to constrain them to communicate using *only* natural language. In addition, an unwanted discrepancy is created between training (continuous embeddings) and test time (discrete embeddings). We alleviate these problems with the Straight-Through estimator (ST) (Bengio et al., 2013). Specifically, in the forward pass of training we discretize $\tilde{e}_t^c$ by using the $\arg\max$ (Eq. 6), whereas in the backward pass we compute the gradients using the GS (Eq. 7). This is a biased estimator due to the mismatch between the forward and backward passes, but works well in practice. ST GS reportedly outperforms scheduled sampling (Goyal et al., 2017) and converges faster than reinforcement learning (Havrylov and Titov, 2017).

2.3 Reconstructor

The reconstructor (upper right of Fig. 2) works like the compressor, but its encoder operates on the embeddings $e_1^c, \ldots, e_M^c$ of the words $y_1, \ldots, y_M$ of the summary (exact embeddings of the sampled words y_t in the forward pass, approximate differentiable embeddings in the backward pass).

2.4 Decoder Initialization

We initialize the hidden state of each decoder using a transformation of the concatenation $[\overrightarrow{h_N^s}; \overleftarrow{h_1^s}]$ of the last hidden states (from the two directions) of its bidirectional encoder and a length vector, following Mallinson et al. (2018). The length vector for the decoder of the compressor C consists of the target summary length M, scaled by a learnable parameter w_v, and the compression ratio $\frac{M}{N}$.

$$h_0^c = \tanh(W_c\,[\overrightarrow{h_N^s}; \overleftarrow{h_1^s}; w_v M; \frac{M}{N}])$$

W_c is a trainable hidden layer. The decoder of the reconstructor R is initialized similarly.

2.5 Loss Functions

Reconstruction Loss $L_R(\mathbf{x}, \hat{\mathbf{x}})$ is the (negative) log-likelihood assigned by the (decoder of) R to the input (correctly reconstructed) words $\mathbf{x} = \langle x_1, \ldots, x_N \rangle$, where p_R is the distribution of R.

$$L_R(\mathbf{x}, \hat{\mathbf{x}}) = -\sum_{i=1}^{N} \log p_R(\hat{x}_i = x_i)$$

We do not expect $L_R(\mathbf{x}, \hat{\mathbf{x}})$ to decrease to zero, as there is information loss through the compression. However, we expect it to drive the compressor to produce such sentences that will increase the likelihood of the target words in the reconstruction.

LM Prior Loss To ensure that the summaries $\mathbf{y}$ are readable, we pretrain an RNN language model (see Appendix) on the *source* texts of the full training set. We compute the Kullback-Leibler divergence D_{KL} between the probability distributions of the (decoder of) the compressor ($p(y_t|y_{<t}, \mathbf{x})$, Eq. 3) and the language model ($p_{\text{LM}}(y_t|y_{<t}, \mathbf{x})$). Similar priors have been used in sentence compression (Miao and Blunsom, 2016) and agent communication (Havrylov and Titov, 2017).

---

[1] $\xi_i = -\log(-\log(x_i)),\ \ x_i \sim U(0, 1)$

We also use the following task-specific losses.

Topic Loss Words with high TF-IDF scores are indicative of the topic of a text (Ramos et al., 2003; Erkan and Radev, 2004). To encourage the compressor to preserve in the summary $\mathbf{y}$ the topic-indicating words of the input $\mathbf{x}$, we compute the TF-IDF-weighted average v^x of the word embeddings of $\mathbf{x}$ and the average v^y of the word embeddings of $\mathbf{y}$ and use their cosine distance as an additional loss $L_T = 1 - \cos(v^x, v^y)$.

$$v^x = \sum_{i=1}^{N} \frac{\text{IDF}(x_i)\, e_i^s}{\sum_{t=1}^{N} \text{IDF}(x_t)} \qquad v^y = \frac{1}{M} \sum_{i=1}^{M} e_i^c$$

(Using TF-IDF in v^y did not help.) All IDF scores are computed on the training set.

Length Penalty A fourth loss L_L (not shown in Fig. 1) helps the (decoder of the) compressor to predict the end-of-sequence (EOS) token at the target summary length M. L_L is the cross-entropy between the distributions $p(y_t|y_{<t}, \mathbf{x})$ (Eq. 3) of the compressor at $t = M + 1$ and onward, with the one-hot distribution of the EOS token.

2.6 Modeling Details

Parameter Sharing We tie the weights of layers encoding similar information, to reduce the number of trainable parameters. First, we use a shared embedding layer for the encoders and decoders, initialized with 100-dimensional GloVe embeddings (Pennington et al., 2014). Additionally, we tie the shared embedding layer with the output layers of both decoders (Press and Wolf, 2017; Inan et al., 2017). Finally, we tie the encoders of the compressor and reconstructor (see Appendix).

OOVs Out-of-vocabulary words are handled as in Fevry and Phang (2018) (see Appendix).

3 Experiments

Datasets We train SEQ^3 on the *Gigaword* sentence compression dataset (Rush et al., 2015).[2] It consists of pairs, each containing the first sentence of a news article ($\mathbf{x}$) and the article's headline ($\mathbf{y}$), a total of 3.8M/189k/1951 train/dev/test pairs. We also test (without retraining) SEQ^3 on DUC-2003 and DUC-2004 shared tasks (Over et al., 2007), containing 624/500 news articles each, paired with 4 reference summaries capped at 75 bytes.

Methods compared We evaluated SEQ^3 and an ablated version of SEQ^3. We only used the article sentences (sources) of the training pairs from Gigaword to train SEQ^3; our model is *never* exposed to target headlines (summaries) during training or evaluation, i.e., it is completely unsupervised. Our code is publicly available.[3]

We compare SEQ^3 to other unsupervised sentence compression models. We note that the extractive model of Miao and Blunsom (2016) relies on a pre-trained attention model using at least 500K parallel sentences, which is crucial to mitigate the inefficiency of sampling-based variational inference and REINFORCE. Therefore it is not comparable, as it is semi-supervised. The results of the extractive model of Fevry and Phang (2018) are also not comparable, as they were obtained on a different, not publicly available test set. We note, however, that they report that their system performs worse than the LEAD-8 baseline in ROUGE-2 and ROUGE-L on Gigaword. The only directly comparable unsupervised model is the abstractive 'Pretrained Generator' of Wang and Lee (2018). The version of 'Adversarial REINFORCE' that Wang and Lee (2018) consider unsupervised is actually weakly supervised, since its discriminator was exposed to the summaries of the same sources the rest of the model was trained on.

As baselines, we use LEAD-8 for Gigaword, which simply selects the first 8 words of the source, and PREFIX for DUC, which includes the first 75 bytes of the source article. We also compare to supervised abstractive sentence compression methods (Tables 1-3). Following previous work, we report the average F1 of ROUGE-1, ROUGE-2, ROUGE-L (Lin, 2004). We implemented SEQ^3 with LSTMs (see Appendix) and during inference we perform greedy-sampling.

Results Table 1 reports the Gigaword results. SEQ^3 outperforms the unsupervised Pretrained Generator across all metrics by a large margin. It also surpasses LEAD-8. If we remove the LM prior, performance drops, esp. in ROUGE-2 and ROUGE-L. This makes sense, since the pretrained LM rewards correct word order. We also tried removing the topic loss, but the model failed to converge and results were extremely poor (Table 1). Topic loss acts as a bootstrap mechanism, biasing the compressor to generate words that maintain the topic of the input text. This greatly reduces variance due to sampling in early stages of training, alleviating the need to pretrain individual

Figure 3: Good/bad example summaries on Gigaword.

components, unlike works that rely on reinforcement learning (Miao and Blunsom, 2016; Wang and Lee, 2018). Overall, both losses work in synergy, with the topic loss driving *what* and the LM prior loss driving *how* words should be included in the summary. SEQ^3 behaves similarly on DUC-2003 and DUC-2004 (Tables 2-3), although it was trained on Gigaword. In DUC-2003, however, it does not surpass the PREFIX baseline.

Finally, Fig. 3 illustrates three randomly sampled outputs of SEQ^3 on Gigaword. In the first one, SEQ^3 copies several words esp. from the beginning of the input (hence the high ROUGE-L) exhibiting extractive capabilities, though still being adequately abstractive (bold words denote paraphrases). In the second one, SEQ^3 showcases its true abstractive power by paraphrasing and compressing multi-word expressions to single content words more heavily, still without losing the overall meaning. In the last example, SEQ^3 progressively becomes ungrammatical though interestingly retaining some content words from the input.

4 Limitations and Future Work

The model tends to copy the first words of the input sentence in the compressed text (Fig. 3). We hypothesize that since the reconstructor is autoregressive, i.e., each word is conditioned on the previous one, errors occurring early in the generated sequence have cascading effects. This inevitably encourages the compressor to select the first words of the input. A possible workaround might be to modify SEQ^3 so that the first encoder-decoder pair would turn the inputs to longer sequences, and the second encoder-decoder would compress them trying to reconstruct the original inputs. In future work, we plan to explore the potential of SEQ^3 in other tasks, such as unsupervised machine translation (Lample et al., 2018a; Artetxe et al., 2018) and caption generation (Xu et al., 2015).

Acknowledgments

We would like to thank Ryan McDonald for helpful discussions and feedback. This work has been partially supported by computational time granted from the Greek Research & Technology Network (GR-NET) in the National HPC facility - ARIS. We thank NVIDIA for donating a TitanX GPU.

A Appendix

A.1 Temperature for Gumbel-Softmax

Even though the value of the temperature τ does not affect the forward pass, it greatly affects the gradient computation and therefore the learning process. Jang et al. (2017) propose to anneal τ during training towards zero. Gulcehre et al. (2017) propose to learn τ as a function of the compressor's decoder state h_t^c, in order to reduce hyper-parameter tuning:

$$\tau(h_t^c) = \frac{1}{\log(1 + \exp(w_\tau^\intercal h_t^c)) + 1} \quad (8)$$

where w_τ is a trainable parameter and $\tau(h_t^c) \in (0, 1)$. Havrylov and Titov (2017) add τ_0 as a hyper-parameter which controls the upper bound of the temperature.

$$\tau(h_t^c) = \frac{1}{\log(1 + \exp(w_\tau^\intercal h_t^c)) + \tau_0} \quad (9)$$

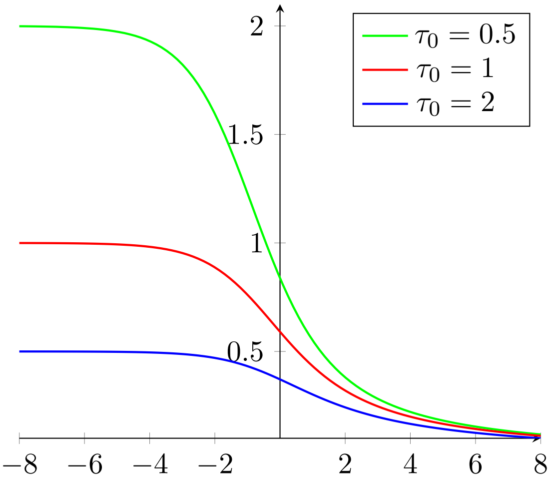

Figure 4: Plot of Eq. 9, with different values for the upper bound τ_0.

In our experiments, we had convergence problems with the learned temperature technique. We found that the compressor preferred values close to the upper bound, which led to unstable training, forcing us to set $\tau_0 > 1$ to stabilize the training process. Our findings align with the behavior reported by Gu et al. (2018). Consequently, we follow their choice and fix $\tau = 0.5$, which worked well in practice.

A.2 Out of Vocabulary (OOV) Words

The vocabulary of our experiments comprises the 15k most frequent words of Gigaword's training input texts (without looking at their summaries). To handle OOVs, we adopt the approach of Fevry and Phang (2018), which can be thought of as a simpler form of copying compared to pointer networks (See et al., 2017). We use a small set (10 in our experiments) of special OOV tokens $\text{OOV}_1, \text{OOV}_2, \ldots, \text{OOV}_{10}$, whose embeddings are updated during learning. Given an input text $\mathbf{x} = \langle x_1, \ldots, x_N \rangle$, we replace (before feeding $\mathbf{x}$ to SEQ^3) each unknown word x_i with the first unused (for the particular $\mathbf{x}$) OOV token, taking care to use the same OOV token for all the occurrences of the same unknown word in $\mathbf{x}$. For example, if 'John' and 'Rome' are not in the vocabulary, then "John arrived in Rome yesterday. While in Rome, John had fun." becomes "OOV_1 arrived in OOV_2 yesterday. While in OOV_2, OOV_1 had fun." If a new unknown word x_i is encountered in $\mathbf{x}$ and all the available OOV tokens have been used, x_i is replaced by 'UNK', whose embedding is also updated during learning. The OOV tokens (and 'UNK') are included in the vocabulary, and SEQ^3 learns to predict them as summary words, in effect copying the corresponding unknown words of $\mathbf{x}$. At test time, we replace the OOV tokens with the corresponding unknown words.

A.3 Reconstruction Word Drop

Our model is an instance of Variational Auto-Encoders (VAE) (Kingma and Welling, 2014). A common problem in VAEs is that the reconstructor tends to disregard the latent variable. We weaken the reconstructor R, in order to force it to fully utilize the latent sequence $\mathbf{y}$ to generate $\hat{\mathbf{x}}$. To this end, we employ word dropout as in Bowman et al. (2016) and randomly drop a percentage of the input words, thus forcing R to rely solely on $\mathbf{y}$ to make good reconstructions.

A.4 Implementation and Hyper-parameters

We implemented SEQ^3 in PyTorch (Paszke et al., 2017). All the RNNs are LSTMs (Hochreiter and Schmidhuber, 1997). We use a shared encoder for the compressor and the reconstructor, consisting of a two-layer bidirectional LSTM with size 300 per direction. We use separate decoders for the compressor and the reconstructor; each decoder is a two-layer unidirectional LSTM with size 300. The (shared) embedding layer of the compressor and the reconstructor is initialized with 100-dimensional GloVe embeddings (Pennington et al., 2014) and is tied with the output (projection) layers of the decoders and jointly finetuned during training. We apply layer normalization (Ba et al., 2016) to the context vectors (Eq. 1) of the compressor and the reconstructor. We apply word dropout (§A.3) to the reconstructor with $p = 0.5$.

During training, the summary length M is sampled from $U(0.4N, 0.6N)$; during testing, $M = 0.5N$. The four losses are summed, λs being scalar hyper-parameters.

$$L = \lambda_R L_R + \lambda_P L_P + \lambda_T L_T + \lambda_L L_L$$

We set $\lambda_R = \lambda_T = 1$, $\lambda_L = \lambda_P = 0.1$. We use the Adam (Kingma and Ba, 2015) optimizer, with batch size 128 and the default learning rate 0.001. The network is trained for 5 epochs.

LM Prior The pretrained language model is a two-layer LSTM of size 1024 per layer. It uses its own embedding layer of size 256, which is randomly initialized and updated when training the language model. We apply dropout with $p = 0.2$ to the embedding layer and dropout with $p = 0.5$ to the LSTM layers. We use Adam (Kingma and Ba, 2015) with batch size 128 and the network is trained for 30 epochs. The learning rate is set initially to 0.001 and is multiplied with $\gamma = 0.5$ every 10 epochs.

Evaluation Following Chopra et al. (2016), we filter out pairs with empty headlines from the test set. We employ the PYROUGE package with "*-m -n 2 -w 1.2*" to compute ROUGE scores. We use the provided tokenizations of the Gigaword and DUC-2003, DUC-2004 datasets. All hyper-parameters were tuned on the development set.

Crowdsourcing Lightweight Pyramids for Manual Summary Evaluation

Abstract

Conducting a manual evaluation is considered an essential part of summary evaluation methodology. Traditionally, the Pyramid protocol, which exhaustively compares system summaries to references, has been perceived as very reliable, providing objective scores. Yet, due to the high cost of the Pyramid method and the required expertise, researchers resorted to cheaper and less thorough manual evaluation methods, such as Responsiveness and pairwise comparison, attainable via crowdsourcing. We revisit the Pyramid approach, proposing a lightweight sampling-based version that is crowdsourcable. We analyze the performance of our method in comparison to original expert-based Pyramid evaluations, showing higher correlation relative to the common Responsiveness method. We release our crowdsourced Summary-Content-Units, along with all crowdsourcing scripts, for future evaluations.

1 Introduction

Evaluating *content* quality of summaries is an integral part of summarization research. Measuring the performance of a summarization system can be done through either automatic or manual evaluation. An automatic evaluation, in practice working at the lexical level, provides an inexpensive means of measuring the validity of a system, both for system comparisons and for quick development cycle testing. Due to the shallowness of the automatic approaches, their reliability is often perceived as insufficient (Owczarzak et al., 2012; Chaganty et al., 2018). This calls for the more expensive manual evaluation, which employs human-in-the-loop protocols for assessment.

The Pyramid method (Nenkova and Passonneau, 2004) is a prominent manual evaluation methodology that is considered highly reliable for comparing summarization systems. It relies on a small set of manually-crafted reference summaries, out of which all summary content units (SCUs) are manually extracted. System summaries are then manually checked for coverage of each individual SCU, from which an overall system score is derived. The Pyramid evaluation method's reliability comes at a cost. It requires laborious manual work performed by annotators who must browse through non-trivial guidelines (Passonneau, 2006). Due to these drawbacks, it was only used in a few DUC and TAC (NIST, 2014, 2018) benchmarks.

Instead, summarization work in recent years has mostly employed simpler manual evaluation approaches, such as Responsiveness and pairwise comparison, which do not rely on reference summaries and can be attained via crowdsourcing. Yet, these methods are quite subjective, since evaluators need to provide only a single global judgment for the quality of a summary (or a pair of summaries). Such judgments are far more subjective than the Pyramid score, which is derived from many, more objective, local decisions, each judging independently the presence of an individual SCU. Indeed, it was shown that the above subjective crowdsourcing-based evaluation methods are not reliable enough to produce consistent scores across experiments (Gillick and Liu, 2010).

We propose a simplified crowdsourcable and reproducible version of the Pyramid method, that suggests appealing advantages over prior crowdsourcable evaluation methods. Like the original Pyramid, our method leverages the strong signal of the reference summaries and similarly bases its score on less subjective SCU judgments. In contrast to the original Pyramid, we rely on statistical sampling rather than exhaustive SCU extraction and testing, lowering overall cost. Empirically, our method correlates with the original Pyra-

Proceedings of NAACL-HLT 2019, pages 682–687
Minneapolis, Minnesota, June 2 - June 7, 2019.

mid scores better than the common Responsiveness method, and shows better stability.

2 Background: Manual Summary Evaluation

The Pyramid method (Nenkova and Passonneau, 2004) consists of two manual phases. The first phase is *pyramid creation*, performed once when a dataset is constructed, per each input topic to be summarized (either a single document or a set of documents). In this phase, experts exhaustively extract all *SCU contributors* ("mentions"), each being a text span describing an individual fact. SCU contributors are extracted from *several* reference summaries of the source text. Coreferring SCU contributors across reference summaries are then merged into a single *SCU*, which is given a representative label. Each SCU is then assigned a weight, equal to the number of reference summaries in which it was found, indicating its salience.

The second phase is *system evaluation*, performed over the summaries produced by the evaluated system. Each Pyramid SCU for the source text is manually checked for its presence in the given system summary, whose Pyramid score is then computed as a normalized sum of the weights of the SCUs it contains. The overall system score is defined as the average Pyramid score over all its evaluated summaries. Although certain normalization variants attempt to weigh in SCU precision, the score is essentially an absolute "recall-style" interpretation reflecting the system's ability to cover the content units found in the reference summaries. Such a fairly robust score allows, in principle, system comparison across experiments (Nenkova and Passonneau, 2004).

We note that due to the Pyramid method's reliability, some research has been carried out on simulating the Pyramid method as a fully automatic one (Yang et al., 2016; Hirao et al., 2018). The hope of such a line of work is to find an automatic evaluation method that is more reliable than the commonly used ones, by taking the reference summary *semantic* content into account. Despite these efforts, automated Pyramid evaluations did not make their way yet to mainstream summary evaluation practices, where variants of the ROUGE metric (Lin, 2004) still prevail. In any case, as this paper focuses on manual evaluation, we compare our results to those of the manual Pyramid.

The *Responsiveness* method, introduced in DUC 2003 (NIST, 2003), does not require reference summaries. Instead, human evaluators typically read both the source text and the system summary. They then assign a single subjective score on a Likert scale for the summary quality, often with respect to a topic statement or guiding question. Finally, compared systems are ranked by the average score of their summaries. This method naturally developed into a crowdsourcing task, and is now used frequently in some variants (Grusky et al., 2018; Paulus et al., 2018).

Another common crowdsourcable evaluation method is pairwise comparison (Gao et al., 2018; Falke et al., 2017; Fan et al., 2018): an evaluator is asked to judge which of two competing summaries of the same text is superior, usually while observing the source text. This protocol allows comparing only two systems at a time, where the superior is determined by the total votes over all input texts. The obvious disadvantage of the approach is the difficulty of comparing many systems, in the absence of absolute scores. Also, this method may tend to suffer from transitivity inconsistencies when comparing multiple system pairs (Gillick and Liu, 2010).

The lightweight crowdsourcable Pyramid version we propose aims to preserve the interpretability and relative objectiveness of the Pyramid scores. This could provide absolute scores for comparing multiple systems, which the pairwise method does not, in a more reliable manner than Responsiveness evaluation.

3 Our Lightweight Pyramid Method

Our Lightweight Pyramid method mimics the two phases of the original Pyramid protocol in a crowdsourced setting, with some adjustments.

Pyramid creation. The input for this phase is several reference summaries of a topic. Each reference is presented to two crowd workers, asking to extract eight SCU-like statements, yielding 16 potential SCUs per reference summary. The instructions guide workers to copy-and-paste extractions from the text, possibly modifying them to stand-alone sentences, that should (a) be brief and focused on a single fact; (b) capture important information; (c) rely solely on the text rather than general knowledge of the worker. Further, the statements should appear in different places in the text.

The copy-and-paste approach allows us to easily detect and filter duplicate statements extracted from the *same* reference by both annotators, which we identify via bag-of-lemmas cosine similarity. Further, too long sentences are filtered. In our experiments (see Section 4), we were left with an average of about 13 SCUs per reference summary. Then, we take the union of SCUs from all reference summaries, which yielded in our experiments 51 SCUs on average per topic, coming from four reference summaries. These SCUs are used to create tasks for the system evaluation phase.

Recall that in the original Pyramid, SCUs are exhaustively collected; then, coreferring SCUs *between* reference summaries are merged and weighted by the number of reference summaries from which they originate. In contrast, our method enables using a *sample* of SCUs for evaluation, out of the SCUs collected in this phase (we have sampled, for uniformity, 32 SCUs per topic). Further, it avoids posing the task of merging coreferring SCUs *across* references, which is difficult and error-prone, particularly when expected from crowd workers. Instead, we rely on the higher likelihood of a repeated fact to be included in our sample, possibly more than once. This implicitly increases the expected impact of repeated facts on our evaluation.

System evaluation. In this phase, a crowd worker is presented with a system summary and a fixed-sized small set of SCUs (we used sets of 16 SCUs). The worker is asked whether each SCU can be inferred from the system summary text. The guidelines advise workers to refrain from using general knowledge and to ignore minor content differences between the SCU and the system summary. Each SCU should be assessed by a few crowd workers, to ensure the stability of the results (in our experiments, each SCU was assigned for evaluation to 5 workers).

Scoring. Following common practice in crowdsourcing, we use techniques of filtering out noisy workers who had high disagreement with others (pairwise worker agreement < 0.5). Then, using the remaining answers, we take the majority vote for each SCU to decide whether it appears in the system summary.[1] We resolve ties with a "not present" default, as the more likely answer. We then compute the system summary score as the percentage of SCUs it matched out of the set of judged SCUs. A system's final score is its average score over all topics.

4 Experiments

Experimental setup. We used the DUC 2005 and 2006 multi-document summarization datasets (NIST, 2014), which contain expert evaluations for both Pyramid and Responsiveness. Each of the two datasets includes 20 document clusters, each pertaining to a target topic, with four reference summaries and 25 (2005) or 22 (2006) system summaries per topic. All summaries are 250 words long. On average, 105 weighted SCUs were extracted, by experts, for each topic. In comparison, our setup gathers 32 sampled crowdsourced unweighted SCUs.

As suggested in Dang (2006) and Passonneau et al. (2006), the 2005 data tends to be easier to evaluate than the 2006 data, seemingly due to "less natural" document clusters with respect to practical summarization settings. Passonneau et al. (2006) show that the document sets in 2005 were overall more difficult for systems to summarize, as reflected by a lower average Pyramid score across all systems. The 2005 topics are more complex as they yield fewer general, context-independent SCUs. For example, as Dang (2006) indicates, there are more topics that had a relatively large number of specific named entities. Consequently, due to the topic hardness, Passonneau et al. (2006) indicate very few significant differences between overall system Pyramid scores, as evident by Tukey's HSD test. While 2006 systems can be divided into eight significantly different Pyramid score groups, in 2005 only two such groups emanate. Additionally, the guidelines and scoring method were slightly improved in 2006, relative to 2005. For these reasons, we focused on the 2006 dataset, fully annotating it, while utilizing half the topics, randomly chosen, from the 2005 data.

Using Amazon Mechanical Turk,[2] we qualified workers with over 5000 approved assignments and a 99% approval rate. We paid workers \$0.50 per reference summary annotation assignment (generating 8 SCUs), yielding a total Pyramid creation cost of \$48 (including fees) for the 2005 dataset (10 topics) and \$96 for 2006 (20 topics). Pyramid

---

[1] In our experiments, we have also examined the option of using the average answer, which was significantly worse.

2005	0.81	0.81	**0.79**	0.77
2006	**0.74**	0.60	**0.69**	0.40

Table 1: Correlations to the original Pyramid scores, for our crowdsourced method and for *expert* Responsiveness method, for DUC '05 and '06.

creation cost per topic is thus \$4.8. For the system summary evaluation phase we split the 32 SCUs to two tasks of 16 SCUs each, in order to ensure that the crowdsourcing platform assigns each SCU to 5 distinct workers. We paid workers \$0.45, and evaluated all 25 (2005) and 22 (2006) systems. The total benchmark evaluation cost was \$1350 (including fees) for 2005 and \$2376 for 2006, equaling \$5.4 per system per topic, or \$108 per system evaluation over all 20 topics.

We release[3] our SCU dataset for DUC 2005 and DUC 2006 as a complementary resource, accompanied by the HTML pages for our tasks on Amazon Mechanical Turk and processing and evaluation scripts. In the SCU dataset, we mark the SCUs we used in our experiments, including their grouping as tasks in the system evaluation phase. These enable future crowdsourced Pyramid evaluations of new systems on these datasets, as well as developing new datasets with crowdsourced pyramids.

Correlations with original Pyramid. We first assess our evaluation methodology by computing the correlation of its system scores (and rankings) to those of the original Pyramid. These are compared with the analogous correlations for the expert Responsiveness scores, available in the datasets. As seen in Table 1, our method produces better correlations, and substantially so on the more characteristic 2006 dataset. Importantly, notice that Responsiveness scores here were obtained by *experts*, and therefore the gap for crowdsourced Responsiveness is expected to be greater, further indicating the advantage of our method as a crowdsourcable approach.

Stability. As an additional assessment, we test the robustness of our method, in terms of its reproducibility. To that end, we reran the system evaluation phase on eight randomly chosen systems of the 2006 data, which enabled us to compare our results with those obtained by Gillick and Liu (2010) for crowdsourced Responsiveness for a similar setting (8 random systems of the 2006 dataset). Notably, the lightweight Pyramid obtained an average 10% relative change in overall system scores, whereas crowdsourced Responsiveness exhibited lower stability with an average of 24% relative change.

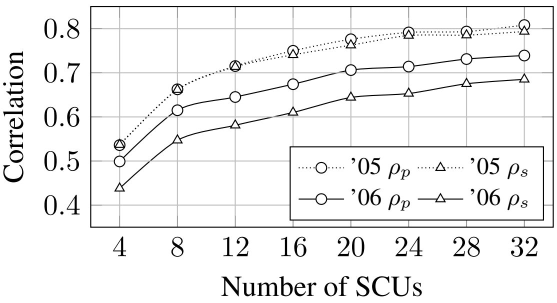

Figure 1: Average Pearson and Spearman correlations with Pyramid scores as a function of number of SCUs evaluated per topic, on the DUC '05 and '06 data.

Cost analysis. We analyze the impact of randomly reducing the various resources involved in our methodology, aiming to see whether overall cost might be reduced without harming correlation with the original Pyramid. The results below, reported as averages over 70 re-sampled iterations for each setting, suggest that such cost reductions would be harmful.

Number of workers. Reducing the number of workers per SCU judgment from five to three drops the correlations by about 8 points in 2006 and 6 points in 2005.

Number of SCUs. Figure 1 shows that correlation increases as a function of the number of judged SCUs per topic. The correlation improvement seems to stabilize around 32 SCUs.

Number of topics. Figure 2 presents the effect of the number of topics on which systems are evaluated, showing a steady correlation increase, which does not necessarily saturate at the number of 20 topics available in these datasets.

Qualitative analysis. To identify certain limitations of our methodology, we manually analyzed some "suspected" topics, for which either worker Krippendorff agreement or correlation with the original Pyramid was low. We noticed two interesting phenomena.

First, some topics seem inherently more difficult to evaluate, particularly for crowd workers. Such difficulty may be attributed to SCUs that are more difficult to assess or to less coher-

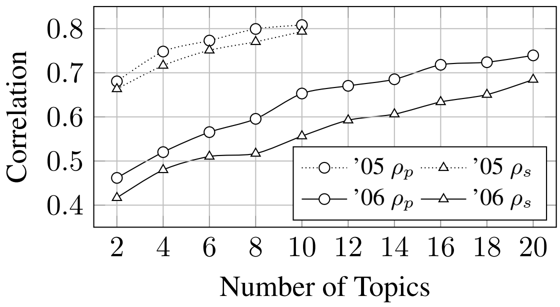

Figure 2: Average Pearson and Spearman correlations with Pyramid scores as a function of number of topics used for evaluation, on the DUC '05 and '06 data.

ent system summaries, due to the respective document set's complexity. Indeed, Passonneau et al. (2006) indicated that topic characteristics and annotator training experience effect evaluation quality. It seems worthwhile investigating, in future research, whether correlations improve by increasing further the overall number of topics, reducing the impact of the problematic ones.

Another possibility may be to filter out topics with low annotator agreement when computing systems' scores by the lightweight Pyramid method. We hypothesize that doing so might improve the reliability of this method, and hence increase its correlation with the original, expert-based, Pyramid method (when the latter is computed over all test topics). Indeed, in a preliminary test, we filtered out those 20% of the topics with lowest Krippendorff annotator agreement. This yielded a 6-point Spearman score increase (relative to the correlations reported in Table 1) when correlated with the original Pyramid ranking, as computed over the full set of topics. We note that while Figure 2 shows a slight decrease in average correlation when removing 4 random topics, removing specifically the 4 low-agreement topics seems to improves it notably. Further analysis might conclude that filtering problematic topics generically improves the reliability of the lightweight Pyramid method.

The second phenomenon observed among the difficult topics was that in some, the 32 sampled SCUs seem to miss important information, causing an unjustified degradation in system scores. In analogy to the variance in the number of SCUs in exhaustive Pyramids, it would be interesting to investigate methods for varying the sample size in our lightweight approach, based on some automatically detected parameters of topic complexity.

5 Conclusion and Future Work

To the best of our knowledge, our method is the first to mimic the reliable Pyramid method as an affordable crowdsourced procedure. Our experiments suggest that this lightweight Pyramid is more reliable than the common Responsiveness method. It also allows comparing multiple systems with absolute scores, which pairwise comparison does not.

Future work may improve correlation with the original Pyramid, or reduce annotation cost, by following our qualitative analysis and by reducing crowdsourcing noise (via qualification tests, enhanced guidelines, and post-processing result normalization (Hovy et al., 2013; Plank et al., 2014; Hosseini et al., 2012)). It would be appealing to investigate applying our methods to additional evaluation datasets, for which original Pyramid evaluations are not available for comparison. For example, addressing the CNN/DailyMail dataset (Nallapati et al., 2016) would involve testing single document summarization, utilizing a single reference summary per source text and addressing varying lengths of reference and system summaries.

The Pyramid method is mainly a measurement of recall, which thus also applies to our lightweight Pyramid; but other measurements for summary quality, such as precision, nonredundancy and grammaticality, may also be considered. In particular, it may be possible to extend our design of crowdsourcing tasks to supply indications for these complementary measurements as well.

Abstract

Serial recall experiments study the ability of humans to recall words in the order in which they occurred. The following serial recall effects are generally investigated in studies with humans: *word length* and *frequency*, *primacy* and *recency*, *semantic confusion*, *repetition*, and *transposition* effects. In this research, we investigate LSTM language models in the context of these serial recall effects. Our work provides a framework to better understand and analyze neural language models and opens a new window to develop accurate language models.

1 Introduction

The goal of language modeling is to estimate the probability of a sequence of words in natural language, typically allowing one to make probabilistic predictions of the next word given preceding ones (Bahl et al., 1983; Berger et al., 1996). For several years now, Long Short-Term Memory (LSTM) (Graves, 2013) language models have demonstrated state-of-the-art performance (Melis et al., 2018; Merity et al., 2018a; Sundermeyer et al., 2012). Recent studies have begun to shed light on the information encoded by LSTM networks. These models can effectively use distant history (about 200 tokens of context) and are sensitive to word order, replacement, or removal (Khandelwal et al., 2018), can learn function words much better than content words (Ford et al., 2018), can remember sentence lengths, word identity, and word order (Adi et al., 2017), can capture syntactic structures (Kuncoro et al., 2018) such as subject-verb agreement (Linzen et al., 2016). These characteristics are often attributed to LSTM's ability in overcoming the *curse of dimensionality*–by associating a distributed feature vector to each word (Hinton et al., 1986; Neubig, 2017)–and modeling long-range dependencies in faraway context (Khandelwal et al., 2018).

The goal of our research is to complement the prior work to provide a richer understanding about how LSTM language models use prior linguistic context. Inspired by investigations in cognitive psychology about serial recall in humans (Avons et al., 1994; Henson, 1998; Polišenská et al., 2015)–where participants are asked to recall a sequence of items in order in which they were presented, we investigate how word length or frequency (*word-frequency* effect), word position (*primacy*, *recency*, and *transposition* effects), word similarity (*semantic confusion* effect), and word repetition (*repetition* effect) influence learning in LSTM language models. Our investigation provides a framework to better understand and analyze language models at a considerably finer-grained level than previous studies, and opens a new window to develop more accurate language models.

We find that LSTM language models (a) can learn frequent/shorter words considerably better than infrequent/longer ones, (b) can learn recent words in sequences better than words in earlier positions,[1] (c) have a tendency to predict words that are semantically similar to target words - indicating that these networks have a tendency to group semantically similar words while suggesting one specific word as target based on prior context, (d) predict as output the words that are observed in prior context, i.e. repeat words from prior context, and (e) may transpose (switch adjacent) words in output depending on word syntactic function.

---

[1] Rats and humans recall the first and last items of sequences best and the middle ones worst (Bolhuis and Van Kampen, 1988; Ebbinghaus, 1913).

Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Serial Recall Effects

Language models estimate the probability of a sequence as $P(w_1^n) = \prod_{i=1}^n P(w_i|w_1^{i-1})$, where w_i is the ith word and w_i^j indicates the sub-sequence from w_i to w_j. These models minimize their prediction error against words in context, using e.g. the negative log likelihood loss function, during training: $\mathcal{L} = -\frac{1}{n}\Sigma_{i=1}^n \log P(w_i|w_1^{i-1})$. In this paper, we show the loss of a model against sequence s and word $w_i \in s$ by $\mathcal{L}(s)$ and $\mathcal{L}(s)[w_i]$ respectively.

We use the LSTM language model developed in (Merity et al., 2018b) for our experiments. Given a sequence of words w_1^{i-1} as context, this model predicts the next word in sequence. We refer to w_i and $\hat{w}_i$ as *target* and *predicted* words respectively; given the global vocabulary $\mathcal{V}$, $\hat{w}_i = \arg\max_{w_j \in \mathcal{V}} \Pr(w_j|w_1^{i-1})$. We study this LSTM in the context of serial recall effects.

2.1 Word-Frequency Effect

What is the effect of word frequency/length[2] on the performance of LSTM language models? For this effect, we report the average loss for each word frequency as follows:

$$\mathcal{L}_{WF}^k = 1/|\mathcal{S}_k| \sum_{s \in \mathcal{S}_k, w_i \in s} \mathcal{L}(s)[w_i], \qquad (1)$$

where $\mathcal{S}_k$ is the set of sequences that, at least, have one target word with term frequency of k, and $\mathcal{L}_{WF}^k$ is the overall loss for target words of frequency k which sheds light on the expected frequency of words for accurate language modeling.

2.2 Primacy and Recency Effect

What is the effect of word position on the performance of LSTM language models? To analyze this effect, we compute the average loss of network with respect to the position of target words as follows:

$$\mathcal{L}_{PR}^i = 1/Z \sum_s \mathcal{L}(s)[w_i], \qquad (2)$$

where w_i is the target word in sequence s, Z is the number of sequences as normalization factor, and $\mathcal{L}_{PR}^i$ is the average of loss at position i. This effect will shed light on network performance at specific positions in texts which can help rationalizing the need for new language modeling architectures, such as bidirectional LSTMs (Schuster and Paliwal, 1997), or the order by which input data should be processed (Sutskever et al., 2014).

2.3 Semantic Confusion Effect

Are predicted words semantically similar to the target ones in case of incorrect predictions? For this analysis, we report the average semantic similarity between target (w_i) and predicted ($\hat{w}_i$) words as follows:

$$\mathcal{SC} = 1/Z \sum_{s, w_i \in s, w_i \neq \hat{w}_i} \mathtt{sim}(w_i, \hat{w}_i), \qquad (3)$$

where the function $\mathtt{sim}(.,.)$ computes word similarity either through WordNet (Miller, 1998) or `cosine` similarity of the corresponding embeddings of its arguments. This effect will shed light on how effective LSTMs are in disentangling semantically-similar concepts. This gives us a powerful metric to compare networks semantically, especially, in case of equal loss/perplexity.

2.4 Repetition Effect

This effect refers to prediction of a word that already exists in context, i.e. in an earlier position in the sequence. Here, for each target w_n, we compute the probability that, instead of w_n, any of w_1^{n-1} words is predicted as output and report average across all samples:

$$\Pr(RE^i) = \qquad (4)$$
$$1/Z \sum_s \Pr(w_i \in w_1^{n-1}, w_i \neq w_n | w_1^{n-1}).$$

This effect will shed light on the extent to which network repeats/predicts observed words as possible responses. Given that words rarely repeat in sentences, the above metric can be used as a good regularizer for language modeling.

2.5 Transposition Effect

This effect refers to word prediction in transposed positions, i.e. the case where the word pair w_i^{i+1} in an original sequence is more likely to be predicted by the network as $w_{i+1}w_i$ in output. Here, for each pair w_i^{i+1} in target sequence, we count the number of times in which w_{i+1} is more probable to be predicted at position i (as compared to w_i) and w_i is more probable to be predicted at position $i+1$ (as compared to w_{i+1}). We report the average number of transposition occurrences for all samples at each word position. This effect will shed light on how network learn nearby grammatical orders such as conjunction and adjective order.

---

[2] Note that word length and frequency are directly correlated (Bell et al., 2009).

Figure 1: (a) Dataset statistics, (b): Word-frequency effect, network learns frequent words better than infrequent ones, (c): Primacy and Recency effect, loss decreases for target words that appear at the end of sequences.

3 Experiments

Datasets. We use two benchmark language modeling datasets: Penn Treebank (PTB) (Marcus et al., 1993; Mikolov et al., 2010) and WikiText-2 (WT2) (Merity et al., 2017). PTB and WT2 have vocabulary sizes of 10K and 33K respectively. We use the POS-tagged versions of these datasets provided by Khandelwal et al. (2018), and treat nouns (NN), verbs (VB), adjectives (JJ), and adverbs (RB) as content words, and others word classes as function words, see details in Figure 1a.

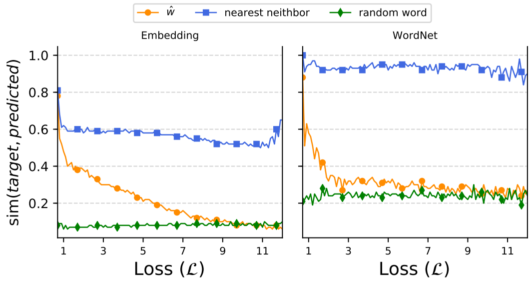
Settings. We set LSTM's parameters as suggested in (Merity et al., 2018b) for PTB and follow its suggested parameter tuning procedure for WT2. For both datasets, we set context size to $n = 100$ obtained from $\{5, 20, 50, 100, 200\}$ and validation data; note that the number of samples are equal for different sequence lengths.

3.1 Results

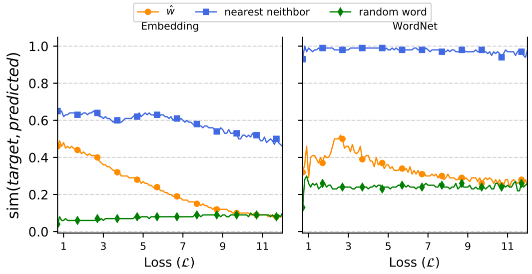
We report LSTM performance in terms of prediction loss on development sets for all experiments.

Word-Frequency Effect: *More frequent target words are predicted (learned) more accurately than less frequent ones.* Figure 1b shows strong inverse correlation between word frequency and LSTM prediction loss. This is expected as neural models learn better with more data. In addition, although the overall loss of function words is considerably lower than that of content words (because of their overall higher frequency), Figure 1b shows that, for the same word frequency, content words are learned better than function words.

Primacy and Recency Effects: *Target words that appear later in sequences are predicted considerably better than those at earlier positions.* Figure 1c shows that prediction loss considerably decreases for target words that appear toward the end of the sequences. The results are consistent across both datasets. This effect can explain why bidirectional LSTMs which read input from opposite directions usually work better in NLP applications such as machine translation (Firat et al., 2016; Domhan, 2018). A remaining question that is worth investigating is whether bidirectional LSTMs learn first and last few words of sequences better than those in the middle, and if yes, how can we make these models more robust against word position.



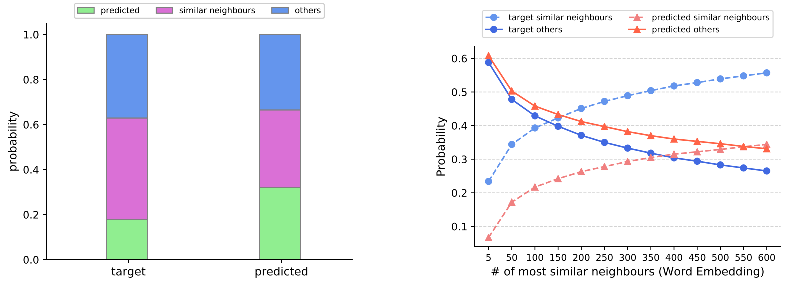
(a) Semantic confusion effect in PTB.



(b) Semantic confusion effect in WT2.

Figure 2: We report semantic similarity between predicted and target words, random and target words (lower bound), and nearest neighbor and target words (upper bound).

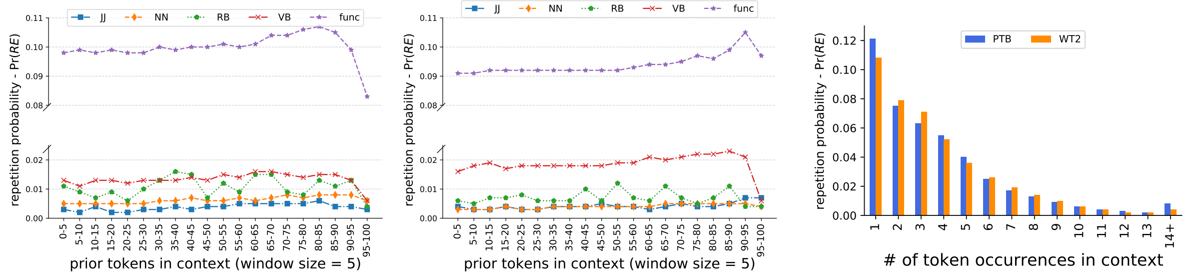
Semantic Confusion Effect. *There is significant tendency to predict words that resemble (are semantically-similar to) target words.* Figure 2 shows the average WordNet and Embedding similarity between target and predicted words in PTB and WT2 across loss values. The results indicate high similarity between predicted and target words



(a) Proportion of neighbors from prediction probability (1 − Loss)

(b) Finding appropriate neighbors size

Figure 3: Semantic confusion effect. (a) The chance of neighbors of target is equal to chance of other words. (b) When the neighbours size is set to 150, the probability of target neighbouring group became equal to the probability of target. Neighbours size of 600, leads to equal chance for predicted token.



(a) Repetition effect in PTB

(b) Repetition effect in WT2

(c) Repetition vs. occurrence in context

Figure 4: (a, b): Repetition effect across POS tag classes in PTB and WT2 and (c): Repetition probability decreases as a function of word occurrences in prior context.

for smaller loss values. However, confusion consistently increases as prediction loss increases. The upper bound similarity (obtained by treating the nearest neighbor of each target word as predicted word) indicates there exists better candidates which LSTM fails to predict. Our further analyses show that LSTM has a tendency to group semantically similar words and then suggest one of them. We consider most similar words as a group of neighbors and examine how network assigns probabilities to them as compared to others. Figure 3a shows that the chance of neighbors of target (with size 150) is equal to chance of other words (with size 9849). As Figure 3a shows, the neighbors of predicted words (with size 600) carry equal chance as compared to other words (with size 9399). To find these thresholds, we gradually increase the number of neighbors and track the trend of approaching the probability of neighboring group to target. As shown in Figure 3b, if the size of neighboring group is set to 150, these probabilities became equal. The similar way is repeated for finding the appropriate size for neighbors of predicted words.

Repetition Effect. *Repetition probability of function words is significantly higher than that of content words.* We report repetition effect, see Eq. (4), at POS tag level (where the predicted word should have the same POS tag as target word in prior context). As Figure 4a and 4b show, function words have higher repetition probability than content words. This is because function words are more frequent, and the average distance among them (i.e. number of intervening words) is considerably smaller than other POS tags (e.g. 2.1 words vs 28.9 and 12.4 words for `RB` and `JJ` respectively). We also find that repetition probability decreases as a function of word frequency in prior context, see Figure 4c. This is because words (especially `NN`s and `VB`s) are often self-contained and their occurrence in prior context helps LSTM to avoid "repeating" them. In addition, we find that function words repeat more frequently than other types and repetition among `NN`s and `VB`s is higher than other POS tag pairs; Table 1 shows the confusion matrix for repetition across POS tag classes Perhaps, this could explain the recent language modeling improvement obtained in (Ford et al., 2018) through developing separate yet sequentially connected network architectures with respect to POS tag class.

There are two factors determining the chance of

WT2	3.6	8.5	15.8	38.5	1.9

Table 2: Average distance of tokens in POS classes.

Transposition Effect: *Transpositions occur more frequently at the beginning of sequences and rarely at the end.* Figure 6 shows average number of transpositions at each word position across datasets. This result is meaningful because miss-predictions occur more frequently at earlier positions (see results for primacy and recency effect). In addition, transpositions are rare at higher positions because more context information can help LSTM to make accurate (transposition-free) prediction. In addition, Table 3 shows the percentage of transpositions across POS tag classes on PTB. The result show that LSTM mainly transposes ‘`RB NN`’ word pairs with ‘`NN RB`.’ In future, we will conduct further analyses to understand the reason.

The findings presented in this paper provide insight into how LSTMs model context. This information can be useful for improving language models. For instance, the discovery that some word types are repeated in predictions more than others can help regularizing neural language models by making them adaptive to the different word types.

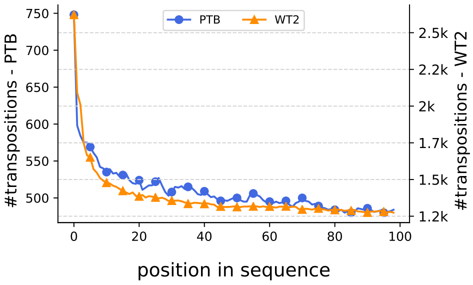

Figure 6: Transposition effect, transpositions occur more at the beginning of sequences.

Table 3: Confusion matrix for transpositions in PTB at POS tag level. LSTM transposes ‘`RB NN`’ and ‘`JJ VB|JJ|RB`,’ more than others pairs.

4 Conclusion

We investigate LSTM language models in the context of serial recall indicators. We find that frequent target words and target words that appear later in sequences are predicted more accurately, predictions often resemble (are semantically similar to) target words, function words of prior context are more likely to be predicted as target words, and word pair transpositions occur more frequently at the beginning of sequences.

Fast Concept Mention Grouping for Concept Map–based Multi-Document Summarization

Department of Computer Science, Technische Universität Darmstadt
`https://www.aiphes.tu-darmstadt.de`

Abstract

Concept map–based multi-document summarization has recently been proposed as a variant of the traditional summarization task with graph-structured summaries. As shown by previous work, the grouping of coreferent concept mentions across documents is a crucial subtask of it. However, while the current state-of-the-art method suggested a new grouping method that was shown to improve the summary quality, its use of pairwise comparisons leads to polynomial runtime complexity that prohibits the application to large document collections. In this paper, we propose two alternative grouping techniques based on locality sensitive hashing, approximate nearest neighbor search and a fast clustering algorithm. They exhibit linear and log-linear runtime complexity, making them much more scalable. We report experimental results that confirm the improved runtime behavior while also showing that the quality of the summary concept maps remains comparable.[1]

1 Introduction

Concept maps are labeled graphs with nodes representing concepts and edges showing relationships between them (Novak and Gowin, 1984). Following earlier work on the automatic extraction of concept maps from text (Rajaraman and Tan, 2002; Valerio and Leake, 2006; Villalon, 2012; Zubrinic et al., 2015), concept maps have recently been promoted as an alternative representation for summaries (Falke and Gurevych, 2017; Handler and O'Connor, 2018). In the corresponding task, concept map–based multi-document summarization (CM-MDS), a set of documents has to be automatically summarized as a concept map that does not exceed a pre-defined size limit.

An important subtask of CM-MDS is *concept mention grouping*, in which all mentions that refer to a specific concept should be grouped together. Without grouping, duplicates can appear in a summary concept map that make the map harder to understand and that waste valuable space.

To approach the mention grouping subtask, Falke et al. (2017) proposed to make pairwise coreference classifications between mentions and to induce a partitioning from those predictions. Their experiments showed that this leads to better summary concept maps, establishing the current state-of-the-art for CM-MDS. However, the computational costs of the approach are high, as it exhibits a $\mathcal{O}(n^4)$ worst-case time complexity. When the number of documents that should be summarized is large, applying that technique can quickly become impractical. But exactly for those large document sets, a summary would be most helpful.

As the first contribution of this paper, we propose two faster grouping techniques. First, we apply *locality sensitive hashing (LSH)* (Charikar, 2002) to word embeddings in order to find similar mentions without making all pairwise comparisons. That directly leads to a simple $\mathcal{O}(n)$ grouping method. Second, we also propose a novel grouping technique that combines the hashing approach with a fast partitioning algorithm called *Chinese Whispers (CW)* (Biemann, 2006). It has $\mathcal{O}(n \log n)$ time complexity and the advantage of being more transparently controllable.

Since the reduced complexity of the two proposed techniques is gained through approximations, the resulting grouping could of course be of lower quality. As the second contribution of this paper, we therefore carry out end-to-end experiments in the context of CM-MDS to analyze this trade-off. We compare both techniques against the state-of-the-art approach in automatic and manual evaluations. For both, we observe orders of mag-

nitude faster runtimes with only small reductions in summary quality. In the future, the techniques could also be applied beyond CM-MDS to speed up other similarity-based partitioning problems in NLP and its applications.

2 Problem and Reference Approach

Given a set of concept mentions M identified in the input documents, the goal of concept mention grouping is to derive a partitioning C of M such that for every set of mentions in C, the set contains all mentions and only mentions of one unique concept. Let n denote the number of mentions $|M|$.

Previous work on concept map mining used stemming (Villalon, 2012), substring matches (Valerio and Leake, 2006) or WordNet (Aguiar et al., 2016) to detect coreferences between mentions. Falke et al. (2017) combined several of those features, including semantic similarities based on WordNet (Miller et al., 1990), latent semantic analysis (Deerwester et al., 1990) and word2vec embeddings (Mikolov et al., 2013), in a log-linear classifier to predict coreferences of mentions.

Since such pairwise predictions can be inconsistent, e.g. the model might classify (m_1, m_2) and (m_2, m_3) as coreferent, but not (m_1, m_3), Falke et al. (2017) further induce a transitive relation from the predictions to obtain a valid partitioning of M. They note that simply ignoring conflicting negative classifications by building the transitive closure over all positive ones typically yields undesired partitionings in which too many mentions are being lumped together. Following previous work on related NLP tasks (Barzilay and Lapata, 2006; Denis and Baldridge, 2007), they instead formulate an integer linear program (ILP) to find the transitive relation that maximally agrees with all pairwise predictions. However, as the resulting ILPs cannot be efficiently solved on the data they work with, they propose a local search algorithm that incrementally improves a greedy solution rather than finding the optimal partitioning,

This technique requires making classifications for all pairs of mentions in $\mathcal{O}(n^2)$ time and running the local search, which has a worst-case complexity of $\mathcal{O}(n^4)$. As we will show in Section 6, that can quickly become prohibitively expensive.

3 Locality Sensitive Hashing

The central idea of LSH is that specific families of hash functions can approximately preserve similarities. Charikar (2002) introduced such a family for cosine similarity between vectors.

3.1 Approximating Cosine Similarity

Let u, v be k-dimensional vectors. First, choose d unit random vectors $r_1, \ldots, r_d$ of k dimensions by sampling every dimension independently from a standard normal distribution. Then, for a vector u, compute a d-dimensional bit vector $h(u)$, the hash, with the i-th dimension defined as

$$h(u)_{[i]} = \begin{cases} 1 & : u \cdot r_i \geq 0 \\ 0 & : u \cdot r_i < 0, \end{cases} \tag{1}$$

where $u \cdot r_i$ is the dot product with the i-th random vector. The Hamming distance ham between two hashes $h(u)$ and $h(v)$, i.e. the number of differing bits, can then be used to approximate the cosine similarity of u and v (Charikar, 2002):

$$\frac{u \cdot v}{|u||v|} \approx \cos\left(\frac{\mathrm{ham}(h(u), h(v))}{d}\,\pi\right) \tag{2}$$

The longer the hashes are, i.e. the larger d is, the more accurate is the estimation of the similarity.

In the past, LSH has been successfully used to speed up a range of NLP tasks, including noun similarity list construction (Ravichandran et al., 2005), word sense induction (Mouton et al., 2009), gender classification (van Durme, 2012) and text classification (Bollegala et al., 2018).

3.2 Naive Partitioning

Given the mapping h from vectors to their bit hashes, we can partition a set of vectors by hash identity. Every unique hash becomes a group consisting of all vectors mapped to that hash. Since the hashes reflect similarity, the most similar vectors will be grouped together. The parameter d controls the degree of grouping: the smaller it is, the less unique hashes and thus fewer groups exist.

In order to apply this technique to concept mention grouping, every mention $m \in M$ has to be represented by a vector in a space where the cosine similarity is indicative of coreference. Since the classifier of Falke et al. (2017) already uses cosine similarity of word2vec embeddings as a feature, we also use those vectors for LSH.[2] Both the computation of the hashes and building groups can be done with a single pass over the mentions. Assuming d and k to be fixed, the overall time complexity of the grouping technique is thus $\mathcal{O}(n)$.

---

[2] Following their work, we represent a mention by the mean of the embedding vectors of the mention's tokens.

4 Fast Nearest Neighbor Partitioning

When grouping similar elements together, one typically wants to control the degree of grouping by defining a similarity threshold δ. For the naive LSH-based partitioning, we can only set d, which does not directly correspond to a similarity. Therefore, we propose a second, more transparent grouping technique with this property.

4.1 Approximate Nearest Neighbor Search

Given vectors and their LSH-based hashes, we can use *approximate nearest neighbor search (ANNS)* to find pairs with a cosine similarity of at least δ (Charikar, 2002; Ravichandran et al., 2005) without making all pairwise comparisons:

1. Sample q permutations of the bit hashes.
2. For each permutation, sort all mentions M according to their permuted hashes.
3. In each sorted list, estimate the cosine similarity of each $m \in M$ with the next b mentions based on the hashes. Keep pairs with a similarity of at least δ.

Since comparing neighbors in a sorted list of bit hashes will primarily find those that differ in the last positions, the random permutations are the key part of the algorithm that ensures similar hashes differing at varying positions are found. Rather than comparing each vector to all others in $\mathcal{O}(n^2)$, only qb comparisons are made for each. The dominant part becomes the sort, resulting in $\mathcal{O}(n \log n)$ time complexity as q and b are constants.

4.2 Chinese Whispers Partitioning

Using ANNS we can obtain an undirected graph of mentions connected with edges if their similarity is at least δ. However, as Falke et al. (2017) observed, simply taking the transitive closure over these pairs tends to yield too big groups that lump many mentions of different concepts together.

Rather than relying on the expensive $\mathcal{O}(n^4)$ local search of Falke et al. (2017) to address this problem, we here resort to the fast graph partitioning algorithm CW (Biemann, 2006). Given a graph $G = (V, E)$, it proceeds as follows:

1. Label nodes initially as $l(v_i) = i \;\; \forall \, v_i \in V$.
2. Iterate over V in randomized order. For each $v \in V$, set $l(v)$ to the label most frequent among the nodes reachable via a direct edge.
3. If at least one label changed, repeat step 2.

While it cannot be guaranteed in general, the algorithm typically converges to a stable labeling after a few iterations. Then, nodes having the same label form a group of the partitioning. In contrast to the local search, CW does not directly optimize the objective function proposed by Falke et al. (2017), however, we empirically found that it yields partitionings that score very well with regard to that objective. To guarantee termination, the number of iterations is bound by a parameter ϵ. Then, CW iterates at most ϵ times over n nodes and their at most $n - 1$ edges, resulting in $\mathcal{O}(n^2)$ complexity.

4.3 Combination

For concept mention grouping, we combine these techniques as follows: First, we represent each mention with a vector and compute its LSH-based hash. Second, we use ANNS to find pairs with a similarity of at least δ. Finally, we partition the resulting nearest neighbor graph with CW.

That grouping technique has four parameters δ, d, q and b. While δ determines the degree of grouping, d influences the quality of the similarity estimates and q and b define the size of the search space explored to find nearest neighbors. Note that the construction of the nearest neighbor graph guarantees that a node has at most qb edges, reducing the runtime of CW to $\mathcal{O}(n)$ in this setting. The runtime behavior of the combination is therefore dominated by ANNS and thus $\mathcal{O}(n \log n)$.

5 Experimental Setup

We evaluate the proposed concept mention grouping techniques for the task of CM-MDS.

Data and Metrics We use the benchmark corpus introduced by Falke and Gurevych (2017), the only existing dataset with manually created reference summary concept maps. It provides reference summaries for document sets of web pages on 30 different topics. As metrics, we compute the ROUGE and METEOR variants proposed with the dataset and also perform a human evaluation following the protocol of Falke et al. (2017).

Implementation As the *reference*, we use the state-of-the-art pipeline of Falke et al. (2017).[3] We test the naive LSH-based partitioning (*LSH-only*)

and the combined approach (*LSH-CW*) by substituting them into that pipeline. For a fair comparison, we use the same 300-dimensional word2vec embeddings (Mikolov et al., 2013) for LSH that have also been used in the log-linear model.

Tuning In the reference pipeline, the regularization constant of the scoring SVM was tuned with leave-one-out cross-validation on the training set. For LSH-only, we use the same procedure to tune d (together with regularization) and found $d = 17$ to be best (testing 10, 11, ..., 25). For LSH-CW, where four hyper-parameters have to be set, running cross-validation for the whole grid is too expensive. We instead evaluate a grid of 130 $d/q/b/\delta$-combinations by concept F1-score after grouping and tune the SVM with cross-validation only for the three best settings, leading to the parameters $d = 200, q = 20, b = 200, \delta = .89$.

6 Results

Runtime Table 1 shows the runtimes for grouping concept mentions.[4] It demonstrates two problems of the reference: First, even on the smallest document set (37 docs, 50k tokens), the grouping already takes hours. And second, on the biggest set (42 docs, 220k tokens), the runtime grows to almost a day, illustrating the analyzed time complexity. Applying the technique to more documents quickly becomes infeasible. Our newly proposed techniques, LSH-only and LSH-CW, are orders of magnitude faster in absolute terms and also show a more moderate runtime growth as expected given their preferable time complexity.

Comparison	Fo	Gr	Me	NR
Reference vs. LSH-only	47.3	47.3	46.7	42.7
Reference vs. LSH-CW	57.3	58.0	58.0	56.7
LSH-CW vs. LSH-only	52.7	50.7	50.0	47.3

Table 3: Human summary preferences, shown as the percentage of annotators preferring the first option.

Quality A crucial question is which price we have to pay for improving runtimes through approximations. Table 2 shows the automatic evaluation results for the created summaries. We included *lemma-only*, a baseline from previous work using lemmatization for grouping, and *w2v-only*, a variation of the reference grouping approach that uses embeddings as the only feature in the coreference classifier. The latter is important for comparison, as it uses the same information as the LSH-based techniques. While lemma-only and w2v-only perform significantly worse than the reference, the two LSH-based techniques come much closer to the more expensive reference.

Table 3 shows the results of our human evaluation. Following previous work, we collected pairwise preferences among the created summaries via Mechanical Turk (150 per pairing) for the dimensions focus (Fo), grammaticality (Gr), meaningfulness (Me) and non-redundancy (NR).[5] As shown, the preferences we collected are almost balanced and annotators repeatedly noted during the study that the summaries are very similar. None of the 12 preferences are significant at $\alpha =$

0.05 (binomial test), showing that the alternative summary concept maps are practically indistinguishable. In contrast, Falke et al. (2017) observed preferences of up to 79% in their study.

Conclusion Based on the automatic and human evaluations, we conclude that both fast grouping techniques proposed in this paper do not substantially decrease the quality of the summaries. Since there is also no clear difference between LSH-only and LSH-CW, we recommend both techniques, which allows practitioners to choose between more transparency or even faster runtimes.

Future Work The comparison of w2v-only and the reference in Table 2 reveals that relying only on word2vec and dropping the other features of the log-linear model hurts performance, suggesting that also adding the remaining features to the LSH techniques could lead to further improvements. However, all other features of the reference model are pairwise features, which makes it difficult to incorporate them in the LSH-based techniques that only use mention features. As an alternative direction, one could instead rely on more powerful word embeddings. While we used word2vec to ensure comparability to previous work, using more recent embedding methods such as fastText (Bojanowski et al., 2017), InferSent (Conneau et al., 2017) or ELMO (Peters et al., 2018) seems to be worth exploring in the future.

7 Summary

In this paper, we proposed two fast concept mention grouping techniques for CM-MDS, the direct application of LSH and a novel combination of LSH and Chinese Whispers. Our analysis and experiments show that they are orders of magnitude faster than previous techniques with only small effects the quality of the resulting summary concept maps. Using these techniques, summary concept maps can now be created for much larger document sets than what was possible before.

Abstract

We introduce a new syntax-aware model for dependency-based semantic role labeling that outperforms syntax-agnostic models for English and Spanish. We use a BiLSTM to tag the text with supertags extracted from dependency parses, and we feed these supertags, along with words and parts of speech, into a deep highway BiLSTM for semantic role labeling. Our model combines the strengths of earlier models that performed SRL on the basis of a full dependency parse with more recent models that use no syntactic information at all. Our local and non-ensemble model achieves state-of-the-art performance on the CoNLL 09 English and Spanish datasets. SRL models benefit from syntactic information, and we show that supertagging is a simple, powerful, and robust way to incorporate syntax into a neural SRL system.

1 Introduction

Semantic role labeling (SRL) is the task of identifying the semantic relationships between each predicate in a sentence and its arguments (Gildea and Jurafsky, 2002). While early research assumed that SRL models required syntactic information to perform well (Punyakanok et al., 2008), recent work has demonstrated that neural networks can achieve competitive and even state-of-the-art performance without any syntactic information at all (Zhou and Xu, 2015; Marcheggiani et al., 2017; He et al., 2017). These systems have the benefits of being simpler to implement and performing more robustly on foreign languages and out-of-domain data, cases where syntactic parsing is more difficult (Marcheggiani et al., 2017).

In this paper, we show that using supertags is an effective middle ground between using full syntactic parses and using no syntactic information at all. A supertag is a linguistically rich description assigned to a lexical item. Supertags impose complex constraints on their local context, so supertagging can be thought of as "almost parsing" (Bangalore and Joshi, 1999). Supertagging has been shown to facilitate Tree-Adjoining Grammar (TAG) parsing (Bangalore et al., 2009; Friedman et al., 2017; Kasai et al., 2017, 2018) and Combinatory Categorial Grammar (CCG) parsing (Clark and Curran, 2007; Kummerfeld et al., 2010; Lewis et al., 2016; Xu, 2016).

We propose that supertags can serve as a rich source of syntactic information for downstream tasks without the need for full syntactic parsing. Following Ouchi et al. (2014), who used supertags to improve dependency parsing, we extract various forms of supertags from the dependency-annotated CoNNL 09 corpus. This contrasts with prior SRL work that uses TAG or CCG supertags (Chen and Rambow, 2003; Lewis et al., 2015). We train a bidirectional LSTM (BiLSTM) to predict supertags and feed the predicted supertag embedding, along with word and predicted part-of-speech embeddings, to another BiLSTM for semantic role labeling. Predicted supertags are represented by real-valued vectors, contrasting with approaches based on syntactic paths (Roth and Lapata, 2016; He et al., 2018) and syntactic edges (Marcheggiani and Titov, 2017; Strubell et al., 2018). This way of incorporating information alleviates the issue of error propagation from parsing.

Supertagging has many advantages as part of a natural language processing pipeline. First, as a straightforward sequence-labeling task, the supertagging architecture is much simpler than comparable systems for structured parsing. Second, it is simple to extract different forms of supertags from a dependency corpus to test different hypotheses about which kinds of syntactic information are most useful for downstream tasks. Our re-

sults show that supertags, by encoding just enough information, can improve SRL performance even compared to systems that incorporate complete dependency parses.

2 Our Models

2.1 Supertag Design

We experiment with four supertag models, two from Ouchi et al. (2014), one from Nguyen and Nguyen (2016), and one of our own design inspired by Tree Adjoining Grammar supertags (Bangalore and Joshi, 1999). Each model encodes a different set of attributes about the syntactic relationship between a word, its parent, and its dependents. Table 2 summarizes what information is expressed in each supertag model.

Model 0. A Model 0 supertag for a word w encodes the dependency relation and the relative position (direction) between w and its head, i.e. left (L), right (R), or no direction (ROOT) (Nguyen and Nguyen, 2016).

Model 1. A Model 1 supertag for w adds to the "parent information" from Model 0 the information of whether w possesses dependents to its left (L) or right (R) (Ouchi et al., 2014).

Model 2. A Model 2 supertag for w extends Model 1 by encoding the dependency relation between w and its obligatory dependents.[1] When w lacks such obligatory children, we encode whether it possesses non-obligatory dependents to the left (L) or right (R) as in Model 1.

Model TAG. We propose Model TAG supertags that represent syntactic information analogously to TAG supertags (elementary trees) (Bangalore and Joshi, 1999). A Model TAG supertag encodes the dependency relation and the direction of the head of a word similarly to Model 0 if the dependency relation is non-obligatory (corresponding to *adjunction* nodes), and the information about obligatory dependents of verbs if any similarly to Model 2 (corresponding to *substitution* nodes).

2.2 Supertagger Model

Motivated by recent state-of-the-art supertaggers (TAG: Kasai et al. (2017, 2018); CCG: Lewis et al. (2016); Xu (2016)), we employ a bi-directional LSTM (BiLSTM) architecture for our supertagging. The input for each word is the conncatenation of a dense vector representation of the word, a vector embedding of a predicted PTB-style POS tag (only for English),[2] and a vector output by character-level Convolutional Neural Networks (CNNs) for morphological information.

For POS tagging before English supertagging, we use the same hyperparameters as in Ma and Hovy (2016). For supertagging, we follow the hyperparameters chosen in Kasai et al. (2018) regardless of the supertag model that is employed. We initialize the word embeddings by the pre-trained 100 dimensional GloVe (Pennington et al., 2014) and the 300 dimensional FastText (Bojanowski et al., 2017) vectors for English and Spanish respectively.

2.3 Semantic Role Labeling

Our SRL model is most similar to the syntax-agnostic SRL model proposed by Marcheggiani et al. (2017). Our model differs in two ways: 1) we add randomly initialized 50 dimensional supertag embeddings to the input layer (Fig. 1), and 2) we use a modified LSTM with highway layers and regularization (0.5 dropout) as in He et al. (2017).

We use the same hyperparameters as in Marcheggiani et al. (2017) with randomly initialized 50 dimensional embeddings for supertags.[3]

---

[1] Following Ouchi et al. (2014), we define obligatory dependents as those with relations 'SBJ,' 'OBJ,' 'PRD,' and 'VC.' For Spanish, we define obligatory syntactic arguments as 'dc,' 'suj,' 'cd,' and 'cpred.'

[2] For the English data, predicted PTB-style POS tags generally contribute to increases, approximately 0.2-0.4% in the dev set, whereas for Spanish adding predicted (coarse-grained) POS tags hurt the performance.

[3] We provide lists of hyperparameters in Appedix A.1.

	English				Spanish		
Supertag	# Stags	Dev	ID	OOD	# Stags	Dev	ID
Model 0	99	92.93	94.17	88.71	88	92.97	92.67
Model 1	298	91.07	92.50	86.51	220	90.63	90.37
Model 2	692	90.60	92.05	85.40	503	90.08	89.84
Model TAG	430	92.60	94.17	87.46	317	92.33	92.18

Table 3: Supertagging accuracies for English and Spanish. ID and OOD indicate the in-domain and out-of-domain evaluation data respectively. The # Stags columns show the number of supertags in the corresponding training set.

For pre-trained word embeddings, we use the same word embeddings as the ones in Marcheggiani et al. (2017) for English and the 300-dimensional FastText vectors (Bojanowski et al., 2017) for Spanish. We use the predicates predicted by the mate-tools (Björkelund et al., 2009) (English) and Zhao et al. (2009) (Spanish) system in our models, again following Marcheggiani et al. (2017) to facilitate comparison. Our code is available online for easy replication of our results.[4]

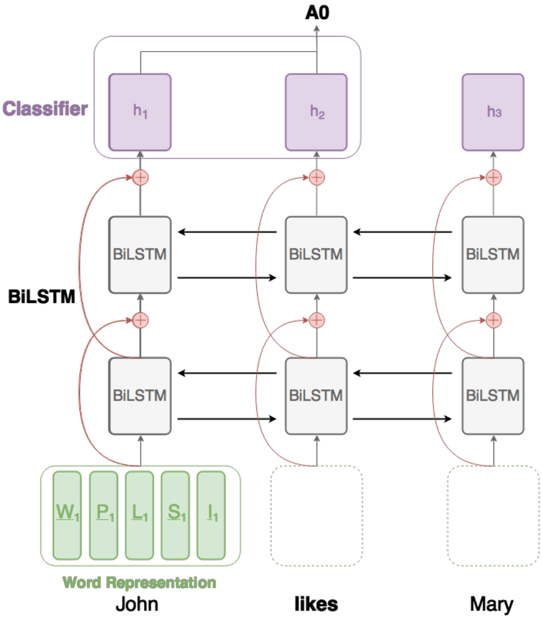

Figure 1: SRL architecture with a highway BiLSTM. W_1, P_1, L_1, S_1, I_1 indicate the word, POS, lemma, supertag, and predicate indicator embeddings for the first token, *John*. Here we only show two layers.

3 Results and Discussion

Table 3 provides our supertagging results for English and Spanish across the different types of supertag described above. Here we clearly see the general pattern that the more granular supertagging becomes, the less reliable it is, and finding the balance between granularity and predictability is critical. We present our SRL results in Tables 4-7 along with the results from a baseline BiLSTM model, which is our implementation of the syntax-agnostic model in Marcheggiani et al. (2017). We also present results for a BiLSTM model with dropout and highway connections but without supertags (BDH model), to distinguish the effects of supertags from the effects of better LSTM regularization. In every experiment we train the model five times, and present the mean score. Table 4 shows that Model 1 yields the best performance in the English dev set, and thus we only use Model 1 supertags for test evaluation. We primarily show results only with word type embeddings to conduct fair comparisons with prior work, but we also provide results with deep contextual word representations, ELMo (Peters et al., 2018), and compare our results with recent work that utilizes ELMo (He et al., 2018). [5]

English in-domain. Table 5 summarizes the results on the English in-domain test set. First, we were able to approximately replicate the results from Marcheggiani et al. (2017). Adding dropout and highway connections to our BiLSTM model improves performance by 0.5 points, to 88.1, and adding supertags improves results even further to 88.6. Our supertag model performs even better than the non-ensemble model in Marcheggiani and Titov (2017), in which the model is given the complete dependency parse of the sentence. This result suggests that supertags can be even more effective for SRL than a more complete representation of syntax. Furthermore, our supertag-based method with contextual representations achieves 90.2, a new state-of-the-art. Interestingly, the gain from supertagging decreases to 0.2 points (90.2 vs. 90.0) in the presence of contextual representations, suggesting that contextual representations encode some of the same syntactic information that supertags provide.

English out-of-domain. One of the advantages of using a syntax-agnostic SRL model is that such a model can perform relatively well on out-of-domain data, where the increased difficulty of syn-

Table 4: Results on the CoNLL 2009 dev set for English. BDH stands for BiLSTM + Dropout + Highway.

tactic parsing can cause errors in a syntax-based system (Marcheggiani et al., 2017). Unfortunately we were not able to replicate the out-of-domain results of Marcheggiani et al. (2017): our implementation of the BiLSTM achieves a score of 76.4, compared to their reported score of 77.7. However, we note that incorporating supertags into our own model improves performance, with our best model achieving a score of 77.6. Our supertag-based model also substantially outperforms the full dependency-based models (Roth and Lapata, 2016; Marcheggiani and Titov, 2017). This suggests that syntax with a certain degree of granularity is useful even across domains. Our supertag-based method alleviates the issue of error propagation from syntactic parsing. Finally, our model with contextual representations yields 80.8, an improvement of 1.5 F1 points over the previous state-of-the-art (He et al., 2018), which also uses ELMo.

Spanish. Table 7 shows the results on the Spanish test data. Our BiLSTM implementation yields lower performance than Marcheggiani et al. (2017): our model achieves a score of 79.1, compared to their reported score of 80.3. However, our BDH model yields a score of 80.8, already achieving state-of-the-art performance. Adding supertags to BDH improves the score further to 81.0. This suggests that while the gains are relatively small, the supertag-based approach still helps Spanish SRL. Supertags slightly improve performance when contextual representations are used (83.0 vs. 82.9). See appendices for details.

Following the analysis in Roth and Lapata (2016), we show plots of the BiLSTM, BDH (BiLSTM + Dropout + Highway), and Model 1 role labeling performance for sentences with varying number of words (in-domain: Fig. 2; out-of-domain: Fig. 3). Note first that BDH outperforms the baseline BiLSTM model in a relatively uniform manner across varying sentence lengths. The benefits of Model 1 supertags, in contrast, come more from longer sentences, especially in the out-

Table 8: English in-domain test results by predicate category and role label. The mate-tools (Björkelund et al., 2009) and Path-LSTM results are taken from Roth and Lapata (2016).

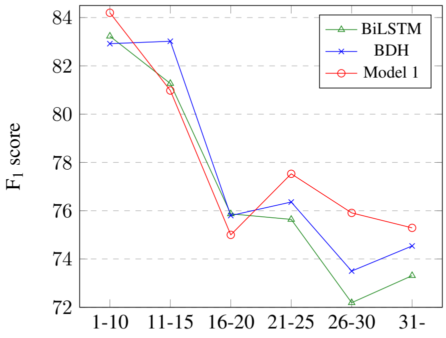

Figure 3: Out-of-domain results by sentence length.

of-domain test set. This implies that the supertag model is robust to the sentence length, probably because supertags encode relations between words that are linearly distant in the sentence, information that a simple BiLSTM is unlikely to recover.

Table 8 reports SRL results broken down by predicate category (V: Verb, Propbank; N: Noun, Nombank) and semantic role. We can observe that the various supertag models differ in their performance for different predicate-role pairs, suggesting that different kinds of linguistic information are relevant for identifying the different roles. Overall, Model 1 supertags achieve the most consistent improvements over BiLSTM and BiLSTM + Dropout + Highway (BDH) in V / A0, V / A1, V / A2, V / AM, N / A2, and N / AM. Moreover, Model 1 even improves on Path-LSTM (Roth and Lapata, 2016) by large margins in V / A0, V / A1, V / AM, and N / AM, even though the Path-LSTM model has the benefit of using the complete dependency path between each word and its head. This shows that supertags can be even more effective for SRL than more granular syntactic information–even quite simple supertags, like Model 0, which encode only the dependency arc between a word and its head.

4 Conclusion and Future Work

We presented state-of-the-art SRL systems on the CoNLL 2009 English and Spanish data that make crucial use of dependency-based supertags. We showed that supertagging serves as an effective middle ground between syntax-agnostic approaches and full parse-based approaches for dependency-based semantic role labeling. Supertags give useful syntactic information for SRL and allow us to build an SRL system that does not depend on a complex architecture. We have also seen that the choice of the linguistic content of a supertag makes a significant difference in its utility for SRL. In this work, all models are developed independently for English and Spanish. However, sharing some part of SRL models could improve performance (Mulcaire et al., 2018, 2019). In future work, we will explore crosslingual transfer for supertagging and semantic role labeling.

Acknowledgments

The authors thank Diego Marcheggiani for assistance in implementing SRL models and Diego Marcheggiani and the anonymous reviewers for their helpful feedback. This work was funded in part by the Funai Overseas Scholarship to JK.

Abstract

We propose a novel transition-based algorithm that straightforwardly parses sentences from left to right by building n attachments, with n being the length of the input sentence. Similarly to the recent stack-pointer parser by Ma et al. (2018), we use the pointer network framework that, given a word, can directly point to a position from the sentence. However, our left-to-right approach is simpler than the original top-down stack-pointer parser (not requiring a stack) and reduces transition sequence length in half, from $2n-1$ actions to n. This results in a quadratic non-projective parser that runs twice as fast as the original while achieving the best accuracy to date on the English PTB dataset (96.04% UAS, 94.43% LAS) among fully-supervised single-model dependency parsers, and improves over the former top-down transition system in the majority of languages tested.

1 Introduction

Dependency parsing, the task of automatically obtaining the grammatical structure of a sentence expressed as a dependency tree, has been widely studied by natural language processing (NLP) researchers in the last decades. Most of the models providing competitive accuracies fall into two broad families of approaches: *graph-based* (McDonald et al., 2005a,b) and *transition-based* (Yamada and Matsumoto, 2003; Nivre, 2003) dependency parsers.

Given an input sentence, a graph-based parser scores trees by decomposing them into factors, and performs a search for the highest-scoring tree.

In the past two years, this kind of dependency parsers have been ahead in terms of accuracy thanks to the graph-based neural architecture developed by Dozat and Manning (2016), which not only achieved state-of-the-art accuracies on the Stanford Dependencies conversion of the English Penn Treebank (hereinafter, PTB-SD), but also obtained the best results in the majority of languages in the CoNLL 2017 Shared Task (Dozat et al., 2017). This tendency recently changed, since a transition-based parser developed by Ma et al. (2018) managed to outperform the best graph-based model in the majority of datasets tested.

Transition-based parsers incrementally build a dependency graph for an input sentence by applying a sequence of transitions. This results in more efficient parsers with linear time complexity for parsing projective sentences, or quadratic for handling non-projective structures, when implemented with greedy or beam search. However, their main weakness is the lack of access to global context information when transitions are greedily chosen. This favours error propagation, mainly affecting long dependencies that require a larger number of transitions to be built (McDonald and Nivre, 2011).

Many attempts have been made to alleviate the impact of error propagation in transition-based dependency parsing, but the latest and most successful approach was developed by Ma et al. (2018). In particular, they make use of *pointer networks* (Vinyals et al., 2015) to implement a new neural network architecture called *stack-pointer network*. The proposed framework provides a global view of the input sentence by capturing information from the whole sentence and all the arcs previously built, crucial for reducing the effect of error propagation; and, thanks to an attention mechanism (Bahdanau et al., 2014; Luong et al., 2015), is able to return a position in that sentence that corresponds to a word related to the word currently on top of the stack. They take advantage of this and propose a novel transition system that follows a top-down depth-first strategy to perform the syntactic analysis. Concretely, it considers the word

Proceedings of NAACL-HLT 2019, pages 710–716
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

pointed by the neural network as the child of the word on top of the stack, and builds the corresponding dependency relation between them. This results in a transition-based algorithm that can process unrestricted non-projective sentences in $O(n^2)$ time complexity and requires $2n$-1 actions to successfully parse a sentence with n words.

We also take advantage of pointer network capabilities and use the neural network architecture introduced by Ma et al. (2018) to design a non-projective left-to-right transition-based algorithm, where the position value pointed by the network has the opposite meaning: it denotes the index that corresponds to the head node of the current focus word. This results in a straightforward transition system that can parse a sentence in just n actions, without the need of any additional data structure and by just attaching each word from the sentence to another word (including the root node). Apart from increasing the parsing speed twofold (while keeping the same quadratic time complexity), it achieves the best accuracy to date among fully-supervised single-model dependency parsers on the PTB-SD, and obtains competitive accuracies on twelve different languages in comparison to the original top-down version.

2 Preliminaries

Ma et al. (2018) propose a novel neural network architecture whose main backbone is a pointer network (Vinyals et al., 2015). This kind of neural networks are able to learn the conditional probability of a sequence of discrete numbers that correspond to positions in an input sequence (in this case, indexes of words in a sentence) and, by means of attention (Bahdanau et al., 2014; Luong et al., 2015), implement a pointer that selects a position from the input at decoding time.

Their approach initially reads the whole sentence, composed of the n words $w_1, \ldots, w_n$, and encodes each w_i one by one into an *encoder hidden state* e_i. As encoder, they employ a combination of CNNs and bi-directional LSTMs (Chiu and Nichols, 2016; Ma and Hovy, 2016). For each word, CNNs are used to obtain its character-level representation that is concatenated to the word and PoS embeddings to finally be fed into BiLSTMs that encode word context information.

As decoder they present a top-down transition system, where parsing configurations use the classic data structures (Nivre, 2008): a *buffer* (that contains unattached words) and a *stack* (that holds partially processed words).

The available parser actions are two transitions that we call Shift-Attach-p and Reduce. Given a configuration with word w_i on top of the stack, as the pointer network just returns a position p from a given sentence, they proceed as follows to determine which transition should be applied:

- If $p \neq i$, then the pointed word w_p is considered as a child of w_i; so the parser chooses a Shift-Attach-p transition to move w_p from the buffer to the stack and build an arc $w_i \rightarrow w_p$.
- On the other hand, if $p = i$, then w_i is considered to have found all its children, and a Reduce transition is applied to pop the stack.

The parsing process starts with a dummy root \$ on the stack and, by applying $2n$-1 transitions, a dependency tree is built for the input in a top-down depth-first fashion, where multiple children of a same word are forced during training to be created in an inside-out manner. More in detail, for each parsing configuration c_t, the decoder (implemented as a uni-directional LSTM) receives the encoder hidden state e_i of the word w_i on top of the stack to generate a *decoder hidden state* d_t. After that, d_t, together with the sequence s_i of encoder hidden states from words still in the buffer plus e_i, are used to compute the attention vector a^t as follows:

$$v_i^t = score(d_t, s_i) \tag{1}$$

$$a^t = softmax(v^t) \tag{2}$$

As attention scoring function ($score()$), they adopt the biaffine attention mechanism described in (Luong et al., 2015; Dozat and Manning, 2016). Finally, the attention vector a^t will be used to return the highest-scoring position p and choose the next transition. The parsing process ends when only the root remains on the stack.

As extra high-order features, Ma et al. (2018) add grandparent and sibling information, whose encoder hidden states are added to that of the word on top of the stack to generate the corresponding decoder hidden state d_t. They prove that these additions improve final accuracy, especially when children are attached in an inside-out fashion.

According to the authors, the original stack-pointer network is trained to maximize the likelihood of choosing the correct word for each possible top-down path from the root to a leaf. More in detail, a dependency tree can be represented as a sequence of top-down paths $p_1, \ldots, p_k$, where each path p_i corresponds to a sequence of words $\$, w_{i,1}, w_{i,2}, \ldots, w_{i,l_i}$ from the root to a leaf. Thus, the conditional probability $P_\theta(y|x)$ of the dependency tree y for an input sentence x can be factorized according to this top-down structure as:

$$\begin{aligned} P_\theta(y|x) &= \prod_{i=1}^{k} P_\theta(p_i | p_{<i}, x) \\ &= \prod_{i=1}^{k} \prod_{j=1}^{l_i} P_\theta(w_{i,j} | w_{i,<j}, p_{<i}, x) \end{aligned}$$

where θ represents model parameters, $p_{<i}$ stands for previous paths already explored, $w_{i,j}$ denotes the jth word in path p_i and $w_{i,<j}$ represents all the previous words on p_i.

For more thorough details of the stack-pointer network architecture and the top-down transition system, please read the original work by Ma et al. (2018).

3 Our approach

We take advantage of the neural network architecture designed by Ma et al. (2018) and introduce a simpler left-to-right transition system that requires neither a stack nor a buffer to process the input sentence and where, instead of selecting a child of the word on top of the stack, the network points to the parent of the current focus word.

In particular, in our proposed approach, the parsing configuration just corresponds to a *focus word pointer* i, that is used to point to the word currently being processed. The decoding process starts with i pointing at the first word of the sentence and, at each parsing configuration, only one action is available: the parameterized Attach-p transition, that links the focus word w_i to the head word w_p in position p of the sentence (producing the dependency arc $w_p \rightarrow w_i$) and moves i one position to the right. Note that, in our algorithm, p can equal 0, attaching, in that case, w_i to the dummy root node. The parsing process ends when the last word from the sentence is attached. This can be easily represented as a loop that traverses the input sentence from left to right, linking each word to another from the same sentence or to the dummy root. Therefore, we just need n steps to process the n words of a given sentence and build a dependency tree.

While our novel transition system intrinsically holds the single-head constraint (since, after attaching the word w_i, i points to the next word w_{i+1} in the sentence), it can produce an output with cycles.[1] Therefore, in order to build a well-formed dependency tree during decoding, attachments that generate cycles in the already-built dependency graph must be forbidden. Please note that the need of a cycle-checking extension does not increase the overall quadratic runtime complexity of the original implementation by Ma et al. (2018) since, as in other transition-based parsers such as (Covington, 2001; Gómez-Rodríguez and Nivre, 2010), cycles can be incrementally identified in amortized constant time by keeping track of connected components using path compression and union by rank. Therefore, the left-to-right algorithm requires n steps to produce a parse. In addition, at each step, the attention vector a_t needs to be computed and cycles must be checked, both in $O(n) + O(n) = O(n)$ runtime. This results in a $O(n^2)$ time complexity for decoding.[2]

On the other hand, while in the top-down decoding only available words in the buffer (plus the word on top of the stack) can be pointed to by the network and they are reduced as arcs are created (basically to keep the single-head constraint); our proposed approach is less rigid: all words from the sentence (including the root node and excluding w_i) can be pointed to, as long as they satisfy the acyclicity constraint. This is necessary because two different words might be attached to the same head node and the latter can be located in the sentence either before or after w_i. Therefore, the sequence s_i, required by the attention score function (Eq.(1)), is composed of the encoder hidden states of all words from the input, excluding e_i, and prepending a special vector representation denoting the root node.

We also add extra features to represent the current focus word. Instead of using grandparent and sibling information (more beneficial for a top-down approach), we just add the encoder hidden

---

[1] In practice, even with the cycle detection mechanism disabled, the presence of cycles in output parses is very uncommon (for instance, just in 1% of sentences in the PTB-SD dev set) since our system seems to adequately model well-formed tree structures.

[2] A practically faster version of the left-to-right parser might be implemented by just ignoring the presence of cycles during decoding, and destroying the cycles generated as a post-processing step that simply removes one of the arcs involved.

states of the previous and next words in the sentence to generate d_t, which seems to be more suitable for a left-to-right decoding.

In dependency parsing, a tree for an input sentence of length n can be represented as a set of n directed and binary links $l_1, \ldots, l_n$. Each link l_i is characterized by the word w_i in position i in the sentence and its head word w_h, resulting in a pair (w_i, w_h). Therefore, to train this novel variant, we factorize the conditional probability $P_\theta(y|x)$ to a set of head-dependent pairs as follows:

$$\begin{aligned} P_\theta(y|x) &= \prod_{i=1}^{n} P_\theta(l_i|l_{<i}, x) \\ &= \prod_{i=1}^{n} P_\theta(w_h|w_i, l_{<i}, x) \end{aligned}$$

Therefore, the left-to-right parser is trained by maximizing the likelihood of choosing the correct head word w_h for the word w_i in position i, given the previous predicted links $l_{<i}$.

Finally, following a widely-used approach (also implemented in (Ma et al., 2018)), dependency labels are predicted by a multiclass classifier, which is trained in parallel with the parser by optimizing the sum of their objectives.

4 Experiments

4.1 Data and Settings

We use the same implementation as Ma et al. (2018) and conduct experiments on the Stanford Dependencies (de Marneffe and Manning, 2008) conversion (using the Stanford parser v3.3.0)[3] of the English Penn Treebank (Marcus et al., 1993), with standard splits and predicted PoS tags. In addition, we compare our approach to the original top-down parser on the same twelve languages from the Universal Dependency Treebanks[4] (UD) that were used by Ma et al. (2018).[5]

Following standard practice, we just exclude punctuation for evaluating on PTB-SD and, for each experiment, we report the average Labelled and Unlabelled Attachment Scores (LAS and UAS) over 3 and 5 repetitions for UD and PTB-SD, respectively.

Parser	UAS	LAS
Chen and Manning (2014)	91.8	89.6
Dyer et al. (2015)	93.1	90.9
Weiss et al. (2015)	93.99	92.05
Ballesteros et al. (2016)	93.56	91.42
Kiperwasser and Goldberg (2016)	93.9	91.9
Alberti et al. (2015)	94.23	92.36
Qi and Manning (2017)	94.3	92.2
Fernández-G and Gómez-R (2018)	94.5	92.4
Andor et al. (2016)	94.61	92.79
Ma et al. (2018)*	95.87	94.19
This work*	**96.04**	**94.43**
Kiperwasser and Goldberg (2016)	93.1	91.0
Wang and Chang (2016)	94.08	91.82
Cheng et al. (2016)	94.10	91.49
Kuncoro et al. (2016)	94.26	92.06
Zhang et al. (2017)	94.30	91.95
Ma and Hovy (2017)	94.88	92.96
Dozat and Manning (2016)	95.74	94.08
Ma et al. (2018)*	95.84	94.21

Table 1: Accuracy comparison of state-of-the-art fully-supervised single-model dependency parsers on PT-SD. The first block contains transition-based algorithms and the second one, graph-based models. Systems marked with *, including the improved variant described in (Ma et al., 2018) of the graph-based parser by (Dozat and Manning, 2016), are implemented under the same framework as our approach and use the same training settings. Like (Ma et al., 2018), we report the average accuracy over 5 repetitions.

Finally, we use the same hyper-parameter values, pre-trained word embeddings and beam size (10 for PTB-SD and 5 for UD) as Ma et al. (2018).

4.2 Results

By outperforming the two current state-of-the-art graph-based (Dozat and Manning, 2016) and transition-based (Ma et al., 2018) models on the PTB-SD, our approach becomes the most accurate fully-supervised dependency parser developed so far, as shown in Table 1.[6]

In addition, in Table 2 we can see how, under the exactly same conditions, the left-to-right algorithm improves over the original top-down variant in nine out of twelve languages in terms of LAS, obtaining competitive results in the remaining three datasets.

Finally, in spite of requiring a cycle-checking procedure, our approach proves to be twice as fast as the top-down alternative in decoding time,

---

[3] `https://nlp.stanford.edu/software/lex-parser.shtml`

[4] `http://universaldependencies.org`

[5] Please note that, since they used a former version of UD datasets, we reran also the top-down algorithm on the latest treebank version (2.2) in order to perform a fair comparison.

[6] It is worth mentioning that all parsers reported in this section make use of pre-trained word embeddings previously learnt from corpora beyond the training dataset. However, it is common practice in the literature that systems that only use standard pre-trained word embeddings are classed as fully-supervised models, even though, strictly, they are not trained exclusively on the official training data.

Table 2: Parsing accuracy of the top-down and left-to-right pointer-network-based parsers on test datasets of twelve languages from UD. Best results for each language are shown in bold and, apart from the average UAS and LAS, we also report the corresponding standard deviation over 3 runs.

achieving, under the exact same conditions, a 23.08-sentences-per-second speed on the PTB-SD compared to 10.24 of the original system.[7]

5 Related work

There is previous work that proposes to implement dependency parsing by independently selecting the head of each word in a sentence, using neural networks. In particular, Zhang et al. (2017) make use of a BiLSTM-based neural architecture to compute the probability of attaching each word to one of the other input words, in a similar way as pointer networks do. During decoding, a post-processing step is needed to produce well-formed trees by means of a maximum spanning tree algorithm. Our approach does not need this post-processing, as cycles are forbidden during parsing instead, and achieves a higher accuracy thanks to the pointer network architecture and the use of information about previous dependencies.

Before Ma et al. (2018) presented their top-down parser, Chorowski et al. (2017) had already employed pointer networks (Vinyals et al., 2015) for dependency parsing. Concretely, they developed a pointer-network-based neural architecture with multitask learning able to perform pre-processing, tagging and dependency parsing exclusively by reading tokens from an input sentence, without needing POS tags or pre-trained word embeddings. Like our approach, they also use the capabilities provided by pointer networks to undertake the parsing task as a simple process of attaching each word as dependent of another. They also try to improve the network performance with POS tag prediction as auxiliary task and with different approaches to perform label prediction. They do not exclude cycles, neither by forbidding them at parsing time or by removing them by post-processing, as they report that their system produces parses with a negligible amount of cycles, even with greedy decoding (matching our observation for our own system, in our case with beam-search decoding). Finally, the system developed by Chorowski et al. (2017) is constrained to projective dependencies, while our approach can handle unrestricted non-projective structures.

6 Conclusion

We present a novel left-to-right dependency parser based on pointer networks. We follow the same neural network architecture as the stack-pointer-based approach developed by Ma et al. (2018), but just using a focus word index instead of a buffer and a stack. Apart from doubling their system's speed, our approach proves to be a competitive alternative on a variety of languages and achieves the best accuracy to date on the PTB-SD.

The good performance of our algorithm can be explained by the shortening of the transition sequence length. In fact, it has been proved by several studies (Fernández-González and Gómez-Rodríguez, 2012; Qi and Manning, 2017; Fernández-González and Gómez-Rodríguez, 2018) that by reducing the number of applied transitions, the impact of error propagation is alleviated, yielding more accurate parsers.

Our system's source code is freely available at `https://github.com/danifg/Left2Right-Pointer-Parser`.

Abstract

We recast dependency parsing as a sequence labeling problem, exploring several encodings of dependency trees as labels. While dependency parsing by means of sequence labeling had been attempted in existing work, results suggested that the technique was impractical. We show instead that with a conventional BILSTM-based model it is possible to obtain fast and accurate parsers. These parsers are conceptually simple, not needing traditional parsing algorithms or auxiliary structures. However, experiments on the PTB and a sample of UD treebanks show that they provide a good speed-accuracy tradeoff, with results competitive with more complex approaches.

1 Introduction

The application of neural architectures to syntactic parsing, and especially the ability of long short-term memories (LSTMs) to obtain context-aware feature representations (Hochreiter and Schmidhuber, 1997), has made it possible to parse natural language with conceptually simpler models than before. For example, in dependency parsing, the rich feature models with dozens of features used in transition-based approaches (Zhang and Nivre, 2011) can be simplified when using feedforward neural networks (Chen and Manning, 2014), and even more with BiLSTM architectures (Kiperwasser and Goldberg, 2016), where in fact two positional features can suffice (Shi et al., 2017). Similarly, in graph-based approaches, Dozat and Manning (2017) have shown that an arc-factored model can achieve state-of-the-art accuracy, without the need for the higher-order features used in systems like (Koo and Collins, 2010).

In the same way, neural feature representations have made it possible to relax the need for structured representations. This is the case of sequence-to-sequence models that translate sentences into linearized trees, which were first applied to constituent (Vinyals et al., 2015) and later to dependency parsing (Wiseman and Rush, 2016; Zhang et al., 2017b; Li et al., 2018). Recently, Gómez-Rodríguez and Vilares (2018) have shown that sequence labeling models, where each word is associated with a label (thus simpler than sequence to sequence, where the mapping from input to output is not one to one) can learn constituent parsing.

Contribution We show that sequence labeling is useful for dependency parsing, in contrast to previous work (Spoustová and Spousta, 2010; Li et al., 2018). We explore four different encodings to represent dependency trees for a sentence of length n as a set of n labels associated with its words. We then use these representations to perform dependency parsing with an off-the-shelf sequence labeling model. The results show that we produce models with an excellent speed-accuracy tradeoff, without requiring any explicit parsing algorithm or auxiliary structure (e.g. stack or buffer). The source code is available at `https://github.com/mstrise/dep2label`

2 Parsing as sequence labeling

Sequence labeling is a structured prediction problem where a single output label is generated for every input token. This is the case of tasks such as PoS tagging, chunking or named-entity recognition, for which different approaches obtain accurate results (Brill, 1995; Ramshaw and Marcus, 1999; Reimers and Gurevych, 2017).

On the contrary, previous work on dependency parsing as sequence labeling is vague and reports results that are significantly lower than those provided by transition-, graph-based or sequence-to-sequence models (Dyer et al., 2015; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017; Zhang et al., 2017a). Spoustová and Spousta

Proceedings of NAACL-HLT 2019, pages 717–723
Minneapolis, Minnesota, June 2 - June 7, 2019.

(2010) encoded dependency trees using a relative PoS-based scheme to represent the head of a node, to then train an averaged perceptron. They did not provide comparable results, but claimed that the accuracy was between 5-10% below the state of the art in the pre-deep learning era. Recently, Li et al. (2018) used a relative positional encoding of head indexes with respect to the target token. This is used to train Bidirectional LSTM-CRF sequence-to-sequence models (Huang et al., 2015), that make use of sub-root decomposition. They compared their performance against an equivalent BiLSTM-CRF labeling model. The reported UAS for the sequence labeling model was 87.6% on the Penn Treebank, more than 8 points below the current best model (Ma et al., 2018), concluding that sequence-to-sequence models are required to obtain competitive results.

In this work, we show that these results can be clearly improved if simpler architectures are used.

3 Encoding of trees and labels

Given a sentence $w_1 \dots w_n$, we associate the words with nodes $\{0, 1, \dots, n\}$, where the extra node 0 is used as a dummy root for the sentence. A dependency parser will find a set of labeled relations encoded as edges of the form (h, d, l), where $h \in \{0, 1, \dots, n\}$ is the head, $d \in \{1, \dots, n\}$ the dependent, and l a dependency label. The resulting dependency graph must be acyclic and such that each node in $\{1, \dots, n\}$ has exactly one head, so it will be a directed tree rooted at node 0.

Thus, to encode a dependency tree, it suffices to encode the unique head position and dependency label associated with each word of $w_1 \dots w_n$. To do so, we will give each word w_i a discrete label of the form (x_i, l_i), where l_i is the dependency label and x_i encodes the position of the head in one of the following four ways (see also Figure 1):

1. Naive positional encoding: x_i directly stores the position of the head, i.e., a label (x_i, l_i) encodes an edge (x_i, i, l_i). This is the encoding used in the CoNLL file format.

2. Relative positional encoding: x_i stores the difference between the head index minus that of the dependent, i.e., (x_i, l_i) encodes an edge $(i + x_i, i, l_i)$. This was the encoding used for the sequence-to-sequence and sequence labeling models in (Li et al., 2018), as well as for the sequence-to-sequence model in (Kiperwasser and Ballesteros, 2018).

3. Relative PoS-based encoding: x_i is a tuple p_i, o_i. If $o_i > 0$, the head of w_i is the o_ith closest among the words to the right of w_i that have PoS tag p_i. If $o_i < 0$, the head of w_i is the $-o_i$th closest among the words to the left of w_i that have PoS tag p_i. For example, $(V, -2)$ means "the second verb to the left" of w_i. This scheme is closer to the notion of valency, and was used by Spoustová and Spousta (2010).

4. Bracketing-based encoding: based on (Yli-Jyrä, 2012; Yli-Jyrä and Gómez-Rodríguez, 2017). In each label (x_i, l_i), the component x_i is a string following the regular expression `(<)?((\)*|(/)*)(>)?` where the presence of character $<$ means that w_{i-1} has an incoming arc from the right, k copies of character $\backslash$ mean that w_i has k outgoing arcs towards the left, k copies of $/$ mean that w_{i-1} has k outgoing arcs towards the right, and the presence of $>$ means that w_i has an incoming arc from the left. Thus, each right dependency from a word i to j is encoded by a $(/, >)$ pair in the label components x_{i+1} and x_j, and each left dependency from j to i by a $(<, \backslash)$ pair in the label components x_{i+1} and x_j. Note that the intuition that explains why information related to a word is encoded in a neighboring node is that each x_i corresponds to a fencepost position (i.e., x_i represents the space between w_{i-1} and w_i), and the character pair associated to an arc is encoded in the most external fencepost positions covered by that arc. These pairs act as pairs of matching brackets, which can be decoded using a stack to reconstruct the dependencies.

The first three encodings can represent any dependency tree, as they encode any valid head position for each node, while the bracketing encoding only supports projective trees, as it assumes that brackets are properly nested. All the encodings are total and injective, but they are not surjective: head indexes can be out of range in the first three encodings, brackets can be unbalanced in encoding 4, and all the encodings can generate graphs with cycles. We will deal with ill-formed trees later.

4 Model

We use a standard encoder-decoder network, to show that dependency parsing as sequence label-

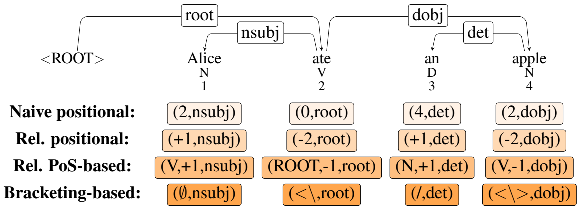

Figure 1: Types of encoding on an example tree.

ing works without the need of complex models.

Encoder We use bidirectional LSTMs (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997). Let $\text{LSTM}_\theta(\mathbf{x})$ be an abstraction of a long short-term memory network that processes the sequence of vectors $\mathbf{x} = [\mathbf{x}_1, ..., \mathbf{x}_{|\mathbf{x}|}]$, then output for $\mathbf{x}_i$ is defined as $\mathbf{h}_i = \text{BiLSTM}_\theta(\mathbf{x}, i) = \text{LSTM}^l_\theta(\mathbf{x}_{[1:i]}) \circ \text{LSTM}^r_\theta(\mathbf{x}_{[|\mathbf{x}|:i]})$. We consider stacked BiLSTMs, where the output $\mathbf{h}^m_i$ of the mth BiLSTM layer is fed as input to the m+1th layer. Unless otherwise specified, the input token at a given time step is the concatenation of a word, PoS tag, and another word embedding learned through a character LSTM.

Decoder We use a feed-forward network, which is fed the output of the last BiLSTM. The output is computed as $P(y_i|\mathbf{h}_i) = \text{softmax}(W \cdot \mathbf{h}_i + \mathbf{b})$.

Well-formedness (i) Each token must be assigned a head (one must be the dummy root), and (ii) the graph must be acyclic. If no token is the real root (no head is the dummy root), we search for candidates by relying on the three most likely labels for each token.[1] If none is found, we assign it to the first token of the sentence. The single-head constraint is ensured by the nature of the encodings themselves, but some of the predicted head indexes might be out of bounds. If so, we attach those tokens to the real root. If a cycle exists, we do the same for the leftmost token in the cycle.

5 Experiments

We use the English Penn Treebank (PTB) (Marcus et al., 1993) and its splits for parsing. We transform it into Stanford Dependencies (De Marneffe et al., 2006) and obtain the predicted PoS tags using Stanford tagger (Toutanova et al., 2003). We also select a sample of UDv2.2 treebanks (Nivre et al., 2018): Ancient-Greek$_{\text{PROIEL}}$, Czech$_{\text{PDT}}$, Chinese$_{\text{GSD}}$, English$_{\text{EWT}}$, Finnish$_{\text{TDT}}$, Hebrew$_{\text{HTB}}$, Kazakh$_{\text{KTB}}$ and Tamil$_{\text{TTB}}$, as a representative sample, following (de Lhoneux et al., 2017). As evaluation metrics, we use Labeled (LAS) and Unlabeled Attachment Score (UAS). We measure speed in sentences/second, both on a single core of a CPU[2] and on a GPU[3].

Encoding	UAS	LAS
Li et al. (2018) (sequence labeling)	87.58	83.81
Li et al. (2018) (seq2seq)	89.16	84.99
Li et al. (2018) (seq2seq+beam+subroot)	93.84	**91.86**
Naive positional	45.41	42.65
Rel. positional	91.05	88.67
Rel. PoS-based	**93.99**	91.76
Bracketing-based	93.45	91.17

Table 1: Performance of our encodings on the PTB dev set with hyperparameters from Gómez-Rodríguez and Vilares (2018). We compare against previous sequence labeling and seq2seq models with more complex architectures, beam search and subroot decomposition.

Setup We use NCRFpp as our sequence labeling framework (Yang and Zhang, 2018). For PTB, we use the embeddings by Ling et al. (2015), for comparison to BIST parser (Kiperwasser and Goldberg, 2016), which uses a similar architecture, but also needs a parsing algorithm and auxiliary structures. For UD, we follow an end-to-end setup and run UDPipe[4] (Straka and Straková, 2017) for tokenization and tagging. We use the pretrained word embeddings by Ginter et al. (2017). Appendix A contains additional hyperparameters.

5.1 Encoding evaluation and model selection

We first examine the four encodings on the PTB dev set. Table 1 shows the results and also compares them against Li et al. (2018), who proposed seq2seq and sequence labeling models that use a relative positional encoding.

As the relative PoS-based encoding and bracketing-based encoding provide the best results, we will conduct the rest of our experiments with these two encodings. Furthermore, we perform a small hyperparameter search involving encoding, number of hidden layers, their dimension and presence of character embeddings, as these parameters influence speed and accuracy. From now on, we write $P^{\text{z}}_{\text{x,y}}$ for a PoS-based encoding model and $B^{\text{z}}_{\text{x,y}}$ for a bracketing-based encoding

---

[1] If single-rooted trees are a prerequisite, the most probable node will be selected among multiple root nodes.

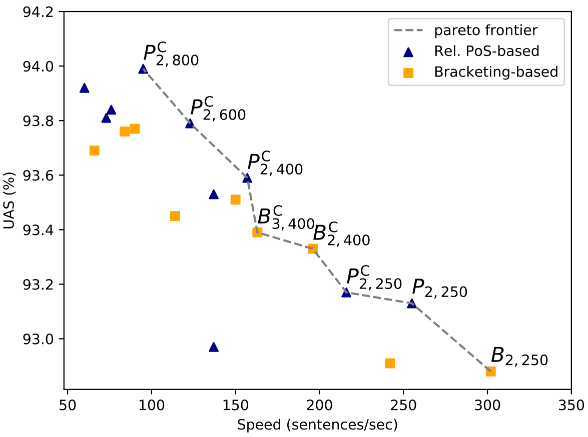

Figure 2: UAS/speed Pareto front on the PTB dev set.

model, where z indicates whether character representation was used in the model, x the number of BiLSTM layers, and y the word hidden vector dimension. We take as starting points (1) the hyperparameters used by the BIST parser (Kiperwasser and Goldberg, 2016), as it uses a BiLSTM architecture analogous to ours, with the difference that it employs a transition-based algorithm that uses a stack data structure instead of plain sequence labeling without explicit representation of structure, and (2) the best hyperparameters used by Gómez-Rodríguez and Vilares (2018) for constituent parsing as sequence labeling, as it is an analogous task for a different parsing formalism.

From there, we explore different combinations of parameters and evaluate 20 models on the PTB development set, with respect to accuracy (UAS) and speed (sentences/second on a single CPU core), obtaining the Pareto front in Figure 2. The two starting models based on previous literature ($P_{2,250}$ and $P^C_{2,800}$, respectively) happen to be in the Pareto front, confirming that they are reasonable hyperparameter choices also for this setting. In addition, we select two more models from the Pareto front (models $P^C_{2,400}$ and $B_{2,250}$) for our test set experiments on PTB, as they also provide a good balance between speed and accuracy.

Model	sent/s CPU	sent/s GPU	UAS	LAS
$P_{2,250}$	$267_{\pm1}$	$777_{\pm24}$	92.95	90.96

5.2 Results and discussion

Table 2 compares the chosen models, on the PTB test set, against state-of-the-art models. Contrary to previous dependency-parsing-as-sequence-labeling attempts, we are competitive and provide a good speed-accuracy tradeoff. For instance, the $P^C_{2,800}$ model runs faster than the BIST parser (Kiperwasser and Goldberg, 2016) while being almost as accurate (-0.18 LAS). This comes in spite of its simplicity. While our BiLSTM architecture is similar to that of BIST, the sequence labeling approach does not need a stack, a specific transition system or a dynamic oracle. Using the BIST hyperparameters for our model ($P_{2,250}$) yields further increases in speed, at some cost to accuracy: 3.34x faster and -0.04 LAS score than the graph-based model, and 3.51x faster and

Treebank	PoS type	$\mathbf{P^C_{2,800}}$ **(sent/s) CPU**	**UAS**	**LAS**	**KG (transition-based) (sent/s) CPU**	**UAS**	**LAS**

[5] In Hebrew, UPoS and XPoS tags are the same.

[6] Kazakh is missing a development set. The scores are based on the test set.

[7] Tamil was run on gold segmented and tokenized inputs, as there is no pretrained UDpipe model. We did not use pretrained word embeddings either.

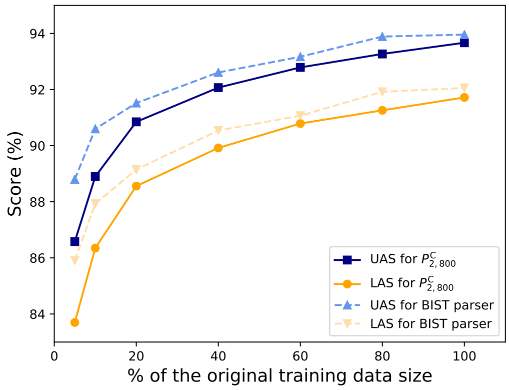

Figure 3: Impact of the PTB data size available for parsers during training on the results from the test set.

-0.94 LAS score than their transition-based one.

We now extend our experiments to the sample of UD-CoNLL18 treebanks. To this end, we focus on the $P^C_{2,800}$ model and since our PoS tag-based encoding can be influenced by the specific PoS tags used, we first conduct an experiment on the development sets to determine what tag set (UPoS, the universal PoS tag set, common to all languages, or XPoS, extended language-specific PoS tags) produces the best results for each dataset.

Table 3 shows how the number of unique UPoS and XPoS tags found in the training set differs in various languages. The results suggest that the performance of our system can be influenced by the size of the tag set. It appears that a very large tag set (for instance the XPoS tag set for Czech and Tamil) can hurt the performance of the model and significantly slow down the system, as it results into a large number of distinct labels for the sequence labeling model, increasing sparsity and making the classification harder. In case of Ancient Greek and Kazakh, the best performance is achieved with the XPoS-based encoding. In these corpora, the tag set is slightly bigger than the UPoS tag set. One can argue that the XPoS tags in this case were possibly more fine-grained and hence provided additional useful information to the system facilitating a correct label prediction, without being so large as to produce excessive sparsity.

Table 4 shows experiments on the UD test sets, with the chosen PoS tag set for each corpus. $P^C_{2,800}$ outperforms transition-based BIST in LAS in 3 out of 8 treebanks,[8] and is clearly faster in all analyzed languages. We believe that the variations between languages in terms of LAS difference with respect to BIST can be largely due to differences in the accuracy and granularity of predicted PoS tags, since our chosen encoding relies on them to encode arcs. The bracketing-based encoding, which does not use PoS tags, may be more robust to this. On the other hand, finding the optimal granularity of PoS tags for the PoS-based encoding can be an interesting avenue for future work.

In this work, we have also examined the impact of the training data size on the performance of our system compared to the performance of BIST parser. The results in Figure 3 suggest that our model requires more data during the training than BIST parser in order to achieve similar performance. The performance is slightly worse when little training data is available, but later on our model reduces the gap when increasing the training data size.

6 Conclusion

This paper has explored fast and accurate dependency parsing as sequence labeling. We tested four different encodings, training a standard BiLSTM-based architecture. In contrast to previous work, our results on the PTB and a subset of UD treebanks show that this paradigm can obtain competitive results, despite not using any parsing algorithm nor external structures to parse sentences.

---

[8] For Ancient Greek, this may be related to the large amount of non-projectivity (BIST is a projective parser). For extra comparison, a non-projective variant of BIST (Smith et al., 2018) obtains 71.58 LAS with mono-treebank training, but from better segmentation and morphology than used here. UDpipe (Straka and Straková, 2017) obtains 67.57 LAS. Czech and Kazakh have a medium amount of non-projectivity.

Abstract

Contextual string embeddings are a recent type of contextualized word embedding that were shown to yield state-of-the-art results when utilized in a range of sequence labeling tasks. They are based on character-level language models which treat text as distributions over characters and are capable of generating embeddings for any string of characters within any textual context. However, such purely character-based approaches struggle to produce meaningful embeddings if a rare string is used in a underspecified context. To address this drawback, we propose a method in which we dynamically aggregate contextualized embeddings of each unique string that we encounter. We then use a pooling operation to distill a global word representation from all contextualized instances. We evaluate these *pooled contextualized embeddings* on common named entity recognition (NER) tasks such as CoNLL-03 and WNUT and show that our approach significantly improves the state-of-the-art for NER. We make all code and pre-trained models available to the research community for use and reproduction.

1 Introduction

Word embeddings are a crucial component in many NLP approaches (Mikolov et al., 2013; Pennington et al., 2014) since they capture latent semantics of words and thus allow models to better train and generalize. Recent work has moved away from the original "one word, one embedding" paradigm to investigate *contextualized* embedding models (Peters et al., 2017, 2018; Akbik et al., 2018). Such approaches produce different embeddings for the same word depending on its context and are thus capable of capturing latent contextualized semantics of ambiguous words.

B-PER	E-PER		S-LOC		S-ORG
Fung	Permadi	(	Taiwan	) v	Indra

Figure 1: Example sentence that provides underspecified context. This leads to an underspecified contextual word embedding for the string "*Indra*" that ultimately causes a misclassification of "*Indra*" as an organization (ORG) instead of person (PER) in a downstream NER task.

Recently, Akbik et al. (2018) proposed a character-level contextualized embeddings approach they refer to as *contextual string embeddings*. They leverage pre-trained character-level language models from which they extract hidden states at the beginning and end character positions of each word to produce embeddings for any string of characters in a sentential context. They showed these embeddings to yield state-of-the-art results when utilized in sequence labeling tasks such as named entity recognition (NER) or part-of-speech (PoS) tagging.

Underspecified contexts. However, such contextualized character-level models suffer from an inherent weakness when encountering rare words in an underspecified context. Consider the example text segment shown in Figure 1: "*Fung Permadi (Taiwan) v Indra*", from the English CONLL-03 test data split (Tjong Kim Sang and De Meulder, 2003). If we consider the word "*Indra*" to be rare (meaning no prior occurrence in the corpus used to generate word embeddings), the underspecified context allows this word to be interpreted as either a person or an organization. This leads to an underspecified embedding that ultimately causes an incorrect classification of "*Indra*" as an organization in a downstream NER task.

Pooled Contextual Embeddings. In this paper, we present a simple but effective approach to address this issue. We intuit that entities are normally only used in underspecified contexts if they are expected to be known to the reader. That is, they are either more clearly introduced in an earlier sentence, or part of general in-domain knowl-

Proceedings of NAACL-HLT 2019, pages 724–728
Minneapolis, Minnesota, June 2 - June 7, 2019.

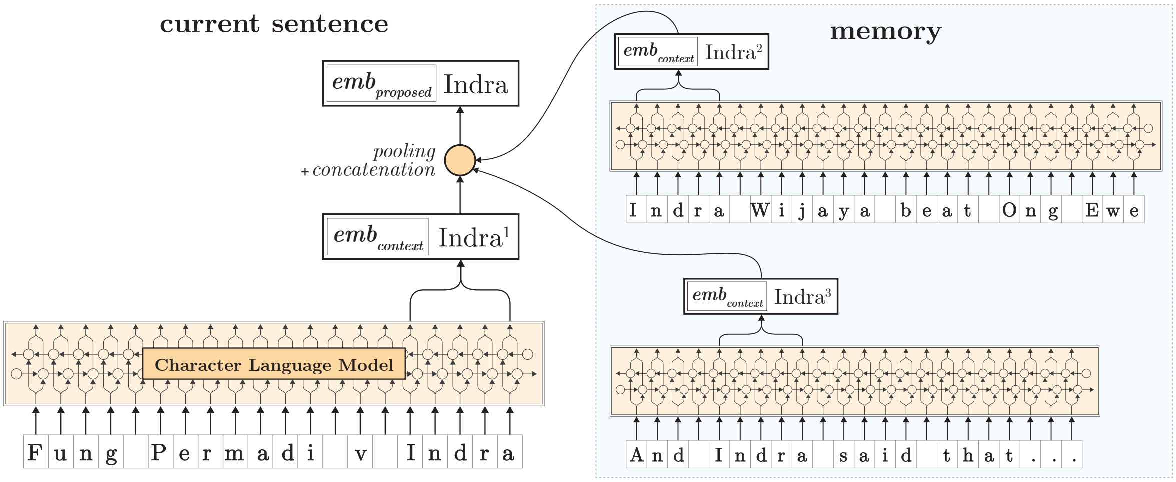

Figure 2: Example of how we generate our proposed embedding ($emb_{proposed}$) for the word "*Indra*" in the example text segment "*Fung Permadi v Indra*". We extract a contextual string embedding ($emb_{context}$) for this word and retrieve from the *memory* all embeddings that were produced for this string on previous sentences. We pool and concatenate all local contextualized embeddings to produce the final embedding.

edge a reader is expected to have. Indeed, the string "*Indra*" in the CoNLL-03 data also occurs in the earlier sentence "*Indra Wijaya (Indonesia) beat Ong Ewe Hock*".

Based on this, we propose an approach in which we dynamically aggregate contextualized embeddings of each unique string that we encounter as we process a dataset. We then use a pooling operation to distill a global word representation from all contextualized instances that we use in combination with the current contextualized representation as new word embedding. Our approach thus produces *evolving word representations* that change over time as more instances of the same word are observed in the data.

We evaluate our proposed embedding approach on the task of named entity recognition on the CoNLL-03 (English, German and Dutch) and WNUT datasets. In all cases, we find that our approach outperforms previous approaches and yields new state-of-the-art scores. We contribute our approach and all pre-trained models to the open source FLAIR[1] framework (Akbik et al., 2019), to ensure reproducibility of these results.

2 Method

Our proposed approach (see Figure 2) dynamically builds up a "memory" of contextualized embeddings and applies a pooling operation to distill a global contextualized embedding for each word. It requires an *embed*() function that produces a contextualized embedding for a given *word* in a *sentence* context (see Akbik et al. (2018)). It also requires a *memory* that records for each unique word all previous contextual embeddings, and a *pool*() operation to pool embedding vectors.

This is illustrated in Algorithm 1: to embed a word (in a sentential context), we first call the *embed*() function (line 2) and add the resulting embedding to the memory for this word (line 3). We then call the pooling operation over all contextualized embeddings for this word in the memory (line 4) to compute the pooled contextualized embedding. Finally, we concatenate the original contextual embedding together with the pooled representation, to ensure that both local and global interpretations are represented (line 5). This means that the resulting *pooled contextualized embedding* has twice the dimensionality of the original embedding.

Algorithm 1 Compute pooled embedding

```
Input: $sentence$, $memory$
1: for $word$ in $sentence$ do
2:     $emb_{context} \leftarrow$
           embed($word$) within $sentence$
3:     add $emb_{context}$ to $memory[word]$
4:     $emb_{pooled} \leftarrow$ pool($memory[word]$)
5:     $word.embedding \leftarrow$
           concat($emb_{pooled}$, $emb_{context}$)
6: end for
```

Pooling operations. We experiment with different pooling operations: *mean* pooling to average a word's contextualized embedding vectors, and *min* and *max* pooling to compute a vector of all

Table 1: Comparative evaluation of proposed approach with different pooling operations (min, max, $mean$) against current state-of-the-art approaches on four named entity recognition tasks († indicates reported numbers). The numbers indicate that our approach outperforms all other approaches on the CoNLL datasets, and matches baseline results on WNUT.

element-wise minimum or maximum values.

Training downstream models. When training downstream task models (such as for NER), we typically make many passes over the training data. As Algorithm 2 shows, we reset the memory at the beginning of each pass over the training data (line 2), so that it is build up from scratch at each epoch.

Algorithm 2 Training

```
1: for $epoch$ in $epochs$ do
2:     $memory \leftarrow$ map of $word$ to list
3:     train and evaluate as usual
4: end for
```

This approach ensures that the downstream task model learns to leverage pooled embeddings that are built up (e.g. *evolve*) over time. It also ensures that pooled embeddings during training are only computed over training data. After training, (i.e. during NER prediction), we do not reset embeddings and instead allow our approach to keep expanding the memory and evolve the embeddings.

3 Experiments

We verify our proposed approach in four named entity recognition (NER) tasks: We use the English, German and Dutch evaluation setups of the CoNLL-03 shared task (Tjong Kim Sang and De Meulder, 2003) to evaluate our approach on classic newswire data, and the WNUT-17 task on emerging entity detection (Derczynski et al., 2017) to evaluate our approach in a noisy user-generated data setting with few repeated entity mentions.

3.1 Experimental Setup

We use the open source Flair framework in all our experiments. It implements the standard BiLSTM-CRF sequence labeling architecture (Huang et al., 2015) and includes pre-trained contextual string embeddings for many languages. To Flair, we add an implementation of our proposed *pooled contextualized embeddings*.

Hyperparameters. For our experiments, we follow the training and evaluation procedure outlined in Akbik et al. (2018) and follow most hyperparameter suggestions as given by the in-depth study presented in Reimers and Gurevych (2017). That is, we use an LSTM with 256 hidden states and one layer (Hochreiter and Schmidhuber, 1997), a locked dropout value of 0.5, a word dropout of 0.05, and train using SGD with an annealing rate of 0.5 and a patience of 3. We perform model selection over the learning rate $\in \{0.01, 0.05, 0.1\}$ and mini-batch size $\in \{8, 16, 32\}$, choosing the model with the best F-measure on the validation set. Following Peters et al. (2017), we then repeat the experiment 5 times with different random seeds, and train using both train and development set, reporting both average performance and standard deviation over these runs on the test set as final performance.

Standard word embeddings. The default setup of Akbik et al. (2018) recommends contextual string embeddings to be used in combination with standard word embeddings. We use GloVe embeddings (Pennington et al., 2014) for the English tasks and FastText embeddings (Bojanowski et al., 2017) for all newswire tasks.

Baselines. Our baseline are contextual string embeddings without pooling, i.e. the original setup proposed in Akbik et al. (2018)[2]. By comparing against this baseline, we isolate the impact of our proposed pooled contextualized embeddings.

---

[2] Our reproduced numbers are slightly lower than we reported in Akbik et al. (2018) where we used the official CoNLL-03 evaluation script over BILOES tagged entities. This introduced errors since this script was not designed for S-tagged entities.

Approach	CoNLL-03 En	CoNLL-03 De	CoNLL-03 Nl	WNUT-17
Pooled Contextualized Embeddings (*only*)	**92.42** ± 0.07	**86.21** ± 0.07	**88.25** ± 0.11	**44.29** ± 0.59
Contextual String Embeddings (*only*)	91.81 ± 0.12	85.25 ± 0.21	86.71 ± 0.12	43.43 ± 0.93

Table 2: Ablation experiment using contextual string embeddings without word embeddings. We find a more significant impact on evaluation numbers across all datasets, illustrating the need for capturing global next to contextualized semantics.

In addition, we list the best reported numbers for the four tasks. This includes the recent BERT approach using bidirectional transformers by Devlin et al. (2018), the semi-supervised multitask learning approach by Clark et al. (2018), the ELMo word-level language modeling approach by Peters et al. (2018), and the best published numbers for WNUT-17 (Aguilar et al., 2018) and German and Dutch CoNLL-03 (Lample et al., 2016).

3.2 Results

Our experimental results are summarized in Table 1 for each of the four tasks.

New state-of-the-art scores. We find that our approach outperforms all previously published results, raising the state-of-the-art for CoNLL-03 on English to 93.18 F1-score (↑0.32 pp vs. previous best), German to 88.27 (↑0.86 pp) and Dutch to 90.44 (↑0.28 pp). The consistent improvements against the contextual string embeddings baseline indicate that our approach is generally a viable option for embedding entities in sequence labeling.

Less pronounced impact on WNUT-17. However, we also find no significant improvements on the WNUT-17 task on emerging entities. Depending on the pooling operation, we find comparable results to the baseline. This result is expected since most entities appear only few times in this dataset, giving our approach little evidence to aggregate and pool. Nevertheless, since recent work has not yet experimented with contextual embeddings on WNUT, as side result we report a new state-of-the-art of 49.59 F1 vs. the previous best reported number of 45.55 (Aguilar et al., 2018).

Pooling operations. Comparing the pooling operations discussed in Section 2, we generally find similar results. As Table 1 shows, min pooling performs best for English and German CoNLL, while $mean$ pooling is best for Dutch and WNUT.

3.3 Ablation: Character Embeddings Only

To better isolate the impact of our proposed approach, we run experiments in which we do not use any classic word embeddings, but rather rely solely on contextual string embeddings. As Table 2 shows, we observe more pronounced improvements of pooling vis-a-vis the baseline approach in this setup. This indicates that pooled contextualized embeddings capture global semantics words similar in nature to classical word embeddings.

4 Discussion and Conclusion

We presented a simple but effective approach that addresses the problem of embedding rare strings in underspecified contexts. Our experimental evaluation shows that this approach improves the state-of-the-art across named entity recognition tasks, enabling us to report new state-of-the-art scores for CoNLL-03 NER and WNUT emerging entity detection. These results indicate that our embedding approach is well suited for NER.

Evolving embeddings. Our dynamic aggregation approach means that embeddings for the same words will change over time, even when used in exactly the same contexts. Assuming that entity names are more often used in well-specified contexts, their pooled embeddings will improve as more data is processed. The embedding model thus continues to "learn" from data even after the training of the downstream NER model is complete and it is used in prediction mode. We consider this idea of constantly evolving representations a very promising research direction.

Future work. Our pooling operation makes the conceptual simplification that all previous instances of a word are equally important. However, we may find more recent mentions of a word - such as words within the same document or news cycle - to be more important for creating embeddings than mentions that belong to other documents or news cycles. Future work will therefore examine methods to learn weighted poolings of previous mentions. We will also investigate applicability of our proposed embeddings to tasks beside NER.

Public release. We contribute our code to the FLAIR framework[3]. This allows full reproduction of all experiments presented in this paper, and al-

---

[3] The proposed embedding is added to FLAIR in release 0.4.1. as the `PooledFlairEmbeddings` class (see Akbik et al. (2019) for more details).

lows the research community to use our embeddings for training downstream task models.

Abstract

Supervised approaches to named entity recognition (NER) are largely developed based on the assumption that the training data is fully annotated with named entity information. However, in practice, annotated data can often be imperfect with one typical issue being the training data may contain incomplete annotations. We highlight several pitfalls associated with learning under such a setup in the context of NER and identify limitations associated with existing approaches, proposing a novel yet easy-to-implement approach for recognizing named entities with incomplete data annotations. We demonstrate the effectiveness of our approach through extensive experiments.[1]

1 Introduction

Named entity recognition (NER) (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) as one of the most fundamental tasks within natural language processing (NLP) has received significant attention. Most existing approaches to NER focused on a supervised setup, where fully annotated named entity information is assumed to be available during the training phase. However, in practice, obtaining high-quality annotations can be a very laborious and expensive process (Snow et al., 2008). One of the common issues with data annotations is there may be incomplete annotations.

Figure 1 shows an example sentence with two named entities "*John Lloyd Jones*" and "*BBC radio*" of type PER (person) and ORG (organization), respectively. Following the standard BIOES tagging scheme (Ramshaw and Marcus, 1999; Ratinov and Roth, 2009), the corresponding gold label sequence is shown below the sentence. When the data annotations are incomplete, certain labels may be missing from the label sequence. Properly defining the task is important, and we argue there are two possible potential pitfalls associated with modeling incomplete annotations, especially for the NER task.

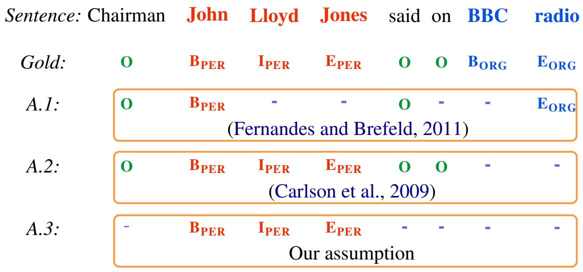

Figure 1: An example sentence with gold named entity annotations and different assumptions (i.e., *A.1* to *A.3*) on *available labels*. "-" represents a missing label.

Several previous approaches assume the incomplete annotations can be obtained by simply removing either word-level labels (Fernandes and Brefeld, 2011) or span-level labels (Carlson et al., 2009). As shown in Figure 1, under both assumptions (i.e., *A.1* and *A.2*), there will be words annotated with O labels. The former approach may even lead to sub-entity level annotations (e.g., "*radio*" is annotated as part of an entity). However, we argue such assumptions can be largely unrealistic. In practice, annotators are typically instructed to annotate named entities for complete word spans only (Settles et al., 2008; Surdeanu et al., 2010). Thus, sub-entity level annotations or O labels [2] should not be assumed to be avail-

---

[1] Our code and data are available at `http://statnlp.org/research/ie`.

[2] Why should the O labels be assumed unavailable? This is because the annotators typically do not actively specify the O labels when working on annotations. If the annotator chooses not to annotate a word, it could either mean it is not part of any entity, *or* the word is actually part of an entity but the annotator neglected it in the annotation process (therefore we have incomplete annotations). However, we note that assigning the O label to a word would precisely indicate it is strictly *not* part of any entity, which is not desirable.

Figure 3: Graphical illustrations on different assumptions on *unavailable labels*, where the entity "*John Lloyd Jones*" of type PER is labeled but "*BBC radio*" of type ORG is missing. Each path refers to one possible complete label sequence, and the density of the color indicates probability (we excluded B and E tags for brevity).

able (*A.3*). Therefore such approaches are making sub-optimal assumptions on the *available labels*.

When the proper assumptions on the available labels are made, one can typically model the missing labels as latent variables and train a latent-variable conditional random fields model (Quattoni et al., 2005). One such approach is presented in (Bellare and McCallum, 2007). Their work focused on the citation parsing[3] (i.e., sequence labeling) task which does not suffer from the above issue as no O label is involved. However, though the approach was shown effective in the citation parsing task, we found its effectiveness does not transfer to the NER task even in the absence of the above available labels issue. As we would highlight later, the reason is related to the undesirable assumptions on the *unavailable labels*.

In this work, we tackle the incomplete annotation problem when building an NER system, under a more realistic yet more challenging scenario. We present a novel, effective, yet easy-to-implement approach, and conduct extensive experiments on various datasets and show our approach significantly outperforms several previous approaches.

2 Related Work

Previous research efforts on partially annotated data are mostly based on the conditional random fields (CRF) (Lafferty et al., 2001), structured perceptron (Collins, 2002) and max-margin (Tsochantaridis et al., 2005) (e.g. structural support vector machine) models. Bellare and McCallum (2007) proposed a missing label linear-chain CRF[4] which is essentially a latent-variable CRF (Quattoni et al., 2005) on citation parsing (McCallum et al., 2000). This model had also been used in part-of-speeching tagging and segmentation task with incomplete annotations (Tsuboi et al., 2008; Liu et al., 2014; Yang and Vozila, 2014). Yang et al. (2018) showed the effectiveness of such a model on Chinese NER with incomplete annotations due to the fact that they required a certain number of fully annotated data to perform joint training. Greenberg et al. (2018) applied this model on a biomedical NER task and achieved promising performance with incomplete annotations. However, in their assumption for the incomplete annotations, the O labels are still considered, which we believe is not realistic. Carlson et al. (2009) modified the structured perceptron algorithm and defined features only on the tokens with annotated labels in partially labeled sequences. Fernandes and Brefeld (2011) and Lou et al. (2012) proposed to use a large-margin learning framework similar to structured support vector machines with latent variables (Yu and Joachims, 2009).

3 Approach

Given the input word sequence $\mathbf{x}$, the NER task is to predict a label sequence $\mathbf{y}$ that encodes the NER information (e.g., in a form following the BIOES tagging scheme). Given a training set that consists of completely labeled data $\mathcal{D}$, one can tackle this problem using a standard linear-chain conditional random field (CRF) (Lafferty et al., 2001) whose loss function is as follows:[5]

$$\mathcal{L}(\mathbf{w}) = -\sum_i \log p_{\mathbf{w}}(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}) \qquad (1)$$

---

[3] The task is to tag the BibTex records with different labels (i.e., "title", "author", "affiliation" and so on).

[4] This model was also named as Partial CRF (Carlson et al., 2009) and EM Marginal CRF (Greenberg et al., 2018).

[5] In practice, we also have an L_2 regularization term, which we exclude from the formula for brevity.

where $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$ is the i-th instance from $\mathcal{D}$.

Now, assume we have an incomplete label sequence $\mathbf{y}_p^{(i)}$. From such a $\mathbf{y}_p^{(i)}$ we should be able to derive a set of all possible complete label sequences that are compatible with (i.e., contain) the incomplete label sequence, and let us call this set $\mathcal{C}(\mathbf{y}_p^{(i)})$. We can rewrite the above function as:

$$\mathcal{L}(\mathbf{w}) = -\sum_i \log \sum_{\mathbf{y} \in \mathcal{C}(\mathbf{y}_p^{(i)})} q_{\mathcal{D}}(\mathbf{y}|\mathbf{x}^{(i)}) p_{\mathbf{w}}(\mathbf{y}|\mathbf{x}^{(i)})$$

We illustrate in Figure 3 several previous approaches as well as our approach. In this example, the entity *BBC radio* of type ORG is not annotated. Figure 3(a) shows a single path that corresponds to the gold label sequence. Figure 3(b) illustrates a naive approach, where we regard all the missing labels as O labels. This essentially assumes that the q distribution in the above equation puts all probability mass to this single label sequence, which is an incorrect assumption.

Now let us look at what assumptions on q have been made by the existing approach of Bellare and McCallum (2007). The model regards the missing labels as latent variables and learns a latent variable CRF using the following loss:

$$-\sum_i \log \sum_{\mathbf{y} \in \mathcal{C}(\mathbf{y}_p^{(i)})} p_{\mathbf{w}}(\mathbf{y}|\mathbf{x}^{(i)}) \qquad (2)$$

The resulting model is called *missing label linear-chain CRF* (*M-CRF*) [6]. As we can see from the above function, this is essentially equivalent to say q is a uniform distribution that assigns equal probabilities to all possible complete label sequences in $\mathcal{C}(\mathbf{y}_p^{(i)})$.

We believe such an assumption on q that describes *unavailable labels* can be improved. As we can see from the above example in Figure 3(d), a more desirable assumption about q is to put more probability mass to a path that is close to the gold path. In practice, their approach worked for the task of citation parsing, where the q distribution may not deviate much from the uniform distribution (Figure 3(c)) in such a task. However, in the task of NER, we find such a simple treatment to the q distribution often leads to sub-optimal results (as we can see in the experiments later) as the q distribution is highly skewed due to the large amount of O labels. This observation motivates us to find a proper way to define q that can approximate the gold label distribution in this work.

Dataset	Training		Validation		Test		Entities	
	#entity	#sent	#entity	#sent	#entity	#sent	#	c (%)

Table 1: Data statistics for the datasets.

3.1 Estimating q

Inspired by the *classifier stacking* technique used in Nivre and McDonald (2008), we empirically found that a reasonable q distribution can be acquired in a k-fold cross-validation fashion.

We first start with an initialization step where we assign specific labels to words without labels, forming complete label sequences (we will discuss our initialization strategy in experiments). Next, we perform k-fold cross-validation on the training set. Specifically, each time we train a model with (k-1) folds of the data and based on the learned model we define our q distribution.

We describe two different ways of defining the q distribution, namely the *hard* approach, and the *soft* approach. In the *hard* approach, the resulting q distribution is a collapsed distribution that assigns probability 1 to a single complete label sequence, whereas in the *soft* approach each possible label sequence will get a certain probability score.

In the *hard* approach, after training a model from (k-1) folds, we apply a constrained Viterbi procedure [7] to the sentences in the remaining fold. In the *soft* approach, we use a constrained version of the forward-backward procedure and calculate the marginal probabilities associated with each label at each unlabeled position. The score of each complete label sequence can then be calculated as a product of all such marginal probabilities. We note that in the above procedure the estimation to q depends on the initialization. Thus we iterate the above procedure, which allows us to converge to an improved q.

4 Experiments

We conduct experiments on two standard NER datasets – CoNLL-2003 English and CoNLL-2002 Spanish datasets that consist of news articles. We

---

[6] Similar assumptions have also been made by (Carlson et al., 2009; Fernandes and Brefeld, 2011), but they used structured perceptron (Collins, 2002) instead.

[7] The algorithm will ensure the resulting complete label sequence is compatible with the incomplete label sequence.

Approach	CoNLL-2003			CoNLL-2002			Taobao			Youku		
	P.	*R.*	*F.*	*P.*	*R.*	*F.*	*P.*	*R.*	*F.*	*P.*	*R.*	*F.*

Table 2: Performance comparison between different baseline models and our approaches on 4 datasets with $\rho = 0.5$ (for *Complete* model, $\rho = 1.0$).

notice that incomplete annotation issue is very common in the industry setup. Therefore we also consider two new datasets from industry – Taobao and Youku datasets[8] consisting of product and video titles in Chinese. We crawled and manually annotated such data with named entities[9]. Table 1 shows the statistics of the datasets. The last two columns show the number of entity types and the percentage of words (i.e., c in Table 1) that are parts of an NE. Based on our assumption on the *available labels* in Section 1, we randomly remove a certain number of entities as well as all O labels and use ρ to represent the ratio of annotated entities. For example, $\rho = 0.6$ means we keep 60% of all the entities and remove the annotations of 40% of the entities. Meanwhile, the O labels are considered unavailable.

We follow Lample et al. (2016) and apply the bidirectional long short-term memory (Hochreiter and Schmidhuber, 1997) (BiLSTM) networks as the neural architecture for all baselines and our approaches. Specifically, we implement the following baselines: a *Simple* model which is a linear-chain LSTM-CRF model and we treat all missing labels as O; the missing label CRF (Bellare and McCallum, 2007; Greenberg et al., 2018) (LSTM-M-CRF) model; the *partial perceptron* (Carlson et al., 2009) model, which is a structured perceptron (Collins, 2002) but only considers the scores on the words with available labels; the *transductive perceptron* (Fernandes and Brefeld, 2011) model where they introduce a Hamming loss function during the perceptron training process; lastly, we train an LSTM-CRF (Lample et al., 2016) with complete annotations as the upper bound (*Complete*). For English and Spanish, we use exactly the same embeddings used in Lample et al. (2016). We train our Chinese character embeddings on the Chinese Gigaword[10] corpus. The resulting implementation achieves 90.9 and 85.8 F-scores on CoNLL-2003 English and CoNLL-2002 Spanish datasets, respectively. These benchmark results are comparable with the results reported in the state-of-the-art NER systems (Lample et al., 2016; Ma and Hovy, 2016; Reimers and Gurevych, 2017).

For initialization in our approaches, we run the *Simple* model on each fold and use the results to initialize our q distribution[11]. Detailed descriptions on experiment settings (e.g., hidden dimension of LSTM and optimizer) and baseline systems are provided in supplementary material.

Main Results Table 2 presents the comparisons among all approaches on four datasets with $\rho = 0.5$ and $k = 2$. Our preliminary experiments show that a larger k value have a negligible effect on the results. A similar finding was also reported in Nivre and McDonald (2008). The *Simple* model has high precision and low recall as it treats unknown labels as O. Previous models for incomplete annotations achieve a much lower F-score compared to the *Simple* model and our approaches. Due to their uniform assumption on q over the missing labels, these models typically can recall more entities. The partial perceptron (Carlson et al., 2009) among these three models yields a relatively lower recall as features are not defined over the words with missing labels.

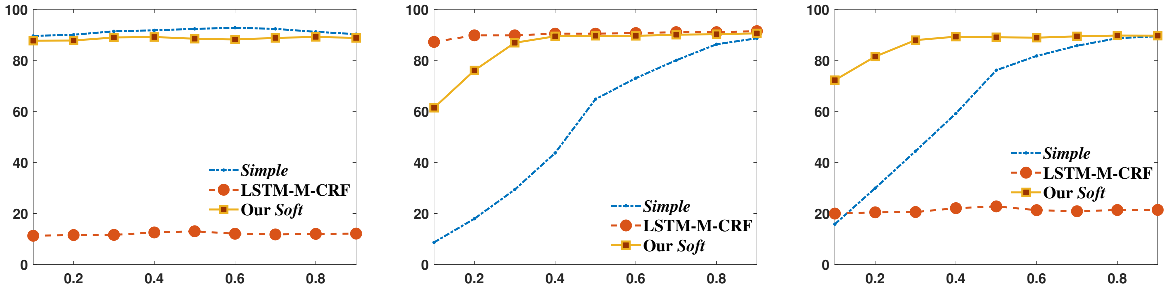
---

[8] http://www.taobao.com/ and http://www.youku.com/

[9] Details of all datasets can be found in the supplementary material.

[10] https://catalog.ldc.upenn.edu/LDC2003T09

[11] Similar to the EM procedure, a good initialization is crucial for our approach. We found using random initialization can lead to substantially worse results and a better initialization can be used to further improve the results.



(a) Precision

(b) Recall

(c) F-score

Figure 4: Precision, Recall and F-score with different ρ on CoNLL-2003 dataset.

The difference in F-score between these three models and the *Simple* model is more significant on the two CoNLL datasets than on Taobao and Youku. As shown in Table 1, the latter two datasets have more words labeled as parts of entities (i.e., a higher c). This means these industrial datasets have less O labels, making such baseline models suffer less from their assumptions on the *unavailable labels*. With a properly learned q distribution, our approaches improves the recall score over the *Simple* model while preserving a high precision. Our *soft* approach consistently achieves a better F-score compared with the *hard* approach on all datasets with $p < 0.001$. Compared to the *Complete* upper bound, our *soft* approach are still more than 3% lower in F-score on the CoNLL-2002, Taobao and Youku datasets. However, we can see that the *soft* approach achieves much higher performance compared to this variant on other datasets. We attribute this phenomenon to our approaches' ability in retrieving most of the entities in the training set. Empirically, we found our *soft* approach can recover 94% of the entities in the training set of the CoNLL-2003 dataset.

The overall results show the underlying scenario is challenging for commonly adopted models in handling incomplete annotations and our approaches can achieve better performance compared with them.

Effect of ρ We conduct experiments with different ρ from 0.1 to 0.9 for our *soft* approach against the *Simple* and LSTM-M-CRF models. Figure 4 shows how the precision, recall and F-score on CoNLL-2003 change as we increase ρ. The F-score of the *Simple* baseline increases progressively as ρ increases. LSTM-M-CRF always maintains a low F-score which is not sensitive to different ρ values because of their high recall and low precision values as we can see in Figure 4 (a, b). The improvement of our approach attributes to the increase of recall as the precision is constantly high and stable. We can see that our *soft* approach performs particularly well when ρ is larger than 0.3 which indicates a modest amount of missing labels in practice.

5 Conclusions and Future Work

In this work, we identified several limitations associated with previous assumptions when performing sequence labeling with incomplete annotations, and focused on the named entity recognition task. We presented a novel and easy-to-implement solution that works under a realistic and challenging assumption on the incomplete annotations. Through extensive experiments and analysis, we demonstrated the effectiveness of our approach.

Although we focused on the task of named entity recognition in this work, we believe the proposed approach may find applications in some other sequence labeling tasks or other more general structured prediction problems where the issue of incomplete annotations is involved. We leave them as future work.

Acknowledgments

We would like to thank the anonymous reviewers for their constructive comments on this work. This work is done under a collaborative agreement between SUTD and Alibaba on an Alibaba Innovative Research (AIR) Program funded by Alibaba, where Alibaba provided data and helped with experiments. We appreciate Alibaba's generosity in the agreement that makes it possible for us to make all data and code in this research publicly available upon acceptance of this paper. Event Detection without Triggers

Abstract

The goal of event detection (ED) is to detect the occurrences of events and categorize them. Previous work solved this task by recognizing and classifying event triggers, which is defined as the word or phrase that *most clearly* expresses an event occurrence. As a consequence, existing approaches required both annotated triggers and event types in training data. However, triggers are nonessential to event detection, and it is time-consuming for annotators to pick out the "*most clearly*" word from a given sentence, especially from a long sentence. The expensive annotation of training corpus limits the application of existing approaches. To reduce manual effort, we explore detecting events without triggers. In this work, we propose a novel framework dubbed as **T**ype-aware **B**ias **N**eural **N**etwork with **A**ttention **M**echanisms (TBNNAM), which encodes the representation of a sentence based on target event types. Experimental results demonstrate the effectiveness. Remarkably, the proposed approach even achieves competitive performances compared with state-of-the-arts that used annotated triggers.

1 Introduction

This work tackles the task of event detection (ED), whose goal is to detect the occurrences of predefined events and categorize them. For example, consider the following sentence "*In Baghdad, a cameraman died when an American tank fired on the Palestine Hotel.*", an ideal event detection system should recognize two events, *Death* and *Attack*(suppose that both *Death* and *Attack* are in the predefined event set) .

Previous work typically solved this task by recognizing and classifying event triggers. According to ACE (Automatic Context Extraction) event evaluation program, event trigger is defined as the word or phrase that *most clearly* expresses an event occurrence. Take the following sentence as an example:

> ***S*:** In Baghdad, a cameraman **died** when an American tank **fired** on the Palestine Hotel.

"*died*" is the trigger word of *Death* event, and "*fired*" is the trigger word of *Attack* event. The majority of existing approaches modeled this task as word classification (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013; Nguyen and Grishman, 2015; Liu et al., 2016b,a; Chen et al., 2017), which predicted whether each word in a given sentence is an event trigger and what type of event it triggered. As a consequence, these approaches required both annotated triggers and event types for training.

However, event triggers are nonessential to this task. Remind that the goal of event detection is to recognize and categorize events, thus triggers could be viewed as intermediate results of this task. Furthermore, it is time-consuming for annotators to pick out the "*most clearly*" word from a given sentence, especially from a long sentence, which limits the application of existing ED approaches. To reduce manual effort, we explore detecting events without triggers. In this study, the only annotated information of each sentence is the types of events occurred in it. Consider the aforementioned example ***S*** again, its annotation is {*Death, Attack*}. On the contrast, previous work also required an annotated trigger for each event, which means the annotated information of ***S*** is {*Death*:died, *Attack*:fired} in previous work.

Without event triggers, it is intuitive to model this task via text classification. However, there are two challenges: (1) **Multi-label problem**: each sentence may contain arbitrary number of events, which means it could have zero or multiple target

Proceedings of NAACL-HLT 2019, pages 735–744
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

labels. In machine learning, this problem is called multi-label problem. (2) **Trigger absence problem**: previous work illustrated that trigger words play important roles in event detection(Chen et al., 2015; Liu et al., 2016a). It is challenging to model this information without annotated triggers.

To solve the first challenge, we transform multi-label classification to multiple binary classification problems. Specifically, a given sentence s attached each pre-defined event type t forms an instance, which is expected to be labeled with 0 or 1 according to whether s contains an event of type t. For example, suppose there totally are 3 predefined types of events(denoted by t_1, t_2 and t_3), and sentence s contains two events of type t_1 and t_3, then it could be transformed to the following three instances:

instance	label
$< s, t_1 >$	1
$< s, t_2 >$	0
$< s, t_3 >$	1

Table 1: Example of instances in binary classifications for sentence s, which contains events of type t_1 and t_3.

In this paradigm, sentences that convey multiple events will yield multiple positive pairs, thus the multi-label problem could be well solved.

Furthermore, each type of events are usually triggered by a set of specific words, which are called event trigger words. For example, *Death* events are usually triggered by “die”, “passed away”, ”gone”, etc. Therefore, event trigger words are important clues to this task. Since existing work explicitly exploited annotated trigger words in their approaches, they can directly model this observation. However, in our case, annotated triggers are unavailable. To model this information, we propose a simple but effective model, called **T**ype-aware **B**ias **N**eural **N**etwork with **A**ttention **M**echanisms (*TBNNAM*).

Figure 1 illustrates the framework of *TBNNAM*. The input is consisted of two parts: a tokenized sentence with NER tags and a target event type. The output o is expected to be 1 if the given sentence conveys an event of the target type, otherwise 0 (the output should be 1 for the example given in Figure 1). Specifically, given a sentence, the proposed model first transforms the input tokens into embeddings, and applies an LSTM layer to calculate a context-dependent representation for each token. Then it computes an attention vector, α, based on the target event type, where the trigger word is expected to obtain higher score. Finally, the sentence representation s_{att} is calculated based on α. Here, s_{att} is expected to focus on local information (trigger word). To capture global information, the final output, o, is also connected to the last LSTM units, which encodes the global information of the input sentence. Furthermore, to reinforce the influence of positive samples, we devise a bias objective function in our model . We call our model “type-aware” because the representation of a sentence, s_{att}, is calculated based on the target event type.

We have conducted experimental comparisons on a widely used benchmark dataset ACE2005[1]. The results illustrate that our approach outperforms all the compared baselines, and even achieves competitive performances compared with exiting approaches that used annotated triggers. We publish our code for further study by the NLP community.[2]

In summary, the main contributions of this work are: (1) To the best of our knowledge, this is the first work that focuses on detecting events without triggers. Compared with existing approaches, the proposed method requires less manual annotations. (2) Without triggers, this task encounters two challenges: multi-label problem and trigger absence problem. We propose a simple but effective model, which even achieves competitive results compared with approaches that using annotated triggers. (3) Since this is the first work on detecting events without triggers, we implement a series of baseline models for this task, and systematically evaluate and analyze them.

2 Background

2.1 Task Definition

Event detection task requires that certain specified types of events, which are mentioned in the annotated data, to be detected. The most common used benchmark dataset in previous work is ACE 2005 corpus. This corpus includes 8 types of events, with 33 subtypes. Following previous work(Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Li et al.,

---

[2] https://github.com/liushulinle/event_detection_without_triggers

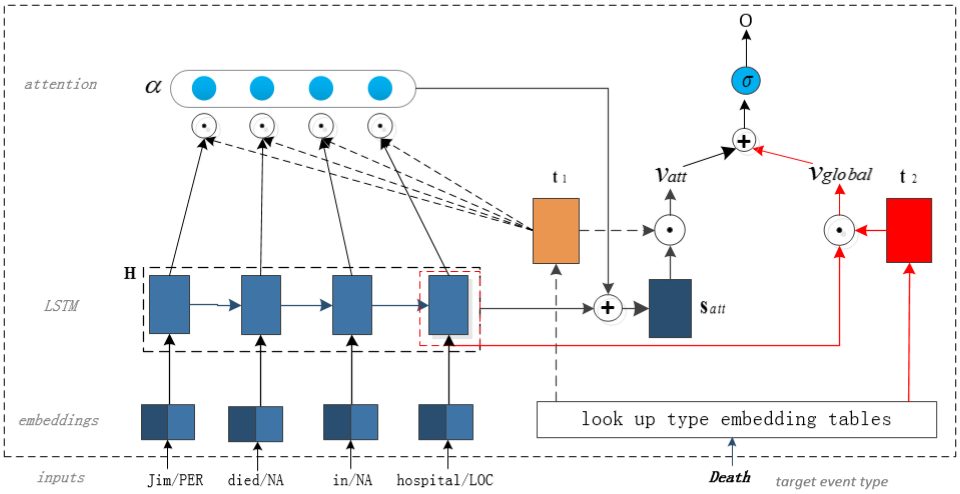

Figure 1: The framework of type-aware bias neural network with attention mechanisms. The input is consisted of two parts: a tokenized sentence with NER tags and a target event type. t_1 and t_2 are two different embedding vectors of the target event type. The output o is expected to be 1 if the given sentence conveys an event of the target type, otherwise 0 (the output should be 1 for the case in this figure). We call it "type-aware" because the representation of sentence, s_{att}, is calculated based on the target event type.

2013; Chen et al., 2015; Nguyen and Grishman, 2016), we treat them simply as 33 separate event types and ignore the hierarchical structure among them. Consider the following sentence "*In Baghdad, a cameraman died when an American tank fired on the Palestine Hotel*", an ideal event detector should detect two events from this sentence: a *Die* event and an *Attack* event.

2.2 Related Work

Event detection is one of important topics in NLP. Many approaches have been proposed for this task. Nearly all the existing methods on ACE event task follow supervised paradigm. We further divide them into feature-based methods and representation-based methods.

In feature-based methods, a diverse set of strategies has been exploited to convert classification clues into feature vectors. Ahn (2006) uses the lexical features(e.g., full word), syntactic features (e.g., dependency features) and external-knowledge features(WordNet (Miller, 1998)) to extract the event. Inspired by the hypothesis of One Sense Per Discourse (Yarowsky, 1995), Ji and Grishman (2008) combined global evidence from related documents with local decisions for the event extraction. To capture more clues from the texts, Gupta and Ji (2009), Liao and Grishman (2010) and Hong et al. (2011) proposed the cross-event and cross-entity inference for the ACE event task. Li et al. (2013) proposed a joint model to capture the combinational features of triggers and arguments. Liu et al. (2016b) proposed a global inference approach to employ both latent local and global information for event detection.

In recent years, representation-based methods have dominated the research. In this paradigm, candidate event mentions are represented by embeddings, which typically are fed into neural networks. Chen et al. (2015) and Nguyen and Grishman (2015) are the first work in this paradigm. Their models are based on CNNs (Convolutional Neural Networks). To model the dependency of triggers and arguments, Nguyen and Grishman (2016) proposed a joint event extraction approach based RNNs(Recurrent Neural Networks). Liu et al. (2017) proposed to encode argument information in event detection via supervised attention mechanisms. Recently, Nguyen and Grishman (2018) and Sha et al. (2018) proposed to exploit syntactic information for event detection.

All the existing approaches required annotated triggers. The expensive annotation of training data limits the application of these approaches. To reduce manual effort, we perform this task without event triggers.

3 Methodology

To deal the multi-label problem, we model this task via multiple binary classifications. Given a sentence, it will be fed into a binary classifier with each candidate event type. We add the label *NA* to sentences that do not contain any events. To capture the hidden trigger information, we propose a simple but effective model, called **T**ype-aware **B**ias **N**eural **N**etwork with **A**ttention **M**echanisms (*TBNNAM*). Our model is "type-aware" because it calculates the representation of a sentence based on the target event type. Figure 1 illustrates the framework of *TBNNAM*. The input is consisted of two parts: a tokenized sentence with NER tags and a target event type. The output o is expected to be 1 if the given sentence conveys an event of the target type, otherwise 0. Next, we describe the structure of this model in bottom-up order.

3.1 Input Tokens

Given a sentence, we use Stanford CoreNLP tools[3](Manning et al., 2014) to convert texts into tokens. The ACE 2005 corpus annotated not only events but also entities for each given sentence. Following previous work, we exploit the annotated entity tags in our model(Li et al., 2013; Chen et al., 2015; Nguyen and Grishman, 2015, 2016; Liu et al., 2016b).

3.2 Word/Entity Embeddings

Word embeddings learned from a large amount of unlabeled data have been shown to be able to capture the meaningful semantic regularities of words(Bengio et al., 2003; Erhan et al., 2010). Much work(Socher et al., 2012; Zeng et al., 2014) has shown its power in many NLP tasks.

In this work, we use the Skip-gram model(Mikolov et al., 2013) to learn word embeddings on the NYT corpus[4]. Furthermore, we randomly initialized an embedding table for each entity tags. All the input word tokens and entity tags will be transformed into low-dimensional vectors by looking up these embedding tables. In this work, we denote the dimension of word embeddings by d_w, and that of entity embeddings by d_e.

3.3 Event Type Embeddings

As illustrated in Figure 1, an event type is transformed into two embedding vectors: $\mathbf{t}_1$ and $\mathbf{t}_2$. The first one (colored with brown) is designed to capture local information (hidden trigger word), and the latter one (colored with red) is designed to capture global information. Both of them are randomly initialized. The dimension of event type embeddings is denoted by d_{evt}.

3.4 LSTM Layer

As shown in Figure 1, the LSTM layer is run over the sequence of concatenation of word and entity embeddings. LSTM has three gates(input i, forget f and output o), and a cell memory vector c. The input gate can determine how incoming vectors $\mathrm{x(t)}$ alter the state of the memory cell. The output gate can allow the memory cell to have an effect on the outputs. Finally, the forget gate allows the cell to remember or forget its previous state.

3.5 Attention Layer

Each type of events are usually triggered by a set of specific words, which are called event trigger words. For example, *Death* events are usually triggered by "die", "passed away", "gone", etc. Therefore, event trigger words are important clues to this task. However, this information is hidden in our task, because annotated triggers are unavailable. To model the hidden triggers, we introduce attention mechanisms in our approach.

As illustrated in Figure 1, the attention vector α is calculated based on the target event type embedding $\mathbf{t}_1$ and the hidden states h yielded by LSTM. Specifically, the attention score for the k-th token in a given sentence is calculated by the following equation:

$$\alpha^k = \frac{\exp(\mathbf{h}_k \cdot \mathbf{t}_1^T)}{\sum_i \exp(\mathbf{h}_i \cdot \mathbf{t}_1^T)} \tag{1}$$

In this model, trigger words of the target event type are expected to obtain higher scores than other words. Finally, the representation of the sentence, $\mathbf{s}_{att}$, is computed by the following equation:

$$\mathbf{s}_{att} = \alpha^T \mathbf{H} \tag{2}$$

where $\alpha = [\alpha_1, ..., \alpha_n]$ is the attention vector, $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n]$ is a matrix, $\mathbf{h}_k$ is the LSTM's output for the k-th token, and $\mathbf{s}_{att}$ is the representation of the given sentence.

3.6 Output Layer

As illustrated in Figure 1, the final output o is connected to two components: v_{att} and v_{global}. On one hand, v_{att} is calculated by the dot product of $\mathbf{s}_{att}$ and $\mathbf{t}_1$, which is designed to capture local features (specifically, features about hidden trigger words). On the other hand, the last output of the LSTM layer, $\mathbf{h}_n$, encodes global information of the whole sentence, thus $v_{global} = \mathbf{h}_n \cdot \mathbf{t}_2^T$ is expected

---

[3] http://stanfordnlp.github.io/CoreNLP

[4] https://catalog.ldc.upenn.edu/LDC2008T19

to capture global features of a sentence. Finally, o is defined as the weighted sum of v_{att} and v_{global}:

$$o = \sigma(\lambda \cdot v_{att} + (1 - \lambda) \cdot v_{global}) \quad (3)$$

where σ is the Sigmoid function, $\lambda \in [0, 1]$ is a hyper-parameter for trade-off between v_{att} and v_{global}.

3.7 Bias Loss Function

We devise a bias loss function to reinforce the influence of positive samples because of the following reasons. 1) **positive samples are much less than negative samples.** In our approach, each training sample is a <sentence,event type> pair, whose label is 1 or 0 according to whether the given sentence conveys an event of type t. For example, we totally have 33 target event types, if a sentence only contains one event, then it will be transformed into 32 negative pairs and 1 positive pair. The majority of sentences convey at most two events, thus negative samples are much more than positive samples. 2) **positive samples are more informative than negatives.** A positive pair $< s, t >$ means that s conveys an event of type t, whereas negative pair means s does not convey any event of type t. Apparently, the former is more informative.

Given all of the (suppose T) training instances $(x^{(i)}, y^{(i)})$, the loss function is defined as follows:

$$J(\theta) = \frac{1}{T}\sum_{i=1}^{T}(o(x^i) - y^{(i)})^2(1 + y^{(i)} \cdot \beta) + \delta||\theta||^2 \quad (4)$$

where x is a pair consisted of a sentence and a target event type, $y \in \{0, 1\}$, θ is the parameter of our model and $\delta > 0$ is the weight of L2 normalization term. $(1 + y^{(i)} \cdot \beta)$ is the bias term. Specifically, the value of this term is 1 for negative samples ($y^{(i)}$ is 0) and 1 + β for positive samples ($y^{(i)}$ is 1), where $\beta \geq 0$.

3.8 Training

We train the model by using a simple optimization technique called stochastic gradient descent (SGD) over shuffled mini-batches with the Adadelta rule (Zeiler, 2012). Regularization is implemented by a dropout and L2 norm.

Given a instance x, the model assign it a label $\widetilde{y}$ according to the following equation:

$$\widetilde{y} = \begin{cases} 0 & o(x) < 0.5 \\ 1 & otherwise \end{cases} \quad (5)$$

where x is a pair $< s, t >$, $o(x)$ is the output of the model for x, and $\widetilde{y}$ is the final predicted result.

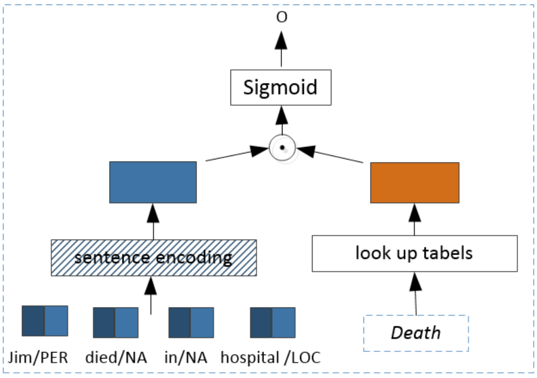

Figure 2: The framework of binary classification based approaches. The output o is expected to be 1 if the given sentence conveys an event of the target type, otherwise 0.

4 Baseline Systems

Since this is the first work to perform event detection without triggers, we implement a series of baseline systems for comparisons, which could be divided into two categories: binary classification based methods and multi-class classification based methods.

4.1 Binary Classification

Similar with the proposed approach, baseline systems in this group solved this task via binary classification. Figure 2 illustrates the framework of these methods. These models take a sentence and a target event type as input. Then all the inputs are transformed into embeddings by looking up embedding tables. These models have the same loss function as the proposed approach (see Equation 4). The key component of these models is sentence encoder. According to the strategy of encoding sentence, we implement three models for comparison: *BC-CNN*, *BC-LSTM*$_{last}$, *BC-LSTM*$_{avg}$.

- *BC-CNN* employs a CNN model to encode sentence.
- *BC-LSTM*$_{last}$ employs LSTM model, and use the hidden state of the last token as the representation of a given sentence.
- *BC-LSTM*$_{avg}$ also employs LSTM model, but use the average of all hidden states as the representation of a given sentence.

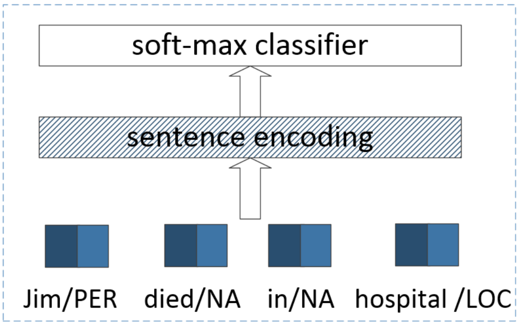

Figure 3: The framework of multi-class classification based approaches.

4.2 Multi-class Classification

All existing approaches model the task of event detection (with triggers) via multi-class classification[5]. Given a sentence, these methods predict whether each token is an event trigger and what type of event it triggered. We also implement several multi-class classification based systems for comparison. Since annotated triggers are unavailable in our task, the sentence is the input of our model. Figure 3 illustrates the framework of these models. Following existing work(Chen et al., 2015; Liu et al., 2017), we employ a negative log-likelihood loss function in the soft-max classifier: $J(\theta) = -\frac{1}{T}\sum_{i=1}^{T}\log(p(y^{(i)}|x^{(i)},\theta))$, where $(x^{(i)}, y^{(i)})$ is a training sample, $y^{(i)}$ is a label from the valid label set (all the predefined event types plus a *NA* for none event), T is the total number of training instances, θ is the parameters of the model. According to the strategy of encoding sentence, we implement three models: *MC-CNN*, $MC\text{-}LSTM_{last}$ and $MC\text{-}LSTM_{avg}$.

- *MC-CNN* employs a CNN model to encode sentence.
- $MC\text{-}LSTM_{last}$ employs LSTM model, and use the hidden state of the last token as the representation of a given sentence.
- $MC\text{-}LSTM_{avg}$ also employs LSTM model, but use the average of all hidden states as the representation of a given sentence.

5 Experimental Results

5.1 Experimental Setup

In this section, we introduce the dataset, evaluation metrics and the settings of hyper parameters.

5.1.1 Dataset

Our experiments are conducted on ACE 2005 dataset. Following the evaluation of previous work(Li et al., 2013; Chen et al., 2015; Nguyen and Grishman, 2016; Liu et al., 2017), we randomly selected 30 articles from different genres as the development set, and subsequently conducted a blind test on a separate set of 40 ACE 2005 newswire documents. We used the remaining 529 articles as our training set.

This work focuses on detecting events without triggers. Therefore, we remove trigger annotations from the corpus. Specifically, we employ Stanford CoreNLP Toolkit to split each document into sentences, and assign each sentence with a set of labels according to the original annotations in ACE 2005 corpus. If a sentence does not contain any event, we assign it with a special label, *NA*. If a sentence contains multiple events of the same type (less than 3% in ACE corpus), we only keep one label for each type. Table 2 shows several samples of the our corpus.

sentence	labels
They got married in 1985.	{*Marry*}
They got married in 1985, and divorced 3 years latter.	{*Marry*, *Divorce*}
They are very happy every day.	{*NA*}

Table 2: Examples of instances in our corpus (without event trigger annotations).

5.1.2 Evaluation Metrics

Following previous work (Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Liu et al., 2017), we use precision (P), recall (R) and F_1-measure (F_1) to evaluate the results.

Precision: the proportion of correctly predicted events in total predicted events.

Recall: the proportion of correctly predicted events in total gold events of the dataset.

F_1-measure: $\frac{2\times P\times R}{P+R}$

5.1.3 Hyper Parameters

Hyper parameters are tuned on the development dataset via grid search. In all experiments, we

---

[5] Multi-class classification means a classification task with more than two classes, but each sample belongs to only one class. "multi-class" is different from "multi-label".

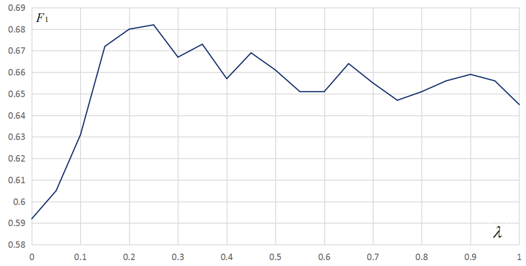

Figure 4: Experimental results on development dataset with different setting of λ.

methods	**P(%)**	**R(%)**	**F_1(%)**
MC-CNN	73.3	46.3	56.8
BC-CNN	**76.6**	**52.9**	**62.6**
MC-LSTM$_{last}$	57.9	42.3	48.9
BC-LSTM$_{last}$	**69.8**	**52.2**	**59.7**
MC-LSTM$_{avg}$	60.3	42.7	50.0
BC-LSTM$_{avg}$	**68.1**	**49.2**	**57.1**

Table 3: Experimental results on ACE 2005 corpus. Methods with name *MC-** are based on multi-class classification, and methods with name *BC-** are based on binary classification.

set the dimension of word embeddings as 200, the dimension of entity type embeddings as 50, batch size as 100, the hyper parameter for the L_2 norm as 10^{-5}, β in the bias term as 1.0. Furthermore, we also tune λ in Equation 3 on the development dataset. Figure 4 illustrates experimental results with different settings of λ, finally we set λ as 0.25. And in all the CNN-based baseline systems, the sizes of filter windows are set to 1, 2, 3 with 100 feature maps each.

5.2 Multi-class Classification vs. Binary Classification

Table 3 illustrates the experimental results, where methods with name *MC-** are based on multi-class classification, and methods with name *BC-** are based on binary classification. According to the strategy to encode a sentence, methods in Table 3 are grouped into three parts. From the table, we make the following observations:

- In each group, binary classification based approach significantly outperforms multi-class classification based approach. The reason is that *BC-** can solve the multi-label problem, but *MC-** can not. Moreover, *MC-** achieve much lower recall than *BC-**, because they predict at most one event for each sentence.

methods	**P(%)**	**R(%)**	**F_1(%)**
BC-CNN	76.6	52.9	62.6
BC-LSTM$_{last}$	69.8	52.2	59.7
BC-LSTM$_{avg}$	68.1	49.2	57.1
BC-LSTM$_{att}$	68.3	64.5	66.3
our TBNNAM	76.2	64.5	**69.9**
Nguyen's CNN†	71.8	66.4	69.0
Chen's DMCNN†	75.6	63.6	69.1
Liu's PSL†	75.3	64.4	69.4
DS-DMCNN‡†	75.7	66.0	70.5

Table 4: Experimental results on ACE 2005 corpus. Methods in the first group are baseline systems. Methods in the second group are the proposed approaches. Methods in the last group are state-of-the-art ED systems. † requiring annotated triggers, ‡ using external data

- Methods with CNN as sentence encoder achieve better performance than that with LSTM. The reason is that trigger words are important clues to event detection, and CNN is good at extracting such local features.

5.3 Overall Performances

In this section, we illustrates the results of the proposed approach (see Table 4). The results of baseline systems are listed in the first group. Methods in the second group are the proposed approaches. They have the same model structure as Figure 1. In *BC-LSTM*$_{att}$, λ (see Equation 3) is set as 1.0, which is designed to show the effects of the proposed attention strategy. In *TBNNAM*, λ is set as 0.25, which is designed to employ both local information (captured by the attention mechanism) and global information (captured by the last output of LSTM). Methods in the last group are state-of-the-art ED systems on ACE 2005 dataset. We give a brief introduction of them as follows:

1). *Nguyen's CNN*: the CNN model proposed by Nguyen and Grishman (2015)

2). *Chen's DMCNN*: the dynamic multi-pooling CNN model proposed by Chen et al. (2015)

3). *Liu's PSL*: the soft probabilistic soft logic model proposed by Liu et al. (2016b)

4). *DS-DMCNN*: the DMCNN model augmented with automatic labeled data, proposed by Chen et al. (2017)

From the table, we make the following observations:

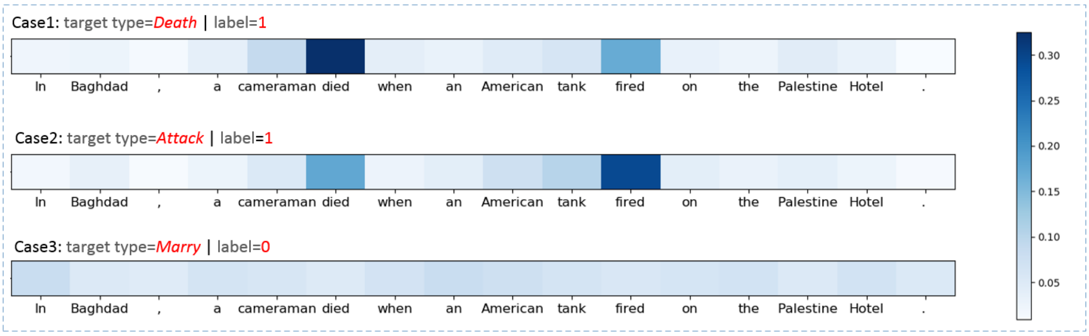

Figure 5: Visualization of attention weight vector α of sample instances learned by our model.

- *BC-LSTM*$_{att}$ outperforms all the baseline systems with remarkable gains, which demonstrates the effectiveness of the proposed attention mechanism.

- *TBNNAM* achieves better performance than *BC-LSTM*$_{att}$ (69.9% vs. 66.3%), which means that global information captured by the last state of LSTM is also important to this task. Such global information and local information captured by the attention mechanisms are complementary to each other.

- All state-of-the-art ED systems require annotated triggers. Without trigger annotations, our approach achieves competitive results, even outperforms some of them.

5.4 Analysis of Weight α

Figure 5 shows several examples of the attention vector α learned by our model. In the first case, “died” is the most significant keyword for the *Death* event, and our model succeeded to capture this feature by assigning it with a large attention score. Similarly, in the second case, “fired” is a key clue of *Attack* event, and our model also learned it and assigned it with a large attention score. Actually, “died” and “fired” are the trigger words of *Death* and *Attack* events, respectively. Therefore, we argue that, although annotated triggers are unavailable, our model still can exploit trigger information for this task. Moreover, our approach also could model the dependencies among different events, which has been demonstrated useful for this task(Liao and Grishman, 2010; Liu et al., 2016b). For example, *Attack* events often co-occur with *Death* events. In Case1 and Case2 (Figure 5), our approach models such information by paying attention on both words “died” and “fired”. Furthermore, the 3-rd case is a negative sample, thus there is no key clues. Our model assigned each token with nearly equivalent attention score.

methods	**P(%)**	**R(%)**	**F$_1$(%)**
BC-LSTM$_{att}\setminus$*Bias*	**74.5**	57.2	64.7
BC-LSTM$_{att}$	68.3	**64.5**	**66.3**
TBNNAM$\setminus$*Bias*	**76.6**	59.8	67.2
TBNNAM	76.2	**64.5**	**69.9**

Table 5: Results of systems without/with bias term in loss function, where *$\setminus$*Bias* do not use bias term.

5.5 Effects of Bias Term in Loss Function

In this section, we illustrates the effectiveness of the bias term in Equation 4. Table 5 shows experimental results. Methods named with “*$\setminus$*Bias*” do not use bias term. From the table, we observe that systems with bias term in loss function significantly outperform those without bias term, which demonstrates the correctness of our analysis in Section 3.7 that positive samples should be reinforced during training.

6 Conclusions

Existing event detection approaches required annotated triggers, which limits their applications because of the expensive annotations. To reduce manual effort, we investigate performing this task without event triggers. In this setting, event detection task encounters two challenges: multi-label problem and trigger absence problem. We propose a simple but effective model to solve them, which computes the representation of a sentence according to the target event type. Experimental results demonstrate its effectiveness. Remarkably, the proposed approach even achieves competitive performances compared with state-of-the-arts that used annotated triggers.

Sub-Event Detection from Twitter Streams as a Sequence Labeling Problem

Giannis Bekoulis **Johannes Deleu** **Thomas Demeester** **Chris Develder**
Ghent University - imec, IDLab
Department of Information Technology
`firstname.lastname@ugent.be`

Abstract

This paper introduces improved methods for sub-event detection in social media streams, by applying neural sequence models not only on the level of individual posts, but also directly on the stream level. Current approaches to identify sub-events within a given event, such as a goal during a soccer match, essentially do not exploit the sequential nature of social media streams. We address this shortcoming by framing the sub-event detection problem in social media streams as a sequence labeling task and adopt a neural sequence architecture that explicitly accounts for the chronological order of posts. Specifically, we (i) establish a neural baseline that outperforms a graph-based state-of-the-art method for binary sub-event detection (2.7% micro-F_1 improvement), as well as (ii) demonstrate superiority of a recurrent neural network model on the posts sequence level for labeled sub-events (2.4% bin-level F_1 improvement over non-sequential models).

1 Introduction

Social media allow users to communicate via real-time postings and interactions, with Twitter as a notable example. Twitter user posts, i.e., tweets, are often related to events. These can be social events (concerts, research conferences, sports events, etc.), emergency situations (e.g., terrorist attacks) (Castillo, 2016), etc. For a single event, multiple tweets are posted, by people with various personalities and social behavior. Hence, even more so than (typically more neutral) traditional media, this implies many different perspectives, offering an interesting aggregated description.

Given this continuous and large stream of (likely duplicated) information in Twitter streams, and their noisy nature, it is challenging to keep track of the main parts of an event, such as a soccer match. Automating such extraction of different sub-events within an evolving event is known as sub-event detection (Nichols et al., 2012). For tracking each of the sub-events, the timing aspect is an important concept (i.e., consecutive tweets in time). Thus, a sequential model could successfully exploit chronological relations between the tweets in a Twitter stream as an informative feature for sub-event detection.

Several methods have been proposed for sub-event detection: clustering methods (Pohl et al., 2012), graph-based approaches (Meladianos et al., 2015), topic models (Xing et al., 2016) and neural network architectures (Wang and Zhang, 2017). None of these studies exploits the chronological relation between consecutive tweets. In contrast, our work does take into account that chronological order and we predict the presence and the type of a sub-event exploiting information from previous tweets. Specifically, we (i) propose a new neural baseline model that outperforms the state-of-the-art performance on the binary classification problem of detecting the presence/absence of sub-events in a sports stream, (ii) establish a new reasonable baseline for predicting also the sub-event *types*, (iii) explicitly take into account chronological information, i.e., the relation among consecutive tweets, by framing sub-event detection as a sequence labeling problem on top of our baseline model, and (iv) perform an experimental study, indicating the benefit of sequence labeling for sub-event detection in sports Twitter streams.

2 Related Work

Twitter streams have been extensively studied in various contexts, such as sentiment analysis (Kouloumpis et al., 2011), stock market prediction (Nguyen and Shirai, 2015) and traffic detection (D'Andrea et al., 2015). Specifically, for sub-event detection in Twitter, several approaches

Proceedings of NAACL-HLT 2019, pages 745–750
Minneapolis, Minnesota, June 2 - June 7, 2019.

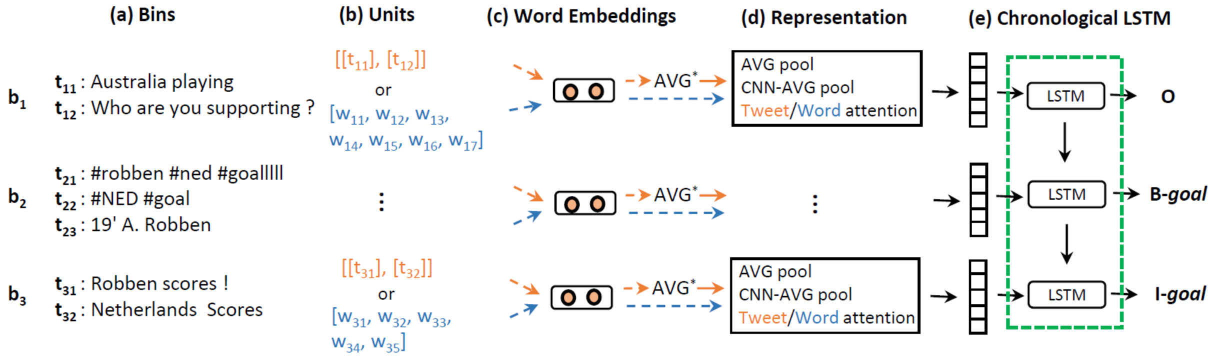

Figure 1: Our sub-event detection model comprises: (a) a bin layer, (b) a unit layer, (c) a word embeddings layer, (d) a representation layer and (e) a **chronological LSTM** layer to model the natural flow of the sub-events within the event. We represent each bin using either (i) a **tweet**- or (ii) a **word**-level representation. The AVG* represents an average pool operation, performed either directly on the embeddings or on the tweet's LSTM representation.

have been tried. *Unsupervised methods* such as clustering aim to group similar tweets to detect specific sub-events (Pohl et al., 2012; Abhik and Toshniwal, 2013) and use simple representations such as tf-idf weighting combined with a similarity measure. Other unsupervised algorithms use topic modeling approaches, based on assumptions about the tweets' generation process (Xing et al., 2016; Srijith et al., 2017). Several methods (Zhao et al., 2011; Zubiaga et al., 2012; Nichols et al., 2012) assume that a sub-event happens when there is a 'burst', i.e., a sudden increase in the rate of tweets on the considered event, with many people commenting on it. Recently, neural network methods have used more complicated representations (Wang and Zhang, 2017; Chen et al., 2018). Also *supervised methods* have been applied (Sakaki et al., 2010; Meladianos et al., 2018) for the sub-event detection task. These methods usually exploit graph-based structures or tf-idf weighting schemes. We believe to be the first to (i) exploit the chronological order of the Twitter stream and take into account its sequential nature, and (ii) frame the sub-event detection problem as a sequence labeling task.

3 Model

3.1 Task Definition

The goal is, given a main event (i.e., soccer match), to identify its core sub-events (e.g., goals, kick-off, yellow cards) from Twitter streams. Specifically, we consider a *supervised* setting, relying on annotated data (Meladianos et al., 2018).

3.2 Word- vs Tweet-Level Representations

Similar to previous works, we split a data stream into time periods (Meladianos et al., 2018): we form bins of tweets posted during consecutive time intervals. E.g., for a soccer game, one-minute intervals (bins) lead to more than 90 bins, depending on the content before and after the game, halftime, stoppage time, and possibly some pre-game and post-game buffer. Thus, for each bin, we predict either the presence/absence of a sub-event (Section 3.3) or the most probable sub-event type (Section 3.4), depending on the evaluation scenario.

We consider representing the content of each bin either on (i) a word-level or (ii) a tweet-level (see Fig. 1). Formally, we assume that we have a set of n bins $b_1, ..., b_n$, where each bin b_i consists of m_i tweets and k_i words (i.e., all words of tweets in bin b_i). Then, the *tweet-level representation* of bin b_i is symbolized as $t_{i1}, ..., t_{im_i}$, where t_{im_i} is the m_i^{th} tweet of bin b_i. In the *word-level representation*, we chronologically concatenate the words from the tweets in the bin: $w_{i1}, .., w_{ik_i}$, where w_{ik_i} is the k_i^{th} word of bin b_i.

3.3 Binary Classification Baseline

To compare with previous work (Meladianos et al., 2018), we establish a simple baseline for binary classification: presence/absence of a sub-event. For this case, we use as input the word-level representation of each bin. To do so, we use word embeddings (randomly initialized) with average (AVG) pooling (Iyyer et al., 2015) in combination with a multilayer perceptron (MLP) for binary classification, i.e., presence/absence of a sub-event. Note that we experimented with pre-trained embeddings as well as max-pooling, but those early experiments led to performance decrease compared to the presented baseline model. We found that training based on average bin representations works substantially better than with max-pooling, and we hypothesize that this is related to the noisy nature of the Twitter stream.

3.4 Sequence Labeling Approach

Building on the baseline above, we establish a new architecture that is able to capture the sub-event types as well as their duration. We phrase sub-event detection in Twitter streams as a sequence labeling problem. This means we assume that the label of a bin is not independent of neighboring bin labels, given the chronological order of bins of the Twitter stream, as opposed to independent prediction for each bin in the binary classification baseline above. For instance, when a *goal* is predicted as a label for bin b_i, then it is probable that the label of the next bin b_{i+1} will also be *goal*. Although a sub-event may occur instantly, an identified sub-event in a Twitter stream can span consecutive bins, i.e., minutes: users may continue tweeting on a particular sub-event for relatively long time intervals. For this reason, we apply the well-known BIO tagging scheme (Ramshaw and Marcus, 1995) for the sub-event detection problem. For example, the beginning of a *goal* sub-event is defined as B-*goal*, while I-*goal* (inside) is assigned to every consecutive bin within the same sub-event, and the O tag (outside) to every bin that is not part of any sub-event. To propagate chronological information among bins, we adopt an LSTM on the sequence of bins as illustrated in Fig. 1, layer (e). Note that this tagging approach assumes that sub-events do not overlap in time, i.e., only at most one is ongoing in the Twitter stream at any point in time.

4 Experimental Setup

We evaluated our system[1] on the dataset from Meladianos et al. (2018), with tweets on 20 soccer matches from the 2010 and 2014 FIFA World Cups, totalling over 2M pre-processed tweets filtered from 6.1M collected ones, comprising 185 events. The dataset includes a set of sub-events, such as *goal*, *kick-off*, *half-time*, etc. To compare our binary classification *baseline system* to previous methods (Table 1), we use the same train/test splits as Meladianos et al. (2018), where 3 matches are used for training and 17 matches as test set. In this setting, we predict only the presence/absence of a sub-event. Similar to previous work, we count a sub-event as correct if at least one of its comprising bins has been classified as a sub-event. For the experimental study of our proposed *sequence labeling approach* for sub-event detection, where sub-event types are predicted, we have randomly split the test set into test (10 matches) and development (7 matches) sets. We use the development set to optimize the F_1 score for tuning of the model parameters, i.e., the word/tweet embedding representation size, LSTM hidden state size, dropout probability. We adopt 2 evaluation strategies. The first one, referred to as *relaxed* evaluation, is commonly used in entity classification tasks (Adel and Schütze, 2017; Bekoulis et al., 2018a,c) and similar to the binary classification baseline system evaluation: score a multi-bin sub-event as correct if at least one of its comprising bin types (e.g., *goal*) is correct, assuming that the boundaries are given. The second evaluation strategy, *bin-level*, is stricter: we count each bin individually, and check whether its sub-event type has been predicted correctly, similar to the token-based evaluation followed in Bekoulis et al. (2018b).

5 Results

5.1 Baseline Results

Table 1 shows the experimental results of our baseline model. The Burst baseline system is based on the tweeting rate in a specific time window (i.e., bin) and if a threshold is exceed, the system identifies that a sub-event has occurred. We report evaluation scores as presented in Meladianos et al. (2018). The second approach is the graph-based method of Meladianos et al. (2018). We observe that our baseline system (Section 3.3) has a 1.2% improvement in terms of macro-F_1 and 2.7% improvement in terms of micro-F_1, compared to the graph-based model from Meladianos et al. (2018), mainly due to increased precision, and despite the recall loss.

5.2 Sequence Labeling Results

Table 2 illustrates the predictive performance of our proposed model (i.e., using the chronological

---

[1] `https://github.com/bekou/subevent_sequence_labeling`

LSTM) compared to models making independent predictions per bin. The upper part of Table 2 contains models without the chronological LSTM. Our experiments study both *word-level* and *tweet-level* bin representations (see Fig. 1), as reflected in the 'Word' vs. 'Tweet' prefix, respectively, in the Model column of Table 2.

The simplest *word-level* representation uses the tf-idf weighting scheme (as in Pohl et al. (2012)) followed by an MLP classifier. For the other word-level models, we exploit several architectures: AVG pooling (Iyyer et al., 2015), a CNN followed by AVG pooling (Kim, 2014) and hierarchical word-level attention (Yang et al., 2016).

For *tweet-level* representations, we adopt similar architectures, where the AVG, CNNs and attention are performed on sentence level rather than on the word-level representation of the bin. In this scenario, we have also exploited the usage of sequential LSTMs to represent the tweets. When comparing models with and without tweet-level LSTMs, we report the strategy that yields the best results, indicated by ✓ and ✗ in the tweet-level LSTM (TL) columns of Table 2. We do not present results for applying sequential LSTMs on the word-level bin representation, because of slow training on the long word sequences.

Benefit of Chronological LSTM: The bottom part of Table 2 presents the results of the same models followed by a chronological LSTM to capture the natural flow of the stream as illustrated in Fig. 1. We report results as described in Section 4, using the micro F_1 score with the two evaluation strategies (*bin-level* and *relaxed*). We observe that when using the chronological LSTM, the performance in terms of *bin-level* F_1 score is substantially improved for almost every model. Note that the best model using the chronological LSTM (Tweet-AVG) achieves 2.4% better F_1 than the best performing model without the use of chronological LSTM (Word-CNN-AVG). In most cases there is also a consistent improvement for both the precision and the recall metrics, which is thanks to the sequential nature of the upper level LSTM capturing the flow of the text.

Table 2: Comparison of our baseline methods in terms of micro *bin-level* and *relaxed* F_1 score with and without chronological LSTM (see Fig. 1). The ✓and ✗ indicate whether the model uses a tweet-level LSTM (TL).

Limitations of *Relaxed* Evaluation: On the other hand, using the *relaxed* evaluation strategy, we observe that the best models are those without the chronological LSTM layer. Yet, we consider the *relaxed* evaluation strategy flawed for our scenario, despite the fact that it has been used for entity classification tasks (Bekoulis et al., 2018a; Adel and Schütze, 2017). Indeed, it is not able to properly capture sub-events which are characterized by duration: e.g., if a model assigns a different label to each of the bins that together constitute a single sub-event, then this sub-event counts as a true positive based on the *relaxed* evaluation strategy (similar to the evaluation proposed by Meladianos et al. (2018) and followed in Table 1). Thus, in this work, we propose to use the *bin-level* evaluation, since it is a more natural way to measure the duration of a sub-event in a supervised sequence labeling setting. Note that due to the noisy nature of Twitter streams, a tweet sequence spanning a particular sub-event is likely to contain also tweets that are not related to the given sub-event: a given bin inside the event may contain only a minority of tweets discussing the event. Therefore, we consider the standard sequence labeling evaluation (requiring to have types as well as boundaries correct) to be not applicable in sub-event detection.

Performance Comparison of the Top-3 Models: Figure 2 shows the performance of our three best performing models in terms of *bin-level* F_1 score on the validation set. The best performing model is the Tweet-AVG model since it attains its maximum performance even from the first training epochs. The Word-AVG model performs well

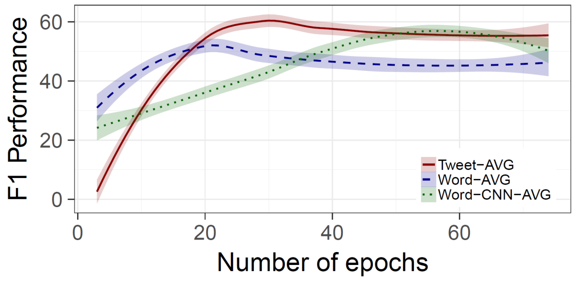

Figure 2: *Bin-level* F_1 performance of the three best performing models on the validation set with respect to the number of epochs. The smoothed lines (obtained by LOWESS smoothing) model the trends and the 95% confidence intervals.

from the first epochs, showing similar behavior to the Tweet-AVG model. This can be explained by the similar nature of the two models. The word-level CNN model attains maximum performance compared to the other two models in later epochs. Overall, we propose the use of the chronological LSTM with the Tweet-AVG model since this model does not rely on complex architectures and it gives consistent results.

6 Conclusion

In this work, we frame the problem of sub-event detection in Twitter streams as a sequence labeling task. Specifically, we (i) propose a binary classification baseline model that outperforms state-of-the-art approaches for sub-event detection (presence/absence), (ii) establish a strong baseline that additionally predicts sub-event *types*, and then (iii) extend this baseline model with the idea of exchanging chronological information between sequential posts, and (iv) prove it to be beneficial in almost all examined architectures.

Acknowledgements

We would like to thank the anonymous reviewers for their constructive feedback. Moreover, we would like to thank Christos Xypolopoulos and Giannis Nikolentzos for providing (i) the Twitter dataset (tweet ids) and (ii) instructions to reproduce the results of their graph-based approach.

Abstract

Most modern Information Extraction (IE) systems are implemented as sequential taggers and only model local dependencies. Non-local and non-sequential context is, however, a valuable source of information to improve predictions. In this paper, we introduce GraphIE, a framework that operates over a graph representing a broad set of dependencies between textual units (i.e. words or sentences). The algorithm propagates information between connected nodes through graph convolutions, generating a richer representation that can be exploited to improve word-level predictions. Evaluation on three different tasks — namely textual, social media and visual information extraction — shows that GraphIE consistently outperforms the state-of-the-art sequence tagging model by a significant margin.[1]

1 Introduction

Most modern Information Extraction (IE) systems are implemented as sequential taggers. While such models effectively capture relations in the local context, they have limited capability of exploiting non-local and non-sequential dependencies. In many applications, however, such dependencies can greatly reduce tagging ambiguity, thereby improving overall extraction performance. For instance, when extracting entities from a document, various types of non-local contextual information such as co-references and identical mentions may provide valuable cues. See for example Figure 1, in which the non-local relations are crucial to discriminate the entity type of the second mention of *Washington* (i.e. PERSON or LOCATION).

Most of the prior work looking at the non-local dependencies incorporates them by constraining the output space in a structured prediction framework (Finkel et al., 2005; Reichart and Barzilay, 2012; Hu et al., 2016). Such approaches, however, mostly overlook the richer set of structural relations in the input space. With reference to the example in Figure 1, the co-referent dependencies would not be readily exploited by simply constraining the output space, as they would not necessarily be labeled as entities (e.g. pronouns). In the attempt to capture non-local dependencies in the input space, alternative approaches define a graph that outlines the input structure and engineer features to describe it (Quirk and Poon, 2017). Designing effective features is however challenging, arbitrary and time consuming, especially when the underlying structure is complex. Moreover, these approaches have limited capacity of capturing node interactions informed by the graph structure.

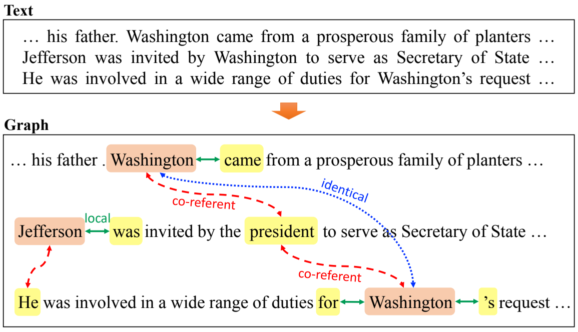

Figure 1: Example of the entity extraction task with an ambiguous entity mention (i.e. "...for Washington's request..."). Aside from the sentential forward and backward edges (green, solid) which aggregate local contextual information, non-local relations — such as the co-referent edges (red, dashed) and the identical-mention edges (blue, dotted) — provide additional valuable information to reduce tagging ambiguity (i.e. PERSON or LOCATION). Best viewed in color.

In this paper, we propose GraphIE, a framework

Minneapolis, Minnesota, June 2 - June 7, 2019.

that improves predictions by automatically learning the interactions between local and non-local dependencies in the input space. Our approach integrates a graph module with the encoder-decoder architecture for sequence tagging. The algorithm operates over a graph, where nodes correspond to textual units (i.e. words or sentences) and edges describe their relations. At the core of our model, a recurrent neural network sequentially encodes local contextual representations and then the graph module iteratively propagates information between neighboring nodes using graph convolutions (Kipf and Welling, 2016). The learned representations are finally projected back to a recurrent decoder to support tagging at the word level.

We evaluate GraphIE on three IE tasks, namely textual, social media, and visual (Aumann et al., 2006) information extraction. For each task, we provide in input a simple task-specific graph, which defines the data structure without access to any major processing or external resources. Our model is expected to learn from the relevant dependencies to identify and extract the appropriate information. Experimental results on multiple benchmark datasets show that GraphIE consistently outperforms a strong and commonly adopted sequential model (SeqIE, i.e. a bi-directional long-short term memory (BiLSTM) followed by a conditional random fields (CRF) module). Specifically, in the textual IE task, we obtain an improvement of 0.5% over SeqIE on the CoNLL03 dataset, and an improvement of 1.4% on the chemical entity extraction (Krallinger et al., 2015). In the social media IE task, GraphIE improves over SeqIE by 3.7% in extracting the EDUCATION attribute from twitter users. In visual IE, finally, we outperform the baseline by 1.2%.

2 Related Work

The problem of incorporating non-local and non-sequential context to improve information extraction has been extensively studied in the literature. The majority of methods have focused on enforcing constraints in the output space during inference, through various mechanisms such as posterior regularization or generalized expectations (Finkel et al., 2005; Mann and McCallum, 2010; Reichart and Barzilay, 2012; Li et al., 2013; Hu et al., 2016).

Research capturing non-local dependencies in the input space have mostly relied on feature-based approaches. Roberts et al. (2008) and Swampillai and Stevenson (2011) have designed intra- and inter-sentential features based on discourse and syntactic dependencies (e.g., shortest paths) to improve relation extraction. Quirk and Poon (2017) used document graphs to flexibly represent multiple types of relations between words (e.g., syntactic, adjacency and discourse relations).

Graph-based representations can be also learned with neural networks. The most related work to ours is the graph convolutional network by Kipf and Welling (2016), which was developed to encode graph structures and perform node classification. In our framework, we adapt GCN as an intermediate module that learns non-local context, which — instead of being used directly for classification — is projected to the decoder to enrich local information and perform sequence tagging.

A handful of other information extraction approaches have used graph-based neural networks. Miwa and Bansal (2016) applied Tree LSTM (Tai et al., 2015) to jointly represent sequences and dependency trees for entity and relation extraction. On the same line of work, Peng et al. (2017) and Song et al. (2018) introduced Graph LSTM, which extended the traditional LSTM to graphs by enabling a varied number of incoming edges at each memory cell. Zhang et al. (2018) exploited graph convolutions to pool information over pruned dependency trees, outperforming existing sequence and dependency-based neural models in a relation extraction task. These studies differ from ours in several respects. First, they can only model word-level graphs, whereas our framework can learn non-local context either from word- or sentence-level graphs, using it to reduce ambiguity during tagging at the word level. Second, all these studies achieved improvements only when using dependency trees. We extend the graph-based approach to validate the benefits of using other types of relations in a broader range of tasks, such as co-reference in named entity recognition, *followed-by* link in social media, and layout structure in visual information extraction.

3 Problem Definition

We formalize information extraction as a sequence tagging problem. Rather than simply modeling inputs as sequences, we assume there exists a graph structure in the data that can be exploited to cap-

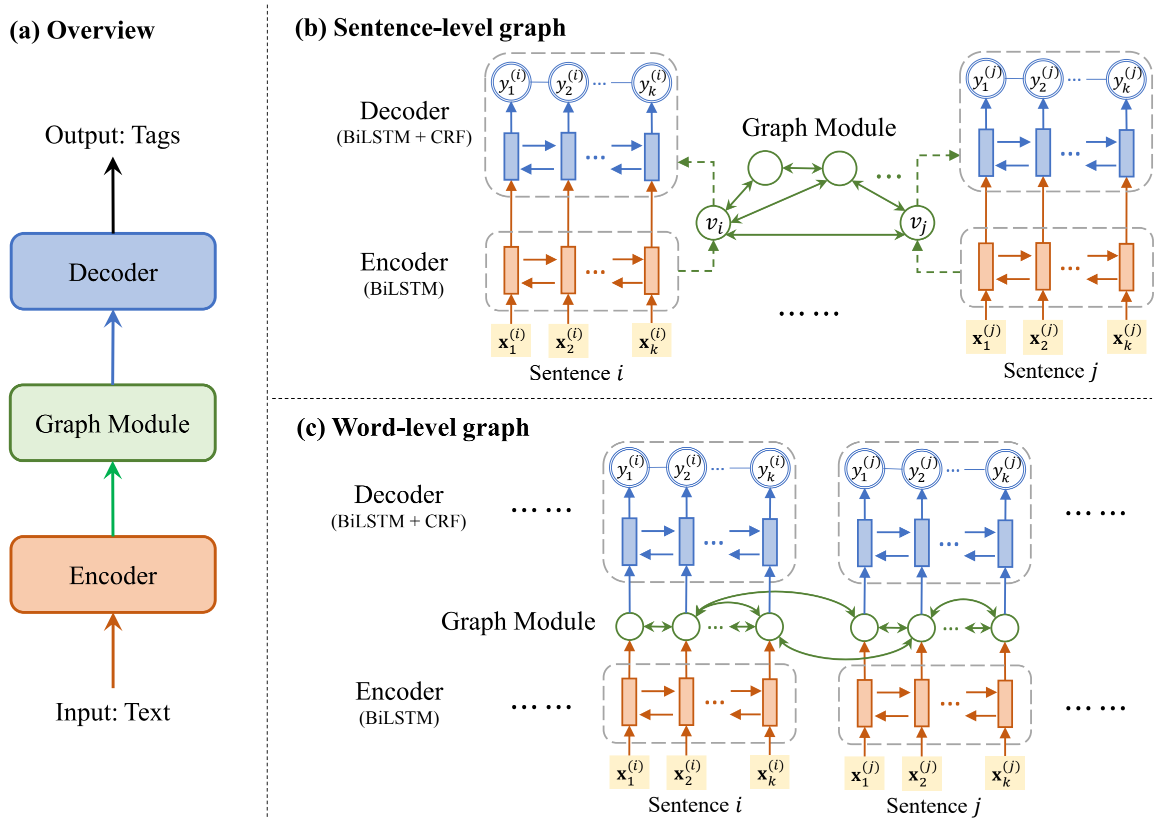

Figure 2: GraphIE framework: (a) an overview of the framework; (b) architecture for *sentence-level graph*, where each sentence is encoded to a node vector and fed into the graph module, and the output of the graph module is used as the initial state of the decoder; (c) architecture for *word-level graph*, where the hidden state for each word of the encoder is taken as the input node vector of the graph module, and then the output is fed into the decoder.

ture non-local and non-sequential dependencies between textual units, namely words or sentences.

We consider the input to be a set of sentences $S = \{s_1, \ldots, s_N\}$ and an auxiliary graph $G = (V, E)$, where $V = \{v_1, \ldots, v_M\}$ is the node set and $E \subset V \times V$ is the edge set. Each sentence is a sequence of words. We consider two different designs of the graph:

(1) *sentence-level graph*, where each node is a sentence (i.e. $M = N$), and the edges encode sentence dependencies;

(2) *word-level graph*, where each node is a word (i.e. M is the number of words in the input), and the edges connect pairs of words, such as co-referent tokens.

The edges $e_{i,j} = (v_i, v_j)$ in the graph can be either directed or undirected. Multiple edge types can also be defined to capture different structural factors underlying the task-specific input data.

We use the BIO (Begin, Inside, Outside) tagging scheme in this paper. For each sentence $s_i = (w_1^{(i)}, w_2^{(i)}, \ldots, w_k^{(i)})$,[2] we sequentially tag each word as $\mathbf{y}_i = (y_1^{(i)}, y_2^{(i)}, \ldots, y_k^{(i)})$.

4 Method

GraphIE jointly learns local and non-local dependencies by iteratively propagating information between node representations. Our model has three components:

- an *encoder*, which generates local context-aware hidden representations for the textual unit (i.e. word or sentence, depending on the task) with a recurrent neural network;
- a *graph module*, which captures the graph structure, learning non-local and non-sequential dependencies between textual units;
- a *decoder*, which exploits the contextual information generated by the graph module to perform labelling at the word level.

---

[2] While sentences may have different lengths, for notation simplicity we use a single variable k.

Figure 2 illustrates the overview of GraphIE and the model architectures for both sentence- and word-level graphs. In the following sections, we first introduce the case of the sentence-level graph, and then we explain how to adapt the model for the word-level graph.

4.1 Encoder

In GraphIE, we first use an encoder to generate text representations. Given a sentence $s_i = (w_1^{(i)}, w_2^{(i)}, \dots, w_k^{(i)})$ of length k, each word $w_t^{(i)}$ is represented by a vector $\mathbf{x}_t^{(i)}$, which is the concatenation of its word embedding and a feature vector learned with a character-level convolutional neural network (CharCNN; Kim et al. (2016)). We encode the sentence with a recurrent neural network (RNN), defining it as

$$\mathbf{h}_{1:k}^{(i)} = \mathtt{RNN}\left(\mathbf{x}_{1:k}^{(i)}\,; \mathbf{0}, \Theta_{\text{enc}}\right), \tag{1}$$

where $\mathbf{x}_{1:k}^{(i)}$ denotes the input sequence $[\mathbf{x}_1^{(i)}, \cdots, \mathbf{x}_k^{(i)}]$, $\mathbf{h}_{1:k}^{(i)}$ denotes the hidden states $[\mathbf{h}_1^{(i)}, \cdots, \mathbf{h}_k^{(i)}]$, $\mathbf{0}$ indicates the initial hidden state is zero, and Θ_{enc} represents the encoder parameters. We implement the RNN as a bi-directional LSTM (Hochreiter and Schmidhuber, 1997), and encode each sentence independently.

We obtain the sentence representation for s_i by averaging the hidden states of its words, i.e. $\mathtt{Enc}(s_i) = \frac{1}{k}\left(\sum_{t=1}^{k} \mathbf{h}_t^{(i)}\right)$. The sentence representations are then fed into the graph module.

4.2 Graph Module

The graph module is designed to learn the non-local and non-sequential information from the graph. We adapt the graph convolutional network (GCN) to model the graph context for information extraction.

Given the sentence-level graph $G = (V, E)$, where each node v_i (i.e. sentence s_i) has the encoding $\mathtt{Enc}(s_i)$ capturing its local information, the graph module enriches such representation with neighbor information derived from the graph structure.

Our graph module is a GCN which takes as input the sentence representation, i.e. $\mathbf{g}_i^{(0)} = \mathtt{Enc}(s_i)$, and conducts graph convolution on every node, propagating information between its neighbors, and integrating such information into a new hidden representation. Specifically, each layer of GCN has two parts. The first gets the information of each node from the previous layer, i.e.

$$\boldsymbol{\alpha}_i^{(l)} = \mathbf{W}_v^{(l)}\, \mathbf{g}_i^{(l-1)}, \tag{2}$$

where $\mathbf{W}_v^{(l)}$ is the weight to be learned. The second aggregates information from the neighbors of each node, i.e. for node v_i, we have

$$\boldsymbol{\beta}_i^{(l)} = \frac{1}{d(v_i)} \cdot \mathbf{W}_e^{(l)} \left(\sum_{e_{i,j} \in E} \mathbf{g}_j^{(l-1)} \right), \tag{3}$$

where $d(v_i)$ is the degree of node v_i (i.e. the number of edges connected to v_i) and is used to normalize $\boldsymbol{\beta}_i^{(l)}$, ensuring that nodes with different degrees have representations of the same scale.[3] In the simplest case, where the edges in the graph are undirected and have the same type, we use the same weight $\mathbf{W}_e^{(l)}$ for all of them. In a more general case, where multiple edge types exist, we expect them to have different impacts on the aggregation. Thus, we model these edge types with different weights in Eq. 3, similar to the relational GCN proposed by Schlichtkrull et al. (2018). When edges are directed, i.e. edge $e_{i,j}$ is different from $e_{j,i}$, the propagation mechanism should mirror such difference. In this case, we consider directed edges as two types of edges (forward and backward), and use different weights for them.

Finally, $\boldsymbol{\alpha}_i^{(l)}$ and $\boldsymbol{\beta}_i^{(l)}$ are combined to obtain the representation at the l-th layer,

$$\mathbf{g}_i^{(l)} = \sigma\left(\boldsymbol{\alpha}_i^{(l)} + \boldsymbol{\beta}_i^{(l)} + b^{(l)}\right), \tag{4}$$

where $\sigma(\cdot)$ is the non-linear activation function, and $b^{(l)}$ is a bias parameter.

Because each layer only propagates information between directly connected nodes, we can stack multiple graph convolutional layers to get a larger receptive field, i.e. each node can be aware of more distant neighbors. After L layers, for each node v_i we obtain a contextual representation, $\mathtt{GCN}(s_i) = \mathbf{g}_i^{(L)}$, that captures both local and non-local information.

4.3 Decoder

To support tagging, the learned representation is propagated to the decoder.

---

[3] We choose this simple normalization strategy instead of the two-sided normalization in Kipf and Welling (2016), as it performs better in the experiments. The same strategy is also adopted by Zhang et al. (2018).

In our work, the decoder is instantiated as a BiLSTM+CRF tagger (Lample et al., 2016). The output representation of the graph module, $\mathtt{GCN}(s_i)$, is split into two vectors of the same length, which are used as the initial hidden states for the forward and backward LSTMs, respectively. In this way, the graph contextual information is propagated to each word through the LSTM. Specifically, we have

$$\mathbf{z}_{1:k}^{(i)} = \mathtt{RNN}\left(\mathbf{h}_{1:k}^{(i)} ; \mathtt{GCN}(s_i), \Theta_{\text{dec}}\right), \quad (5)$$

where $\mathbf{h}_{1:k}^{(i)}$ are the output hidden states of the encoder, $\mathtt{GCN}(s_i)$ represents the initial state, and Θ_{dec} is the decoder parameters. A simpler way to incorporate the graph representation into the decoder is concatenating with its input, but the empirical performance is worse than using as the initial state.

Finally, we use a CRF layer (Lafferty et al., 2001) on top of the BiLSTM to perform tagging,

$$\mathbf{y}_i^* = \underset{\mathbf{y}\in\mathbf{Y}_k}{\arg\max}\, p\left(\mathbf{y} \mid \mathbf{z}_{1:k}^{(i)} ; \Theta_{\text{crf}}\right), \quad (6)$$

where $\mathbf{Y}_k$ is the set of all possible tag sequences of length k, and Θ_{crf} represents the CRF parameters, i.e. transition scores of tags. CRF combines the local predictions of BiLSTM and the transition scores to model the joint probability of the tag sequence.[4]

4.4 Adaptation to Word-level Graphs

GraphIE can be easily adapted to model word-level graphs. In such case, the nodes represent words in the input, i.e. the number of nodes M equals the total number of words in the N sentences. At this point, each word's hidden state in the encoder can be used as the input node vector $\mathbf{g}_i^{(0)}$ of the graph module. GCN can then conduct graph convolution on the word-level graph and generate graph-contextualized representations for the words. Finally, the decoder directly operates on the GCN's outputs, i.e. we change the BiLSTM decoder to

$$\mathbf{z}_{1:k}^{(i)} = \mathtt{RNN}\left(\left[\mathtt{GCN}(w_1^{(i)}), \cdots, \mathtt{GCN}(w_k^{(i)})\right] ; \mathbf{0}, \Theta_{\text{dec}}\right),$$

where $\mathtt{GCN}(w_t^{(i)})$ is the GCN output for word $w_t^{(i)}$. In this case, the BiLSTM initial states are set to the default zero vectors. The CRF layer remains unchanged.

As it can be seen in Figure 2(c), the word-level graph module differs from the sentence-level one because it directly takes the word representations from the encoder and feeds its output to the decoder. In sentence-level graph, the GCN operates on sentence representations, which are then used as the initial states of the decoder BiLSTM.

5 Experimental Setup

We evaluate the model on three tasks, including two traditional IE tasks, namely textual information extraction and social media information extraction, and an under-explored task — *visual information extraction*. For each of these tasks, we created a simple task-specific graph topology, designed to easily capture the underlying structure of the input data without any major processing. Table 1 summarizes the three tasks.

5.1 Task 1: Textual Information Extraction

In this task, we focus on named entity recognition at discourse level (DiscNER). In contrast to traditional sentence-level NER (SentNER), where sentences are processed independently, in DiscNER, long-range dependencies and constraints across sentences have a crucial role in the tagging process. For instance, multiple mentions of the same entity are expected to be tagged consistently in the same discourse. Here we propose to use this (soft) constraint to improve entity extraction.

Dataset We conduct experiments on two NER datasets: the CoNLL-2003 dataset (CONLL03) (Tjong et al., 2003), and the CHEMDNER dataset for chemical entity extraction (Krallinger et al., 2015). We follow the standard split of each corpora. Statistics are shown in Table 2.

Graph Construction In this task, we use a word-level graph where nodes represent words. We create two types of edges for each document:

- *Local edges*: forward and backward edges are created between neighboring words in each sentence, allowing local contextual information to be utilized.
- *Non-local edges*: re-occurrences of the same token other than stop words are connected, so

---

[4] In GraphIE, the graph module models the input space structure, i.e. the dependencies between textual units (i.e. sentences or words), and the final CRF layer models the sequential connections of the output tags. Even though loops may exist in the input graph, CRF operates sequentially, thus the inference is tractable.

Evaluation Task	Graph Type	Node	Edge
Textual IE	word-level	word	1. non-local consistency (identical mentions) 2. local sentential forward and backward
Social Media IE	sentence-level	user's tweets	*followed-by*
Visual IE	sentence-level	text box	spatial layout (horizontal and vertical)

Table 1: Comparisons of graph structure in the three IE tasks used for evaluation.

	#sent	30,739	30,796	26,399

Table 2: Statistics of the CONLL03 and the CHEMDNER datasets (Task 1).

	EDUCATION	JOB
Users	7,208	1,772
Edges	11,167	3,498
Positive Tweets	49,793	3,694
Negative Tweets	393,683	172,349

Table 3: Statistics of the EDUCATION and JOB datasets (Task 2).

that information can be propagated through, encouraging global consistency of tagging.[5]

5.2 Task 2: Social Media Information Extraction

Social media information extraction refers to the task of extracting information from users' posts in online social networks (Benson et al., 2011; Li et al., 2014). In this paper, we aim at extracting *education* and *job* information from users' tweets. Given a set of tweets posted by a user, the goal is to extract mentions of the organizations to which they belong. The fact that the tweets are short, highly contextualized and show special linguistic features makes this task particularly challenging.

Dataset We construct two datasets, EDUCATION and JOB, from the Twitter corpus released by Li et al. (2014). The original corpus contains millions of tweets generated by $\approx$ 10 thousand users, where the *education* and *job* mentions are annotated using distant supervision (Mintz et al., 2009). We sample the tweets from each user, maintaining the ratio between positive and negative posts.[6] The obtained EDUCATION dataset consists of $443,476$ tweets generated by $7,208$ users, and the JOB dataset contains $176,043$ tweets generated by $1,772$ users. Dataset statistics are reported in Table 3.

The datasets are both split in 60% for training, 20% for development, and 20% for testing. We perform 5 different random splits and report the average results.

Graph Construction We construct the graph as *ego-networks* (Leskovec and Mcauley, 2012), i.e. when we extract information about one user, we consider the subgraph formed by the user and his/her direct neighbors. Each node corresponds to a Twitter user, who is represented by the set of posted tweets.[7] Edges are defined by the *followed-by* link, under the assumption that connected users are more likely to come from the same university or company. An example of the social media graph is reported in the appendices.

5.3 Task 3: Visual Information Extraction

Visual information extraction refers to the extraction of attribute values from documents formatted in various layouts. Examples include invoices and forms, whose format can be exploited to infer valuable information to support extraction.

Dataset The corpus consists of 25,200 Adverse Event Case Reports (AECR) recording drug-related side effects. Each case contains an average of 9 pages. Since these documents are produced by multiple organizations, they exhibit large variability in the layout and presentation styles (e.g.

---

[5] Note that other non-local relations such as co-references (cf. the example in Figure 1) may be used for further improvement. However, these relations require additional resources to obtain, and we leave them to future work.

[6] Positive and negative refer here to whether or not the *education* or *job* mention is present in the tweet.

[7] As each node is a set of tweets posted by the user, we encode every tweet with the encoder, and then average them to obtain the node representation. In the decoding phase, the graph module's output is fed to the decoder for each tweet.

text, table, etc.).[8] The collection is provided with a separate human-extracted ground truth database that is used as a source of distant supervision.

Our goal is to extract eight attributes related to the patient, the event, the drug and the reporter (cf. Table 6 for the full list). Attribute types include dates, words and phrases — which can be directly extracted from the document.

The dataset is split in 50% cases for training, 10% for development, and 40% for testing.

Graph Construction We first turn the PDFs to text using PDFMiner,[9] which provides words along with their positions in the page (i.e. bounding-box coordinates). Consecutive words are then geometrically joined into *text boxes*. Each text box is considered as a "sentence" in this task, and corresponds to a *node* in the graph.

Since the page layout is the major structural factor in these documents, we work on page-by-page basis, i.e. each page corresponds to a graph. The *edges* are defined to horizontally or vertically connect *nodes* (text boxes) that are close to each other (i.e. when the overlap of their bounding boxes, in either the vertical or horizontal direction, is over 50%). Four types of edge are considered: left-to-right, right-to-left, up-to-down, and down-to-up. When multiple nodes are aligned, only the closest ones are connected. An example of visual document graph is reported in the appendices.

5.4 Baseline and Our Method

We implement a two-layer BiLSTM with a conditional random fields (CRF) tagger as the sequential baseline (SeqIE). This architecture and its variants have been extensively studied and demonstrated to be successful in previous work on information extraction (Lample et al., 2016; Ma and Hovy, 2016). In the textual IE task (Task 1), our baseline is shown to obtain competitive results with the state-of-the-art method in the CONLL03 dataset. In the visual IE task (Task 3), in order to further increase the competitiveness of the baseline, we sequentially concatenate the horizontally aligned text boxes, therefore fully modeling the horizontal edges of the graph.

Our baseline shares the same encoder and decoder architecture with GraphIE, but without the graph module. Both architectures have similar computational cost. In Task 1, we apply GraphIE with word-level graph module (cf. Figure 2(c)), and in Task 2 and Task 3, we apply GraphIE with sentence-level graph module (cf. Figure 2(b)).

DATASET	Model	F1

	Ma and Hovy (2016)	91.21
	Ye and Ling (2018)	91.38
	SeqIE	91.16
	GraphIE	**91.74***
CHEMDNER	Krallinger et al. (2015)	87.39
	SeqIE	88.28
	GraphIE	**89.71***

Table 4: NER accuracy on the CONLL03 and the CHEMDNER datasets (Task 1). Scores for our methods are the average of 5 runs. * indicates statistical significance of the improvement over SeqIE ($p < 0.01$).

5.5 Implementation Details

The models are trained with `Adam` (Kingma and Ba, 2014) to minimize the CRF objective. For regularization, we choose dropout with a ratio of 0.1 on both the input word representation and the hidden layer of the decoder. The learning rate is set to 0.001. We use the development set for early-stopping and the selection of the best performing hyperparameters. For CharCNN, we use 64-dimensional character embeddings and 64 filters of width 2 to 4 (Kim et al., 2016). The 100-dimensional pretrained GloVe word embeddings (Pennington et al., 2014) are used in Task 1 and 2, and 64-dimensional randomly initialized word embeddings are used in Task 3. We use a two-layer GCN in Task 1, and a one-layer GCN in Task 2 and Task 3. The encoder and decoder BiLSTMs have the same dimension as the graph convolution layer. In Task 3, we concatenate a positional encoding to each text box's representation by transforming its bounding box coordinates to a vector of length 32, and then applying a $\tanh$ activation.

6 Results

6.1 Task 1: Textual Information Extraction

Table 4 describes the NER accuracy on the CONLL03 (Tjong et al., 2003) and the CHEMDNER (Krallinger et al., 2015) datasets.

For CONLL03, we list the performance of existing approaches. Our baseline SeqIE obtains competitive scores compared to the best methods. The fact that GraphIE significantly outperforms

DATASET	Dictionary			SeqIE			GraphIE		
	P	R	F1	P	R	F1	P	R	F1
EDUCATION	78.7	93.5	85.4	85.2	93.6	89.2	92.9	92.8	**92.9***
JOB	55.7	70.2	62.1	66.2	66.7	66.2	67.1	66.1	**66.5**

Table 5: Extraction accuracy on the EDUCATION and JOB datasets (Task 2). Dictionary is a naive method which creates a dictionary of entities from the training set and extracts their mentions during testing time. Scores are the average of 5 runs. * indicates the improvement over SeqIE is statistically significant (Welch's t-test, $p < 0.01$).

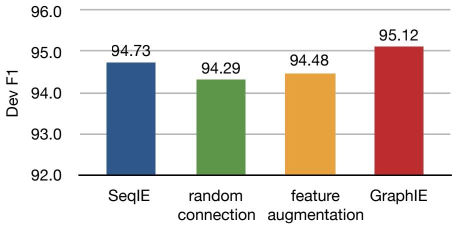

Figure 3: Analysis on the CoNLL03 dataset. We compare with two alternative designs: (1) *random connection*, where we replace the constructed graph by a random graph with the same number of edges; (2) *feature augmentation*, where we use the average embedding of each node and its neighbors as the input to the decoder, instead of the GCN which has additional parameters. We report F1 scores on the development set.

it, highlights once more the importance of modeling non-local and non-sequential dependencies and confirms that our approach is an appropriate method to achieve this goal.[10]

For CHEMDNER, we show the best performance reported in Krallinger et al. (2015), obtained with a feature-based method. Our baseline outperforms the feature-based method, and GraphIE further improves the performance by 1.4%.

Analysis To understand the advantage of GraphIE, we first investigate the importance of graph structure to the model. As shown in Figure 3, using random connections clearly hurts the performance, bringing down the F1 score of GraphIE from 95.12% to 94.29%. It indicates that the task-specific graph structures introduce beneficial inductive bias. Trivial feature augmentation also does not work well, confirming the necessity of learning the graph embedding with GCN.

We further conduct error analysis on the test set to validate our motivation that GraphIE resolves tagging ambiguity by encouraging consistency among identical entity mentions (cf. Figure 1). Here we examine the word-level tagging accuracy. We define the words that have more than one possible tags in the dataset as *ambiguous*. We find that among the 1.78% tagging errors of SeqIE, 1.16% are *ambiguous* and 0.62% are *unambiguous*. GraphIE reduces the error rate to 1.67%, with 1.06% to be *ambiguous* and 0.61% *unambiguous*. We can see that most of the error reduction indeed attributes to the *ambiguous* words.

6.2 Task 2: Social Media Information Extraction

Table 5 shows the results for the social media information extraction task. We first report a simple dictionary-based method as a baseline. Neural IE models achieve much better performance, showing that meaningful patterns are learned by the models rather than simply remembering the entities in the training set. The proposed GraphIE outperforms SeqIE in both the EDUCATION and JOB datasets, and the improvements are more significant for the EDUCATION dataset (3.7% versus 0.3%). The reason for such difference is the variance in the affinity scores (Mislove et al., 2010) between the two datasets. Li et al. (2014) underline that affinity value for EDUCATION is 74.3 while for JOB it is only 14.5, which means that in the datasets neighbors are 5 times more likely to have studied in the same university than worked in the same company. We can therefore expect that a model like GraphIE, which exploits neighbors' information, obtains larger advantages in a dataset characterized by higher affinity.

6.3 Task 3: Visual Information Extraction

Table 6 shows the results in the visual information extraction task. GraphIE outperforms the SeqIE baseline in most attributes, and achieves 1.2% improvement in the mirco average F1 score. It confirms that the benefits of using layout graph structure in visual information extraction.

The extraction performance varies across the attributes, ranging from 61.4% for *Drug Name* to

---

[10] We achieve the best reported performance among methods not using the recently introduced ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), which are pretrained on extra-large corpora and computationally demanding.

Model	Dev F1
GraphIE	77.8
– Edge types	77.0 (↓ 0.8)
– Horizontal edges	74.7 (↓ 3.1)
– Vertical edges	72.4 (↓ 5.4)
– CRF	72.1 (↓ 5.7)

Table 7: Ablation study (Task 3). Scores are micro average F1 on the development set. "–" means removing the element from GraphIE.

95.8% for *Patient Birthday* (similar variations are visible in the baseline). Similarly, the gap between GraphIE and SeqIE varies in relation to the attributes, ranging between -0.5% in *Patient Birthday* and 2.4% in *Event*.

In the ablation test described in Table 7, we can see the contribution of: using separate weights for different edge types ($+0.8\%$), horizontal edges ($+3.1\%$), vertical edges ($+5.4\%$), and CRF ($+5.7\%$).

Generalization We also assess GraphIE's capacity of dealing with unseen layouts through an extra analysis. From our dataset, we sample $2,000$ reports containing the three most frequent templates, and train the models on this subset. Then we test all models in two settings: 1) *seen templates*, consisting of $1,000$ additional reports in the same templates used for training; and 2) *unseen templates*, consisting of $1,000$ reports in two new template types.

The performance of GraphIE and SeqIE is reported in Figure 4. Both models achieve good results on *seen templates*, with GraphIE still scoring 2.8% higher than SeqIE. The gap becomes even larger when our model and the sequential one are tested on *unseen templates* (i.e. 20.3%), demonstrating that by explicitly modeling the richer structural relations, GraphIE achieves better generalizability.

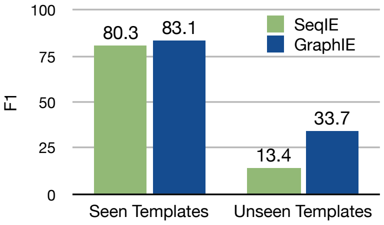

Figure 4: Micro average F1 scores tested on *seen* and *unseen* templates (Task 3).

7 Conclusions

We introduced GraphIE, an information extraction framework that learns local and non-local contextual representations from graph structures to improve predictions. The system operates over a task-specific graph topology describing the underlying structure of the input data. GraphIE jointly models the node (i.e. textual units, namely words or sentences) representations and their dependencies. Graph convolutions project information through neighboring nodes to finally support the decoder during tagging at the word level.

We evaluated our framework on three IE tasks, namely textual, social media and visual information extraction. Results show that it efficiently models non-local and non-sequential context, consistently enhancing accuracy and outperforming the competitive SeqIE baseline (i.e. BiLSTM+CRF).

Future work includes the exploration of automatically learning the underlying graphical structure of the input data.

Abstract

In this paper, we consider advancing web-scale knowledge extraction and alignment by integrating OpenIE extractions in the form of (subject, predicate, object) triples with Knowledge Bases (KB). Traditional techniques from universal schema and from schema mapping fall in two extremes: either they perform instance-level inference relying on embedding for (subject, object) pairs, thus cannot handle pairs absent in any existing triples; or they perform predicate-level mapping and completely ignore background evidence from individual entities, thus cannot achieve satisfying quality.

We propose *OpenKI* to handle sparsity of OpenIE extractions by performing instance-level inference: for each entity, we encode the rich information in its neighborhood in both KB and OpenIE extractions, and leverage this information in relation inference by exploring different methods of aggregation and attention. In order to handle unseen entities, our model is designed without creating entity-specific parameters. Extensive experiments show that this method not only significantly improves state-of-the-art for conventional OpenIE extractions like ReVerb, but also boosts the performance on OpenIE from semi-structured data, where new entity pairs are abundant and data are fairly sparse.

1 Introduction

Web-scale knowledge extraction and alignment has been a vision held by different communities for decades. The Natural Language Processing (NLP) community has been focusing on knowledge extraction from texts. They apply either closed information extraction according to an ontology (Mintz et al., 2009; Zhou et al., 2005), restricting to a subset of relations pre-defined in the ontology, or open information extraction (OpenIE) to extract free-text relations (Banko et al., 2007; Fader et al., 2011), leaving the relations unaligned and thus potentially duplicated. The Database (DB) community has been focusing on aligning relational data or WebTables (Cafarella et al., 2008) by schema mapping (Rahm and Bernstein, 2001), but the quality is far below adequate for assuring correct data integration.

We propose advancing progress in this direction by applying *knowledge integration* from OpenIE extractions. OpenIE extracts SPO (subject, predicate, object) triples, where each element is a text phrase, such as **E1:** *("Robin Hood", "Full Cast and Crew", "Leonardo Decaprio")* and **E2**: *("Ang Lee", "was named best director for", "Brokeback")*. OpenIE has been studied for text extraction extensively (Yates et al., 2007; Fader et al., 2011; Mausam et al., 2012), and also for semi-structured sources (Bronzi et al., 2013), thus serves an effective tool for web-scale knowledge extraction. The remaining problem is to align text-phrase predicates[1] from OpenIE to knowledge bases (KB). Knowledge integration answers the following question: given an OpenIE extraction (s, p, o), how can one populate an existing KB using relations in the pre-defined ontology?

The problem of knowledge integration is not completely new. The DB community has been solving the problem using schema mapping techniques, identifying mappings from a source schema (OpenIE extractions in our context) to a target schema (KB ontology in our context) (Rahm and Bernstein, 2001). Existing solutions consider *predicate-level* (*i.e.*, attribute) similarity on names, types, descriptions, instances, and so on, and generate mappings like "email" mapped to "email-

---

[*] This work was performed while at Amazon.

[1] We also need to align text-phrase entities, which falls in the area of entity linking (Dredze et al., 2010; Ji et al., 2014); it is out of scope of this paper and we refer readers to relevant references.

Proceedings of NAACL-HLT 2019, pages 762–772
Minneapolis, Minnesota, June 2 - June 7, 2019.

address"; "first name" and "last name" together mapped to "full name". However, for our example "Full Cast and Crew", which is a union of multiple KB relations such as "directed_by", "written_by", and "actor", it is very hard to determine a mapping at the predicate level.

On the other hand, the NLP community has proposed *Universal Schema* (Riedel et al., 2013) to apply *instance-level* inference from both OpenIE extractions and knowledge in existing knowledge bases: given a set of extractions regarding an entity pair (s, o) and also information of each entity, infer new relations for this pair. One drawback of this method is that it cannot handle unseen entities and entity pairs. Also, the technique tends to overfit when the data is sparse due to large number of parameters for entities and entity pairs. Unfortunately, in the majority of the real extractions we examined in our experiments, we can find only 1.4 textual triples on average between the subject and object. The latest proposal *Rowless Universal Schema* (Verga et al., 2017) removes the entity-specific parameters and makes the inference directly between predicates and relations, thereby allowing us to reason about unseen entity pairs. However, it completely ignores the entities themselves, so in a sense falls back to *predicate-level* decisions, especially when only one text predicate is observed.

In this paper we propose a solution that leverages information about the individual entities whenever possible, and falls back to predicate-level decisions only when both involved entities are new. Continuing with our example **E1** – if we know from existing knowledge that "Leonardo" is a famous actor and has rarely directed or written a movie, we can decide with a high confidence that this predicate maps to @film.actor in this triple, even if our knowledge graph knows nothing about the new movie "Robin Hood". In particular, we make three contributions in this paper.

1. We design an embedding for each entity by exploring rich signals from its neighboring relations and predicates in KB and OpenIE. This embedding provides a soft constraint on which relations the entities are likely to be involved in, while keeping our model free from creating new entity-specific parameters so allowing us to handle unseen entities during inference.
2. Inspired by predicate-level mapping from schema mapping and instance-level inference from universal schema, we design a joint model that leverages the neighborhood embedding of entities and relations with different methods of aggregation and attention.
3. Through extensive experiments on various OpenIE extractions and KB, we show that our method improves over state-of-the-arts by 33.5% on average across different datasets.

In the rest of the paper, we define the problem formally in Section 2, present our method in Section 3, describe experimental results in Section 4, and discuss related work in Section 5.

2 Problem Overview

Problem Statement. *Given (i) an existing knowledge base* KB *of triples* (s, p, o) *– where* $s, o \in E^{KB}$ *(set of KB entities) and* $p \in R^{KB}$ *(set of KB relations), and (ii) a set of instances* (s', p', o') *from OpenIE extraction (*s' *and* o' *may not belong to* E^{KB}*, and* p' *are text predicates)*[2]*: predict* $score(s', p, o')$ *– where* $p \in R^{KB}$.

For example, given **E1** and **E2** as OpenIE extractions and background knowledge bases (KB) like IMDB, we want to predict "@film.actor" relation given E1 and "@film.directed_by" relation given E2 as the target KB relations between the participating entities. Particularly, we want to perform this relation inference at *instance-level*, which can be different for different entities sharing the same predicate. Table 1 introduces important notations used in this paper.

s	Subject
o	Object
p	KB relation or text predicate
$v_s, v_p, v_o, v_{s,o}$	Embedding vectors of s, p, o and (s, o)
$S(s, p, o)$	Scoring function for (s, p, o) to be true
$Agg_{p \in R(s,o)}(v_p)$	Aggregation function over embeddings (v_p) of p shared by s and o.

Table 1: Notation table.

2.1 Existing Solution and Background

Universal Schema (F-Model) (Riedel et al., 2013) is modeled as a matrix factorization task where entity pairs, e.g., *(RobinHood, Leonardo Decaprio)* form the rows, and relations from OpenIE and KB form the columns (e.g., @film.actor, "Full Cast and Crew"). During training, we observe some positive entries in the matrix and the objective is to predict the missing cells at test time.

---

[2] In this paper, a 'relation' always refers to a KB relation, whereas a 'predicate' refers to an OpenIE textual relation.

Each (subject, predicate, object) triple is scored as:

$$S_F(s, p, o) = v_{s,o} \cdot v_p^T$$

where, $v_{s,o} \in \mathcal{R}^d$ is the embedding vector of the entity pair (subject, object), v_p is the embedding vector of a KB relation or OpenIE predicate, and the triple score is obtained by their dot product. The parameters v_p and $v_{s,o}$ are randomly initialized and learned via gradient descent.

One of the drawbacks of universal schema is the explicit modeling of entity pairs using free parameters $v_{s,o}$. Therefore, it cannot model unseen entities. This also makes the model overfit on our data as the number of OpenIE text predicates observed with each entity pair is rather small (1.4 on average in our datasets).

Universal Schema (E-Model) (Riedel et al., 2013) considers <u>e</u>ntity-level information, thus decomposing the scoring function from the F-model as follows:

$$\begin{aligned} S_E(s, p, o) &= S_{subj}(s, p) + S_{obj}(p, o) \\ &= v_s \cdot v_p^{subj^T} + v_o \cdot v_p^{obj^T} \end{aligned} \quad (1)$$

where each relation is represented by two vectors corresponding to its argument type for a subject or an object. The final score is an additive summation over the subject and object scores S_{subj} and S_{obj} that implicitly contain the argument type information of the predicate p. Thus, a joint F- and E-model of $S_{F+E} = S_F + S_E$ can perform relation inference at *instance-level* considering the entity information. Although the E-model captures rich information about entities, it still cannot deal with unseen entities due to the entity-specific free parameters v_s and v_o.

Rowless Universal Schema (Rowless) (Verga et al., 2017) handles new entities as follows. It considers all relations in KB and OpenIE that the subject s and object o co-participates in (denoted by $R(s, o)$), and represents the entity pair with an aggregation over embeddings of these relations.

$$\begin{aligned} v_{s,o}^{Rowless} &= Agg_{p' \in R(s,o)}(v_{p'}) \\ S_{Rowless}(s, p, o) &= v_{s,o}^{Rowless} \cdot v_p^T \end{aligned} \quad (2)$$

$Agg(.)$ is an aggregation function like average pooling, max pooling, hard attention (Rowless MaxR) or soft attention given query relations (Rowless Attention) (Verga et al., 2017). The Rowless model ignores the individual information of entities, and therefore falls back to making *predicate-level* decisions in a sense, especially when there are only a few OpenIE predicates for an entity pair.

3 Our Approach

We propose *OpenKI* for *instance-level* relation inference such that it (i) captures rich information about each entity from its neighborhood KB relations and text predicates to serve as background knowledge and generalizes to unseen entities by *not* learning any entity-specific parameters (only KB relations and OpenIE predicates are parameterized) (ii) considers both shared predicates and entity neighborhood information to encode entity pair information. Figure 1 shows the architecture of our model.

3.1 Entity Neighborhood Encoder (ENE)

The core of our model is the Entity Neighborhood Encoder. Recall that Rowless Universal Schema represents each entity pair with common relations shared by this pair. However, it misses critical information when entities do not only occur in the current entity pair, but also interact with other entities. This *entity neighborhood* can be regarded as a soft and fine-grained entity type information that could help infer relations when observed text predicates are ambiguous (polysemous), noisy (low quality of data source) or low-frequency (sparsity of language representation). [3]

Our aim is to incorporate this entity neighborhood information into our model for *instance-level* relation inference while keeping it free of entity-specific parameters. To do this, for each entity, we leverage all its *neighboring KB relations and OpenIE predicates* for relation inference. We aggregate their embeddings to obtain two scores for the subject and object separately in our ENE model. The subject score S_{subj}^{ENE} for an entity considers the aggregated embedding of its participating KB relations and OpenIE predicates where it serves as a subject (similar for the object score S_{obj}^{ENE}):

---

[3] Note that, the notion of *entity neighborhood* is different from the *Neighborhood* model in the Universal Schema work (Riedel et al., 2013). Our *entity neighborhood* captures information of each entity, whereas their Neighborhood model leverages prediction from similar predicates.

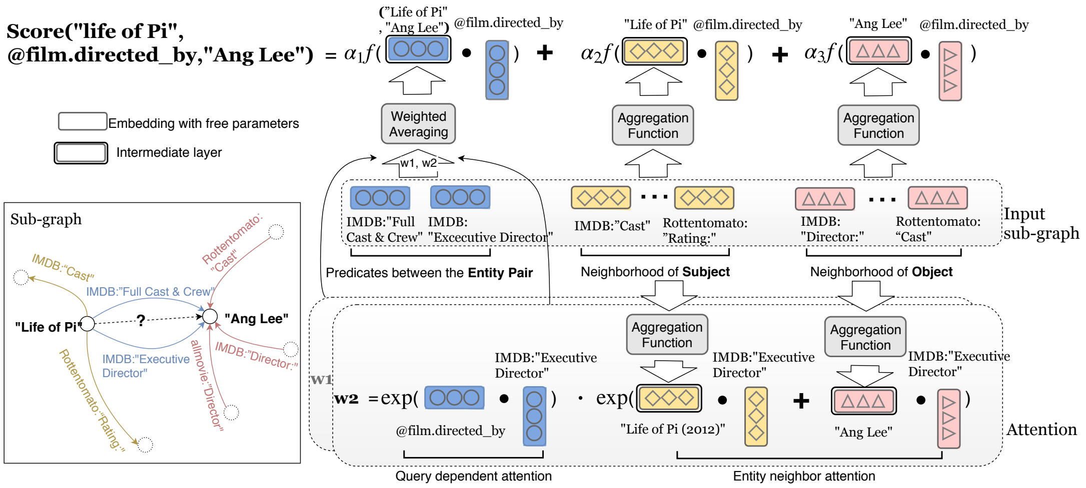

Figure 1: Architecture of the proposed method. In this example, the ENE model uses "Ang Lee's" neighboring predicates "IMDB:Director" and "allmovie:Director" for predicting the target KB relation "@film.directed_by". The attention mechanism assigns a larger weight over "IMDB:Executive Director" for generating entity pair embedding. Different colors of vectors represent different sets of parameters. The Entity Neighborhood Encoder (ENE) (square & triangle fillers) model contributes the following components to the final scoring function: (1) entity neighborhood scores S^{ENE}_{subj} and S^{ENE}_{obj} of the subject and object respectively; (2) neighborhood signal for the attention module to calculate the weight of each text predicate and the attention score $S^{Att}(s,p,o)$ (circle filler).

$$
\begin{aligned}
v^{agg}_{subj} &= Agg_{p' \in R(s,\cdot)}(v^{subj}_{p'}) \\
S^{ENE}_{subj}(s,p) &= v^{agg}_{subj} \cdot v^{subj\ T}_{p} \\
v^{agg}_{obj} &= Agg_{p' \in R(\cdot,o)}(v^{obj}_{p'}) \\
S^{ENE}_{obj}(p,o) &= v^{agg}_{obj} \cdot v^{obj\ T}_{p}
\end{aligned} \tag{3}
$$

$R(s,.)$ denotes all neighboring relations and predicates of the subject s (similar for the object). v^{subj}_p and v^{obj}_p are the only free parameters in ENE. These are randomly initialized and then learned via gradient descent. We choose average pooling as our aggregation function to capture the proportion of different relation and predicate types within the target entity's neighborhood.

3.2 Attention Mechanism

Given multiple predicates between a subject and an object, only some of them are important for predicting the target KB relation between them. For example, in Figure 1, the predicate "Executive Director" is more important than "Full Cast & Crew" to predict the KB relation "@film.directed_by" between "Life of Pi" and "Ang Lee".

We first present a query-based attention mechanism from earlier work, and then present our own solution with a neighborhood attention and combining both in a dual attention mechanism.

3.2.1 Query Attention

The first attention mechanism uses a query relation q (i.e., the target relation we may want to predict) to find out the importance (weight) $w_{p|q}$ of different predicates p with respect to q with v_p and v_q as the corresponding relation embeddings.

$$
w_{p|q} = \frac{\exp(v_q \cdot v_p^T)}{\sum_{p'} \exp(v_q \cdot v_{p'}^T)}
$$

Thus, given each query relation q, the model tries to find evidence from predicates that are most relevant to the query. Similar techniques have been used in (Verga et al., 2017). We can also use hard attention (referred as MaxR) instead of soft attention where the maximum weight is replaced with one and others with zero. One potential shortcoming of this attention mechanism is its sensitivity to noise, whereby it may magnify sparsely observed predicates between entities.

3.2.2 Neighborhood Attention

In this attention mechanism, we use the subject and object's neighborhood information as a filter to remove unrelated predicates. Intuitively, the entity representation generated by the ENE from its neighboring relations can be regarded as a soft and fine-grained entity type information.

Consider the embedding vectors v^{agg}_{subj} and v^{agg}_{obj} in Equation 3 that are aggregated from the entity's neighboring predicates and relations using an aggregation function. We compute the similarity $w_{p|Nb}$ between an entity's neighborhood information given by the above embeddings and a text predicate p to enforce a soft and fine-grained argument type constraint over the text predicate:

$$w_{p|Nb} = \frac{\exp(v_{subj}^{agg} \cdot v_p^{subj^T} + v_{obj}^{agg} \cdot v_p^{obj^T})}{\sum_{p'} \exp(v_{subj}^{agg} \cdot v_{p'}^{subj^T} + v_{obj}^{agg} \cdot v_{p'}^{obj^T})}$$

Finally, we combine both the query-dependent and neighborhood-based attention into a *Dual Attention* mechanism:

$$w_{p|q+Nb} = w_{p|q} \cdot w_{p|Nb}$$
$$w_p = \frac{w_{p|q+Nb}}{\sum_{p'} w_{p'|q+Nb}}$$

And the score function is given by:

$$\begin{aligned} S^{Att}(s,q,o) &= Agg_{p \in R(s,o)}(v_p) \cdot v_q^T \\ &= \Big(\sum_p w_p v_p\Big) \cdot v_q^T \qquad (4) \end{aligned}$$

3.3 Joint Model: OpenKI

All of the above models capture different types of features. Given a target triple (s,p,o), we combine scores from Eq. 3 and Eq. 4 in our final OpenKI model. It aggregates the neighborhood information of s and o and also uses an attention mechanism to focus on the important predicates between s and o. Refer to Figure 1 for an illustration. The final score of (s,p,o) is given by:

$$\begin{aligned} score(s,p,o) &= f_1(S^{Att}(s,p,o)) * ReLU(\alpha_1) \\ &+ f_2(S_{subj}^{ENE}(s,p)) * ReLU(\alpha_2) \\ &+ f_3(S_{obj}^{ENE}(p,o)) * ReLU(\alpha_3) \end{aligned}$$

where $f_i(X) = \sigma(a_i X + b_i)$ normalizes different scores to a comparable distribution. $ReLU(\alpha_i)$ enforces non-negative weights that allow scores to only contribute to the final model without canceling each other. a_i, b_i, α_i are free parameters that are learned during the back propagation gradient descent process.

3.4 Training Process

Our task is posed as a ranking problem. Given an entity pair, we want the observed KB relations between them to have higher scores than the unobserved ones. Thus, a pair-wise ranking based loss function is used to train our model:

$$\begin{aligned} L(s,p_{pos},p_{neg},o) = \max(0, \gamma - score(s,p_{pos},o) \\ + score(s,p_{neg},o)) \end{aligned}$$

where p_{pos} refers to a positive relation, p_{neg} refers to a uniformly sampled negative relation, and γ is the margin hyper-parameter. We optimize the loss function using Adam (Kingma and Ba, 2014). The training process uses early stop according to the validation set.

3.5 Explicit Argument Type Constraint

Subject and object argument types of relations help in filtering out a large number of candidate relations that do not meet the argument type, and therefore serve as useful constraints for relation inference. Similar to (Yu et al., 2017), we identify the subject and object argument type of each relation by calculating its probability of co-occurrence with subject / object entity types. During inference, we select candidate relations by performing a post-processing filtering step using the subject and object's type information when available.

4 Experiments

4.1 Data

We experiment with the following OpenIE datasets and Knowledge Bases.

(i) Ceres (Lockard et al., 2019) works on semi-structured web pages (e.g., IMDB) and exploits the DOM Tree and XPath (Olteanu et al., 2002) structure in the page to extract triples like *(Incredibles 2, Cast and Crew, Brad Bird)* and *(Incredibles 2, Writers, Brad Bird)*. We apply Ceres on the SWDE (Hao et al., 2011) movie corpus to generate triples. We align these triples to two different knowledge bases: (i) IMDB and (ii) subset of Freebase with relations under */film* domain. The average length of text predicates is 1.8 tokens for Ceres extractions.

(ii) ReVerb (Fader et al., 2011) works at sentence level and employs various syntactic constraints like part-of-speech-based regular expressions and lexical constraints to prune incoherent and uninformative extractions. We use 3 million ReVerb extractions from ClueWeb where the subject is already linked to Freebase (Lin et al., 2012) [4]. We align these extractions to (i) entire Freebase and (ii) subset of Freebase with relations under */film* domain. The average length of text predicates is 3.4 tokens for ReVerb extractions.

---

OpenKI with Dual Att.	**0.505**	0.365	0.658	**0.814**

Table 3: Mean average precision (MAP) of different models over four data settings.

In order to show the generalizability of our approach to traditional (non OpenIE) corpora, we also perform experiments in the New York Times (NYT) and Freebase dataset (Riedel et al., 2010), which is a well known benchmark for distant supervision relation extraction. We consider the sentences (average length of 18.8 tokens) there to be a proxy for text predicates. These results are presented in Section 4.5.

Data preparation: We collect all entity mentions M from OpenIE text extractions, and all candidate entities E_{KB} from KB whose name exists in M. We retain the sub-graph G_{KB} of KB triples where the subject and object belongs to E_{KB}. Similar to (Riedel et al., 2013), we use string match to collect candidate entities for each entity mention. For each pair of entity mentions, we link them if two candidate entities in E_{KB} share a relation in KB. Otherwise, we link each mention to the most common candidate. For entity mentions that cannot be linked to KB, we consider them as new entities and link together mentions that share same text .

For validation and test, we randomly hold-out a part of the entity pairs from G_{KB} where text predicates are observed. Our training data consists of the rest of G_{KB} and all the OpenIE text extractions. In addition, we exclude direct KB triples from training where corresponding entity pairs appear in the test data (following the data setting of (Toutanova et al., 2015)). Table 2 shows the data statistics [5].

We adopt a similar training strategy as Universal Schema for the Ceres dataset – that not only learns direct mapping from text predicates to KB relations, but also clusters OpenIE predicates and KB relations by their co-occurrence. However, for the ReVerb data containing a large number of text predicates compared to Ceres, we only learn the direct mapping from text predicates to KB relations that empirically works well for this dataset.

4.2 Verifying Usefulness of Neighborhood Information: Bayesian Methods

To verify the usefulness of the entity's neighborhood information, we devise simple Bayesian methods as baselines. The simplest method counts

---

[5] Our datasets with train, test, validation split are downloadable at `https://github.com/zhangdongxu/relation-inference-naacl19` for benchmarking.

the co-occurrence of text predicates and KB relations (by applying Bayes rule) to find the conditional probability $P(p|\overline{p}')$ of a target KB relation p given a set of observed text predicates $\overline{p}'$. This performs relation inference at *predicate-level*.

Then, we can include the entity's relational neighbors in the Bayesian network by adding the neighboring predicates and relations of the subject (given by p_s^N) and object (given by p_o^N) to find $P(p|s, \overline{p}', o)$, which performs relation inference at the *instance-level*. The graph structures of these three Bayesian methods are shown in Figure 2. For detailed formula derivation, please refer to *Appendix* A.1.

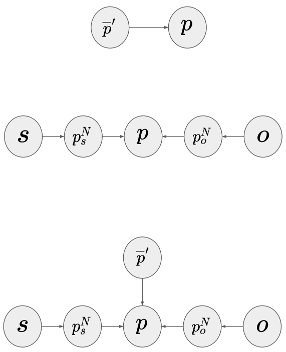

Figure 2: Structures of $P(p|\overline{p}')$, $P(p|s, o)$, $P(p|s, \overline{p}', o)$ are listed from top to bottom.

4.3 Baselines and Experimental Setup

Angeli et al. (2015) employ point-wise mutual information (PMI) between target relations and observed predicates to map OpenIE predicates to KB relations. This is similar to our Bayes conditional probability $P(p|\overline{p}')$. This baseline operates at *predicate-level*. To indicate the usefulness of entity neighborhood information, we also compare with $P(p|s, \overline{p}', o)$ as mentioned in Section 4.2. For the advanced embedding-based baselines, we compare with the E-model and the Rowless model (with MaxR and query attention) introduced in Section 2.1.

Hyper-parameters: In our experiments, we use 25 dimensional embedding vectors for the Rowless model, and 12 dimensional embedding vectors for the E- and ENE models. We use a batch-size of 128, and 16 negative samples for each positive sample in a batch. Due to memory constraints, we sample at most 8 predicates between entities and 16 neighbors for each entity during training. We use $\gamma = 1.0$ and set the learning rate to 5e-3 for ReVerb and 1e-3 for Ceres datasets.

Evaluation measures: Our task is a multi-label task, where each entity pair can share multiple KB relations. Therefore, we consider each KB relation as a query and compute the Mean Average Precision (MAP) – where entity pairs sharing the query relation should be ranked higher than those without the relation. In Section 4.4 we report MAP statistics for the 50 most common KB relations for ReVerb and Freebase dataset, and for the 10 most common relations in other domain specific datasets. The left out relations involve few triples to report any significant statistics. We also report the area under the precision recall curve (AUC-PR) for evaluation in Section 4.5.

4.4 Results

Table 3 shows that the overall results. OpenKI achieves significant performance improvement over all the baselines. Overall, we observe 33.5% MAP improvement on average across different datasets.

From the first two rows of Table 3, we observe the performance to improve as we incorporate neighborhood information into the Bayesian method. This depicts the strong influence of the entity's neighboring relations and predicates for relation inference.

The results show that our Entity Neighbor Encoder (ENE) outperforms the E-Model significantly. This is because the majority of the entity pairs in our test data have *at least one unseen entity* (refer to Table 4), which is very common in the OpenIE setting. The E-model cannot handle unseen entities because of its modeling of entity-specific parameters. This demonstrates the benefit of encoding entities with their neighborhood information (KB relations and text predicates) rather than learning entity-specific parameters. Besides, ENE outperforms the Rowless Universal Schema model, which does not consider any information surrounding the entities. This becomes a disadvantage in sparse data setting where only a few predicates are observed between an entity pair.

Finally, the results also show consistent improvement of OpenKI model over only-Rowless and only-ENE models. This indicates that the models are complementary to each other. We further observe significant improvements by applying different attention mechanisms over the OpenKI MaxR model – thus establishing the effectiveness of our attention mechanism.

Unseen entity: Table 4 shows the data statistics of unseen entity pairs in our test data. The most common scenario is that only one of the entity in a pair is observed during training, where our model benefits from the extra neighborhood information of the observed entity in contrast to the Rowless model.

Dataset	Both seen	One unseen	Both unseen
ReVerb + Freebase	864	3232	842
ReVerb + Freebase(/film)	27	147	228
Ceres + Freebase(/film)	383	561	42
Ceres + IMDB	462	533	3

Table 4: Statistics for unseen entities in test data. "Both seen" indicates both entities exist in training data; "One unseen" indicates only one of the entities in the pair exist in training data; "Both unseen" indicates both entities were unobserved during training.

Models	All data	At least one seen
Rowless Model	0.278	0.282
OpenKI with Dual Att.	0.365	0.419

Table 5: Mean average precision (MAP) of Rowless and OpenKI on ReVerb + Freebase (/film) dataset.

Table 5 shows the performance comparison on test data where at least one of the entity is known at test time. We choose ReVerb+Freebase(/film) for analysis because it contains the largest proportion of test triples where both entities are unknown during training. From the results, we observe that OpenKI outperforms the Rowless model by 48.6% when at least one of the entity in the triple is observed during training. Overall, we obtain 31.3% MAP improvement considering all of the test data. This validates the efficacy of encoding entity neighborhood information where at least one of the entities is known at test time. In the scenario where both entities are unknown at test time, the model falls back to the Rowless setting.

Models	MAP
Rowless Model	0.695
+Type Constraint	0.769 ↑ 10.6%
ENE Model	0.808
+Type Constraint	0.818 ↑ 1.2%
OpenKI with Dual Att.	0.814
+Type Constraint	**0.828** ↑ 1.7%

Table 6: MAP improvement with argument type constraints on Ceres + IMDB dataset.

Explicit Argument Type Constraint: As discussed in Section 3.5, incorporating explicit type constraints can improve the model performance. However, entity type information and argument type constraints are not always available especially for new entities. Table 6 shows the performance improvement of different models with entity type constraints. We observe the performance improvement of the ENE model to be much less than that of the Rowless model with explicit type constraint. This shows that the ENE model already captures soft entity type information while modeling the neighborhood information of an entity in contrast to the other methods that require explicit type constraint.

4.5 Results on NYT + Freebase Dataset

Prior works (Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016; Qin et al., 2018) on distantly supervised relation extraction performed evaluations on the New York Times (NYT) + Freebase benchmark data developed by Riedel et al. (2010)[6]. The dataset contains sentences whose entity mentions are annotated with Freebase entities as well as relations. The training data consists of sentences from articles in 2005-2006 whereas the test data consists of sentences from articles in 2007. There are 1950 relational facts in our test data[7]. In contrast to our prior experiments in the semi-structured setting with text predicates, in this experiment we consider the sentences to be a proxy for the text predicates.

Models	AUC-PR
PCNN + MaxR (Zeng et al., 2015)	0.325
PCNN + Att. (Lin et al., 2016)	0.341
ENE	0.421
OpenKI with Dual Att.	**0.461**

Table 7: Performances on NYT + Freebase data.

Table 7 compares the performance of our model with two state-of-the-art works (Zeng et al., 2015; Lin et al., 2016) on this dataset using AUC-PR as the evaluation metric.

Overall, OpenKI obtains 35% MAP improvement over the best performing PCNN baseline. In contrast to baseline models, our approach leverages the neighborhood information of each entity from the text predicates in the 2007 corpus and predicates / relations from the 2005-2006 corpus. This background knowledge contributes to the significant performance improvement.

---

[6] This data can be downloaded from `http://iesl.cs.umass.edu/riedel/ecml/`

[7] Facts of 'NA' (no relation) in the test data are not included in the evaluation process.

Note that, our model uses only the graph information from the entity neighborhood and does not use any text encoder such as Piecewise Convolutional Neural Nets (PCNN) (Zeng et al., 2015), where convolutional neural networks were applied with piecewise max pooling to encode textual sentences. This further demonstrates the importance of entity neighborhood information for relation inference. It is possible to further improve the performance of our model by incorporating text encoders as an additional signal. Some prior works (Verga et al., 2016; Toutanova et al., 2015) also leverage text encoders for relation inference.

5 Related Work

Relation Extraction: Mintz et al. (2009) utilize the entity pair overlap between knowledge bases and text corpus to generate signals for automatic supervision. To avoid false positives during training, many works follow the at-least-one assumption, where at least one of the text patterns between the entity pair indicate an aligned predicate in the KB (Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016). These works do not leverage graph information. In addition, Universal Schema (Riedel et al., 2013; Verga et al., 2017) tackled this task by low-rank matrix factorization. Toutanova et al. (2015) exploit graph information for knowledge base completion. However, their work cannot deal with unseen entities since entities' parameters are explicitly learned during training.

Schema Mapping: Traditional schema mapping methods (Rahm and Bernstein, 2001) involve three kinds of features, namely, language (name or description), type constraint, and instance level co-occurrence information. These methods usually involve hand-crafted features. In contrast, our model learns all the features automatically from OpenIE and KB with no feature engineering. This makes it easy to scale to different domains with little model tuning. Also, the entity types used in traditional schema mapping is always pre-defined and coarse grained, so cannot provide precise constraint of relations for each entity. Instead, our ENE model automatically learns soft and fine-grained constraints on which relations entities are likely to participate in. It is also compatible with pre-defined type systems.

Relation Grounding from OpenIE to KB: Instead of modeling existing schema, open information extraction (OpenIE) (Banko et al., 2007; Yates et al., 2007; Fader et al., 2011; Mausam et al., 2012) regards surface text mentions between entity pairs as separate relations, and do not require entity resolution or linking to KB. Since they do not model KB, it is difficult to infer KB relations only based on textual observations. Soderland et al. (2013) designed manual rules to map relational triples to slot types. Angeli et al. (2015) used PMI between OpenIE predicates and KB relations using distant-supervision from shared entity pairs for relation grounding. Yu et al. (2017) used word embedding to assign KB relation labels to OpenIE text predicates without entity alignment. These works do not exploit any graph information.

Entity Modeling for Relation Grounding: People leveraged several entity information to help relation extraction. Zhou et al. (2005) employed type information and observed 8% improvement of F-1 scores. Ji et al. (2017) encoded entity description to calculate attention weights among different text predicates within an entity pair. However, entity type and description information is not commonly available. Instead, the neighborhood information is easier to obtain and can also be regarded as entities' background knowledge. Universal Schema (Riedel et al., 2013) proposed an E-Model to capture entity type information. However, it can easily overfit in the OpenIE setting with large number of entities and a sparse knowledge graph.

6 Conclusion

In this work we jointly leverage relation mentions from OpenIE extractions and knowledge bases (KB) for relation inference and aligning OpenIE extractions to KB. Our model leverages the rich information (KB relations and OpenIE predicates) from the neighborhood of entities to improve the performance of relation inference. This also allows us to deal with new entities without using any entity-specific parameters. We further explore several attention mechanisms to better capture entity pair information. Our experiments over several datasets show 33.5% MAP improvement on average over state-of-the-art baselines.

Some future extensions include exploring more advanced graph embedding techniques without modeling entity-specific parameters and using text encoders as additional signals.

Abstract

Existing entity typing systems usually exploit the type hierarchy provided by knowledge base (KB) schema to model label correlations and thus improve the overall performance. Such techniques, however, are not directly applicable to more open and practical scenarios where the type set is not restricted by KB schema and includes a vast number of free-form types. To model the underlying label correlations without access to manually annotated label structures, we introduce a novel label-relational inductive bias, represented by a graph propagation layer that effectively encodes both global label co-occurrence statistics and word-level similarities. On a large dataset with over 10,000 free-form types, the graph-enhanced model equipped with an attention-based matching module is able to achieve a much higher recall score while maintaining a high-level precision. Specifically, it achieves a 15.3% relative F1 improvement and also less inconsistency in the outputs. We further show that a simple modification of our proposed graph layer can also improve the performance on a conventional and widely-tested dataset that only includes KB-schema types.[1]

1 Introduction

Fine-grained entity typing is the task of identifying specific semantic types of entity mentions in given contexts. In contrast to general entity types (*e.g.*, organization, event), fine-grained types (*e.g.*, political party, natural disaster) are often more informative and can provide valuable prior knowledge for a wide range of NLP tasks, such as coreference resolution (Durrett and Klein, 2014), relation extraction (Yaghoobzadeh et al., 2016) and question answering (Lee et al., 2006; Yavuz et al., 2016).

Table 1: Examples of inconsistent predictions produced by existing entity typing system that does not model label correlations. We use different subscript symbols to indicate contradictory type pairs and show the ground-truth types in *italics*.

In practical scenarios, a key challenge of entity typing is to correctly predict *multiple* ground-truth type labels from a large candidate set that covers a wide range of types in different granularities. In this sense, it is essential for models to effectively capture the inter-label correlations. For instance, if an entity is identified as a "criminal", then the entity must also be a "person", but it is less likely for this entity to be a "police officer" at the same time. When ignoring such correlations and considering each type separately, models are often inferior in performance and prone to inconsistent predictions. As shown in Table 1, an existing model that independently predicts different types fails to reject predictions that include apparent contradictions.

Existing entity typing research often address this aspect by explicitly utilizing a given type hierarchy to design hierarchy-aware loss functions (Ren et al., 2016b; Xu and Barbosa, 2018) or enhanced type label encodings (Shimaoka et al., 2017) that enable parameter sharing between related types. These methods rely on the assump-

tion that the underlying type structures are predefined in entity typing datasets. For benchmarks annotated with the knowledge base (KB) guided distant supervision, this assumption is often valid since all types are from KB ontologies and naturally follow tree-like structures. However, since knowledge bases are inherently incomplete (Min et al., 2013), existing KBs only include a limited set of entity types. Thus, models trained on these datasets fail to generalize to lots of unseen types. In this work, we investigate entity typing in a more open scenario where the type set is not restricted by KB schema and includes over 10,000 free-form types (Choi et al., 2018). As most of the types do not follow any predefined structures, methods that explicitly incorporate type hierarchies cannot be straightforwardly applied here.

To effectively capture the underlying label correlations without access to known type structures, we propose a novel label-relational inductive bias, represented by a graph propagation layer that operates in the latent label space. Specifically, this layer learns to incorporate a label affinity matrix derived from global type co-occurrence statistics and word-level type similarities. It can be seamlessly coupled with existing models and jointly updated with other model parameters. Empirically, on the Ultra-Fine dataset (Choi et al., 2018), the graph layer alone can provide a significant 11.9% relative F1 improvement over previous models. Additionally, we show that the results can be further improved ($11.9\% \rightarrow 15.3\%$) with an attention-based mention-context matching module that better handles *pronouns* entity mentions. With a simple modification, we demonstrate that the proposed graph layer is also beneficial to the widely used OntoNotes dataset, despite the fact that samples in OntoNotes have lower label multiplicity (*i.e.*, average number of ground-truth types for each sample) and thus require less label-dependency modeling than the Ultra-Fine dataset.

To summarize, our major contribution includes:

- We impose an effective label-relational bias on entity typing models with an easy-to-implement graph propagation layer, which allows the model to implicitly capture type dependencies;
- We augment our graph-enhanced model with an attention-based matching module, which constructs stronger interactions between the mention and context representations;
- Empirically, our model is able to offer significant improvements over previous models on the Ultra-Fine dataset and also reduces the cases of inconsistent type predictions.

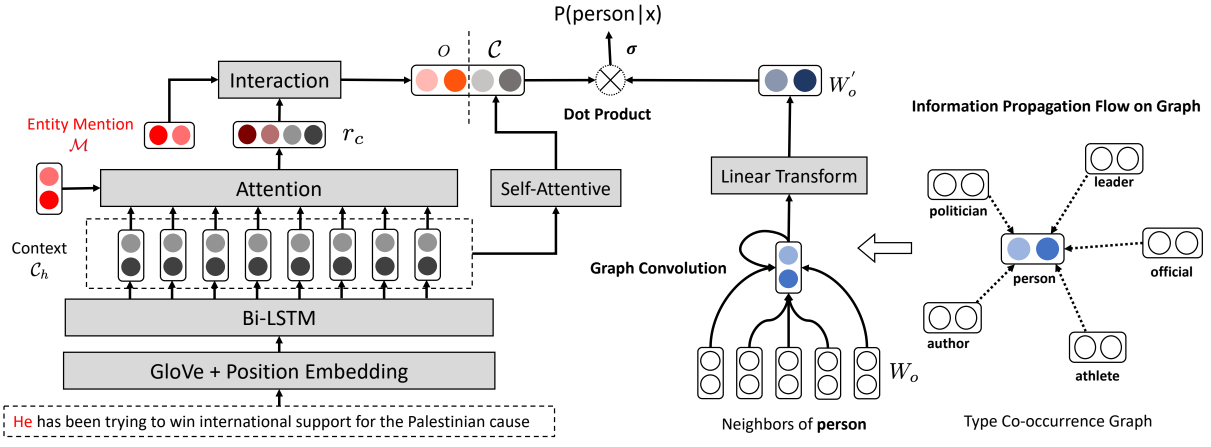
2 Related Work

Fine-Grained Entity Typing The task of fine-grained entity typing was first thoroughly investigated in (Ling and Weld, 2012), which utilized Freebase-guided distant supervision (DS) (Mintz et al., 2009) for entity typing and created one of the early large-scale datasets. Although DS provides an efficient way to annotate training data, later work (Gillick et al., 2014) pointed out that entity type labels induced by DS ignore entities' local context and may have limited usage in context-aware applications. Most of the following research has since focused on testing in context-dependent scenarios. While early methods (Gillick et al., 2014; Yogatama et al., 2015) on this task rely on well-designed loss functions and a suite of hand-craft features that represent both context and entities, Shimaoka et al. (2016) proposed the first attentive neural model which outperformed feature-based methods with a simple cross-entropy loss.

Modeling Entity Type Correlations To better capture the underlying label correlations, Shimaoka et al. (2017) employed a hierarchical label encoding method and AFET (Ren et al., 2016a) used the predefined label hierarchy to identify noisy annotations and proposed a partial-label loss to reduce such noise. A recent work (Xu and Barbosa, 2018) proposed hierarchical loss normalization which alleviated the noise of too specific types. Our work differs from these works in that we do not rely on known label structures and aim to learn the underlying correlations from data. Rabinovich and Klein (2017) recently proposed a structure-prediction approach which used type correlation features. The inference on their learned factor graph is approximated by a greedy decoding algorithm, which outperformed unstructured methods on their own dataset. Instead of using an explicit graphical model, we enforce a relational bias on model parameters, which does not introduce extra burden on label decoding.

3 Task Definition

Specifically, the task we consider takes a raw sentence C as well as an entity mention span M inside



a) Mention-Context Encoding

b) GCN over Type Vectors

Figure 1: Overview of the process to make predictions on the type **"person"**. **a)** Modules used to extract mention and context aware representations. **b)** An illustration of the graph layer operating over the type vector of **"person"**.

C as inputs, and aims to predict the correct type labels T_m of M from a candidate type set $\mathcal{T}$, which includes more than 10,000 free-form types. The entity span M here can be named entities, nominals and also pronouns. The ground-truth type set T_m here usually includes more than one types (approximately five types on average), making this task a multi-label classification problem.

4 Methodology

In this section, we first briefly introduce the neural architecture to encode raw text inputs. Then we describe the matching module we use to enhance the interaction between the mention span and the context sentence. Finally, we move to the label decoder, on which we impose the label-relational bias with a graph propagation layer that encodes type co-occurrence statistics and word-level similarities. Figure 1 provides a graphical overview of our model, with 1a) illustrating both the text encoders and the matching module, and 1b) showing an example of graph propagation.

4.1 Representation Model

Our base model to encode the context and the mention span follows existing neural approaches (Shimaoka et al., 2016; Xu and Barbosa, 2018; Choi et al., 2018). To encode the context, we first apply a standard Bi-LSTM, which takes GloVe (Pennington et al., 2014) embeddings and position embeddings (three vectors representing positions before, inside or after the mention span) as inputs and outputs the hidden states at each time step $t \in [1, l_c]$. With the derived hidden states $\mathcal{C}_h \in \mathbb{R}^{l_c \times h_c}$, we then apply a self-attentive encoder (McCann et al., 2017) on the top to get the final context representation $\mathcal{C}$. For the entity mention span, we concatenate the features derived by a character-level CNN and a similar self-attentive encoder. We denote the final mention representation as $\mathcal{M}$.[2]

4.2 Mention-Context Interaction

Since most previous datasets only consider *named entities*, a simple concatenation of the two features $[\mathcal{C}; \mathcal{M}]$ followed by a linear output layer (Shimaoka et al., 2016, 2017) usually works reasonably well when making predictions. This suggests that $\mathcal{M}$ itself provides important information for recognizing entity types. However, as in our target dataset, a large portion of entity mentions are actually *pronouns*, such as "he" or "it", this kind of mentions alone provide only limited clues about general entity types (*e.g.*, "he" is a "person") but little information about fine-grained types. In this case, directly appending representation of pronouns does not provide extra useful information for making fine-grained predictions. Thus, instead of using the concatenation operator, we propose to construct a stronger interaction between the mention and context with an attention-based matching module, which has shown its effectiveness in recent natural language inference models (Mou et al., 2016; Chen et al., 2017).

Formally consider the mention representation $\mathcal{M} \in \mathbb{R}^{h_m}$ and context's hidden feature $\mathcal{C}_h \in$

---

[2] Please refer to (Shimaoka et al., 2017) and (Choi et al., 2018) for more detailed descriptions.

$\mathbb{R}^{l_c \times h_c}$, where l_c indicates the number of tokens in the context sentence and h_m, h_c denote feature dimensions. We first project the mention feature $\mathcal{M}$ into the same dimension space as $\mathcal{C}_h$ with a linear layer ($W_1 \in \mathbb{R}^{h_m \times h_c}$) and a $tanh$ function[3]:

$$m_{proj} = tanh(W_1^T \mathcal{M}), \tag{1}$$

then we perform bilinear attention matching between m_{proj} and $\mathcal{C}_h$, resulting in an affinity matrix $\mathcal{A}$ with dimension $\mathcal{A} \in \mathbb{R}^{1 \times l_c}$:

$$\mathcal{A} = m_{proj} \times W_a \times \mathcal{C}_h, \tag{2}$$

where $W_a \in \mathbb{R}^{h_c \times h_c}$ is a learnable matrix. If we consider the mention feature as query and the context as memory, we can use the affinity matrix to retrieve the relevant parts in the context:

$$\bar{\mathcal{A}} = softmax(\mathcal{A}) \tag{3}$$

$$r_c = \bar{\mathcal{A}} \times \mathcal{C}_h. \tag{4}$$

With the projected mention representation m_{proj} and the retrieved context feature r_c, we define the following interaction operators:

$$r = \rho(W_r[r_c; m_{proj}; r_c - m_{proj}]) \tag{5}$$

$$g = \sigma(W_g[r_c; m_{proj}; r_c - m_{proj}]) \tag{6}$$

$$o = g * r + (1 - g) * m_{proj}, \tag{7}$$

where $\rho(\cdot)$ is a gaussian error linear unit (Hendrycks and Gimpel, 2016) and r is the fused context-mention feature; $\sigma(\cdot)$ indicates a *sigmoid* function and g is the resulting gating function, which controls how much information in mention span itself should be passed down. We expect the model to focus less on the mention representation when it is not informative. The concatenation $[r_c; m_{proj}; r_c - m_{proj}]$ here is supposed to capture different aspects of the interactions. To emphasize the context's impact, we finally concatenate the extracted context feature ($\mathcal{C}$) with the output (o) of the matching module ($f = [o; \mathcal{C}]$) for prediction.

4.3 Imposing Label-Relational Inductive Bias

For approaches that ignore the underlying label correlations, the type predictions are considered as N independent binary classification problems, with N being the number of types. If we denote the feature extracted by any arbitrary neural model as $f \in \mathbb{R}^{d_f}$, then the probability of being any given type is calculated by:

$$p = \sigma(W_o f), W_o \in \mathbb{R}^{N \times d_f}. \tag{8}$$

We can see that every row vector of W_o is responsible for predicting the probability of one particular type. We will refer the row vectors as type vectors for the rest of this paper. As these type vectors are independent, the label correlations are only implicitly captured by sharing the model parameters that are used to extract f. We argue that the paradigm of parameter sharing is not enough to impose strong label dependencies and the values of type vectors should be better constrained.

A straightforward way to impose the desired constraints is to add extra regularization terms on W_o. We first tested several auxiliary loss functions based on the heuristics from GloVe (Pennington et al., 2014), which operates on the type co-occurrence matrix. However, the auxiliary losses only offer trivial improvements in our experiments. Instead, we find that directly imposing a model-level inductive bias on the type vectors turns out to be a more principled solution. This is done by adding a graph propagation layer over randomly initialized W_o and generating the updated type vectors $W_o^{'}$, which is used for final prediction. Both W_o and the graph convolution layer are learned together with other model parameters. We view this layer as the key component of our model and use the rest of this section to describe how we create the label graph and compute the propagation over the graph edges.

Label Graph Construction In KB-supervised datasets, the entity types are usually arranged in tree-like structures. Without any prior about type structures, we consider a more general graph-like structure. While the nodes in the graph straightforwardly represent entity types, the meaning of the edges is relatively vague, and the connections are also unknown. In order to create meaningful edges using training data as the only resource, we utilize the type co-occurrence matrix: if two type t_1 and t_2 both appear to be the true types of a particular entity mention, we will add an edge between them. In other words, we are using the co-occurrence statistics to approximate the pair-wise dependencies and the co-occurrence matrix now serves as the adjacent matrix. Intuitively, if t_2 co-appears with t_1 more often than another type t_3, the probabilities of t_1 and t_2 should have stronger depen-

---

[3] $tanh$ here is used to make m_{proj} in the same scale as $\mathcal{C}_h$, which was the output of a $tanh$ function inside LSTM.

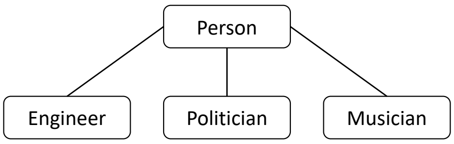


Figure 2: A snippet of the underlying type co-occurrence graph. Multiple edges between nodes are omitted here for clarity.

dencies and the corresponding type vectors should be more similar in the vector space. In this sense, we expect each type vector to effectively capture the local neighbor structure on the graph.

Correlation Encoding via Graph Convolution To encode the neighbor information into each node's representation, we follow the propagation rule defined in Graph Convolution Network (GCN) (Kipf and Welling, 2016). In particular, with the adjacent or co-occurrence matrix A, we define the following propagation rule on W_o:

$$W_o^{'} = \tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}W_oT \tag{9}$$

$$\tilde{A} = A + I_N. \tag{10}$$

Here $T \in \mathbb{R}^{d_f \times d_f}$ is the transformation matrix and I_N is an identity matrix used to add self-connected edges. $\tilde{D}$ is a diagonal degree matrix with $\tilde{D}_{ii} = \sum_j \tilde{A}_{ij}$, which is used to normalize the feature vectors such that the number of neighbors does not affect the scale of transformed feature vectors. In our experiments, we find that an alternative propagation rule

$$W_o^{'} = \tilde{D}^{-1}\tilde{A}W_oT \tag{11}$$

works similarly well and is more efficient as it involves less matrix multiplications. If we look closely and take each node out, the propagation can be written as

$$W_o^{'}[i,:] = \frac{1}{\sum_j \tilde{A}_{ij}}(\sum_j \tilde{A}_{ij}W_o[j,:]T). \tag{12}$$

From this formula, we can see that the propagation is essentially gathering features from the first-order neighbors. In this way, the prediction on type t_i is dependent on its neighbor types.

Compared to original GCNs that often use multi-hop propagations (*i.e.*, multiple graph layers connected by nonlinear functions) to capture higher-order neighbor structures. We only apply one-hop propagation and argue that high-order label dependency is not necessarily beneficial in our scenario and might introduce false bias. A simple illustration is shown in Figure 2. We can see that propagating 2-hop information introduces undesired inductive bias, since types that are more than 1-hop away (*e.g.*, "Engineer" and "Politician") usually do not have any dependencies. In fact, some of the 2-hop type pairs can be contradictory types (*e.g.*, "police" and "prisoner"). This hypothesis is consistent with our experiment results: adding more than one graph layer leads to worse results. Additionally, we also omit GCN's nonlinear activation which introduces unnecessary constraints on the scale of $W_o^{'}$, with which we calculate the unscaled scores before calculating the probability via a sigmoid function.

4.4 Leveraging Label Word Embeddings

As the type labels are all written as text phrases, an interesting question is whether we can exploit the semantics provided by pre-trained word embeddings to improve entity typing. We explore this possibility by using the cosine similarity of word embeddings. We first calculate type embeddings by simply summing the embeddings of all tokens in the type name. Then we build a label affinity matrix A_{word} by calculating pair-wise cosine similarities. With the assumption that word-level similarity measures some degree of label dependency, we propose to integrate A_{word} into the graph convolution layer following

$$A_{word}^{'} = (A_{word} + 1)/2 \tag{13}$$

$$W_o^{'} = \tilde{D}^{-1}(\tilde{A} + \lambda A_{word}^{'})W_oT. \tag{14}$$

Here Equation 13 scales the similarity value into $(0, 1]$ to avoid negative edge weights, which might introduce numerical issues when calculating $\tilde{D}^{-1}$. λ is a trainable parameter used to weight the impact of word-level similarities. As will be shown in Section 5, this simple augmentation provides further improvement over our original model.

5 Experiments

5.1 Experiment Setup

Datasets Our experiments mainly focus on the Ultra-Fine entity typing dataset which has 10,331 labels and most of them are defined as free-form text phrases. The training set is annotated with heterogeneous supervisions based on KB, Wikipedia and head words in dependency trees,

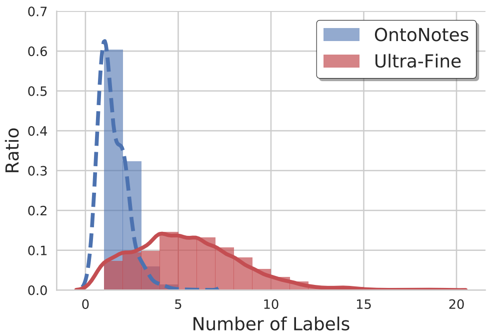

Figure 3: Label multiplicity distribution of the datasets.

resulting in about 25.2M[4] training samples. This dataset also includes around 6,000 crowdsourced samples. Each of these samples has five ground-truth labels on average. For a fair comparison, we use the original test split of the crowdsourced data for evaluation. To better understand the capability of our model, we also test our model on the commonly-used OntoNotes (Gillick et al., 2014) benchmark. It is worth noting that this dataset is much smaller and has lower label multiplicity than the Ultra-Fine dataset, *i.e.*, each sample only has around 1.5 labels on average. Figure 3 shows a comparison of these two datasets.

Baselines For the Ultra-Fine dataset, we compare our model with AttentiveNER (Shimaoka et al., 2016) and the multi-task model proposed with the Ultra-Fine dataset. Note that *other models that require pre-defined type hierarchy are not applicable to this dataset*. For experiments on OntoNotes, in addition to the two neural baselines for Ultra-Fine, we compare with several existing methods that explicitly utilize the pre-defined type structures in loss functions. Namely, these methods are AFET (Ren et al., 2016a), LNR (Ren et al., 2016b) and NFETC (Xu and Barbosa, 2018).

Evaluation Metrics On Ultra-Fine, we first evaluate the mean reciprocal rank (MRR), macro precision(P), recall (R) and F1 following existing research. As P, R and F1 all depend on a chosen threshold on probabilities, we also consider a more transparent comparison using precision-recall curves. On OntoNotes, we use the standard metrics used by baseline models: accuracy, macro, and micro F1 scores.

Implementation Details Most of the model hyperparameters, such as embedding dimensions, learning rate, batch size, dropout ratios on context and mention representations are consistent with existing models. Since the mention-context matching module brings more parameters, we apply a dropout layer over the extracted feature f to avoid overfitting. We list all the hyperparameters in the appendix. Models for OntoNotes are trained with standard binary cross-entropy (BCE) losses defined on all candidate labels. When training on Ultra-Fine, we adopt the multi-task loss proposed in Choi et al. (2018) which divides the cross-entropy loss into three separate losses over different type granularities. The multi-task objective avoids penalizing false negative types and can achieve higher recalls.

5.2 Evaluation on the Ultra-Fine Dataset

We report the results on Ultra-Fine in Table 2. It is worth mentioning that our model, denoted as LABELGCN, is trained using the unlicensed training set which is smaller than the one used by compared baselines. Even though our model significantly outperforms the baselines, for a fair comparison, we first test our model using the same decision threshold (0.5) used by previous models. In terms of F1, our best model (LABELGCN) outperforms existing methods by a large margin. Compared to Choi et al. (2018), our model improves on both precision and recall significantly. Compared to the AttentiveNER trained with standard BCE loss, our model achieves much higher recall but performs worse in precision. This is due to the fact that when trained with BCE loss, the model usually retrieves only one label per sample and these types are mostly general types[5] which are easier to predict. With higher recalls or more retrieved types, achieving high precision requires being accurate on fine-grained types, which are often harder to predict.

As the precision and recall scores both rely on the decision threshold, different models or different metrics can have different optimal thresholds. As shown by the "LABELGCN + thresh tuning" entry in Table 2, with threshold tuning, our model beats baselines in all metrics. We also see that recall is usually lagging behind precision on this dataset, indicating that F1 score is mainly affected

---

[4] Choi et al. (2018) use the licensed Gigaword to build part of the dataset, while in our experiments we only use the open-sourced training set which has approximately 6M training samples.

[5] According to the results of our own implementation of BCE-trained model which achieves similar performance as AttentiveNER.

Choi et al. (2018)	35.8	32.0
Choi et al. (2018) + inter	38.2 (↑ 2.4)	32.8
LabelGCN w/o inter	38.6	36.8
LabelGCN	39.3 (↑ 0.7)	36.5

Table 3: Decomposed validation performance on pronouns and the other entities. Each entry is obtained using the best threshold among the 50 equal-interval thresholds. The corresponding PR curves can be found in the appendix (Figure 5).

by the recall and tuning towards recall can usually lead to higher F1 scores. For more transparent comparisons, we show the precision-recall curves in Figure 4. These data points are based on the validation performance given by 50 equal-interval thresholds between 0 and 1. We can see there is a clear margin between our model and the multi-task baseline method (LabelGCN vs Choi et al.).

5.3 Ablation Studies

To quantify the effect of different model components, we report the performance of model variants in Table 2 and Figure 4. We can clearly see that the graph convolution layer is the most essential component. The information provided by word embedding is useful and can further improve both precision and recall. Although Table 2 seems to indicate the interaction module decreases the precision, we can see from Figure 4 that with a proper threshold, the enhanced interaction actually improves both precision and recall. In term of this, we recommend future research to use PR curves for more accurate model analysis.

5.4 Fine-Grained Performance for Pronouns

As discussed in Section 4.2, the mention representation of pronouns provide limited information about fine-grained types. We investigate the effect of the enhanced mention-context interaction by analyzing the decomposed performance on pronouns and other kinds of entities. From the results in Table 3, we can see that the enhanced interaction offers consistent improvements over pronouns entities and also maintains the performance on other kinds of entities.

5.5 Qualitative Analysis

To gain insights on the improvements provided by our model, we manually analyze 100 error cases[6] of the baseline model (Choi et al. (2018) with threshold 0.5) and see if our model can generate high-quality predictions. We first observe that many errors actually results from incomplete annotations. This suggests models' precision scores are often underestimated in this dataset. We discuss several typical error cases shown in Table 4 and list more samples in the appendix (Table 7).

A key observation is that while the baseline model tends to make inconsistent predictions (see examples 1, 2, 3), our model can avoid predicting such inconsistent type pairs. This indeed validates our model's ability to encode label correlations. We also notice that our model is more sensitive to gender information indicated by pronouns, while

---

[6] The baseline model achieves the lowest precision on these 100 samples.

1) Context	**Today**, Taiwan is manifesting the elegance of a democratic island, once again attracting global attention, as the people on this land create a new page in our history.
Groundtruth	*time, date, day, today, present*
Prediction	**Baseline**: {day†, person*, organization, religion} **Ours**: {day}
2) Context	**A gigantic robot** emerges, emitting a sound that paralyzes humans and disrupts all electrical systems in New York City.
Groundtruth	*object, device, machine, mechanism*
Prediction	**Baseline**: {object, person†, robot*} **Ours**: {object, robot}
3) Context	**He** also has been accused of genocide in Bosnia and other war crimes in Croatia, but the date to try those two indictments together has not been set.
Groundtruth	*person*
Prediction	**Baseline**:{person, god†, title, criminal*} **Ours**: {person, politician, criminal, male, prisoner}
4) Context	**Her** status was uncertain for Wimbledon, which begins June 23.
Groundtruth	*person, athlete, adult, player, professional, tennis player, contestant*
Prediction	**Baseline**: {person, female, woman, spouse} **Ours**: {person, artist, female, woman}
5) Context	For eight years **he** treated thousands of wounded soldiers of the armed forces led by the CPC.
Groundtruth	*person, doctor, caretaker, nurse*
Prediction	**Baseline**: {person, soldier, suspect, serviceman} **Ours**: {person, soldier, man}

LNR	57.2	71.5	66.1
NFETC	**60.2**	76.4	70.2
Choi et al. (2018)	59.5	76.8	71.8
LABELGCN	59.6	**77.8**	**72.2**

Table 5: Results on OntoNotes. Upper rows show the results of baselines that explicitly use the hierarchical type structures.

the baseline model sometimes holds the gender-indicating predictions and predict other types, our model predicts the gender-indicating types more often (examples 3, 4, 5). We conjecture that our model learns this easy way to maintain precision.

For cases that both models fail, some of them actually require background knowledge (example 4) to make accurate predictions. Another typical case is that both models predict some other entities in the context (example 5). We think this potentially results from the data bias introduced by the head-word supervision.

5.6 Evaluation on OntoNotes

To better understand the requirements for applying our model, we further evaluate on the OntoNotes dataset. Here we do not apply the proposed mention-context matching module as this dataset does not include any pronoun entities. To obtain more reliable co-occurrence statistics, we use the augmented training data released by Choi et al. (2018). However, since the training set is still much smaller than that of the Ultra-Fine dataset, the derived co-occurrence statistics are relatively noisy and might introduce undesired bias. We thus add an additional residual connection to our graph convolution layer, which allows the model to selectively use co-occurrence statistics. This indeed gives us improvements over previous state-of-the-arts, as shown in Table 5. However, compared to Ultra-Fine, the margin of the improvement is smaller. In view of the key differences of these two datasets, we highlight two key requirements for our proposed model to offer substantial improvements. First, there should be a large-scale training set so that the derived co-occurrence statistics can reasonably reflect the true label correlations. Second, the samples themselves should also have higher label multiplicity. In fact, most of the samples in OntoNotes only have 1 or 2 labels. This property actually alleviates the need for models to capture label dependencies.

6 Conclusion

In this paper, we present an effective method to impose label-relational inductive bias on fine-grained entity typing models. Specifically, we utilize a graph convolution layer to incorporate type co-occurrence statistics and word-level type similarities. This layer implicitly captures the label correlations in the latent vector space. Along with an attention-based mention-context matching module, we achieve significant improvements over previous methods on a large-scale dataset. As our method does not require external knowledge about the label structures, we believe our method is general enough and has the potential to be applied to other multi-label tasks with plain-text labels.

Abstract

Argument compatibility is a linguistic condition that is frequently incorporated into modern event coreference resolution systems. If two event mentions have incompatible arguments in any of the argument roles, they cannot be coreferent. On the other hand, if these mentions have compatible arguments, then this may be used as information toward deciding their coreferent status. One of the key challenges in leveraging argument compatibility lies in the paucity of labeled data. In this work, we propose a transfer learning framework for event coreference resolution that utilizes a large amount of unlabeled data to learn the argument compatibility between two event mentions. In addition, we adopt an interactive inference network based model to better capture the (in)compatible relations between the context words of two event mentions. Our experiments on the KBP 2017 English dataset confirm the effectiveness of our model in learning argument compatibility, which in turn improves the performance of the overall event coreference model.

1 Introduction

Events are essential building blocks of all kinds of natural language text. An event can be described several times from different aspects in the same document, resulting in multiple surface forms of event mentions. The goal of event coreference resolution is to identify event mentions that correspond to the same real-world event. This task is critical for natural language processing applications that require deep text understanding, such as storyline extraction/generation, text summarization, question answering, and information extraction.

[1] KMT to **elect**$_{m1}$ new party chief

[2] The ruling Chinese Kuomingtang Party (KMT) in Taiwan is scheduled to **elect**$_{m2}$ a new chairperson in January 2012, it was decided at the top-level KMT **meeting**$_{m3}$ on Wednesday.

[3] KMT chairman Ma Ying-jeou stressed fair paly during the **election**$_{m4}$ at Wednesday's **meeting**$_{m5}$, saying guest-feting or gift-giving must be banned during the process.

[4] Ma was twice **elected**$_{m6}$ the party's chairman, first in 2005 and then in 2009.

ev_1: m_1, m_2, m_4
ev_2: m_3, m_5
ev_3: m_6

Figure 1: A document with three events described in six event mentions. Coreferent event mentions are highlighted with the same color.

Figure 1 shows a document consisting of three events described by six different event mentions. Among these event mentions, m_1, m_2 and m_4 are coreferent, since they all correspond to the event of the KMT party electing a new party chief. Similarly, m_3 and m_5 are also coreferent, while m_6 is not coreferent with any other event mentions.

An event mention consists of a trigger and zero or more arguments. The trigger of an event mention is the word/phrase that is considered the most representative of the event, such as the word *meeting* for m_3 or the word *elected* for m_6. Triggers of coreferent event mentions must be related, that is, they should describe the same type of events. For example, m_1 and m_3 cannot be coreferent, since their trigger words — *elect* and *meeting* — are not related.

Arguments are the participants of an event, each having its role. For example, *KMT* is the AGENT-argument and *new party chief* is the PATIENT-argument of m_1. Argument compatibility is an important linguistic condition for determining the coreferent status between two event mentions. Two arguments are incompatible if they do not correspond to the same real-world entity when they are expressed in the same level of specificity;

Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

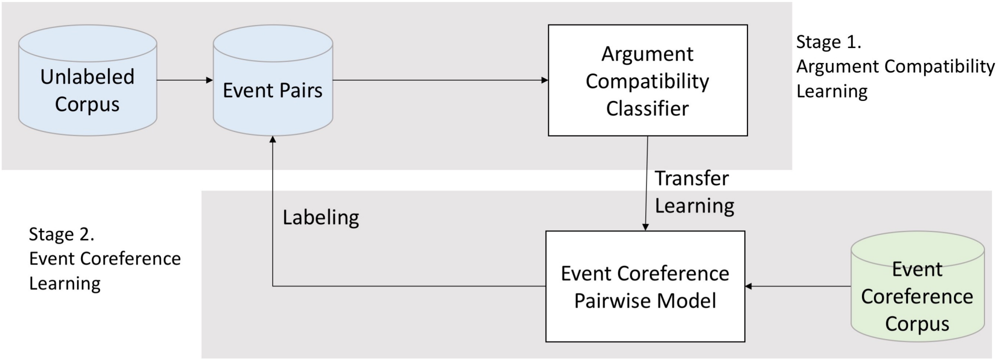

Figure 2: System overview.

otherwise, they are compatible. For example, a pair of TIME-arguments — *Wednesday* and *2005* — which are expressed in different level of specificity, are considered compatible. If two event mentions have incompatible arguments in some specific argument roles, they cannot be coreferent. For example, m_2 and m_6 are not coreferent since their TIME-arguments — *January 2012* and *2005* — and their PATIENT-arguments — *a new chairperson* and *Ma* — are incompatible. On the other hand, coreferent event mentions can only have compatible arguments. For example, m_3 and m_5 both have *Wednesday* as TIME-arguments. In this example, argument compatibility in the TIME argument role is a strong hint suggesting their coreference.

Despite its importance, incorporating argument compatibility into event coreference systems is challenging due to the lack of sufficient labeled data. Many existing works have relied on implementing argument extractors as upstream components and designing argument features that capture argument compatibility in event coreference resolvers. However, the error introduced in each of the steps propagates through these resolvers and hinders their performance considerably.

In light of the aforementioned challenge, we propose a framework for transferring argument (in)compatibility knowledge to the event coreference resolution system, specifically by adopting the interactive inference network (Gong et al., 2018) as our model structure. The idea is as follows. First, we train a network to determine whether the corresponding arguments of an event mention pair are compatible on automatically labeled training instances collected from a large unlabeled news corpus. Second, to transfer the knowledge of argument (in)compatibility to an event coreference resolver, we employ the network (pre)trained in the previous step as a starting point and train it to determine whether two event mentions are coreferent on manually labeled event coreference corpora. Third, we iteratively repeat the above two steps, where we use the learned coreference model to relabel the argument compatibility instances, retrain the network to determine argument compatibility, and use the resulting pretrained network to learn an event coreference resolver. In essence, we mutually bootstrap the argument (in)compatibility determination task and the event coreference resolution task.

Our contributions are three-fold. First, we utilize and leverage the argument (in)compatibility knowledge acquired from a large unlabeled corpus for event coreference resolution. Second, we employ the interactive inference network as our model structure to iteratively learn argument compatibility and event coreference resolution. Initially proposed for the task of natural language inference, the interactive inference network is suitable for capturing the semantic relations between word pairs. Experimental results on the KBP coreference dataset show that this network architecture is also suitable for capturing the argument compatibility between event mentions. Third, our model achieves state-of-the-art results on the KBP 2017 English dataset (Ellis et al., 2015, 2016; Getman et al., 2017), which confirms the effectiveness of our method.

2 Related Work

Ablation experiments conducted by Chen and Ng (2013) provide empirical support for the usefulness of event arguments for event coreference resolution. Hence, it should not be surprising that, with just a few exceptions (e.g., Sangeetha and

	event mention	DATE-compatibility with m_a
m_a	The result of the **election** last October surprised everyone.	-
m_1	He was **elected** as president in 2005.	no
m_2	The presidential **election** took place on October 20th.	yes
m_3	The opposition party won the **election**.	yes

Table 1: Examples of NER-based sample filtering. The phrases tagged as DATE are underlined, and the trigger words are boldfaced.

Arock (2012); Araki and Mitamura (2015); Lu and Ng (2017)), argument features have been extensively exploited in event coreference systems to capture the argument compatibility between two event mentions. Basic features such as the number of overlapping arguments and the number of unique arguments, and a binary feature encoding whether arguments are conflicting have been proposed (Chen et al., 2009; Chen and Ji, 2009; Chen and Ng, 2016). More sophisticated features based on different kinds of similarity measures have also been considered, such as the surface similarity based on Dice coefficient and the WuPalmer WordNet similarity between argument heads (McConky et al., 2012; Cybulska and Vossen, 2013; Araki et al., 2014; Liu et al., 2014; Krause et al., 2016). However, these features are computed using either the outputs of event argument extractors and entity coreference resolvers (Ahn, 2006; Chen and Ng, 2014, 2015; Lu and Ng, 2016) or semantic parsers (Bejan and Harabagiu, 2014; Yang et al., 2015; Peng et al., 2016) and therefore suffer from serious error propagation issues (see Lu and Ng (2018)). Several previous works proposed joint models to address this problem (Lee et al., 2012; Lu et al., 2016), while others utilized iterative methods to propagate argument information (Liu et al., 2014; Choubey and Huang, 2017) in order to alleviate this issue. However, all of these methods still rely on argument extractors to identify arguments and their roles.

3 Method

Our proposed transfer learning framework consists of two learning stages, the pretraining stage of an argument compatibility classifier and the fine-tuning stage of an event coreference resolver (Figure 2). We provide the details of both stages in sections 3.1 and 3.2, and describe the iterative strategy combining the two training stages in section 3.3. Details on the model structure are covered in section 3.4.

3.1 Argument Compatibility Learning

In the pretraining stage, we train the model as an argument compatibility classifier with event mentions extracted from a large unlabeled news corpus.

Task definition Given a pair of event mentions (m_a, m_b) with related triggers, predict whether their arguments are compatible or not.

Here, an event mention is represented by a trigger word and the context words within an n-word window around the trigger.

Related trigger extraction We analyze the event coreference resolution corpus and extract trigger pairs that are coreferent more than k times in the training data. We define these trigger pairs to be *related* triggers in our experiment. In this work, we set k to 10. Table 2 shows some examples of related triggers with high counts.

trigger pair	count
kill - death	86
shoot - shooting	35
retire - retire	34
demonstration - protest	30

Table 2: Examples of related triggers.

If the triggers of an event mention pair are related, their coreferent status cannot be determined by looking at the triggers alone, and this is the case in which argument compatibility affects the coreferent status most directly. Thus, we focus on the event mention pairs with related triggers in the pretraining stage of argument compatibility learning.

Compatible samples extraction From each document, we extract event mention pairs with related triggers and check whether the following conditions are satisfied:

1. DATE-compatibility (Table 1):
   First, we perform named entity recognition

(NER) on the context words. If both event mentions have phrases tagged as DATE in the context, these two phrases must contain at least one overlapping word. If there are multiple phrases tagged as DATE in the context, only the phrase closest to the trigger word is considered.

2. PERSON-compatibility: Similar to 1.
3. NUMBER-compatibility: Similar to 1.
4. LOCATION-compatibility: Similar to 1.
5. Apart from function words, the ratio of overlapping words in their contexts must be under 0.3 for both event mentions. We add this constraint in order to remove trivial samples of nearly identical sentences.

Conditions 1–4 are heuristic filtering rules based on NER tags, which aim to remove samples with apparent incompatibilities. Here, we consider four NER types — DATE, PERSON, NUMBER, and LOCATION — because these types of words are the most salient types of incompatibility that can be observed between event mentions. Condition 5 aims to remove event mention pairs that are "too similar". We add this condition because we do not want our model to base its decisions on the number of overlapping words between the event mentions.

We collect event mention pairs satisfying all the above conditions as our initial set of compatible samples.

Incompatible sample extraction From different documents in the corpus, we extract event mentions with related triggers and check whether the following conditions are satisfied:

1. The creation date of the two documents must be at least one month apart.
2. Apart from the trigger words and the function words, the context of the event mentions must contain at least one overlapping word.

In the unlabeled news corpus, articles describing similar news events are sometimes present. Thus, we use condition 1 to roughly assure that the event mention pairs extracted are not coreferent. Mention pairs extracted from the same document tend to contain overlapping content words, so to prevent our model to make decisions based on the existence of overlapping words, we add condition 2 as a constraint.

We collect event mention pairs satisfying all the above conditions as our initial set of incompatible samples.

Argument compatibility classifier With the initial set of compatible and incompatible samples acquired above, we train a binary classier to distinguish between samples of the two sets.

3.2 Event Coreference Learning

In the fine-tuning stage, we adapt the argument compatibility classifier on the labeled event coreference data to a mention-pair event coreference model.

3.2.1 Event Mention Detection

Before proceeding to the task of event coreference resolution, we have to identify the event mentions in the documents. We train a separate event mention detection model to identify event mentions along with their subtypes.

We model event mention detection as a multi-class classification problem. Given a candidate word along with its context, we predict the subtype of the event mention triggered by the word. If the given candidate word is not a trigger, we label it as NULL. We select the words that have appeared as a trigger at least once in the training data as candidate trigger words. We do not consider multi-word triggers in this work.

Given an input sentence, we first represent each of its comprising words by the concatenation of the word embedding and the character embedding of the word. These representation vectors are fed into a bidirectional LSTM (biLSTM) layer to obtain the hidden representation of each word.

For each candidate word in the sentence, its hidden representation is fed into the inference layer to predict the class label. Since the class distribution is highly unbalanced, with the NULL label significantly outnumbering all the other labels, we use a weighted softmax at the inference layer to obtain the probability of each class. In this work, we set the weight to 0.1 for the NULL class label and 1 for all the other class labels.

Intuitively, candidate triggers with the same surface form in the same document tend to have the same class label. However, it is difficult to model this consistency since our model operates at the sentence level. Thus, we account for this consistency across sentences by the following post-processing step: If a candidate word is assigned the NULL label but more than half of the candidates sharing the same surface form is detected as triggers of a specific subtype, then we change the label to this given subtype. Also, we disregard event mentions with types *contact*, *movement* and *transaction* in this post-processing step, since the subtypes under these three types do not have a good consistency across different sentences in the same document.

3.2.2 Mention-Pair Event Coreference Model

With the argument compatibility classifier trained in the previous stage, we use the labeled event coreference corpus to fine-tune the model into an event coreference resolver. We design the event coreference resolver to be a mention-pair model (Soon et al., 2001), which takes a pair of event mentions as the input and outputs the likelihood of them being coreferent.

With the pairwise event coreference predictions, we further conduct best-first clustering (Ng and Cardie, 2002) on the pairwise results to build the event coreference clusters of each document. Best-first clustering is an agglomerative clustering algorithm that links each event mention to the antecedent event mention with the highest coreference likelihood given the likelihood is above an empirically determined threshold.

3.3 Iterative Relabeling Strategy

Previously, we collected a set of compatible event mentions from the same document with simple heuristic filtering. Despite this filtering step, the initial compatible set is noisy. Here, we introduce an iterative relabeling strategy to improve the quality of the compatible set of event mentions.

First, we calculate the coreference likelihood of the event mentions in the initial compatible set. Mention pairs with a coreference likelihood above threshold θ_M are added to the new compatible set. On the other hand, mention pairs with a coreference likelihood below θ_m are added to the initial incompatible set to form the new incompatible set. With the new compatible and incompatible sets, we can start another iteration of transfer learning to train a coreference resolver with improved quality. In this work, we set θ_M to 0.8 and θ_m to 0.2.

3.4 Model Structure

We adopt an interactive inference network as the model structure of our proposed method (Figure 3). A qualitative analysis of an interactive inference network shows that it is good at capturing word overlaps, antonyms and paraphrases between sentence pairs (Gong et al., 2018). Thus, we believe this network is suitable for capturing the argument compatibility between two event mentions. The model consists of the following components:

Model inputs The input to the model is a pair of event mentions (m_a, m_b), with m_a being the antecedent mention of m_b:

$$\begin{aligned} m_a &= \{w_a^1, w_a^2, ..., w_a^N\} \\ m_b &= \{w_b^1, w_b^2, ..., w_b^N\} \end{aligned} \tag{1}$$

Each event mention is represented by a sequence of N tokens consisting of one trigger word and its context. Here, we take the context to be the words within an n-word window around the trigger. In this work, n is set to 10.

Embedding layer We represent each input token by the concatenation of the following components:

Word embedding The word representation of the given token. We use pretrained word vectors to initialize the word embedding layer.

Character embedding To identify (in)compatibilities regarding person, organization or location names, the handling of out-of-vocabulary (OOV) words is critical.

Adding character-level embeddings can alleviate the OOV problem (Yang et al., 2017). Thus, we apply a convolutional neural network over the comprising characters of each token to acquire the corresponding character embedding.

POS and NER one-hot vectors One-hot vectors of the part-of-speech (POS) tag and NER tag.

Exact match A binary feature indicating whether a given token appears in the context of both event mentions. This feature is proved useful for several NLP tasks operating on pairs of texts (Chen et al., 2017; Gong et al., 2018; Pan et al., 2018).

Trigger position We encode the position of the trigger word by adding a binary feature to indicate whether a given token is a trigger word.

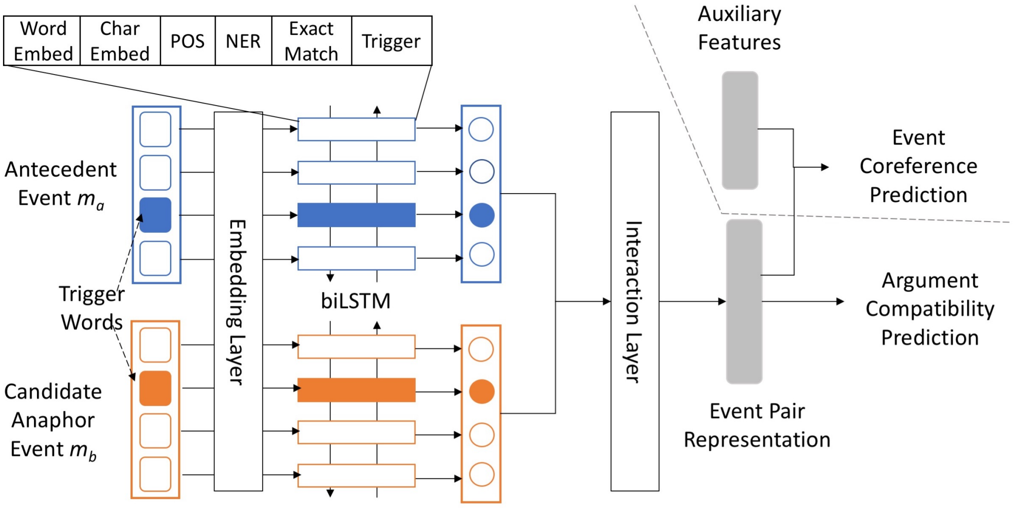

Figure 3: Model structure.

Encoding layer We pass the sequence of embedding vectors into a biLSTM layer (Hochreiter and Schmidhuber, 1997), resulting in a sequence of hidden vectors of size $|h|$:

$$\begin{aligned} h_a^i &= biLSTM(emb(w_a^i), h_a^{i-1}) \\ h_b^i &= biLSTM(emb(w_b^i), h_b^{i-1}) \end{aligned} \tag{2}$$

where $emb(w)$ is the embedding vector of token w.

Interaction layer The interaction layer captures the relations between two event mentions based on the hidden vectors h_a and h_b. The interaction tensor I, a 3-D tensor of shape (N, N, $|h|$), is calculated by taking the pairwise multiplication of the corresponding hidden vectors:

$$I_{ij} = h_a^i \circ h_b^j \tag{3}$$

Finally, we apply a multi-layer convolutional neural network to extract the event pair representation vector f_{ev}.

Inference layer In the pretraining stage, we feed f_{ev} to a fully-connected inference layer to make a binary prediction of argument compatibility.

As for the fine-tuning stage, we concatenate an auxiliary feature vector f_{aux} to f_{ev} before feeding it into the inference layer. f_{aux} consists of two features, a one-hot vector that encodes the sentence distance between the two event mentions and the difference of the word embedding vectors of the two triggers.

4 Evaluation

4.1 Experimental Setup

4.1.1 Corpora

We use English Gigaword (Parker et al., 2009) as the unlabeled corpus for argument compatibility learning. This corpus consists of the news articles from five news sources, each annotated with its creation date.

As for event coreference resolution, we use the English portion of the KBP 2015 and 2016 datasets (Ellis et al., 2015, 2016) for training, and the KBP 2017 dataset (Getman et al., 2017) for evaluation. The KBP datasets comprise news articles and discussion forum threads. The KBP 2015, 2016, and 2017 corpora contain 648, 169, and 167 documents, respectively. Each document is annotated with event mentions of 9 types and 18 subtypes, along with the coreference clusters of these event mentions.

4.1.2 Implementation Details

Preprocessing We use the Stanford CoreNLP toolkit (Manning et al., 2014) to perform preprocessing on the input data.

Network structure Each word embedding is initialized with the 300-dimensional pretrained GloVe embedding (Pennington et al., 2014). The character embedding layer is a combination of an 8-dimensional embedding layer and three 1D convolution layers with a kernel size of 5 with 100 filters. The size of the biLSTM layer is 200. The maximum length of a word is 16 characters; shorter words are padded with zero and longer

	MUC	B^3	$CEAF_e$	BLANC	AVG-F
biLSTM (standard)	29.49	43.15	39.91	24.15	34.18
biLSTM (transfer)	33.84	42.91	38.39	26.59	35.43
Interact (standard)	31.12	42.84	39.01	24.99	34.49
Interact (transfer)	34.28	42.93	39.95	32.12	36.24
Interact (transfer, 2^{nd} iter)	35.66	43.20	40.02	32.43	**36.75**
Interact (transfer, 3^{rd} iter)	36.05	43.07	39.69	28.06	36.72
Jiang et al. (2017)	30.63	43.84	39.86	26.97	35.33

Table 3: Event coreference resolution results of our proposed system, compared with the biLSTM baseline model and the current state-of-the-art system.

words are cropped. For the interaction layer, we use convolution layers with a kernel size of 3 in combination with max-pooling layers. The size of the inference layer is 128. Sigmoid activation is used for the inference layer, and all other layers use ReLU as the activation function.

Event mention detection model For word embeddings, we use the concatenation of a 300-dimensional pretrained GloVe embedding and the 50-dimensional embedding proposed by Turian et al. (2010). The character embedding layer is a combination of an 8-dimensional embedding layer and three 1D convolution layers with kernel sizes of 3, 4, 5 with 50 filters.

4.1.3 Evaluation Metrics

We follow the standard evaluation setup adopted in the official evaluation of the KBP event nugget detection and coreference task. This evaluation setup is based on four distinct scoring measures — MUC (Vilain et al., 1995) , B^3 (Bagga and Baldwin, 1998), $CEAF_e$ (Luo, 2005) and BLANC (Recasens and Hovy, 2011) — and the unweighted average of their F-scores (AVG-F). We use AVG-F as the main evaluation measure when comparing system performances.

4.2 Results

We present the experimental results on the KBP 2017 corpus in Table 3. In the following, we compare the performance of methods with different network architectures and experimental settings.

Comparison of network architectures We compare the results of the interactive inference network (Interact) with the biLSTM baseline model (biLSTM).

The biLSTM baseline model does not have the interaction layer. Instead, the last hidden vectors of the biLSTM layer are concatenated and fed into the inference layer directly.

When trained solely on the event coreference corpus (standard), the model with the interactive inference network performs slightly better than the biLSTM baseline model, as shown in rows 1 and 3. However, with an additional pretraining step of argument compatibility learning (transfer), the interact inference network outperforms the biLSTM baseline model by a considerable margin, as shown in rows 2 and 4. We conclude that the interactive inference network can better capture the complex interactions between two event mentions, accounting for the difference in performance.

Effect of transfer learning Regardless of the network structure, we observe a considerable improvement in performance by pretraining the model as an argument compatibility classifier. The biLSTM baseline model achieves an improvement of 1.25 points in AVG-F by doing transfer learning, as can be seen in rows 1 and 2. As for the interactive inference network, an improvement of 1.75 points in AVG-F is achieved, as can be seen in rows 3 and 4. These results provide suggestive evidence that our proposed transfer learning framework, which utilizes a large unlabeled corpus to perform argument compatibility learning, is effective.

Effect of iterative relabeling We achieve another boost in performance by using the trained event coreference resolver to relabel the training samples for argument compatibility learning. The best result is achieved after two iterations (row 5) with an improvement of 2.26 points in AVG-F compared to the standard interactive inference network (row 3). However, we are not able to obtain further gains with more iterations of relabeling (row 6). We speculate that the difference in event coreference model predictions across different iterations is not big enough to have a perceivable impact, but additional experiments are needed to determine the reason.

Type	Event Mention Pair	Gold	System
Explicit	m_1: ... the building where 13 people were **killed** will be razed, and a memorial ... m_2: In that case, George Hennard **killed** 23 people at a Luby 's restaurant, ...	non-coref	non-coref
Explicit	m_1: Ten relatives of the victims arrived at the airport Sunday before **traveling** to the city of Jiangshan. m_2: On Monday , the victims' relatives **went** to the Jiangshan Municipal Funeral Parlor.	non-coref	non-coref

General	m_1: Industrial accidents have injured and **killed** Foxconn workers, and the company also experienced ... m_2: ... explosion in May 2011 at Foxconn 's Chengdu factory **killed** three workers ...	non-coref	non-coref

Table 4: Examples of event pairs with related triggers. Trigger words are boldfaced, and words with (in)compatibility information are colored in blue.

Comparison with the state of the art Comparing row 5 and 7, we can see that our method outperforms the previous state-of-the-art model (Jiang et al., 2017) by 1.42 points in AVG-F.

5 Discussion

In this section, we conduct a qualitative analysis of the outputs of our best-performing system (the Interact (transfer, 2^{nd} iter) system in Table 3) on the event coreference dataset and the unseen event mention pairs extracted from the unlabeled corpus.

5.1 Compatibility Classification

We focus on the samples with related triggers having either compatible or incompatible arguments (Table 4). These samples can be roughly classified into the following categories:

Explicit argument compatibility The existence of identical/distinct time phrases, numbers, location names or person names in the context is the most explicit form of (in)compatibility.

For these event pairs, the existence of identical/distinct phrases with the same NER type is a direct clue toward deciding their coreferent status. Making use of this nature, we perform filtering on the set of compatible samples acquired from the unlabeled corpus in order to remove samples with explicit incompatibility.

Our model can recognize this type of (in)compatibility with a relatively high accuracy. Both examples shown in Table 4 are predicted correctly.

Implicit argument compatibility Event pairs with implicit (in)compatible arguments require external knowledge to resolve.

We present three examples in Table 4. In the first example, the knowledge that a woman *in her 60s* is generally not referred to as being *young* is required to determine the incompatibility. Similarly, the knowledge that both *brain hemorrhage* and *car accident* are causes of people's death are required to classify the second example correctly.

While the performance on samples with implicit (in)compatibility is not as good as that on samples with explicit (in)compatibility, our system is able to capture implicit (in)compatibility to some extent. We believe that this type of (in)compatibility is difficult to be captured with the argument features that are designed based on the outputs of argument extractors and entity coreference resolvers, and that the ability to resolve implicit (in)compatibility contributes largely to our system's performance improvements.

General-specific incompatibilities Event mentions describing general events pose special challenges to the task of event coreference resolution.

In Table 4, we present two typical examples of this category. In the first example, the second event mention does not refer to any specific shooting event in the real world, in contrast to the first event mention, which describes a specific school shooting event. Similarly for the second example, where the first event mention depicts a general event and the second event mention depicts a specific one.

General event mentions typically have few or even no arguments and modifiers, making the identification of non-coreference relations very challenging. Since we cannot rely on argument compatibility, a deeper understanding of the semantics of the event mentions is needed. General

	Event Mention Pair	Type	System
I	m_1: What would have happened if Steve Jobs had never **left** Apple ...	-	-
	m_2^a: ...in the state that is today if John hadn't **left**.	Explicit	non-coref
	m_2^b: ...in the state that is today if she hadn't **left**.	Implicit	non-coref
	m_2^c: ...in the state that is today if he hadn't **left**.	Implicit	coref
II	m_1: Police arrest 6 men for **gangraping** housewife in northern India.	-	-
	m_2^a: Indian police have arrested six men for allegedly **gangraping** a 29-year-old housewife ...	Explicit	coref
	m_2^b: Indian police have arrested six men for allegedly **gangraping** a woman ...	Implicit	coref
	m_2^c: Indian police have arrested six men for allegedly **gangraping** a medical student ...	Implicit	non-coref
III	m_1: Nationwide demonstrations in France to **protest** gay marriage.	-	-
	m_2^a: ...took to the streets across the country to **protest** against the country's plan to legalize same-sex marriage.	Implicit	coref
	m_2^b: ...took to the streets across the country to **protest** against the contentious citizenship amendment bill.	Implicit	non-coref

Table 5: Case study on manually-generated event mention pairs. Trigger words are boldfaced, and the target arguments are colored in blue.

event mentions account for a considerable fraction of our system's error, since they are quite pervasive in both news articles and discussion forum threads.

5.2 Case Study

To better understand the behavior of our system, we perform a case study on manually-generated event pairs. Specifically, for a given pair of event mentions, we first alter only one of the arguments and keep the rest of the content fixed. We then observe the behavior of the system across different variations of the altered argument (Table 5).

Example I In this example, we pick the AGENT-argument as the target and alter the AGENT-argument of the second event mention. The event pair (m_1, m_2^a) is non-coreferent due to the explicit incompatibility between *Steve Jobs* and *John*, and the system's prediction is also non-coreferent. Further, we alter the target argument to the pronoun *she* (m_2^b), resulting in an implicit incompatibility in the AGENT argument since the *Steve Jobs* is generally not considered a feminine name. As expected, the system classifies the event pair (m_1, m_2^b) as non-coreferent. Finally, when we alter the target argument to *he* (m_2^c), the system correctly classifies the resulting pair as coreferent.

Example II In this example, we pick the PATIENT-argument as the target and alter the PATIENT-argument of the second event mention. The system classifies the event pair (m_1, m_2^a) as coreferent, which is reasonable considering the presence of the explicit compatible arguments *housewife* and *29-year-old housewife*. Further, when we alter the target argument to *woman* (m_2^b), the system output is still coreferent. This is consistent with our prediction: the event mentions are likely to be coreferent judging only from the context of the two event mentions. However, when we alter the target argument to *medical student* (m_2^c), the event pair would become non-coreferent due to the incompatibility between *medical student* and *housewife*. The system classifies the event pair correctly.

Example III In this example, we pick the REASON-argument as the target and alter the REASON-argument of the second event mention. The event pair (m_1, m_2^a) has a pair of implicit compatible arguments in the REASON-argument role and is likely to be coreferent. In contrast, altering the target argument to *contentious citizenship amendment bill* (m_2^b) would yield an pair of implicit incompatible arguments, and the resulting event pair would become non-coreferent. Our system classifies both event pairs correctly.

6 Conclusion

We proposed an iterative transfer learning framework for event coreference resolution. Our method exploited a large unlabeled corpus to learn a wide range of (in)compatibilities between arguments, which contributes to the improvement in performance on the event coreference resolution task. We achieved state-of-the-art results on the KBP 2017 English event coreference dataset, outperforming the previous state-of-the-art system. In addition, a qualitative analysis of the system output confirmed the ability of our system to capture (in)compatibilities between two event mentions.

Abstract

Conventional approaches to relation extraction usually require a fixed set of pre-defined relations. Such requirement is hard to meet in many real applications, especially when new data and relations are emerging incessantly and it is computationally expensive to store all data and re-train the whole model every time new data and relations come in. We formulate such a challenging problem as lifelong relation extraction and investigate memory-efficient incremental learning methods without catastrophically forgetting knowledge learned from previous tasks. We first investigate a modified version of the stochastic gradient methods with a replay memory, which surprisingly outperforms recent state-of-the-art lifelong learning methods. We further propose to improve this approach to alleviate the forgetting problem by anchoring the sentence embedding space. Specifically, we utilize an explicit alignment model to mitigate the sentence embedding distortion of the learned model when training on new data and new relations. Experiment results on multiple benchmarks show that our proposed method significantly outperforms the state-of-the-art lifelong learning approaches.

1 Introduction

The task of relation detection/extraction aims to recognize entity pairs' relationship from given contexts. As an essential component for structured information extraction, it has been widely used in downstream tasks such as automatic knowledge-based completion (Riedel et al., 2013) and question answering (Yih et al., 2015; Yu et al., 2017).

Existing relation detection methods always assume a closed set of relations and perform once-and-for-all training on a fixed dataset. While making the evaluation straightforward, this setting clearly limits the usage of these methods in realistic applications, where new relations keep emerging over time. To build an evolving system which automatically keeps up with the dynamic data, we consider a more practical lifelong learning setting (also called *continual learning*) (Ring, 1994; Thrun, 1998; Thrun and Pratt, 2012), where a learning agent learns from a sequence of tasks, where each of them includes a different set of relations. In such scenarios, it is often infeasible to combine the new data with all previous data and re-train the model using the combined dataset, especially when the training set for each task is huge.

To enable efficient learning in such scenarios, recent lifelong learning research (Kirkpatrick et al., 2016; Lopez-Paz and Ranzato, 2017) propose to learn the tasks incrementally, while at the same time preventing catastrophic forgetting (McCloskey and Cohen, 1989; Ratcliff, 1990; McClelland et al., 1995; French, 1999), i.e., the model abruptly forgets knowledge learned on previous tasks when learning on the new task. Current lifelong learning approaches address such challenge by either preserving the training loss on previously learned tasks (GEM) (Lopez-Paz and Ranzato, 2017), or selectively dimming the updates on important model parameters (EWC) (Kirkpatrick et al., 2016). These methods usually involve adding additional constraints on the model's parameters or the updates of parameters by utilizing stored samples. Despite the effectiveness of these methods on simple image classification tasks, there is little research validating the practical usage of these methods in realistic NLP tasks. In fact, when applying these methods to our relation extraction task, we observe that they underperform a simple baseline that updates the model parameters (i.e., learning by SGD) with a mix

of stored samples from previous tasks and new samples from the incoming task. We further test this simple baseline on commonly used continual learning benchmarks and get similar observations.

In this work, we thoroughly investigate two existing continual learning algorithms on the proposed lifelong relation extraction task. We observe that recent lifelong learning methods only operate on the models' parameter space or gradient space, and do not explicitly constraint the feature or embedding space of neural models. As we train the model on the new task, the embedding space might be distorted a lot, and become infeasible for previous tasks. We argue that the embedding space should not be distorted much in order to let the model work consistently on previous tasks. To achieve this, we propose an alignment model that explicitly anchors the sentence embeddings derived by the neural model. Specifically, the alignment model treats the saved data from previous tasks as anchor points and minimizes the distortion of the anchor points in the embedding space in the lifelong relation extraction. The aligned embedding space is then utilized for relation extraction. Experiment results show that our method outperforms the state-of-the-art significantly in accuracy while remaining efficient.

The main contributions of this work include:

- We introcduce the lifelong relation detection problem and construct lifelong relation detection benchmarks from two datasets with large relation vocabularies: SimpleQuestions (Bordes et al., 2015) and FewRel (Han et al., 2018).
- We propose a simple memory replay approach and find that current popular methods such as EWC and GEM underperform this method.
- We propose an alignment model which aims to alleviate the catastrophic forgetting problem by slowing down the fast changes in the embedding space for lifelong learning.

2 Problem Definition

Generic definition of lifelong learning problems In lifelong learning, there is a sequence of K tasks $\{\mathcal{T}^{(1)}, \mathcal{T}^{(2)}, \ldots, \mathcal{T}^{(K)}\}$. Each task $\mathcal{T}^{(k)}$ is a conventional supervised task, with its own label set $L^{(k)}$ and training/validation/testing data $(T^{(k)}_{\text{train}}, T^{(k)}_{\text{valid}}, T^{(k)}_{\text{test}})$, each of which is a set of labeled instances $\{(x^{(k)}, y^{(k)})\}$. Note that $x^{(k)}$ is the input data of the context and candidate relations, and $y^{(k)}$ is the ground-truth label. The goal of lifelong learning is to learn a classification model f. At each step k, f observes the task $\mathcal{T}^{(k)}$, and optimizes the loss function on its training data with a loss function $\ell(f(x), y)$. At the same time, we require the model f learned after step k could still perform well on the previous $k-1$ tasks. That is, we evaluate the model by using the average accuracy of k tasks at each step as $\frac{1}{k}\sum_{j=1}^{k} acc_{f,j}$.

To make f perform well on the previous tasks, during the lifelong learning process, we usually allow the learner to maintain and observe a memory $\mathcal{M}$ of samples from the previous tasks. Practically, with the growth of the number of tasks, it is difficult to store all the task data[1]. Therefore, in lifelong learning research, the learner is usually constrained on the memory size, denoted as a constant B. Thus at each step k, the learner is allowed to keep training samples from $\{\mathcal{T}^{(j)} | j = 1, \ldots, k-1\}$ with size less or equal to B.

Lifelong relation detection In this paper we introduce a new problem, *lifelong relation detection*. Relation detection is an important task that aims to detect whether a relation exists between a pair of entities in a paragraph. In many real-world scenarios, relation detection naturally forms a lifelong learning problem because new relation types emerge as new knowledge is constantly being discovered in various domains. For example, in the Wikidata (Vrandečić and Krötzsch, 2014) knowledge graph, the numbers of new items and properties are constantly increasing[2]. So we need to keep collecting data and updating the model over time in order to handle newly added relations.

The problem of lifelong relation detection has the same definition as above with only one difference: during prediction time, we hope to know whether an input paragraph contains any relation observed before. Therefore at time k, given an input x from task $j'<k$, instead of predicting an $y \in L^{(j')}$, we predict $y^{(k)} \in \bigcup_{j=1}^{k} L^{(j)}$. That says, the candidate label set is expanding as the learner observes more tasks, and the difficulty of each previous task is increasing over time as well.

---

[1] Even the data can be stored, it is unrealistic to make full usage of the stored data. For example, random sampling from all previous task data (e.g., for the methods in Section 4) will become statistically inefficient.

3 Evaluation Benchmarks for Lifelong Learning

3.1 Previous non-NLP Benchmarks

Lifelong MNIST MNIST is a dataset of handwriting ten digits (LeCun, 1998), where the input for each sample is an image, and the label is the digit the image represents. Two variants of the MNIST dataset were proposed for lifelong learning evaluation. One is MNIST *Permutations* (Kirkpatrick et al., 2016), where a task is created by rearranging pixels according to a fixed permutation. K different permutations are used to generate K tasks. Another variant is MNIST *Rotations* (Lopez-Paz and Ranzato, 2017), where each task is created by rotating digits by a fixed angle. K angles are chosen for creating K tasks. In our experiments, we follow (Lopez-Paz and Ranzato, 2017) to have $K = 20$ tasks for each benchmark.

Lifelong CIFAR CIFAR (Krizhevsky and Hinton, 2009) is a dataset used for object recognition, where the input is an image, and the label is the object the image contains. Lifelong CIFAR100 (Rebuffi et al., 2017a) is a variant of CIFAR-100 (CIFAR with 100 classes) by dividing 100 classes into K disjoint subsets. Each task contains samples from $\frac{100}{K}$ classes in one subset. Following (Lopez-Paz and Ranzato, 2017), we have $K = 20$ tasks, where each of them has 5 labels.

3.2 The Proposed Lifelong Relation Detection Benchmarks

Lifelong FewRel FewRel (Han et al., 2018) is a recently proposed dataset for few-shot relation detection. There are 80 relations in this dataset. We choose to create a lifelong benchmark based on FewRel because there are a sufficient number of relation labels. We extract the sentence-relation pairs from FewRel and build our lifelong FewRel benchmark as follows. Each sample contains a sentence with the ground-truth relation it refers, and a set of 10 randomly chosen false relations from all the whole relations set. The model is required to distinguish the right relation from the candidates. We apply K-Means over the averaged word embeddings of the relation names and divide 80 relations into 10 disjoint clusters. This results in 10 tasks in this benchmark, and each task contains relations from one cluster. Candidate relations will be masked if they do not appear in the history tasks.

Lifelong SimpleQuestions SimpleQuestions is a KB-QA dataset containing single-relation questions (Bordes et al., 2015). (Yu et al., 2017) created a relation detection dataset from SimpleQuestions that contains samples of question-relation pairs. For each sample, a candidate set of relations is also provided. Similar to lifelong FewRel, we divide relations into 20 disjoint clusters by using K-Means. This results in 20 tasks, and each task contains relations from one cluster.

4 Simple Episodic Memory Replay Algorithm for Lifelong Learning

Catastrophic forgetting is one of the biggest obstacles in lifelong learning. The problem is particularly severe in neural network models, because the learned knowledge of previous tasks is stored as network weights, while a slight change of weights when learning on the new task could have an unexpected effect on the behavior of the models on the previous tasks (French, 1999).

Currently, the memory-based lifelong learning approaches, which maintain a working memory of training examples from previous tasks, are proved to be one of the best solutions to the catastrophic forgetting problem. In this section, we first propose a memory-based lifelong learning approach, namely Episodic Memory Replay (EMR), which uses the working memory by sampling stored samples to replay in each iteration of the new task learning. Surprisingly, such a straightforward approach with a clear motivation was never used in previous research. We first compare EMR with the state-of-the-art memory-based algorithm Gradient Episodic Memory (GEM). We also show that the EMR outperforms GEM on many benchmarks, suggesting that it is likely to be among the top-performed lifelong learning algorithms, and it should never be ignored for comparison when developing new lifelong learning algorithms.

4.1 Episodic Memory Replay (EMR)

EMR is a modification over stochastic gradient descent algorithms. It replays randomly sampled data from memory while training on a new task, so the knowledge of previous tasks could be retained in the model. After training on each task k, EMR selects several training examples to store in the memory $\mathcal{M}$, denoted as $\mathcal{M} \bigcap T_{\text{train}}^{(k)}$.[3]

---

[3] (Rebuffi et al., 2017b) propose to dynamically change the size of memory set for each task during training. The

To handle the scalability, EMR stochastically replays the memory. Specifically, when training on task k with each mini-batch $D^{(k)}_{\text{train}} \subset T^{(k)}_{\text{train}}$, EMR samples from the memory $\mathcal{M}$ to form a second mini-batch $D^{(k)}_{\text{replay}} \subset \mathcal{M}$. Then two gradient steps are taken on the two mini-batches of $D^{(k)}_{\text{train}}$ and $D^{(k)}_{\text{replay}}$. Note that EMR could work with any stochastic gradient optimization algorithm, such as SGD, Adagrad, AdaDelta, and Adam, to optimize the model f with the mixed mini-batches.

We try two variations of $D^{(k)}_{\text{replay}}$ sampling: first, *task-level sampling*, which samples from one previous task j each time, i.e., $D^{(k)}_{\text{replay}} \subset \mathcal{M} \bigcap T^{(j)}_{\text{train}}$. Second, *sample-level sampling*, which samples all over the memory, i.e., $D^{(k)}_{\text{replay}} \subset \mathcal{M}$.

The two approaches differ in the task instance sampling probability. The task-level approach assumes a uniform distribution over tasks, while the sample-level approach has a marginal distribution on tasks that is proportional to the number of their training data in $\mathcal{M}$.[4] When tasks are balanced like MNIST and CIFAR, or when the stored data in the memory for different tasks are balanced, the two approaches become equivalent.

However, the sample-level strategy could sometimes make the code implementation more difficult: for some lifelong learning benchmarks such as MNIST Rotation, MNIST Permutation, and CIFAR-100 used in (Lopez-Paz and Ranzato, 2017), the tasks could differ from each other in the input or output distribution, leading to different computation graphs for different training examples. From our preliminary study, the task-level approach could always give results as good as those of the sample-level approach on our lifelong relation detection benchmarks (see Table 1) , so in our experiments in Section 6 we always use the task-level approach.

4.2 Comparing EMR with State-of-the-art Memory-based Lifelong Algorithm

In this part, we will first thoroughly introduce a state-of-the-art memory-based lifelong learning algorithm called Gradient Episodic Memory (GEM) (Lopez-Paz and Ranzato, 2017), and then compare EMR with it in both time complexity and experimental results on several benchmarks.

Gradient Episodic Memory (GEM) The key idea of GEM (Lopez-Paz and Ranzato, 2017) is to constrain the new task learning with previous task data stored in memory. Specifically, it constrains the gradients during training with the following operation. When training on task k, for each mini-batch $D^{(k)}_{\text{train}} \subset T^{(k)}_{\text{train}}$, it first computes the gradient $g^{(k)}_{\text{train}}$ on $D^{(k)}_{\text{train}}$, and the average gradients on the stored data of each previous task j, denoted as $g^{(j)}_{\text{task}}$. More concretely, we define

$$g^{(j)}_{\text{task}} = \frac{\sum_{i'} \nabla \ell(f(x^{(j)}_{i'}), y^{(j)}_{i'})}{|\mathcal{M} \bigcap T^{(j)}_{\text{train}}|},$$

where $j<k$, $\ell(\cdot)$ is the loss function, and $(x^{(j)}_{i'}, y^{(j)}_{i'}) \in \mathcal{M} \bigcap T^{(j)}_{\text{train}}$, i.e. $(x^{(j)}_{i'}, y^{(j)}_{i'})$ is a training instance in $\mathcal{T}^{(j)}$ that was stored in memory $\mathcal{M}$. Then the model f is updated along the gradient $\tilde{g}$ that solves the following problem:

$$\begin{aligned} &\min_{\tilde{g}} \quad ||\tilde{g} - g^{(k)}_{\text{train}}||^2 \\ &\text{s.t.} \quad \langle \tilde{g}, g^{(j)}_{\text{task}} \rangle \geq 0, \; j = 1, \ldots, k-1. \end{aligned}$$

$\tilde{g}$ is the closest gradient to the gradient on the current training mini-batch, $g^{(k)}_{\text{train}}$, without decreasing performance on previous tasks much since the angle between $\tilde{g}$ and $g^{(j)}_{\text{task}}$ is smaller than 90°.

Time Complexity One difference between EMR and GEM is that EMR deals with unconstrained optimization and does not require the gradient projection, i.e., solving $\tilde{g}$. But since the model f is deep networks, empirically the time complexity is mainly dominated by the computation of forward and backward passes. We analyze the time complexity as below:

In task k, suppose the mini-batch size is $|D|$ and the memory replay size is m, our EMR takes $|D| + m$ forward/backward passes in each training batch. Note that m is a fixed number and set to be equal to the number of instances stored for each previous task in our experiments. While for GEM, it needs to compute the gradient of all the data stored in the memory $\mathcal{M}$, thus $|D| + |\mathcal{M}|$ forward/backward passes are taken. Its complexity is largely dominated by the size $|\mathcal{M}|$ (upper bounded by the budget B). When the budget B is large, with the number of previous tasks increases, $\mathcal{M}$ grows linearly, and GEM will become infeasible.

---

followup work and this paper all use fixed sets, and we will investigate the usage of dynamic sets in future work.

[4] The two approaches hence favor different evaluation metrics – the former fits macro averaging better and the latter fits micro averaging better.

Task	EMR		GEM
	sample	task	
MNIST Rotation	–	0.828	**0.860**
MNIST Permutation	–	0.824	**0.826**
CIFAR-100	–	**0.675**	**0.675**
FewRel	0.606	**0.620**	0.598
SimpleQuestions	0.804	**0.808**	0.796

Table 1: The average accuracy across all the tasks at last time step for EMR and GEM on both non-NLP and our lifelong relation detection benchmarks. For the experiments on MNIST and CIFAR, we follow the setting in (Lopez-Paz and Ranzato, 2017) (see Appendix A.2 for details). For the experiments on FewRel and SimpleQuestions, we use the same setting in Section 6. We only implement task-level EMR for MNIST and CIFAR because of the relatively easy implementation.

Superior Empirical Results of EMR The EMR algorithm is much simpler compared to the GEM. However, one interesting finding of this paper is that the state-of-the-art GEM is unnecessarily more complex and more inefficient, because EMR, a simple stochastic gradient method with memory replay, outperforms it on several benchmarks.

The results are shown in Table 1. The numbers are the average accuracy, i.e. $\frac{1}{k}\sum_{j=1}^{k} acc_{f,j}$, at last time step. For both algorithms, the training data is randomly sampled to store in the memory, following (Lopez-Paz and Ranzato, 2017). On lifelong relation detection, the EMR outperforms GEM on both of our created benchmarks. To further show its generalizability, we apply the EMR to previous lifelong MNIST and CIFAR benchmarks and compare to the results in (Lopez-Paz and Ranzato, 2017) with all the hyperparameters set as the same. Still, EMR performs similarly to GEM except for the MNIST Rotation benchmark.[5]

From the above results, we learned the lesson that previous lifelong learning approaches actually fail to show improvement compared to doing memory replay in a stochastic manner. We hypothesise that GEM performs worse when there is positive transfer among tasks, making the gradient projection an inefficient way to use gradients computed from memory data. Therefore, in the next section, we start with the basic EMR and focus on more efficient usage of the historical data.

5 Embedding Aligned EMR (EA-EMR)

Based on our basic EMR, this section proposes our solution to lifelong relation detection. We improve the basic EMR with two motivations: (1) previous lifelong learning approaches work on the parameter space. However, the number of parameters in a deep network is usually huge. Also, deep networks are highly non-linear models, and the parameter dimensions have complex interactions, making the Euclidean space of parameters not a proper delegate of model behavior (French, 1999). That is, a slight change in parameter space could affect the model prediction unexpectedly. The above two reasons make it hard to maintain deep network behaviors on previous tasks with constraints or Fisher information. Therefore, we propose to alleviate catastrophic forgetting in the hidden space (i.e., the sentence embedding space). (2) for each task, we want to select the most informative samples to store in the memory, instead of random sampling like in (Lopez-Paz and Ranzato, 2017). Therefore the budget of memory can be better utilized.

5.1 Embedding Alignment for Lifelong Learning

This section introduces our approach which performs lifelong learning in the embedding space, i.e., the Embedding Aligned EMR (EA-EMR).

In EA-EMR, for each task k, besides storing the original training data $(x^{(k)}, y^{(k)})$ in the memory $\mathcal{M}$, we also store the embeddings of $x^{(k)}$. In the future after a new task is trained, the model parameters are changed thus the embeddings for the same $(x^{(k)}, y^{(k)})$ would be different. Intuitively, a lifelong learning algorithm should allow such parameter changes but ensure the changes do not distort the previous embedding spaces too much.

Our EA-EMR alleviates the distortion of embedding space with the following idea: if the embedding spaces at different steps are not distorted much, there should exist a simple enough transformation a (e.g., a linear transformation in our case) that could transform the newly learned embeddings to the original embedding space, without much performance degeneration on the stored instances. So we propose to add a transformation a on the top of the original embedding and learn the basic model f and the transformation a automatically. Specifically, at the k-th task, we start with the model $f^{(k-1)}$, and the transformation $a^{(k-1)}$,

---

[5] Even on MNIST Rotation, it has achieved a competitive result, since the conventional training on shuffled data from all the tasks in this benchmark gives ~ 0.83 according to (Lopez-Paz and Ranzato, 2017).

that trained on the previous $k-1$ tasks. We want to learn the basic model f and the transformation a such that the performance on the new task and stored instances are optimized without distorting the previous embedding spaces much.

$$\min_{f(\cdot),a(\cdot)} \sum_{(x,y)\in D^{(k)}_{\text{train}}} \ell(a(f(x)),y) + \sum_{(x,y)\in D^{(k)}_{\text{replay}}} \left(\ell(a(f(x)),y) + \|a(f(x)) - a^{(k-1)}(f^{(k-1)}(x))\|^2\right)$$

We propose to minimize the above objective through two steps. In the first step, we optimize the basic model f by:

$$\min_{f(\cdot)} \sum_{(x,y)\in D^{(k)}_{\text{train}} \cup D^{(k)}_{\text{replay}}} \ell\left(a^{(k-1)}(f(x)),y\right)$$

This step mainly focuses on learning the new task without performance drop on the stored samples.

In second step, we optimize a to keep the embedding space of the current task and restore the previous embedding space of all stored samples:

$$\min_{a(\cdot)} \sum_{(x,y)\in D^{(k)}_{\text{train}}} \|a(f(x)) - a^{(k-1)}(f(x))\|^2 + \sum_{(x,y)\in D^{(k)}_{\text{replay}}} \|a(f(x)) - a^{(k-1)}(f^{(k-1)}(x))\|^2$$

Embedding Alignment on Relation Detection Model We introduce how to add embedding alignment to relation detection models. The basic model we use is a ranking model that is similar to HR-BiLSTM (Yu et al., 2017). Two BiLSTMs (Hochreiter and Schmidhuber, 1997) are used to encode the sentence and relation respectively given their GloVe word embedding (Pennington et al., 2014). Cosine similarity between the sentence and relation embedding is computed as the score. Relation with maximum score is predicted by the model for the sentence. Ranking loss is used to train the model[6]. This base model is our model f, which is trained on a new task k at each step and results in an updated model $f^{(k)}$. Our proposed approach (Figure 1) inserts an alignment model a to explicitly align to embedding space for stored instances and maintain the embedding space of the current task. Note that the label y (the relation here) also has embedding, so it needs to pass through the alignment model a as well.

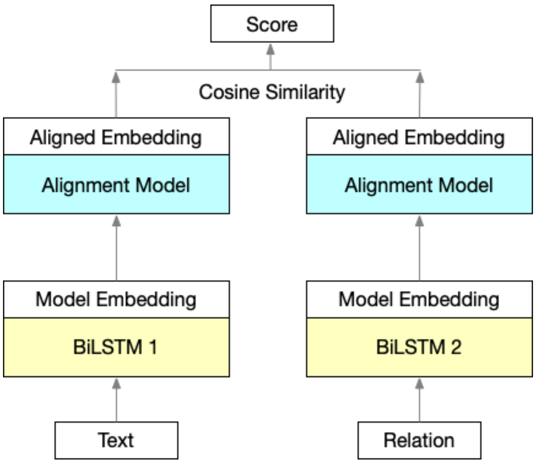

Figure 1: This figure shows how we add the alignment model (a linear model in our case) on the basic relation detection model, where two BiLSTMs are used to encode the text and relation, and cosine similarity between their embeddings are computed as the score.

5.2 Selective Storing Samples in Memory

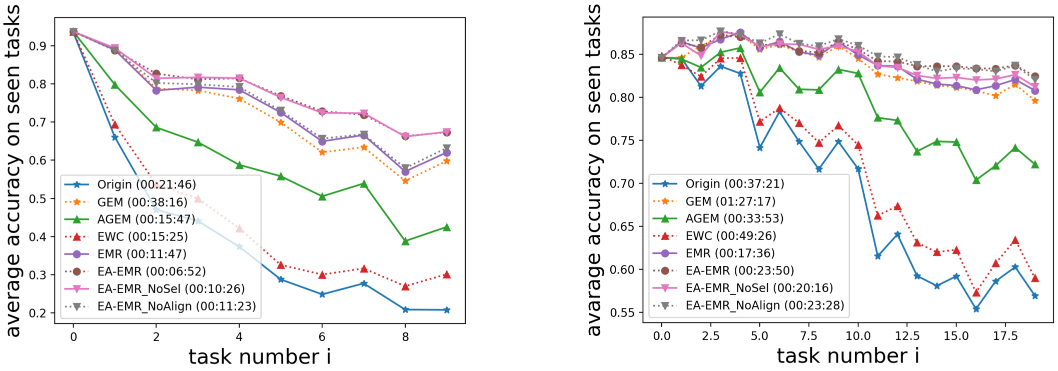
When the budget of memory is relatively smaller, how to select previous samples will greatly affect the performance. Ideally, in order to make the memory best represents a previous task, we hope to choose diverse samples that best approximate the distribution of task data. However, distribution approximation itself is a hard problem and will be inefficient due to its combinatorial optimization nature. Therefore, many recent works such as GEM ignore this step and randomly select samples from each task to store in the memory.

Rebuffi et al. (2017b) proposed to select exemplars that best approximate the mean of the distribution. This simplest distribution approximation does not give an improvement in our experiments because of the huge information loss. Therefore, we propose a better approach of sample selection by clustering over the embedding space from the model, and choose one representative from each cluster to store in the memory. More specifically, The embedding after alignment model is used to represent the input because the model makes prediction based on that. Then we apply K-Means (the number of clusters equals the budget given to the specific task) to cluster all the samples of the task. For each cluster, we select the sample closest to the centroid to store in the memory.

We leave more advanced approaches of representative sample selection and their empirical comparison to future work.

---

[6] Though the basic model is simple, it achieves reasonable results on the two datasets when training with all the data, i.e., 0.837 on FewRel and 0.927 on SimpleQuestions.



(a) FewRel (b) SimpleQuestions

Figure 2: This figure shows the average accuracy of all the observed tasks on the benchmarks of lifelong FewRel and lifelong SimpleQuestions during the lifelong learning process. The average performance of 5 runs is reported, and the **average running time** is shown in the brackets.

6 Experiments

6.1 Experimental Setting

We conduct experiments on our lifelong benchmarks: lifelong SimpleQuestions (Bordes et al., 2015) and lifelong FewRel (Han et al., 2018) to compare our proposed methods EA-EMR, EA-EMR without Selection (EA-EMR_NoSel), EA-EMR without Alignment (EA-EMR_noAlign), and EMR with the following baselines.

- **Origin**, which simply trains on new tasks based on the previous model.
- **EWC** (Kirkpatrick et al., 2016), which slows down updates on important parameters by adding L_2 regularization of parameter changes to the loss.
- **GEM** (Lopez-Paz and Ranzato, 2017), which projects the gradient to benefit all the tasks so far by keeping a constraint for each previous task.
- **AGEM** (Anonymous, 2019), which only uses one constraint that the projected gradient should decrease the average loss on previous tasks.

On both FewRel and SimpleQuestions, the epoch to train on each task is set to be 3. Learning rate for the basic model is set to be 0.001. The hidden size of LSTM is set to be 200. The batch size is set to be 50. For each sample in the memory, 10 candidate relations is randomly chosen from all observed relations to alleviate the problem that new relations are emerging incessantly.

Parameters for our model and baselines are set as follows. For EA-EMR and EA-EMR_NoSel, when training the alignment model, the learning rate is set to be 0.0001, and the training epoch is set to be 20 and 10 for FewRel and SimpleQuestions respectively. For AGEM, 100 samples are randomly chosen from all the previous tasks to form a constraint. For EWC, we set the balancing parameter $\alpha = 100$. For GEM and EMR related methods, memory size of each task is set to be 50.

Method	FewRel		SimpleQuestions	
	Whole	Avg	Whole	Avg
Origin	0.189	0.208	0.632	0.569
Baselines				
GEM	0.492	0.598	0.841	0.796
AGEM	0.361	0.425	0.776	0.722
EWC	0.271	0.302	0.672	0.590
Ours				
Full EA-EMR	**0.566**	0.673	**0.878**	**0.824**
w/o Selection	0.564	**0.674**	0.857	0.812
w/o Alignment	0.526	0.632	0.869	0.820
w/o Alignment but keep the architecture	0.545	0.655	0.871	0.813
EMR Only	0.510	0.620	0.852	0.808

Table 2: This table shows the accuracy on the whole testing data (”Whole” column), and average accuracy on all observed tasks (”Avg” column) after the last time step. The average performance of 5 runs are listed here and the best result on each dataset is marked in bold.

6.2 Lifelong Relation Detection Results

Evaluation Metrics We use two metrics to evaluate the performance of the model:

- Average performance on all seen tasks after time step k, which highlights the catastrophic problem:

$$\text{ACC}_{\text{avg}} = \frac{1}{k}\sum_{i=1}^{k} acc_{f,i}$$

- Accuracy on the whole testing data of all tasks:

$$\text{ACC}_{\text{whole}} = acc_{f,D_{\text{test}}}$$

Results on FewRel and SimpleQuestions We run each experiment 5 times independently by shuffling sequence of tasks, and the average performance is reported. The average accuracy over all observed tasks during the whole lifelong learning process is presented in Figure 2, and the accuracy on the whole testing data during the process is shown in Appendix A.1. We also list the result at last step in Table 2. From the results, we can see that EWC and GEM are better than the Origin baseline on both two datasets, which indicates that they are able to reduce the catastrophic forgetting problem. However, our EA-EMR perform significantly better than these previous state-of-the-arts. The proposed EMR method itself achieves better results than all baselines on both datasets. The ablation study shows that both the *selection* and the *alignment* modules help on both tasks.

The Effect of Embedding Alignment To investigate the effect of our embedding alignment approach, we conduct two ablation studies as below: First, we remove both the alignment loss in equation 5.1, as well as the alignment module a, which results in significant drop on most of the cases (the line "w/o Alignment" in Table 2). Second, to make sure that our good results do not come from introducing a deeper model with the module a, we propose to only remove the embedding alignment loss, but keep everything else unchanged. That means, we still keep the module a and the training steps, with the only change on replacing the loss in step 2 with the one in step 1 (the line "w/o Alignment but keep the architecture" in Table 2). We can see that this decreases the performance a lot. The above results indicate that by explicitly doing embedding alignment, the performance of the model can be improved by alleviating the distortion of previous embedding space.

Comparison of Different Sample Selection Strategies Here we compare different selection methods on lifelong FewRel and SimpleQuestions. EMR Only randomly choose samples. (Rebuffi et al., 2017b) propose to choose samples that can best approximate the mean of the distribution. We compare their sampling strategy (denoted as iCaRL) with our proposed method (K-Means) which encourages to choose diverse samples by choosing the central sample of the cluster in the embedding space. From the results in Table 3, we can see that our method outperforms iCaRL and the random baseline. While iCaRL is not significantly different from the random baseline.

Method	FewRel		SimpleQuestions	
	Whole	Avg	Whole	Avg
EMR Only	0.510	0.620	0.852	0.808
+ K-Means	**0.526**	**0.632**	**0.869**	**0.820**
+ iCaRL	0.501	0.615	0.854	0.806

Table 3: Comparison of different methods to select data for EMR. The accuracy on the whole testing data (”Whole” column), and average accuracy on all observed tasks (”Avg” column) is reported. We run each method 5 times, and give their average results.

7 Related Work

Lifelong Learning without Catastrophic Forgetting Recent lifelong learning research mainly focuses on overcoming the *catastrophic forgetting* phenomenon (French, 1999; McCloskey and Cohen, 1989; McClelland et al., 1995; Ratcliff, 1990), i.e., knowledge of previous tasks is abruptly forgotten when learning on a new task.

Existing research mainly follow two directions: the first one is *memory-based approach* (Lopez-Paz and Ranzato, 2017; Anonymous, 2019), which saves some previous samples and optimizes a new task with a forgetting cost defined on the saved samples. These methods have shown strength in alleviating catastrophic forgetting, but the computational cost grows rapidly with the number of previous tasks. The second direction is to *consolidate parameters that are important to previous tasks* (Kirkpatrick et al., 2016; Liu et al., 2018; Ritter et al., 2018; Zenke et al., 2017). For example, Elastic Weight Consolidation (EWC) (Kirkpatrick et al., 2016) slows down learning on weights that are important to previous tasks. These methods usually do not need to save any previous data and only train on each task once. But their abilities to overcome catastrophic forgetting are limited.

Lifelong Learning with Dynamic Model Architecture There is another related direction on dynamically changing the model structure (i.e., adding new modules) in order to learn the new task without interfering learned knowledge for previous tasks, such as (Xiao et al., 2014; Rusu et al., 2016; Fernando et al., 2017). These approaches could successfully prevent forgetting. However, they do not suit many lifelong settings in NLP. First, it cannot benefit from the positive transfer between tasks. Second, the size of the model grows dramatically with the number of observed tasks, which makes it infeasible for real-world problems where there are a lot of tasks.

Remark It is worth noting that the term lifelong learning is also widely used in (Chen et al., 2015; Chen, 2015; Shu et al., 2016, 2017), which mainly focus on how to represent, reserve and extract knowledge of previous tasks. These works belong to a research direction different from lifelong learning without catastrophic forgetting.

8 Conclusion

In this paper, we introduce lifelong learning into relation detection, and find that two state-of-the-art lifelong learning algorithms, GEM and EWC, are outperformed by a simple memory replay method EMR on many benchmarks. Based on EMR, we further propose to use embedding alignment to alleviate the problem of embedding space distortion, which we think is one reason that causes catastrophic forgetting. Also, we propose to choose diverse samples to store in the memory by conducting K-Means in the model embedding space. Experiments verify that our proposed methods significantly outperform other baselines.

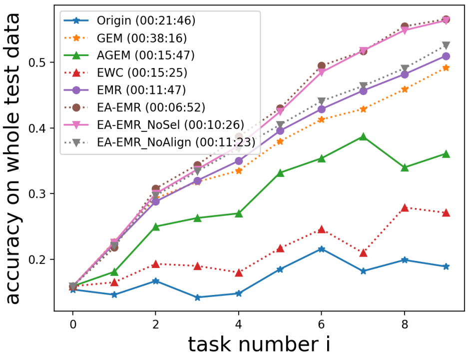
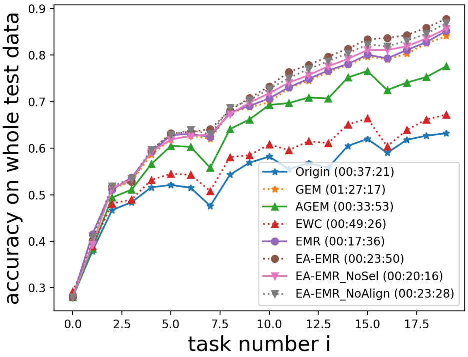
A.1 Performance on the whole testing data over time



(a) FewRel



(b) SimpleQuestions

Figure 3: This figure shows the accuracy on the whole testing data on the benchmark of lifelong FewRel and lifelong SimpleQuestions during the lifelong learning process. The average performance of 5 runs is reported, and the **average running time** is shown in the brackets.

The performance on the whole testing data over time is shown in Figure 3.

A.2 Experiment setting for MNIST and CIFAR

Following the setting in (Lopez-Paz and Ranzato, 2017), the size of memory for each task is set to be 256. The learning rate is set to be 0.1. The epoch for training the model on each task is set to be 1. Plain SGD and minibatch of 10 samples are used. For the MNIST dataset, each task has 1000 samples of 10 classes. For the CIFAR dataset, each task has 2500 samples of 5 classes.

Description-Based Zero-shot Fine-Grained Entity Typing

Abstract

Fine-grained Entity typing (FGET) is the task of assigning a fine-grained type from a hierarchy to entity mentions in the text. As the taxonomy of types evolves continuously, it is desirable for an entity typing system to be able to recognize novel types without additional training. This work proposes a *zero-shot* entity typing approach that utilizes the type description available from Wikipedia to build a distributed semantic representation of the types. During training, our system learns to align the entity mentions and their corresponding type representations on the known types. At test time, any new type can be incorporated into the system given its Wikipedia descriptions. We evaluate our approach on FIGER, a public benchmark entity tying dataset. Because the existing test set of FIGER covers only a small portion of the fine-grained types, we create a new test set by manually annotating a portion of the noisy training data. Our experiments demonstrate the effectiveness of the proposed method in recognizing novel types that are not present in the training data.

1 Introduction

Entity Typing assigns a semantic type (e.g., *person*, *location*, *organization*) to an entity mention in text based on the local context. It is useful for enhancing a variety of Natural Language Processing(NLP) tasks such as question answering (Han et al., 2017; Das et al., 2017), relation extraction (Liu et al., 2014; Yaghoobzadeh et al., 2016), and entity linking (Stern et al., 2012). Traditional Named Entity Typing systems consider a small set of coarse types (e.g., *person*, *location*, *organization*) (Tjong Kim Sang and De Meulder, 2003; Krishnan and Manning, 2006; Chieu and Ng, 2002). Recent studies address larger sets of fine-grained types organized in type hierarchies (e.g., *person/artist*, *person/author*) (Ling and Weld, 2012; Corro et al., 2015; Xu and Barbosa, 2018; Murty et al., 2018). Fine-Grained Entity Typing (FGET) is usually approached as a multi-label classification task where an entity mention can be assigned multiple types that usually constitute a path in the hierarchy (Ren et al., 2016).

In real-world scenarios, there is a need to deal with ever-growing type taxonomies. New types emerge, and existing types are refined into finer sub-categories. Traditional methods for entity typing assume that the training data contains all possible types, thus require new annotation effort for each new type that emerges. *Zero-shot learning (ZSL)*, a special kind of transfer learning, allows for new types to be incorporated at the prediction stage without the need for additional annotation and retraining. The main idea behind ZSL is to learn a shared semantic space for representing both the seen and unseen types, which allows the knowledge about how examples link to the seen types to be transferred to unseen types.

For fine-grained entity types, we observe that their associated Wikipedia pages often provide a rich description of the types. To capture this, we propose a *Description-based* Zero-shot Entity Typing (DZET) approach that utilizes the Wikipedia description of each type (e.g., see `https://en.wikipedia.org/wiki/Artist` for description of the type *person/artist*) to generate a representation of that type. We learn to project the entity-mention representations and the type representations into a shared semantic space, such that the mention is closer to the correct type(s) than the incorrect types. The mid-level type representation derived from the Wikipedia page along with the learned projection function allows the system to recognize new types requiring zero training examples.

We investigate different approaches for constructing the type representation based on

Proceedings of NAACL-HLT 2019, pages 807–814
Minneapolis, Minnesota, June 2 - June 7, 2019.

Wikipedia descriptions. Note that the descriptions can be quite long, often containing many different parts that are useful for recognizing different entity mentions. This motivates us to generate a bag of representations for each type and apply average pooling to aggregate the results.

We evaluate the performance of our methods on FIGER, a benchmark dataset for the FNET task, in which types are organized in 2-levels hierarchy. In this work, We focus on testing our method's capability in recognizing unseen fine-grained types (Level-2 types in this dataset). As the current test set of FIGER contains examples from only a few level-2 types, we created a new test data that covers most of the level-2 types by manually annotating a portion of the noisy training data. Below we summarize our main contributions.

- We proposed a description-based zero-shot fine-grained entity typing framework that uses Wikipedia descriptions to represent and detect novel types unseen in training.
- We created a new test set for fine-grained entity typing that provides much better coverage of the level-2 (fine-grained) types compared to the original FIGER test data.
- We provided experimental evidence of the effectiveness of our approach in comparison with established baselines.

2 Related Work

Existing work on FGET focuses on performing context-sensitive typing (Gillick et al., 2014; Corro et al., 2015), learning from noisy training data (Abhishek et al., 2017; Ren et al., 2016; Xu and Barbosa, 2018), and exploiting the type hierarchies to improve the learning and inference (Yogatama et al., 2015; Murty et al., 2018). More recent studies support even finer granularity (Choi et al., 2018; Murty et al., 2018). However, all the methods above have the limitation that they assume all types are present during training.

Zero-Shot Learning has been extensively studied in Computer Vision (CV) (Wang et al., 2019) for tasks such as image classification (Lampert et al., 2014; Zhang and Saligrama, 2015; Socher et al., 2013), object localization (Li et al., 2014, 2017) and image retrieval (Xu et al., 2017; Zhang et al., 2018). A common approach for zero-shot learning in CV is to represent each class (e.g., Zebra) by a set of semantic attributes such as its shape and color. The semantic attributes serve as the intermediate level that connects the visual features with the classes. The model is trained to learn an alignment between the semantic attributes and the visual features where a new class can be recognized using its semantic attributes without the need for any training examples. In contrast, this type of approach tends not to work well for NLP applications as the semantic concepts/classes in NLP are often more complex and cannot be easily described by a set of pre-defined attributes. This explains why the few studies of ZSL for NLP use very different methods to create the transferable intermediate representations.

Zero-Shot Learning has been studied for a number of NLP tasks including event extraction (Huang et al., 2018; Lee and Jha, 2018; Srivastava et al., 2018), relation extraction(Liu et al., 2014), Conversational Language Understanding (Lee and Jha, 2018). Specifically, Zero shot entity typing has also been explored, where most of the prior methods adopt the idea of learning a shared semantic space for representing the entities as well as the types, but differ in how they construct the type embeddings. In OTyper (Yuan and Downey, 2018), each type is represented by averaging the embedding of the words constitutes the type label. On the other hand, ProtoLE (Ma et al., 2016) represents each type by a prototype that consists of manually selected entity mentions, where the type embedding is obtained by averaging the prototype mentions' word embeddings.In contrast, our work differs from OTyper and ProtoLE by constructing the type representations based on the Wikipedia descriptions of the types, which not only carry more information about the type but also can be easily adapted to other tasks such as event typing and text classification.

3 Proposed Approaches

Following prior work on fine-grained entity typing, we formulate it as a multi-class multi-label classification problem. Given an entity mention m along with its left textual context c_l and right context c_r, We learn a classifier that predicts a binary label vector $y \in \{0,1\}^{|L|}$, where L denotes the set of all types, which forms a hierarchy Ψ. Here $y^{(t)} = 1$ if the mention m is of type t, and 0 otherwise. In the case of zero-shot FGET, new types can be introduced and added to L during testing.

3.1 The Typing Function

We will begin by introducing our typing function that is used to compute a score between a given mention and type pair, given their corresponding vector representations. We will discuss how to construct the representations in later sections.

Formally, the input to this typing function consists of the representation of the mention, denoted by $x \in \mathbf{R}^d$; and the representation of a candidate type t, denoted by $y_t \in \mathbf{R}^{\acute{d}}$. It computes a bi-linear score for the (x, y_t) pair as follows:

$$f(x, y_t, W) = x^T W y_t$$

where $W \in \mathbf{R}^{d \times \acute{d}}$ is a compatibility matrix. Following (Yogatama et al., 2015; Ma et al., 2016), we factorize W as a product of two low-rank matrices to reduce the number of parameters. That is $W = A^T B$, where $A \in \mathbf{R}^{h \times d}$ and $B \in \mathbf{R}^{h \times \acute{d}}$ (We use $h = 20$). The scoring function f can be rewritten as:

$$f(x, y_t, A, B) = \theta(x, A) \cdot \phi(y_t, B) = (Ax)^T B y_t$$

where $\theta(x, A) : x \to Ax$ and $\phi(y_t, B) : y_t \to B y_t$ serve as the projection functions that map x and y_t into a shared semantic space.

3.2 Entity Mention Representation

To obtain the representation for entity mentions, we adopt the same neural approach proposed by Shimaoka et al. (2017). Given an entity mention with its context, we compute a vector v_m to present the mention m itself, and another vector v_c to represent its left and right contexts c^l and c^r. v_m is computed by simply averaging the embedding of the individual words in m.

To compute the context embedding v_c, we first encode c^l and c^r using a bidirectional-LSTM. Let $c_1^l, ..., c_s^l$ and $c_1^r, ..., c_s^r$ be the word embedding of the left and the right context respectively, where s is the window size (we use $s = 10$), the output layer of the bi-LSTM is denoted as: $\overrightarrow{h_1^l}, \overleftarrow{h_1^l} ..., \overrightarrow{h_s^l}, \overleftarrow{h_s^l}$ and $\overrightarrow{h_1^r}, \overleftarrow{h_1^r} ..., \overrightarrow{h_s^r}, \overleftarrow{h_s^r}$. We then compute a scalar attention for each context word using a 2-level feedforward neural network:

$$e_i^j = tanh(W_e \begin{bmatrix} \overrightarrow{h_i^j} \\ \overleftarrow{h_i^j} \end{bmatrix}); \tilde{a}_i^j = exp(W_a e_i^j)$$

Where $W_e \in \mathbf{R}^{d_h \times 2 \times d_a}$, $W_a \in \mathbf{R}^{1 \times d_a}$, d_h is the dimension of LSTM, d_a is the attention dimension, $j \in \{l, r\}$. Next, we normalize a_i^js such that they sum up to 1. i.e., $a_i^j = \frac{\tilde{a}_i^j}{\sum_{i=1}^{s}(\tilde{a}_i^l + \tilde{a}_i^r)}$. Finally the context representation is computed as $v_c = \sum_{i=1}^{s}(a_i^l \begin{bmatrix} \overrightarrow{h_i^l} \\ \overleftarrow{h_i^l} \end{bmatrix} + a_i^r \begin{bmatrix} \overrightarrow{h_i^r} \\ \overleftarrow{h_i^r} \end{bmatrix})$. The final representation of the entity mention $x \in \mathbf{R}^d$ is a concatenation of v_m and v_c.

3.3 Type Representation

Let P_t be the Wikipedia page that is used to build a representation for type t. Some types do not have a Wikipedia page with a title the same as the type label. In such cases, we manually look for a Wikipedia page of a similar concept. For example, we represent the type *living-thing* by the Wikipedia page *organism*.

To get a type representation, We started by the simplest possible method which is averaging the embedding of words in the Wikipedia page (we call this **Avg encoder**). Since some words in the Wikipedia page carry more of the type semantic than the other words we also consider a (tf-idf)-weighted version of the Avg encoder.

Learning multiple representations. Wikipedia descriptions are often long and contain multiple parts, where different parts may capture different aspects of the type and relate to different mentions. Moreover, sequence models such as LSTM cannot be applied to such long sequences. This motivates us to consider the approach of constructing a bag of multiple representations for each type based on its Wikipedia description. To obtain a bag of representations for type t, we first use a fixed-length window to incrementally break P_t into multiple parts, one paragraph at a time. If a paragraph fits in the current Window, it is added. Otherwise, a new window is initiated. Each window of text r_{ti} is then used to generate one representation. To construct an embedding for r_{ti}, we adopt the same Bidirectional LSTM and attention mechanism that are used to embed the mention context.

To compute the score for type t given its multiple representations, we compute the score with each individual representation and average them to produce the final score. This is equivalent to applying average pooling to the multiple representations to obtain a single representation due to the bi-linear typing function.

3.4 Training and inference

Given the training data, we jointly train the representation and the scoring function by minimizing a ranking score. Let $\mathcal{Y}^{(i)}$ and $\overline{\mathcal{Y}}^{(i)}$ denote the set of correct and incorrect types assigned to the example $x^{(i)}$ respectively, we learn to score types in $\mathcal{Y}^{(i)}$ higher than types in $\overline{\mathcal{Y}}^{(i)}$ with a multi-label max-margin ranking objective as follows:

$$\sum_{y\in\mathcal{Y}}\sum_{\acute{y}\in\overline{\mathcal{Y}}} max(0, 1-f(x,y,A,B)+f(x,\acute{y},A,B))$$

At testing, both seen and unseen types are mapped to their learned representations, which are then scored for a given input. Given the scores, we conduct a top-down search following the type hierarchy Ψ. Starting from the root we recursively find the type with the highest score among the children. Since we focus on the fine-grained types, we stop the search when a leaf type is reached and predict that the mention is positive for all types along the path leading the to leaf type.

4 Experiments

Datasets. Our experiments use FIGER, a publicly available fine-grained entity typing benchmark dataset in which types are organized into a 2-level hierarchy. The training data consists of sentences sampled from Wikipedia articles and automatically annotated via distant supervision (Ling and Weld, 2012). The test data consisting of manually annotated sentences sampled from news reports.

Setting. To evaluate our capability to recognize fine-grained types in zero-shot setting, we assume all second-level types are unseen during training, i.e., we remove all level-2 types from the train and dev data but keep them in the test data. We observe that the FIGER test set covers only a small number of second-level types. This renders it insufficient for testing under the evaluation setting we adopt. Moreover, the training data is noisy since it is automatically annotated by distant supervision. As a result, we cannot just use part of it for testing.

	Original dataset			New dataset		
	train	dev	test	train	dev	test
# of mentions	2000k	10k	563	1999k	10k	917
# of types	111	111	47	46	46	66
# of level-2 types	65	65	26	0	0	40

Table 1: Statistics of FIGER dataset.

To overcome this limitation, We manually annotated a new test set from the noisy training data. We first divide the train set into clean and noisy as suggested in (Ren et al., 2016). Clean examples are those whose types fall on a single path (not necessarily ending with a leaf) in Ψ. For instance, the mention with labels *person*, *person/author*, and *person/doctor* is considered as noisy example because the labels form two paths. We then manually verify the correctness of up to 20 examples from the clean training data for every level-2 type. These examples are removed from training and added to the test set. We ignore the types with no clean examples. The statistics of the new and original datasets are reported in Table 1.

Baselines. We consider two baselines that employ the same neural architecture but use different type representations. The **Label embd** baseline use the average of the embedding of the words in the type label as the type representation. **ProtoLE** baseline uses the prototypes-based label embedding learned by Ma et al. (2016), where each type is represented by the set of the most representative entity mentions. The type embedding is the average of all mentions in the corresponding prototype.

Evaluation metrics. Following prior works in FGET, we report *Accuracy (Strict-$F1$)*, *loose Macro-averaged $F1$* ($F1_{ma}$) and *loose Micro-averaged $F1$* ($F1_{mi}$) (Ling and Weld, 2012). The training and hyperparameter tuning details are described in the Appendices.

Results and discussions. Table 2 presents the results on FIGER, evaluated on all types (Overall), the seen types (Level-1) and the unseen types (Level-2) respectively. From the results, we can see that our description based methods have a particularly strong advantage over baselines on level-2 types. This is consistent with our expectation because Wikipedia descriptions tend to be highly informative for fine-grained types, but less so for coarser types.

Among the average encoders, we found that weighting the word embedding by the word tf-idf produces better results than treating the words equivalently. As expected, using LSTM based multi-representation adds a noticeable benefit to our system as it produces the best performance among all tested methods, achieving the best performance for level-2 types and outperforming oth-

Approach	Overall			Level-1		Level-2	
	Acc	$F1_{ma}$	$F1_{mi}$	$F1_{ma}$	$F1_{mir}$	$F1_{ma}$	$F1_{mir}$
Label embd	0.2846	0.5510	0.5603	**0.8165**	**0.8163**	0.2854	0.2954
ProtoLE	0.2541	0.4982	0.5093	0.7424	0.7422	0.2541	0.2657
DZET + Avg encoder	0.3141	0.5522	0.5614	0.7903	0.7902	0.3141	0.3247

Table 2: Level-1 , Level-2 and overall performance of the models on FIGER dataset.

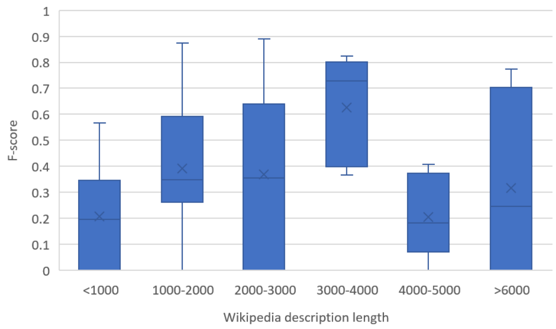

Figure 1: The relationship between the length of the Wikipedia description (word count) of level-2 types and the F-score obtained by *DZET+Multi-rep* method.

ers by a large margin while maintaining a highly competitive performance for level-1 types.

The effect of description quality. Figure 1 analyzes the relationship between the length of the Wikipedia description as one criterion of the description quality and the performance of *Multi-rep* method. In particular, we group the types based on the length of their Wikipedia descriptions and provide the five-number summary box plot of the F-scores for each group. It can be readily observed that the performance is low when the description of the type's Wikipedia page is too short ($<$ 1000 words) or too long ($>$ 4000 words). Short descriptions are less informative and carry less shared semantics with the type's mentions. On the other hand, overly long descriptions could also be confusing as it might share a significant number of common words with the descriptions of other types. A closer look into the results unveils some exceptions. For example, the F-score on the type '/education/educational-degree' is 0.7742 even it has a long description (6845 words). The description of this type is indeed very informative and includes a comprehensive list of the educational degrees awarded all around the world.

The length of the description is not the only factor that affects the performance of DZET methods. One factor is the performance on the Level-1 types. Since the inference is performed by following the type hierarchy, if an incorrect type is inferred at level-1, there is no hope to get the correct level-2 type. Another factor is the amount of overlapping between the descriptions of the related types. For instance, *Multi-rep* produces zero F-score on the types'/event/protest' and '/location/province' because they share a lot of common words with the types '/event/attack' and '/location/county' respectively, which negatively affects the ability of *Multi-rep* to distinguish between the related types. Both '/event/protest' and '/location/province' have a description length between 2000 and 3000 words.

To mitigate the effect of the contents overlapping between the highly related type, We plan to apply mention-sensitive attention mechanisms for future work to aggregate the scores in Multi-rep instead of max-pooling.

5 Conclusions

In this paper, we propose a novel zero-shot entity typing approach that uses Wikipedia descriptions to construct type embeddings. Our architecture relies on the type embeddings to make predictions for unseen types. Experimental results demonstrate the effectiveness of the proposed methods.

A Appendices

A.1 Training and Hyperparamters

For every model we trained, we tune all of the hyper-parameters using a dev set. We use the version of FIGER provided by (Shimaoka et al., 2017) which already withhold a portion of the train set as a dev set. For each experiment, we report that testing results of the model that has the best *accuracy* on the dev set. We adopt *glove* 300-dimensional word embedding (Pennington et al., 2014) throughout this work except for *prototype* baselines; we use word2vec (Mikolov et al., 2013) as it is used to compute the prototypes embedding in the original works (Ma et al., 2016). The hyper-parameters used in the feature representation component are the same as in (Shimaoka et al., 2017). we set both of the hidden-size of the LSTM was set and the hidden-layer size of the attention module to 100. We use Adam optimizer (Kingma and Ba, 2014) with the learning rate .001. The model is trained for five epochs. We use Window of size 200 to build a bag of representations for each type from its Wikipedia description.

Adversarial Decomposition of Text Representation

Abstract

In this paper, we present a method for adversarial decomposition of text representation. This method can be used to decompose a representation of an input sentence into several independent vectors, each of them responsible for a specific aspect of the input sentence. We evaluate the proposed method on two case studies: the conversion between different social registers and diachronic language change. We show that the proposed method is capable of fine-grained controlled change of these aspects of the input sentence. It is also learning a continuous (rather than categorical) representation of the style of the sentence, which is more linguistically realistic. The model uses adversarial-motivational training and includes a special motivational loss, which acts opposite to the discriminator and encourages a better decomposition. Furthermore, we evaluate the obtained meaning embeddings on a downstream task of paraphrase detection and show that they significantly outperform the embeddings of a regular autoencoder.

1 Introduction

Despite the recent successes in using neural models for representation learning for natural language text, learning a meaningful representation of input sentences remains an open research problem. A variety of approaches, from sequence-to-sequence models that followed the work of Sutskever et al. (2014) to the more recent proposals (Arora et al., 2017; Nangia et al., 2017; Conneau et al., 2017; Logeswaran and Lee, 2018; Subramanian et al., 2018; Cer et al., 2018) share one common drawback. Namely, all of them encode the input sentence into just *one* single vector of a fixed size. One way to bypass the limitations of a single vector representation is to use an attention mechanism (Bahdanau et al., 2014; Vaswani et al., 2017). We propose to approach this problem differently and design a method for adversarial decomposition of the learned input representation into multiple components. Our method encodes the input sentence into *several* vectors, where each vector is responsible for a specific aspect of the sentence.

In terms of learning different separable components of input representation, our work most closely relates to the style transfer work, which has been applied to a variety of different aspects of language, from diachronic language differences (Xu et al., 2012) to authors' personalities (Lipton et al., 2015) and even sentiment (Hu et al., 2017; Fu et al., 2018). The style transfer work effectively relies on the more classical distinction between **meaning** and **form** (de Saussure, 1959), which accounts for the fact that multiple surface realizations are possible for the same meaning. For simplicity, we will use this terminology throughout the rest of the paper.

Consider encoding an input sentence into a meaning vector and a form vector. This enables a controllable change of meaning or form by a simple change applied to these vectors. For example, we can encode two sentences written in two different styles, then swap the form vectors while leaving the meaning vectors intact. We can then generate new unique sentences with the original meaning, but written in a different style.

We propose a novel model for this type of decomposition based on adversarial-motivational training, GAN architecture (Goodfellow et al., 2014) and adversarial autoencoders (Makhzani et al., 2015). In addition to the adversarial loss, we use a special motivator (Albanie et al., 2017), which, in contrast to the discriminator, is used to provide a motivational loss to encourage better decomposition of the meaning and the form. All the code is available on GitHub [1].

Proceedings of NAACL-HLT 2019, pages 815–825
Minneapolis, Minnesota, June 2 - June 7, 2019.

We evaluate the proposed methods for learning separate aspects of input representation in the following case studies:

1. Diachronic language change. Specifically, we consider the Early Modern English (e.g. *What would she have?*) and the contemporary English (*What does she want?*).
2. Social register (Halliday et al., 1968), i.e. subsets of language appropriate in a given context or characteristic of a certain group of speakers. Social registers include formal vs informal language, the language used in different genres (e.g., fiction vs. newspapers vs. academic texts), different dialects, and literary idiostyles. We experiment with the titles of scientific papers vs. newspaper articles.

2 Related work

As mentioned above, the most relevant previous work comes from research on style transfer[2]. It can be divided into two groups:

1. Approaches that aim to generate text in a given form. For example, the task may be to produce just any verse as long as it is in the "style" of the target poet.
2. Approaches that aim to induce a change in either the "form" or the "meaning" of an utterance. For example, "Good bye, Mr. Anderson." can be transformed to "Fare you well, good Master Anderson" (Xu et al., 2012)).

An example of the first group is the work of Potash et al. (2015), who trained several separate networks on verses by different hip-hop artists. An LSTM network successfully generated verses that were stylistically similar to the verses of the target artist (as measured by cosine distance on tf-idf vectors). More complicated approaches use language models that are conditioned in some way. For example, Lipton et al. (2015) produced product reviews with a target rating by passing the rating as an additional input at each timestep of an LSTM model. Tang et al. (2016) generated reviews not only with a given rating but also for a specific product. At each timestep a special context vector was provided as input, gated so as to enable the model to decide how much attention to pay to that vector and the current hidden state. Li et al. (2016) used "speaker" vectors as an additional input to a conversational model, improving consistency of dialog responses. Finally, Ficler and Goldberg (2017) performed an extensive evaluation of conditioned language models based on "content" (theme and sentiment) and "style" (professional, personal, length, descriptiveness). Importantly, they showed that it is possible to control both "content" and "style" simultaneously.

Work from the second group can further be divided into two clusters by the nature of the training data: parallel aligned corpora, or non-aligned datasets. The aligned corpora enable approaching the problem of form shift as a paraphrasing or machine translation problem. Xu et al. (2012) used statistical and dictionary-based systems on a dataset of original plays by Shakespeare and their contemporary translations. Carlson et al. (2017) trained an LSTM network on 33 versions of the Bible. Jhamtani et al. (2017) used a Pointer Network (Vinyals et al., 2015), an architecture that was successfully applied to a wide variety of tasks (Merity et al., 2016; Gulcehre et al., 2016; Potash et al., 2017), to enable direct copying of the input tokens to the output. All these works use BLEU (Papineni et al., 2002) as the main, or even the only evaluation measure. This is only possible in cases where a parallel corpus is available.

Recently, new approaches that do not require a parallel corpora were developed in both computer vision (CV) (Zhu et al., 2017) and NLP. Hu et al. (2017) succeeded in changing tense and sentiment of sentences with a two steps procedure based on a variational auto-encoder (VAE) (Kingma and Welling, 2013). After training a VAE, a discriminator and a generator are trained in an alternate manner, where the discriminator tries to correctly classify the target sentence attributes. A special loss component forces the hidden representation of the encoded sentence to not have any information about the target sentence attributes. Mueller et al. (2017) used a VAE to produce a hidden representation of a sentence, and then modify it to match the desired form. Unlike Hu et al. (2017), they do not separate the form and meaning embeddings. Shen et al. (2017) applied a GAN to align the hidden representation of sentences from two corpora and forced them not to have any information about the form an via adversarial loss. During the decoding, similarly to Lipton et al. (2015),

---

[2] The term "style" is not entirely appropriate here, but in NLP it is often used in work on any kind of form change while preserving meaning, from translation to changing sentiment polarity.

special “style” vectors are passed to the decoder at every timestep to produce a sentence with the desired properties. The model is trained using the Professor-Forcing algorithm (Lamb et al., 2016). Kim et al. (2017) worked directly on hidden space vectors that are constrained with the same adversarial loss instead of outputs of the generator, and use two different generators for different “styles”. Finally, Fu et al. (2018) generate sentences with the target properties using an adversarial loss, similarly to Shen et al. (2017) and Kim et al. (2017).

Comparison with previous work In contrast to the proposals of Xu et al. (2012), Carlson et al. (2017), Jhamtani et al. (2017), our solution does not require a parallel corpus. Unlike the model by Shen et al. (2017), our model works directly on representations of sentences in the hidden space.

Most importantly, in contrast to the proposals by Mueller et al. (2017), Hu et al. (2017), Kim et al. (2017), Fu et al. (2018), our model produces a representation for both meaning and form and does not treat the form as a categorical (in the vast majority of works, binary) variable[3].

Treating meaning and form not as binary/categorical, but continuous variables is more consistent with the reality of language use, since there are different degrees of overlap between the language used by different registers or in different diachronic slices. Indeed, language change is gradual, and the acceptability of expressions in a given register also forms a continuum, so one expects a substantial overlap between the grammar and vocabulary used, for example, on Twitter and by New York Times. To the best of our knowledge, this is the first model that considers linguistic form in the task of text generation as a continuous variable.

A significant consequence of learning a continuous representation for form is that it allows the model to work with a large, and potentially infinite, number of forms. Note that in this case the locations of areas of specific forms in the vector form space would reflect the similarity between these forms. For example, the proposed model could be directly applied to the authorship attribution problem: each author would have their own area in the form space, their proximity should mirror the similarity in writing style. Preliminary experiments on this are reported in subsection 6.4.

3 Formulation

Let us formulate the problem of decomposition of text representation on an example of controlled change of linguistic form and conversion of Shakespeare plays in the original Early Modern to contemporary English. Let $\boldsymbol{X}^a$ be a corpus of texts $\boldsymbol{x}_i^a \in \mathcal{X}^a$ in Early Modern English $\mathbf{f}^{\boldsymbol{a}} \in \mathcal{F}$, and $\boldsymbol{X}^b$ be a corpus of texts $\boldsymbol{x}_i^b \in \mathcal{X}^b$ in modern English $\mathbf{f}^{\boldsymbol{b}} \in \mathcal{F}$. We assume that the texts in both $\boldsymbol{X}^a$ and $\boldsymbol{X}^b$ have the same distribution of meaning $\mathbf{m} \in \mathcal{M}$. The form $\mathbf{f}$, however, is different and generated from a mixture of two distributions:

$$\mathbf{f}_i = \alpha_i^a p(\mathbf{f}^a) + \alpha_i^b p(\mathbf{f}^b)$$

where $\mathbf{f}^a$ and $\mathbf{f}^b$ are two different languages (Early Modern and contemporary English). Intuitively, we say that a sample $\boldsymbol{x}_i$ has the form $\mathbf{f}^{\boldsymbol{a}}$ if $\alpha_i^a > \alpha_i^b$, and it has the form $\mathbf{f}^{\boldsymbol{b}}$ if $\alpha_i^b > \alpha_i^a$.

The goal of dissociation meaning and form is to learn two encoders $E_{\mathbf{m}} : \mathcal{X} \rightarrow \mathcal{M}$ and $E_{\mathbf{f}} : \mathcal{X} \rightarrow \mathcal{F}$ for the meaning and form correspondingly, and the generator $G : \mathcal{M}, \mathcal{F} \rightarrow \mathcal{X}$ such that

$$\forall j \in \{a, b\}, \forall k \in \{a, b\} : G(E_{\mathbf{m}}(\boldsymbol{x}^k), E_{\mathbf{f}}(\boldsymbol{x}^j)) \rightarrow \mathcal{X}^j$$

The form of a generated sample depends exclusively on the provided $\mathbf{f}_j$ and can be in the same domain for two different $\mathbf{m}_u$ and $\mathbf{m}_v$ from two samples from different domains $\mathcal{X}^a$ and $\mathcal{X}^b$.

Note that, in contrast to the previous proposals, the form $\mathbf{f}$ is not a categorical variable but a continuous vector. This enables fine-grained controllable change of form: the original form $\mathbf{f}_i$ is changed to reflect the form of the specific target sentence $\mathbf{f}_j$ with its own unique α^a and α^b while preserving the original meaning $\mathbf{m}_i$.

An important caveat concerns the core assumption of the similar meaning distribution in the two corpora, which is also made in all other works reviewed in Section 2. It limits the possible use of this approach to cases where the distributions are in fact similar (i.e. comparable corpora are available; note that they do not have to be parallel). It does not apply to many cases that could be analyzed in terms of meaning and form. For example, books for children and scholarly papers are both registers, they have their own form (i.e. specific subsets of linguistic means and structure conventions) – but there is little overlap in the content.

---

[3] Although the form was represented as dense vectors in previous work, it is still just a binary feature, as they use a single pre-defined vector for each form, with all sentences of the same form assigned the same form vector.

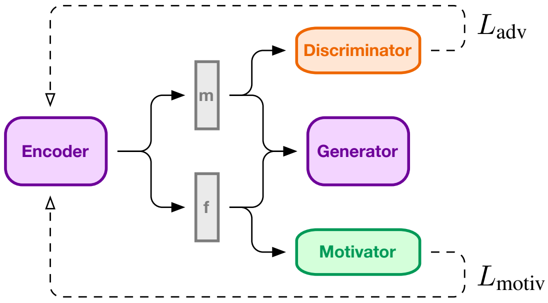

Figure 1: Overview of ADNet. *Encoder* encodes the inputs sentences into two latent vectors $\mathbf{m}$ and $\mathbf{f}$. The *Generator* takes them as the input and produces the output sentence. During the training, the *Discriminator* is used for an adversarial loss that forces $\mathbf{m}$ to not carry any information about the form, and the *Motivator* is used for a motivational loss that encourages $\mathbf{f}$ to carry the information about the form.

This would make it hard even for a professional writer to turn a research paper into a fairy tale.

4 Method description

Inspired by Makhzani et al. (2015), Kim et al. (2017), and Albanie et al. (2017), we propose ADNet, a new model for adversarial decomposition of text representation (Figure 1).

Our solution is based on a widely used sequence-to-sequence framework (Sutskever et al., 2014) and consists of four main parts. The encoder E encodes the input sequence $\boldsymbol{x}$ into two latent vectors $\mathbf{m}$ and $\mathbf{f}$ which capture the meaning and the form of the sentence correspondingly. The generator G then takes these two vectors as the input and produces a reconstruction of the original input sequence $\hat{\boldsymbol{x}}$.

The encoder and generator by themselves will likely not achieve the dissociation of the meaning and form. We encourage this behavior in a way similar to Generative Adversarial Networks (GANs) (Goodfellow et al., 2014), which had an overwhelming success the past few years as a way to enforce a specific distribution and characteristics on the output of a model.

Inspired by the work of Albanie et al. (2017) and the principle of "carrot and stick" (Safire, 1995), in contrast to the majority of work that promotes purely adversarial approach (Goodfellow et al., 2014; Shen et al., 2017; Fu et al., 2018; Zhu et al., 2017), we propose two additional components, the discriminator D and the motivator M to force the model to learn the dissociation of the meaning and the form. Similarly to a regular GAN model, the adversarial discriminator D tries to classify the form $\mathbf{f}$ based on the latent meaning vector $\mathbf{m}$, and the encoder E is penalized to make this task as hard as possible.

Opposed to such vicious behaviour, the motivator M tries to classify the form based on the latent form vector $\mathbf{f}$, as it should be done, and encourages the encoder E to make this task as simple as possible. We could apply the adversarial approach here as well and force the distribution of the form vectors to fit a mixture of Gaussians (in this particular case, a mixture of two Guassians) with another discriminator, as it is done by Makhzani et al. (2015), but we opted for the "dualistic" path of two complimentary forces.

4.1 Encoder-Decoder

Both the encoder E and the generator G are neural networks. Gated Recurrent Unit (GRU) (Chung et al., 2014) is used for E to encode the input sentence $\boldsymbol{x}$ into a hidden vector

$$\boldsymbol{h} = \text{GRU}(\boldsymbol{x})$$

The vector $\boldsymbol{h}$ then passes through two different fully connected layers to produce the latent vectors of the form and the meaning of the input sentence:

$$\mathbf{m} = \tanh(\boldsymbol{W}_{\boldsymbol{m}}\boldsymbol{h} + \boldsymbol{b}_m)$$
$$\mathbf{f} = \tanh(\boldsymbol{W}_{\boldsymbol{f}}\boldsymbol{h} + \boldsymbol{b}_f)$$

We use $\boldsymbol{\theta}_E$ to denote the parameters of the encoder E: $\boldsymbol{W}_{\boldsymbol{m}}$, $\boldsymbol{b}_m$, $\boldsymbol{W}_{\boldsymbol{f}}$, $\boldsymbol{b}_f$, and the parameters of the GRU unit.

The generator G is also modelled with a GRU unit. The generator takes as input the meaning vector $\mathbf{m}$ and the form vector $\mathbf{f}$, concatenates them, and passes trough a fully-connected layer to obtain a hidden vector $\boldsymbol{z}$ that represents both meaning and form of the original input sentence:

$$\boldsymbol{z} = \tanh(\boldsymbol{W}_z[\mathbf{m}; \mathbf{f}] + \boldsymbol{b}_m)$$

After that, we use a GRU unit to generate the output sentence as a probability distribution over the vocabulary tokens:

$$p(\hat{\boldsymbol{x}}) = \prod_{t=1}^{T} p(\hat{\boldsymbol{x}}_t | \boldsymbol{z}, \hat{\boldsymbol{x}}_1, \ldots, \hat{\boldsymbol{x}}_{t-1})$$

We use $\boldsymbol{\theta}_G$ to denote the parameters of the generator G: $\boldsymbol{W}_z$, $\boldsymbol{b}_m$, and the parameters of the used GRU. The encoder and generator are trained using the standard reconstruction loss:

$$\mathcal{L}_{\text{rec}}(\boldsymbol{\theta}_E, \boldsymbol{\theta}_G) = \mathbb{E}_{\boldsymbol{x}\sim \boldsymbol{X}^a}[-\log p(\hat{\boldsymbol{x}}|\boldsymbol{x})] + \mathbb{E}_{\boldsymbol{x}\sim \boldsymbol{X}^b}[-\log p(\hat{\boldsymbol{x}}|\boldsymbol{x})]$$

4.2 Discriminator

The representation of the meaning $\mathbf{m}$ produced by the encoder E should not contain any information about the form $\mathbf{f}$. We achieve this by using an adversarial approach. First, we train a discriminator D, consisting of several fully connected layers with `ELU` activation function (Clevert et al., 2015) between them, to predict the form $\mathbf{f}$ of a sentence by its meaning vector:

$$\hat{\boldsymbol{f}}_D = D(\mathbf{m})$$

where $\hat{\boldsymbol{f}}$ is the score (logit) reflecting the probability of the sentence $\boldsymbol{x}$ to belong to one of the form domains.

Motivated by the Wasserstein GAN (Arjovsky et al., 2017), we use the following loss function instead of the standard cross-entropy:

$$\mathcal{L}_D(\boldsymbol{\theta}_D) = \mathbb{E}_{\boldsymbol{x}\sim\boldsymbol{X}^a}[D(E_{\mathbf{m}}(\boldsymbol{x}))] - \mathbb{E}_{\boldsymbol{x}\sim\boldsymbol{X}^b}[D(E_{\mathbf{m}}(\boldsymbol{x}))]$$

Thus, a successful discriminator will produce negative scores $\hat{\boldsymbol{f}}$ for sentences from $\boldsymbol{X}^a$ and positive scores for sentences from $\boldsymbol{X}^b$. This discriminator is then used in an adversarial manner to provide a learning signal for the encoder and force dissociation of the meaning and form by maximizing $\mathcal{L}_D$:

$$\mathcal{L}_{\text{adv}}(\boldsymbol{\theta}_E) = -\lambda_{\text{adv}}\mathcal{L}_D$$

where λ_{adv} is a hyperparameter reflecting the strength of the adversarial loss. Note that this loss applies to the parameters of the encoder.

4.3 Motivator

Our experiments showed that the discriminator D and the adversarial loss $\mathcal{L}_{\text{adv}}$ by themselves are sufficient to force the model to dissociate the form and the meaning. However, in order to achieve a better dissociation, we propose to use a motivator M (Albanie et al., 2017) and the corresponding motivational loss. Conceptually, this is the opposite of the adversarial loss, hence the name. As the discriminator D, the motivator M learns to classify the form $\mathbf{f}$ of the input sentence. However, its input is not the meaning vector but the form vector:

$$\hat{\boldsymbol{f}}_M = M(\mathbf{f})$$

The motivator has the same architecture as the discriminator, and the same loss function. While the adversarial loss forces the encoder E to produce a meaning vector $\mathbf{m}$ with no information about the form $\mathbf{f}$, the motivational loss encourages E to encode this information in the form vector by minimizing $\mathcal{L}_M$:

$$\mathcal{L}_{\text{motiv}}(\boldsymbol{\theta}_E) = \lambda_{\text{motiv}}\mathcal{L}_M$$

4.4 Training procedure

The overall training procedure follows the methods for training GANs (Goodfellow et al., 2014; Arjovsky et al., 2017) and consists of two stages: training the discriminator D and the motivator M, and training the encoder E and the generator G.

In contrast to Arjovsky et al. (2017), we do not train the D and M more than the E and the G. In our experiments we found that simple training in two stages is enough to achieve dissociation of the meaning and the form. Encoder and generator are trained with the following loss function that combines reconstruction loss with the losses from the discriminator and the motivator:

$$\mathcal{L}_{\text{total}}(\theta_E, \theta_G) = \mathcal{L}_{\text{rec}} + \mathcal{L}_{\text{adv}} + \mathcal{L}_{\text{motiv}}$$

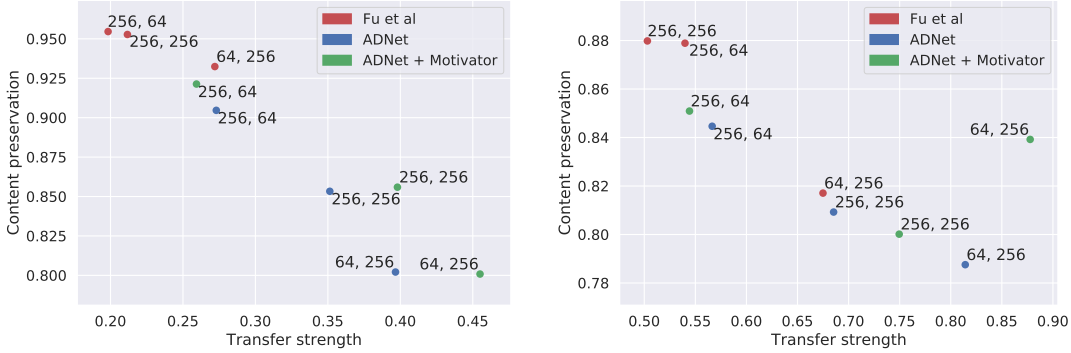
5 Experimental setup

5.1 Evaluation

Similarly to the evaluation of style transfer in CV (Isola et al., 2017), evaluation of this task is difficult. We follow the approach of Isola et al. (2017); Shen et al. (2017) and recently proposed by Fu et al. (2018) methods of evaluation of “transfer strength” and “content preservation”. The authors showed that the proposed automatic metrics correlate with human judgment to a large degree and can serve as a proxy. Below we give an overview of these metrics.

Transfer Strength. The goal of this metric is to capture whether the form has been changed successfully. To do that, a classifier C is trained on the two corpora, $\boldsymbol{X}^a$ and $\boldsymbol{X}^b$ to recognize the linguistic “form” typical of each of them. After that a sentence, for which the form/meaning has been changed, is passed to the classifier. The overall accuracy reflects the degree of success of changing the form/meaning. This approach is widely used in CV (Isola et al., 2017), and was applied in NLP as well (Shen et al., 2017).

In our experiments we used a GRU unit followed by four fully-connected layers with `ELU` activation functions between them as the classifier.



(a) Shakespeare dataset

(b) Headlines dataset

Figure 2: Transfer strength vs content preservation (see subsection 5.1) for different sizes of the meaning and form vectors. Each point is labeled with "⟨meaning vector size⟩, ⟨form vector size⟩".

Content preservation Note that the transfer strength by itself does not capture the overall quality of a changed sentence. A extremely overfitted model that produces the most characteristic sentence of one corpus all the time would have a high score according to this metric. Thus, we need to measure how much of the meaning was preserved while changing the form. To do that, Fu et al. (2018) proposed to use a cosine similarity based metric using pretrained word embeddings. First, a sentence embedding is computed by concatenation of max, mean, and average pooling over the timesteps:

$$\boldsymbol{v} = [\max(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_T); \min(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_T); \mathrm{mean}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_T)]$$

Next, the cosine similarity score s_i between the embedding $\boldsymbol{v}_i^s$ of the original source sentence and the target sentence with the changed form $\boldsymbol{v}_i^t$ is computed, and the scores across the dataset are averaged to obtain the total score s.

5.1.1 Continuous form

The metrics described above treat the form as a categorical (in most cases, even binary) variable. This was not a problem in previous work since the change of form could be done by simply inverting the form vector. Since we treat the form as a continuous variable, we cannot just use the proposed metrics directly. To enable a fair comparison, we propose the following procedure.

For each sentence s_s^a in the test set from the corpus $\boldsymbol{X}^a$ we sample $k = 10$ random sentences from the corpus $\boldsymbol{X}^b$ of the opposite form. After that, we encode them into the meaning $\boldsymbol{m}_i$ and form $\boldsymbol{f}_i$ vectors, and average the form vectors to obtain a single form vector

$$\boldsymbol{f}_{\text{avg}} = \frac{1}{k} \sum_{i=1}^{k} \boldsymbol{f}_i$$

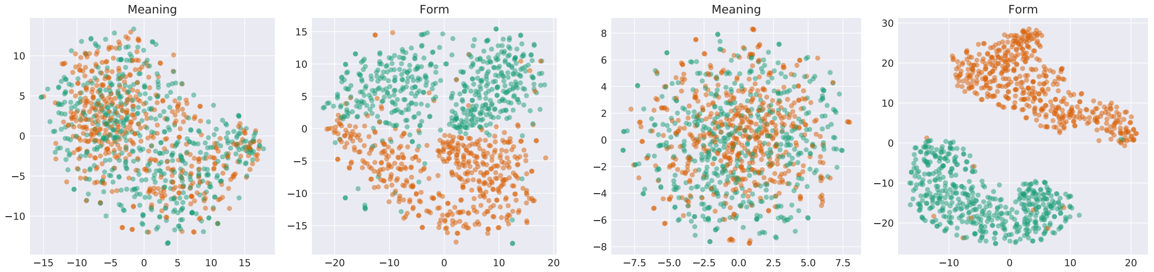
We then generate a new sentence with its original meaning vector $\boldsymbol{m}_s$ and the resulting form vector $\boldsymbol{f}_{\text{avg}}$, and use it for evaluation. This process enables a fair comparison with the previous approaches that treat form as a binary variable.

5.2 Datasets

We evaluated the proposed method on several datasets that reflect different changes of meaning and form.

Changing form: register. This experiment is conducted with a dataset of titles of scientific papers and news articles published by Fu et al. (2018). This dataset (referred to as "Headlines") contains titles of scientific articles crawled from online digital libraries, such as "ACM Digital Library" and "arXiv". The titles of the news articles are taken from the "News Aggregator Data Set" from UCI Machine Learning Repository (Dheeru and Karra Taniskidou, 2017)

Changing form: language diachrony. Diachronic language change is explored with the dataset composed by Xu et al. (2012). It includes the texts of 17 plays by William Shakespeare in the original Early Modern English, and their translations into contemporary English. We randomly permuted all sentences from all plays and sampled the training, validation, and test sets. Note that this dataset is much smaller than the Headlines dataset.



(a) Without motivator

(b) With motivator

Figure 3: t-SNE visualization of the form and meaning embeddings of 1000 random sentences. Green point represent sentences form news headlines, and red points represent titles of scientific articles.

6 Results and discussion

The most recent and similar to our work is the model proposed by Fu et al. (2018), in particular the "style-embedding" model. We implemented this model to provide a baseline for comparison.

The classifier used in the transfer strength metric achieves high accuracy (0.832 and 0.99 for the Shakespeare and Headlines datasets correspondingly). These results concur with the results of Shen et al. (2017) and Fu et al. (2018), and show that the two corpora are significantly different.

Following Fu et al. (2018), we show the result of different configuration of the size of the form and meaning vectors on Figure 2. Namely, we report combinations of 64 and 256-dimensional vectors. Note that the sizes of the form vector are important. If the form vector is larger, the transfer strength is gre,ta erbut the content preservation is lessened. This is consistent with Fu et al. (2018), where they observed a similar behaviour.

It is clear that the proposed method achieves significantly better transfer strength than the previously proposed model. It also has a lower content preservation score, which means that it repeats fewer exact words from the source sentence. Note that a low transfer strength and very high (~0.9) content preservation score means that the model was not able to successfully learn to transfer the form and the target sentence is almost identical to the source sentence. The Shakespeare dataset is the hardest for the model in terms of transfer strength, probably because it is the smallest dataset, but the proposed method performs consistently well in transfer of both form and meaning and, in contrast to the baseline.

Storing meaning in the form vector Note that, theoretically, nothing is stopping the model from storing the meaning in the form vector, except from the size limitations, which would ensure that storing non-form-related information elsewhere would improve model performance. Figure 2 shows that as the meaning vectors get smaller, and the form vectors larger, the higher is transfer strength and the lower is content preservation. If the model would store meaning in the form vector, then the reduction in size of the meaning vector would not have negative impact on content preservation. This shows that the model tends to not store the meaning in the form vector.

Nevertheless, to force this behaviour we experimented with adding one more discriminator D_f. This discriminator works on the form vector $\mathbf{f}$ in the same manner as the discriminator D works on the meaning vector $\mathbf{m}$. Namely, during the training it tries to predict the meaning of a sentence from its form vector: $\boldsymbol{u} = D_f(\mathbf{f})$. Note that the vectors $\boldsymbol{u}$ and $\mathbf{m}$ are completely different. $\mathbf{m}$ is the meaning of a sentence for the purpose of the model, whereas $\boldsymbol{u}$ are pre-defined meaning of a sentence for training of the discriminator. In the simplest case, $\boldsymbol{u}$ can be a multi-hot representation of the input sentence, with the exception of pre-defined "style" words, which would always have 0 in the corresponding dimension, as it is done by John et al. (2018).

We, however, take a different approach. First, we find the "form" dimensions in the used word embeddings by taking the argmax of the difference between averaged word embeddings of the sentences from two forms (i.e. Early Modern English and contemporary English). Next, for a given sentence we discard the top-k tokens with the maximum and minimum values in those dimensions. Finally, we average word embeddings of the remaining tokens in the sentence to get the vector $\boldsymbol{u}$.

Aye, sir. (EME)	→	Yes, sir. (CE)
Fare thee well, my lord (EME)	→	Fare you well, my lord (CE)
This guy will tell us everything. (CE)	→	This man will tell us everything. (EME)
I've done no more to caesar than you will do to me. (CE)	→	I have done no more to caesar than, you shall do to me. (EME)

Table 1: Decoding of the source sentence from Early Modern English (EME) into contemporary English (CE), and vice versa.

Semantic approach to event processing		Security flaw to verify leaks

Table 2: Flipping the meaning and the form embeddings of two sentence from different registers. Note the use of colon in the first example, and the use of the "to"-constructions in the second example, consistent with the form of the source sentences.

Such incorporation of the discriminator D_f helped to mitigate this issue.

Fluency of generated sentences Note that there is no guarantee that the generated sentences would be coherent after switching the form vector. In order to estimate how this switch affects the fluency of generated sentences, we trained a language model on the Shakespeare dataset and calculated the perplexity of the generated sentences using the original form vector and the average of form vectors of k random sentences from the opposite form (see subsubsection 5.1.1). While the perplexity of such sentences does go up, this change is not big (6.89 vs 9.74).

6.1 Impact of the motivational training

To investigate the impact of the motivator, we visualized form and meaning embeddings of 1000 random samples from the Headlines dataset using t-SNE algorithm (Van Der Maaten, 2014) with the Multicore-TSNE library (Ulyanov, 2016). The result is presented in Figure 3.

There are three important observations. First, there is no clear separation in the meaning embeddings, which means that any accurate form transfer is due to the form embeddings, and the dissociation of form and meaning was successful.

Second, even without the motivator the model is able to produce the form embeddings that are clustered into two groups. Recall from section 4 that without the motivational loss there are no forces that influence the form embeddings, but nevertheless the model learns to separate them.

However, the separation effect is much more pronounced in the presence of motivator. This explains why the motivator consistently improved transfer strength of ADNet, as shown in Figure 2.

6.2 Qualitative evaluation

Table 1 and Table 2 show several examples of successful form/meaning transfer achieved by ADNet. Table 1 presents the results of an experiment that to some extent replicates the approach taken by the authors who treat linguistic form as a binary variable (Shen et al., 2017; Fu et al., 2018). The sentences the original Shakespeare plays were averaged to get the "typical" Early Modern English form vector. This averaged vector was used to decode a sentence from the modern English translation back into the original. The same was done in the opposite direction.

Table 2 illustrates the possibilities of ADNet on fine-grained transfer applied to the change of register. We encoded two sentences in different registers from the Headlines dataset to produce form and meaning embeddings, and then decoded the first sentence with the meaning embedding of the second, and vice versa. Table 2 shows that the model correctly captures the meaning of sentences and decodes them using the form of the source sentences, preserving specific words and the structure of the source sentence. Note that in the first example, the model decided to put the colon after the "crisis management", as the source form sentence has this syntactic structure ("A review:"). This is not possible in the previously proposed models, as they treat form as just a binary variable.

6.3 Performance of meaning embeddings on downstream tasks

We conducted some experiments to test the assumption that the derived meaning embeddings should improve performance on downstream tasks

(a) Meaning embeddings

(b) Form embeddings

Figure 4: t-SNE visualization of the form and meaning embeddings. Each color corresponds to a different author.

BoW	Seq2Seq	InferSent	Fu et al. (2018)	ADNet

Table 3: F1 scores on the task of paraphrase detection using the SentEval toolkit (Conneau et al., 2017)

that require understanding of the meaning of the sentences regardless of their form. We evaluated embeddings produced by the ADNet, trained in the Headlines dataset, on the paraphrase detection task. We used the SentEval toolkit (Conneau et al., 2017) and the Microsoft Research Paraphrase Corpus (Dolan et al., 2004). The F1 scores on this task for different models are presented in Table 3. Note that all models, except InferSent, are unsupervised. The InferSent model was trained on a big SNLI dataset, consisting of more than 500,000 manually annotated pairs. ADNet achieves the the highest score among the unsupervised systems and far outperforms the regular sequence-to-sequence autoencoder.

6.4 Multiple forms and stylistic similarities

In order to go beyond just two different forms, we experimented with training the model on a set of literature novels from six different authors from Project Gutenberg[4] written in two different time periods. A t-SNE visualization of the resulting meaning and form embeddings is presented in Figure 4. Note how form embeddings create a six-pointed star. After further examination, we observed that common phrases (for example, “Good morning” or “Hello!”) were embedded into the center of the star, whereas the most specific sentences from a given author were placed into the rays of the star. In particular, some sentences included character names, thus further research is required to mitigate this problem. Stamatatos (2017) provides a promising direction for solving this.

7 Conclusion

We presented ADNet, a new model that performs adversarial decomposition of text representation. In contrast to previous work, it does not require a parallel training corpus and works directly on hidden representations of sentences. Most importantly, it does not treat the form as a binary variable (as done in most previously proposed models), enabling a fine-grained change of the form of sentences or specific aspects of meaning. We evaluate ADNet on two tasks: the shift of language register and diachronic language change. Our solution achieves superior results, and t-SNE visualizations of the learned meaning and form embeddings illustrate that the proposed motivational loss leads to significantly better separation of the form embeddings.

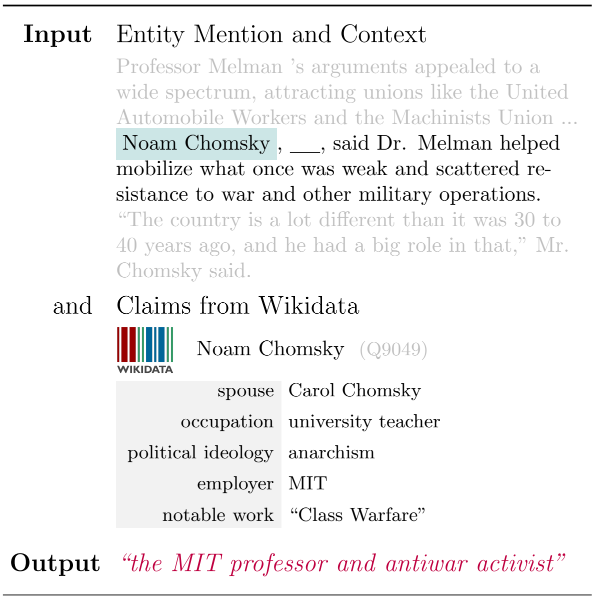
Abstract

We introduce entity post-modifier generation as an instance of a collaborative writing task. Given a sentence about a target entity, the task is to automatically generate a post-modifier phrase that provides contextually relevant information about the entity. For example, for the sentence, "Barack Obama, ______, supported the #MeToo movement.", the phrase "a father of two girls" is a contextually relevant post-modifier. To this end, we build `PoMo`, a post-modifier dataset created automatically from news articles reflecting a journalistic need for incorporating entity information that is relevant to a particular news event. `PoMo` consists of more than 231K sentences with post-modifiers and associated facts extracted from Wikidata for around 57K unique entities. We use crowdsourcing to show that modeling contextual relevance is necessary for accurate post-modifier generation.

We adapt a number of existing generation approaches as baselines for this dataset. Our results show there is large room for improvement in terms of both identifying relevant facts to include (knowing which claims are relevant gives a $> 20\%$ improvement in BLEU score), and generating appropriate post-modifier text for the context (providing relevant claims is not sufficient for accurate generation). We conduct an error analysis that suggests promising directions for future research.



Input Entity Mention and Context

Professor Melman 's arguments appealed to a wide spectrum, attracting unions like the United Automobile Workers and the Machinists Union ... Noam Chomsky , ___, said Dr. Melman helped mobilize what once was weak and scattered resistance to war and other military operations. "The country is a lot different than it was 30 to 40 years ago, and he had a big role in that," Mr. Chomsky said.

and Claims from Wikidata

Noam Chomsky (Q9049)

occupation	university teacher
political ideology	anarchism
employer	MIT
notable work	"Class Warfare"

Output *"the MIT professor and antiwar activist"*

Figure 1: Post-Modifier Generation Task

1 Introduction

The goal of machine-in-the-loop writing systems is to assist human writers by directly augmenting their text. Examples include systems that refine human text for grammar (Rao and Tetreault, 2018), collaborate on story plot generation systems (Clark et al., 2018; Yu and Riedl, 2012), or modify the content for style (Hu et al., 2017; Shen et al., 2017; Yang et al., 2018). In this paper, we introduce post-modifier generation as an instance of such an assistive writing task in the news domain. Journalists use post-modifiers to introduce background information about entities discussed in news articles. To write these post-modifiers journalists often need to look up relevant facts about entities. A post-modifier generation system can be seen as a collaborative assistant that automatically finds relevant facts and inserts a small text fragment that augments the text produced by the human writer.

Post-modifier generation is a *contextual* data-to-text generation problem, where the data is the set of known facts about the target entity, and the text to be generated is a post-modifier that is relevant to the rest of the information conveyed in the text. Figure 1 shows an example. Given a sentence about the anti-war resistance work of Noam Chomsky, the target entity, and a set of known facts about him, the task is to generate a post-modifier that introduces Chomsky as a professor and mentions

Proceedings of NAACL-HLT 2019, pages 826–838
Minneapolis, Minnesota, June 2 - June 7, 2019.

his background as an anti-war activist. An effective post-modifier generation system must: (i) select suitable facts about the entity given the text, and (ii) produce text that covers these facts in a way that fits in with the rest of the text.

We introduce `PoMo`, an automatically generated dataset for developing post-modifier generation systems.[1] `PoMo` is a collection of sentences that contain entity post-modifiers, along with a collection of facts about the entities obtained from Wikidata (Vrandečić and Krötzsch, 2014). We use a small number of dependency patterns to automatically identify and extract post-modifiers of entities in sentences. We then link the extracted entities with the entries in Wikidata. The resulting dataset has 231,057 instances covering 57,966 unique entities. Our analysis show that the post-modifiers often combine multiple facts and are specific to the sentential context.

We conduct two sets of experiments that highlight the challenges in post-modifier generation. **(i) Claim Selection:** Given an input sentence, the first step in generating a post-modifier is to figure out which facts to use. We formulate this as a distantly-supervised ranking problem, where we train neural models that learn to identify relevant claims for a given sentence. These claim ranking models perform well when predicting the relevance of coarse-grained facts (e.g. occupation), but fare poorly when predicting finer-grained facts (e.g. place of birth). **(ii) Generation:** We adapt recent sequence-to-sequence generation models for this task. Results show that generation remains a challenge. Even though our automatic claim ranking does not improve generation, further experiments with oracle selected claims demonstrate that when relevant claims are known, the models can generate post-modifiers which humans deem comparable in quality to ones written by professional journalists.

In summary, the main contributions of this work are: 1) a data-to-text problem that introduces new challenges, 2) an automated dataset creation pipeline and a large resulting dataset, 3) a crowdsourcing study that verifies the contextual relevance of post-modifiers, and 4) a characterization of the difficulty of the task via performance analysis of numerous baselines.

Table 1: Dataset distribution by sources.

2 PoMo: Task and Dataset

Post-modifier generation can be formulated as a data-to-text generation problem. The input is text mentioning a target entity and a set of known facts about the entity. The output is a phrase that: (i) fits as a post-modifier of the target entity mentioned in the input text, and (ii) conveys a subset of facts relevant to the context of the input text.

Figure 1 shows an example for the target entity `Noam Chomsky`. The input includes a sentence mentioning Chomsky's work on mobilizing anti-war groups along with its surrounding context, and a listing of all facts about Chomsky that are available in Wikidata. Given these inputs, the task is to output a post-modifier phrase that conveys facts about Chomsky that fit within the sentence. In this example the post-modifier conveys both general background information about Chomsky (his occupation), and specific information relevant to the context of the sentence (being an anti-war activist).

This task can be seen as an instance of collaborative writing, where the journalist writes text about specific news events involving entities, and the generation system assists the journalist by inserting new text that augments the story. Given a large collection of news articles, we can automatically create training data for such systems by removing the pieces of text that we want the assistant to generate. This requires reliable ways to identify text to remove and sources of information that can be used to generate the text. Here we describe a pipeline for generating such a dataset for our task.

2.1 Dataset

We construct the `PoMo` dataset using three different news corpora: NYTimes (Sandhaus, 2008), CNN and DailyMail (Hermann et al., 2015). We use Wikidata to collect facts about entities.[2]

---

[1] `https://stonybrooknlp.github.io/PoMo/`

[2] Wikidata dump from `https://www.wikidata.org/wiki/Wikidata:Database_download` (Dump date: 2018/06/25)

2.1.1 Post-Modifier and Entity Identification

We use Stanford CoreNLP (Manning et al., 2014) to parse each sentence in the news articles and to identify named entities. We extract post-modifiers by finding noun phrases that share an *appos* relation[3] with any recognized named entity in the sentence. In this work, we only consider post-modifiers for *people*. In the future, we plan to expand `PoMo` to include more post-modifiers for other targets, such as organizations. We extract only one such pair from a given sentence to reduce the possible noise in the extraction process.

In our running example from Figure 1, `Noam Chomsky` is recognized as a person entity. The word "professor" is an appositive dependency of the word "Chomsky" and therefore, we extract the NP "the Massachusetts Institute of Technology professor and antiwar activist" which includes the word "professor" as a post-modifier for the target entity `Noam Chomsky`.

2.1.2 Entity Claim Matching

Wikidata provides information about entities in the form of key-value pairs that are called *claims*. To collect the facts about a target entity, we need to link the target to a specific entity in Wikidata. We first search through Wikidata labels and aliases to find candidates with the same name as the target. We sort the candidates based on the number of claims that have a significant word overlap with the extracted post-modifier. We link the entity to the highest ranked candidate whose claims cover at least 30% of the non stop words in the post-modifier. If such a candidate is found we record the claims that overlap with the post-modifier. If no such candidate is found then we discard the entity.

We evaluate this simple heuristic by comparing the results to using an off-the-shelf entity linking system AIDA-light (Nguyen et al., 2014) and show the results in Table 2. We find that AIDA-light agrees with our entity linking in 91.2% of the cases. AIDA-light is able to link 94.3% of the entities we found from NYTimes, but for CNN and DailyMail, it links only 87.0% and 86.34% of the entities, respectively. This decrease is likely due to the fact that AIDA-light was last updated in 2014 while the CNN/DailyMail datasets contain articles collected until the end of April 2015. On the other hand, NYTimes articles range from 1987 to 2007. Our heuristic seems to be reasonably reliable as it does not depend on anything else but the data sources: news articles and Wikidata.

	AIDA Succ.	Agreement
Overall	93.66	91.22
Train	93.65	91.16
Valid	94.06	91.13
Test	93.80	93.65
CNN	87.03	90.34
DM	86.34	85.66
NYT	94.29	91.53

Table 2: Percent agreement with AIDA-light's named entity disambiguation results.

2.2 Analysis

Table 1 shows the distribution of the data sources over train, validation, and test sets. All splits maintain the relative distributions of the data sources to prevent stylistic mismatches from influencing generation. We also ensure that there is no entity overlap among the splits. Within the NYTimes data, we verify that the distribution over years between 1987 and 2007 is also similar over the sets.

Distribution of Post-Modifiers and Entities Figure 2a shows the distribution of post-modifier lengths in terms of token counts. Most post-modifiers are three to eight words long, and about 17.3% are even longer. Figure 2b shows an estimate of the number of relevant facts covered by the post-modifiers; this estimate uses the number of claims that overlap with the post-modifier via heuristic matching. More than half of the post-modifiers convey two or more facts. About 11.4% convey five or more facts. These results suggest that generating post-modifiers requires composing together multiple relevant facts.

Table 3 lists the most frequent types of facts used in the post-modifiers in our dataset. Most relate to generic biographical information such as the entity's occupation, organizations they belong to, place of birth, etc. Here again we see a range of types of information being conveyed which is likely to present a challenge for generation systems.

The dataset also covers a wide variety of entity types. We cluster the target entities by their occupation listed in Wikidata. We also use WordNet (Miller, 1995) to traverse the hypernyms of the words to find frequent ones. Then, we manually select the top ten occupation types. Any entity that

J. K. Rowling , __________ , was a 30-year-old single mother living on welfare in a cold one-bedroom flat in Edinburgh when she began writing it in longhand during her baby daughter 's nap times .

Q. Please score the below phrases based on *their relevance* to the above sentence.
In other words, would they fit well in the sentence if they were put into the blank?
Please disregard the factual correctness of the phrases.

a teacher by training	Completely relevant	5 ○	4 ○	3 ○	2 ○	1 ○	Completely irrelevant
she of the Harry Potter books and new-found fame	Completely relevant	5 ○	4 ○	3 ○	2 ○	1 ○	Completely irrelevant
the author of the popular Harry Potter children 's books	Completely relevant	5 ○	4 ○	3 ○	2 ○	1 ○	Completely irrelevant
the author of the Harry Potter series	Completely relevant	5 ○	4 ○	3 ○	2 ○	1 ○	Completely irrelevant

Figure 3: Screenshot of the crowdsourcing task. We asked crowd to rate the quality of post-modifiers.

does not belong to the top ten is assigned to a single *other* group. The resulting distribution is shown in Table 4.

Quality of Post-Modifiers We conduct a crowdsourcing study to understand how often the post-modifiers are specific to the particular context. For each (entity, context, post-modifier) triple in the validation set, we create multiple alternative post-modifiers by randomly choosing up to ten other post-modifiers that are found in some other sentences for the same entity. Crowd workers rate the quality of these post-modifiers. Figure 3 shows a screenshot of a task given to crowd workers. If the true post-modifier, the one that is actually used in the context, is rated the highest compared to the rest, then we assume the post-modifier is indeed specific to the context. On the other hand, if the crowd workers rate multiple other post-modifiers as good fits for the context, then the true post-modifier is not context specific. Figure 2c shows the distribution of ratings for true and other post-modifiers. The true post-modifiers tend to be rated *very good* or *good* more often than the other post-modifiers. This suggests that in many cases post-modifiers are specific to the context and cannot be simply replaced by other post-modifiers.

3 Relevant Claim Selection

One of the key challenges of generating post-modifiers is to identify the claims about an entity that are relevant to the given context. In this section, we explore methods for solving this task.

3.1 Methods

We consider three different models: a most-common claim baseline and two neural baselines.

Most-Common Claim This model employs a simple frequency heuristic: rank claims by the frequency of their types in the training post-modifiers (e.g. as in the order given in Table 3) and deem the top n claims in this ranking as relevant.

Neural Baselines We use two neural baselines with the following architecture. Word embeddings are used to represent words in the context (e.g. current and previous sentence) and claims. The sequences of embeddings are then fed through 2-layer LSTM's (Hochreiter and Schmidhuber, 1997) to obtain separate representations of the context and claims. These representations are subsequently concatenated together and fed through a fully-connected layer with sigmoid activation, producing a scalar value for each claim representing the probability that it is relevant. We use this model in two ways: as a classifier, and as a ranking model. When used as a classifier, any claim whose score exceeds a threshold τ is predicted to be relevant. When used as a ranking model, the top n highest-scoring claims are predicted to be relevant.

3.2 Experiments

We train our baselines on the `PoMo` dataset, using the claims detected during dataset collection as a (distant) source of supervision. Precision, recall, and F_1 score are used to evaluate model performance. Model hyperparameters are chosen using (coarse) grid search to maximize F_1 score on the validation set. The neural baselines use a vocabulary size of 50,000, 100-dimensional word embeddings, and 256 hidden units in the LSTM layers. Dropout (Srivastava et al., 2014) is applied between the LSTM layers with a 0.5 keep probability. The neural classifier uses threshold $\tau = 0.37$. We find the optimal value of n is 4 for the most-common claims model and 2 for the neural ranker.

Quantitative results are provided in Table 5. Both neural baselines perform considerably better than the most-common claims model. This indicates that the provided contexts and claim values contain useful information for claim selection that goes beyond the information captured by global statistics of the dataset alone. We additionally observe that the ranking-based approach outperforms the classification-based approach in terms of both precision and F_1 score, while having only slightly worse recall.

	Prec.	**Recall**	**F_1**
Most-Common Claim (n=4)	39.9	51.6	45.0
Neural Classifier (τ=0.37)	52.0	63.8	57.4
Neural Ranker (n=2)	66.5	62.7	64.5

Table 5: Baseline model performance on the claim selection task.

Fact Type	**F_1**
employer	76.95
position played on team / speciality	76.65
position held	63.10
occupation	50.02
member of political party	48.71
member of	45.60
member of sports team	38.53
award received	37.53
nominated for	30.87
educated at	29.56
participant of	29.04
country of citizenship	16.28
place of death	14.72
place of birth	6.80
languages spoken, written or signed	0.00

Table 6: F_1 score of neural ranker ($n = 2$) on top 15 fact types.

To better understand the cases where the neural models fail and succeed, we examine the distribution of F_1 scores over the top 15 fact types (see Table 6). Interestingly, when ranked by F_1 score we observe that fact types fall naturally into topically related groups:

1. position / occupation-related facts: *position played, position held, occupation*
2. membership-related facts: *member of political party, member of, member of sports team*
3. achievement-related facts: *award received, nominated for*
4. location-related facts: *country of citizenship, place of death, place of birth*

With the exception of *employer*, the overarching trend is that the model identifies the relevance of coarse-grained claims better than fine-grained claims (e.g occupations, political parties, and sports positions are much more likely to be shared between entities than birth and death places). This suggests that developing better methods for determining the relevance of fine-grained claims is a promising avenue for future research on this task.

4 Post-Modifier Generation

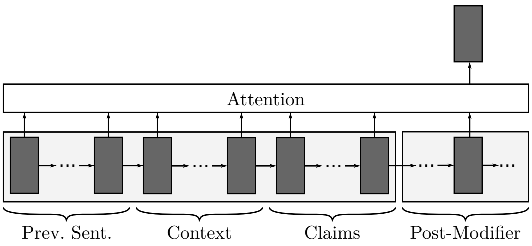
We move our focus to the main task of post-modifier generation.

4.1 Methods

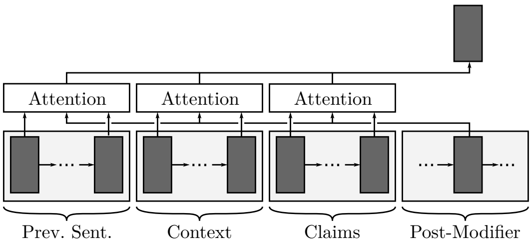
At its core, post-modifier generation involves producing a variable-length sequence output conditioned on two variable-length inputs: the words in the current and previous sentence (e.g. the context), and the collection of claims about the entity. Accordingly, the sequence-to-sequence (seq2seq) framework (Sutskever et al., 2014) is a natural fit for the task — we use it as the foundation for all of our baseline models. Since research has shown that attention (Bahdanau et al., 2015) and copy mechanisms (Gu et al., 2016) consistently improve seq2seq model performance, we use these in our baselines as well.

One choice that must be made when using this framework is how to combine the different inputs. The default approach we use is to concatenate the claim and context into a linear sequence of tokens during preprocessing (shown in Figure 4a). We also experiment with encoding the claims and each of the context sentences separately, then concatenating their vector representations before decoding. We refer to this as the *tri-encoder* approach (shown in Figure 4b).

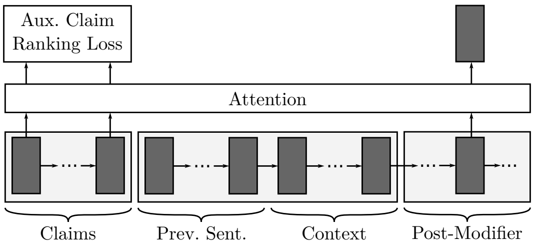
As discussed earlier, selecting relevant claims is crucial to generating good post-modifiers. One way to incorporate claim selection is to use our baseline models from Section 3 to cut out irrelevant claims from the input before feeding them to the encoder (e.g. performing hard claim selection). This pipelined approach is not differentiable, and can suffer from cascading errors. An alternative way is to use the model's attention mechanism as a form of soft claim selection that attends only to the relevant claims. The drawback of this approach is that it does not make use of the available claim annotations, which are an important source of supervision.



(a) Basic sequence-to-sequence model



(b) Tri-encoder model



(c) End-to-end claim selection model

Figure 4: `PoMo` Models for post-modifier generation. Grey boxes at the bottom represent individual encoder/decoder modules. (a) For baseline BiLSTM and transformer models all inputs are concatenated into one sequence. (b) The tri-encoder model has a separate encoder and attention for each type of input. The outputs of attention layers are concatenated together before generation. (c) The end-to-end claim selection model attends to only the claim embeddings and uses an auxiliary loss term to encourage high attention scores for relevant claims.

Building on these observations, we propose an *end-to-end claim selection* model which incorporates an additional term to the loss function that encourages the claim-level attention probabilities to be higher for the identified relevant claims as shown in Figure 4c. The process for computing this loss term works as follows. We begin by summing together attention scores for tokens within claims to obtain a claim-level score. These scores are then fed through a sigmoid activation function to obtain a soft claim selection probability. For each claim, we measure the binary cross entropy between the predicted selection probability and a binary variable indicating whether or not the claim was identified as relevant. The final loss term is the average of these binary cross entropies. Note that we do not use a copy mechanism in this model to avoid double-counting (since relevant claims were identified using word overlap).

4.2 Experiments

We experiment with two types of encoder/decoder modules: bidirectional LSTMs, and transformers (Vaswani et al., 2017). We use a vocabulary of size 50K, truncate the maximum input sequence length to 500, and use a batch size of 32 in all experiments. To help models distinguish between claims and context we demarcate claim fields with special `<claim>`, `<key>`, and `<value>` tokens. We train all the models for 150k steps, and evaluate on the validation dataset every 10k steps. Evaluation is performed using the BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) translation metrics, and Precision, Recall and F_1 score of the predicted bag-of-words (omitting stopwords). The model with the highest F_1 score on the validation set is used during test time.

For the bidirectional LSTM, we use 2 hidden layers with 512 hidden units, 500-dimensional word embeddings, and apply dropout between layers with a keep probability of 0.7. Models are trained using stochastic gradient descent with a learning rate of 1.0. For the transformer model, we use 4 attention heads, 4 layers of transformer blocks with 64 hidden units for the encoder and the decoder, a penultimate hidden layer with 256 units, and 64-dimensional word embeddings. Transformer models are trained using Adam (Kingma and Ba, 2015) with an initial learning rate of 2.0, and a label smoothing (Szegedy et al., 2016) factor of 0.1 when calculating loss.

We perform a variety of experiments, the results of which are displayed in Table 7. In this table, *Transformer* and *BiLSTM* refer to models trained using the default approach to combining context and claims, while *Tri-encoder* refers to a BiLSTM model trained using the approach described in 4.1 (we do not train a transformer version since its performance is lackluster). Here are detailed descriptions of the experiments performed in each section:

- **All Claims**: Results for vanilla seq2seq models.
- **Oracle**: Hard claim selection is performed using the oracle relevant claims.
- **Neural Ranker** ($n = 10$): Hard claim selection is performed using the top-10 claims returned by the neural ranker baseline.
- **End-to-End Claim Selection**: Results for the end-to-end claim selection model.

In order to understand the relative contribution of the different inputs, we also include results for the BiLSTM model trained using either only the claims, or only the context sentences. In Figure 5 and 6, we show the performances by post-modifier and sentence lengths to examine the impact of the such variables.

Discussion of Quantitative Results Our results contain a few key findings. The first is that knowing the relevant claims is critical to obtaining state-of-the-art performance; even knowing only oracle claims is sufficient to perform better than all of the other baselines, although there is a still a large improvement when context is additionally provided. However, model-based approaches for claim selection do not seem to help: hard claim selection using the neural ranker performs just as well as the vanilla models, and our proposed approach for end-to-end claim selection has a negative impact. This motivates the need for more effective methods of claim selection. The decreasing performances of the BiLSTM seq2seq models by the increasing target post-modifier and sentence lengths show the difficulty of generating long texts and handling long input data. Finally, we observe that the transformer-based seq2seq models are not particularly well-suited to this task. In all cases their performance is inferior to the BiLSTM-based approaches. Large-scale, pre-trained transformer-based language models, such as GPT-2 (Radford et al., 2019) and BERT (Devlin et al., 2018), might be an interesting addition to the baselines, by framing the task as filling in the blanks for post-modifiers. However, when restricted to approaches that only use our dataset for training, we expect those based on language models to struggle due to the separation of entities among train, validation, and test.

Qualitative Analysis A cursory examination of model predictions (see Table 8 for examples) provides insight into why post-modifier generation is a challenging task. One issue that consistently appears is temporal inconsistency between the target and generated post-modifiers. That is, the model may make an error since it is unaware of the time period that the article is written in (and also may not be aware of the periods of time for which a claim are true). For example, in the first instance in Table 8 the Oracle model predicts an almost correct post-modifier but misses the fact that Kenneth Clarke is a *former* Chancellor of the Exchequer. Another apparent issue is that models tend to generate shorter post-modifiers than humans. As is indicated in Figure 2a the post-modifiers in the dataset on average contain 5.8 tokens, whereas generated post-modifiers have only 3.8. Lastly, we

	Prec.	Rec.	F_1	BLEU	MET.
All Claims					
Transformer	41.9	22.2	29.0	7.0	12.1
Tri-Encoder	53.9	32.4	40.5	17.0	17.6
BiLSTM	51.1	34.7	41.4	19.4	18.8
Oracle					
Transformer	69.4	38.6	49.6	15.7	20.0
Tri-Encoder	68.8	47.3	56.1	24.0	24.5
BiLSTM	66.4	48.8	56.2	25.1	25.3
Neural Ranker ($n = 10$)					
Transformer	41.5	22.4	29.1	6.9	12.1
Tri-Encoder	53.5	34.1	41.6	17.6	18.3
BiLSTM	49.0	34.2	40.3	18.5	18.5
End-to-End Claim Selection					
BiLSTM	47.5	27.9	35.2	13.7	15.3
Context Only					
BiLSTM	13.3	8.5	10.3	3.4	6.2
Claims Only					
BiLSTM	47.3	28.5	35.6	13.5	15.0
Oracle Claims Only					
BiLSTM	63.8	44.7	52.5	21.3	22.7

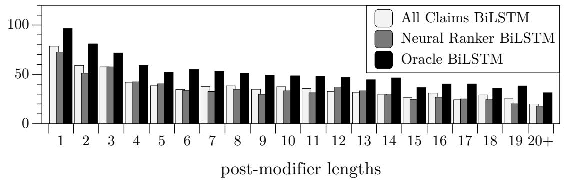
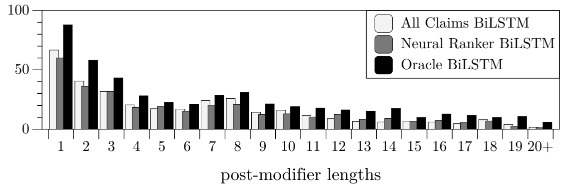
observe that our quantitative evaluation metrics can be too strict. Take for example the second instance in Table 8. Here the content of the target and generated post-modifiers is almost exactly the same, however our metrics would give very low scores due to low overlap.



(a) F_1 scores



(b) BLEU scores

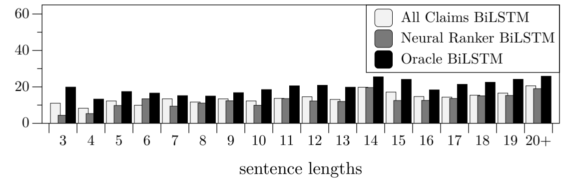
(a) F_1 scores



(b) BLEU scores

Figure 6: Performances by input sentence lengths of BiLSTM model. Sentences with 20 or more tokens are put into one group, 20+.

Human Evaluation We additionally evaluate the generated post-modifiers by performing a human evaluation using Amazon Mechanical Turk. We randomly select 500 instances from test set and show crowdworkers the sentence context, along with the true post-modifier and a generated one. For each instance, workers are asked to select the better phrase, or indicate that the two phrases are of equal quality. For the Oracle BiLSTM model, the true post-modifiers are preferred 46% of the time, while generated post-modifiers are preferred 43.2% of the time. For the Neural Ranker ($n = 10$) BiLSTM model, true post-modifiers are favored much more (57.60%) than the generated ones (20%). Consistent with our quantitative results, we see that claim selection is a crucial factor in this task. We also observe a few trends in the results. People tend to prefer generated post-modifiers over the ones written by professional journalists when they are shorter and to use more general terms without elaborating too much about the entity. In contrast, longer and more detailed human written post-modifiers are preferred when they are especially relevant to the rest of the sentence.

5 Related Work

There is a large body of previous work on claim selection (Kukich, 1983; Duboue and McKeown, 2003; Reiter and Dale, 1997; Tanaka-Ishii et al., 1998; Barzilay and Lapata, 2005) and language generation from structured data (Reiter et al., 2005; Goldberg et al., 1994). Initially, hand-crafted grammars were employed for language generation, which later evolved to statistical machine translation style models (Wong and Mooney, 2007) or PCFG based models (Belz, 2008). More recently, the focus has shifted to learning both fact selection and language generation jointly (Liang et al., 2009; Angeli et al., 2010; Kim and Mooney, 2010; Lu and Ng, 2011; Konstas and Lapata, 2013).

Input	Sky News reported Thursday night that Kenneth Clarke , _______, had not yet decided whether to support Mr. Howard 's candidacy , raising the possibility the party could face a divisive battle for leadership .
Claims	+ (position held: *Chancellor of the Exchequer*) (position held: *Secretary of State for the Home Department*)
Target	a former chancellor of the exchequer
All Claims	the Home Secretary
Oracle	the Chancellor of the Exchequer
Input	" A lot of people think it 's something we just started , but we actually opened the season with our first drive using it against Indianapolis , " said Howard Ballard , _______.
Claims	+ (member of sports team: *Buffalo Bills*) + (position played on team / speciality: *offensive tackle*) (mass: *325 pound*) (height: *78 inch*)
Target	Buffalo 's robust , 6-foot-6-inch , 325-pound right tackle
All Claims & Oracle	the Bills ' offensive tackle

Table 8: **Challenging `PoMo` instances**. Two examples along with outputs of the best All Claims and Oracle models are displayed. Claims deemed relevant during dataset curation are prefaced with a +. In the first example, knowing the relevant claims helps the Oracle model produce an output that closely matches the Target, however lack of temporal information causes the model to miss the word *former*. In the second example, the All Claims and Oracle models produce the same post-modifier. Although it is similar to the Target in meaning, it receives a low score using our evaluation metrics. Futhermore, our data curation method fails to identify relevant claims.

Modern approaches employ neural networks to solve this problem end-to-end. Mei et al. (2016) utilize an encoder-decoder framework to map weather conditions to a weather forecast. Ahn et al. (2016) and Yang et al. (2017) introduce a new class of language models which are capable of entity coreference and copying facts from an external knowledge base. Building upon these models, Wiseman et al. (2017) introduce an auxiliary reconstruction loss which use the hidden states of the decoder to recover the facts used to generate the text. Liu et al. (2018) introduce a hierarchical attention model for fact selection, with the higher level focusing on which records in the table to select and the lower level focusing on which cells in a particular row to pay attention to.

In order to train complex neural models, the quest for larger datasets has become paramount. Lebret et al. (2016) introduce the WikiBio dataset containing Wikipedia articles of famous people and the corresponding infobox tables. One drawback of this dataset is that it is easily solved using template-based models. To address this issue, Wiseman et al. (2017) introduce the ROTOWire dataset, which contains summaries of basketball games that are very long and syntactically diverse. A comprehensive list of datasets is provided in Appendix B.

6 Conclusions and Future Work

Inspired by recent work on collaborative writing and data-to-text generation, we introduce post-modifier generation, a task that bridges the gap between these two fields. The task is to generate a factual description of an entity which fits within the context of a human written sentence. In order to promote research on this task we present `PoMo`, a large dataset of automatically extracted post-modifiers from news articles, aligned to the Wikidata knowledge graph. We study the performance of numerous strong baseline models on this dataset, with a particular focus on the specific sub-task of claim selection. Our results demonstrate that when relevant claims are known, sequence-to-sequence models are capable of generating post-modifiers which humans deem comparable in quality to ones written by professional journalists. However, according to both quantitative metrics and human judgment, performance is much lower when models must determine for themselves which claims are relevant. These experiments suggest plausible pathways to achieving human-level performance on this task that are both challenging and interesting problems for future research.

Acknowledgments

We would like to thank the Toyota Technological Institute at Chicago for hosting the Workshop on Collaborative and Knowledge-Backed Language Generation which initiated the efforts for this project. The authors would also like to thank David Yarowsky, Jason Eisner, Kevin Duh, Kyle Gorman, and Philipp Koehn for feedback on early ideas for post-modifier generation.

A Additional Claim Selection Materials

Table 9 lists the evaluation results of most-common claim baseline for n, the number of claims to predict, from 1 to 5. We obtain highest F1 with $n = 4$.

n	Precision	Recall	F1
1	57.7	31.8	41.0
2	49.6	38.3	43.2
3	43.4	45.2	44.3
4	39.9	51.6	45.0
5	36.0	56.8	44.0

Table 9: Evaluation metrics for most-common claim baseline for different values of n.

Neural baseline shows improved performance compared to most-common claim baseline, showing its best performance when $n = 2$.

n	Precision	Recall	F1
1	75.2	42.4	54.3
2	66.5	62.7	64.5
3	56.0	69.6	62.1
4	48.7	76.2	59.4

Table 10: Evaluation metrics for neural baseline for different values of n.

B Existing Data-to-Text Datasets

Table 11 provides a comprehensive list of data-to-text datasets. `PoMo` presents a different set of challenges from these datasets. While the target text is shorter and less diverse, the task adds an additional challenge of figuring out which claims to use, a task which our evaluation shows is quite challenging.

Dataset	**Size**	**Domain of structured data to language**
WEATHER.GOV	29.5k	Weather conditions to forecast report
ALLRECIPES	31k	Table of ingredients to recipes
ROBOCUP	1.5k	Game statistics to summaries
ROTOWIRE	4.9k	Basketball statistics to game summaries
WIKIBIO	728k	Infobox to Wikipedia biography articles

Abstract

Lexically-constrained sequence decoding allows for explicit positive or negative phrase-based constraints to be placed on target output strings in generation tasks such as machine translation or monolingual text rewriting. We describe vectorized dynamic beam allocation, which extends work in lexically-constrained decoding to work with batching, leading to a five-fold improvement in throughput when working with positive constraints. Faster decoding enables faster exploration of constraint strategies: we illustrate this via data augmentation experiments with a monolingual rewriter applied to the tasks of natural language inference, question answering and machine translation, showing improvements in all three.

1 Introduction

For many natural language generation tasks, we often know word(s) that should (or should not) be in the output sentence. Examples include terminology databases in Machine Translation (MT) (Hokamp and Liu, 2017), names (and generic responses) in dialogue generation (Li et al., 2016; Gu et al., 2016), objects in image captioning (Anderson et al., 2017), and facts in abstractive summarization (See et al., 2017). One approach to enforce hard lexical constraints in the output is to modify the inference procedure to enforce their presence directly (Hokamp and Liu, 2017). These constraints could be either *positive* (a word must appear in the output) or *negative* (a word must be avoided). While negative constraints could be easily enforced by preventing hypotheses with prohibited tokens from entering the beam, placing positive constraints in natural and meaningful ways is less straightforward. We improve upon previous work by vectorizing the dynamic beam allocation (DBA) algorithm from Post and Vilar (2018) and by incorporating *multi-state* tries, which track a subset of nodes at each decoding timestep. These improvements lead to a five-fold speedup in decoding with positive constraints and in some cases better constraint placements (with respect to BLEU).

Post and Vilar (2018) motivated the utility of lexically-constrained decoding in MT for scenarios such as interactive translation and domain adaptation. Translation applications handling large amounts of data will clearly benefit from improvements in speed: the same is true for large-scale data augmentation via rewriting. In this case, a practitioner will ideally explore various task-specific rewriting strategies that may lead to improvements as observed during development, and then incorporate the best strategy into a test-final model. Recently, sentential paraphrasing gained the ability to enforce lexical constraints (Hu et al., 2019), but constrained decoding was still too inefficient to be practical (Hokamp and Liu, 2017) at a large scale. Even with the approach described by Post and Vilar, exploring the space of possible rewriting strategies on a task-specific basis may be overly time consuming: our performance improvements to their algorithm lowers the barrier of entry, where one may more practically experiment with various strategies during development. To illustrate our point, we build an improved monolingual sentential rewriter that can be conditioned on arbitrary positive and negative lexical constraints and use this to augment data for three external NLP tasks with different strategies: Natural Language Inference (NLI), Question Answering (QA) and MT.

Our main contributions are:

- A more efficient and robust approach to lexically-constrained decoding with vectorized DBA and trie representations;
- A trained and freely available lexically-

Proceedings of NAACL-HLT 2019, pages 839–850
Minneapolis, Minnesota, June 2 - June 7, 2019.

constrained monolingual rewriter[1] with improvements in both human-judged semantic similarity and fluency over the initial PARABANK rewriter (Hu et al., 2019);

- Monolingual rewriting constraint heuristics for automatic data augmentation leading to improvements on NLI / QA / MT.

2 Background

Constrained decoding Prior work explored methods to apply lexical constraints to a Neural Machine Translation (NMT) decoder (Hokamp and Liu, 2017; Anderson et al., 2017). However, most of these methods are slow and impractical as they change beam sizes at different time steps, which breaks the optimized computation graph. Post and Vilar (2018) proposed a means of dynamically allocating the slots in a fixed-size beam to ensure that even progress was made in meeting an arbitrary number of constraints provided with the input sentence. However, despite it being their motivation, their approach did not scale to batching, instead they sequentially processed constraints for sentences within the batch.

Paraphrases and Rewriting Many works sought to create paraphrases or paraphrastic expressions through existing corpora. For example, DIRT (Lin and Pantel, 2001) extracts paraphrastic expressions from paths in dependency trees. Weisman et al. (2012) explored learning inference relations between verbs in broader scopes (document or corpus level). PPDB (Ganitkevitch et al., 2013) constructs paraphrase pairs by linking words or phrases that share the same translation in another language. PARANMT (Wieting and Gimpel, 2018) and PARABANK (Hu et al., 2019) used back-translation to build a large paraphrase collection from bilingual corpora.

For arbitrary sentence rewriting, Napoles et al. (2016) used statistical machine translation in tandem with PPDB as a black box monolingual sentential rewriter. Mallinson et al. (2017) used a series of NMT model pairs to perform back-translations for monolingual paraphrasing. A similar approach was adopted by PARANMT to create a large paraphrase collection, which is used to train a monolingual sentence rewriter for canonicalization. PARABANK (Hu et al., 2019) extends PARANMT's approach and produced a NMT-based rewriter with the ability to apply lexical constraints to produce multiple paraphrases.

However, Hu et al. (2019) did not: evaluate the rewriter's performance on in-the-wild sentences; explore more sophisticated versions of the rewriter; nor demonstrate its utility on NLP tasks.

Data augmentation Data augmentation has been used to improve performance and robustness in deep neural models. In NMT, the most common approach is back-translation, where monolingual text in the target language is translated to create synthetic source sentences (Sennrich et al., 2016). Variants of back-translation target specific words with high prediction loss (Fadaee and Monz, 2018), employed sampling to increase diversity (Edunov et al., 2018), replace rare words (Fadaee et al., 2017), or replace at random (Wang et al., 2018).

Automatic data generation has also been successfully used for community question answering (Chen and Bunescu, 2017), semantic parsing (Jia and Liang, 2016), and task-oriented dialogue (Hou et al., 2018) by generating new data from the training dataset. In contrast, our model is trained on a much larger external corpus and is fixed, independent of the task. Kobayashi (2018) utilized a pretrained language model for automated data augmentation, though they only consider word-level rewrites and encourage label-preservation, while we paraphrase whole sentences with lexical constraints, independent of a gold label.

Most similar to our experiments, Iyyer et al. (2018) explored *syntactic* paraphrasing for augmentation in sentiment and NLI tasks, extending prior work on PARANMT.

3 Improved Constrained Decoding

Lexically-constrained decoding is a modification to beam search that yields decoder outputs honoring user-supplied constraints. These constraints can be provided in the form of: *positive constraints*, which specify that certain tokens or token sequences must be present in the output; or *negative constraints*, which specify token or token sequences that must *not* be generated. Take positive constraints for example, in translating the sentence *Das stimmt einfach nicht* to English, the user can specify the constraint "not the case" to (presumably) get the output *That's just not the case* instead of model-preferred output *That's just not*

---

[1] `http://nlp.jhu.edu/parabank`

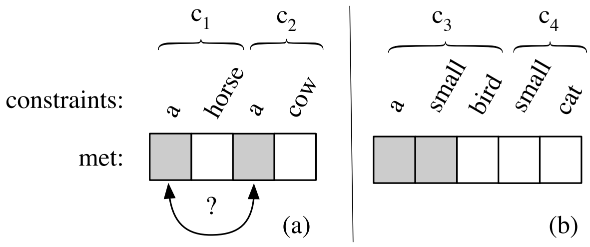

Figure 1: Two corner cases that arise when using an array implementation to track constraints. The gray boxes denote constraints that have been generated by the currently-tracked hypothesis. In (a), the decoder has to guess which constraint it is generating since they share a prefix. In (b), the decoder may start tracking constraint c_3 only to generate c_4 without realizing it.

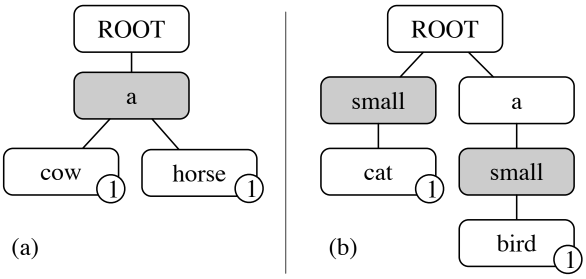

Figure 2: The trie representation solves both problems depicted in Figure 1. The constraint tracker no longer has to predict the constraint to track (a), and it can track multiple constraints by using multiple states (b). Counters are added to end nodes to denote how many times each constraint must be generated.

true. While there is no guarantee that the decoder will use the constraints in a sensible way, constraints are often well-placed empirically.

The implementation of positively constrained decoding comprises two key pieces: tracking which of the supplied constraints each hypothesis has already generated, and ensuring progress through the constraints by dynamically allocating the beam to hypotheses that have generated different numbers of them. We describe an improvement to each of these over Post and Vilar (2018), which includes: (1) a vectorized approach to beam allocation that works with batch decoding; and (2) the use of tries for recording constraint state, and thereby offsetting certain corner cases.

These contributions allow the decoder to find much better placement of constraints (as evidenced by an almost 2 point BLEU score increase) and to increase throughput for batch decoding.

Here, we assume the reader is familiar with beam decoding for NMT, the details of which are provided by Post and Vilar (2018).

3.1 Tracking constraints with tries

The implementation by Post and Vilar used a flat one-dimension array listing the word indexes of all positive constraints (duplicates allowed). A parallel array was used to mark which words in this list were non-final words in a sequence, so that progress could be tracked through sequences of tokens. Progress through the constraints was tracked by maintaining, for each slot in the beam, a third array, which marked which of the constraints had already been generated by that hypothesis.

However, this leads to corner cases when two constraints c_1 and c_2 share a subsequence. The first case occurs when two constraints have an identical prefix. Consider the constraints in Fig. 1(a) when translating the French sentence *une vache et un cheval*. The array-based implementation has to choose which constraint to generate when it has only generated the first word of the English translation, *a cow and a horse*. Suppose it chooses constraint c_1, *a horse*. If the subsequent step generates *cow* instead, the constraint tracking for the phrase *a horse* will be marked as incomplete and reset, and the decoder will not realize that it has satisfied a different constraint.

A second corner case arises when a constraint c_4 is a non-prefix substring of a constraint c_3. In this situation, the decoder may begin generating the longer constraint, only to generate the shorter one, without realizing it. For example, consider a target sentence that should be *a small cat saw a small bird*, with constraints *a small bird* and *small cat* (Figure 1b). When generating the first word, *a*, the decoder begins tracking c_3. It continues by adding to this hypothesis the second word, *small*. However, suppose it then extends this hypothesis with *cat*. It will abort tracking of c_3, and not realize that it completed c_4.

A more natural representation that addresses these corner cases is to organize constraints that haven't yet been generated into a trie. Nodes in the trie that represent the ends of constraints are augmented with a counter that indicates how many times that constraint must be generated.[2] Each time a constraint is completed, the number is decremented, and nodes of the trie can be trimmed when they lead only to paths ending in zero counts.

---

[2] Because one constraint can be a subsequence of another, some interior nodes will also have these counts.

sentno	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
unmet	0	0	1	1	1	1	2	2	2	3	4	4	5	5	5

Figure 3: The hypothesis matrix during vectorized dynamic beam allocation (VDBA). Each column denotes a candidate hypothesis, each of which contains sufficient information to identify it. Hypotheses are sorted by sentence number, number of unmet constraints, and sequence scores. The "unmet" row indicates how many constraints each hypothesis has not yet generated. After sorting by sentence ID and "unmet", we assign monotonically increasing numbers across columns that share (sentno, unmet) values (the "step" row). We can now sort by the "step" row to ensure that the beam for a sentence contains hypotheses having met each number of constraints. We populate the next beam by taking the first k hypotheses (in gray) after sorting the matrix by **step**. Here, $k = 7$.

Finally, in order to address the second corner case, we track multiple states in each constraint trie.

In summary, we represent all the constraints as a compact trie. Each hypothesis in the decoder beam has its version of the trie. The set of active states in each hypothesis' trie tracks all suffixes of the target words that match against the constraint trie. When a constraint is generated, its counter is decremented and zero paths are pruned.

3.2 Negative constraints

Negative constraints are used to denote words and phrases that the decoder must not generate. Blocking single-word negative constraints can be done by setting their costs to infinity before doing top-k selection, at each time step. These negative constraints are also represented in a trie, although it is slightly different, because it does not have a counter and never needs to be pruned. Instead, it records at each node the list of word IDs that end phrases for which the current word is the penultimate. We similarly track all suffixes of the current hypothesis' target word string that match the negative constraint trie. At each time-step, we block the generation of active phrases by setting to infinity all word IDs marked in the current node (if any). This includes the root node, which handles single-word constraints. Each state is then extended by following outgoing arcs, if present, or else resetting them to the root state.

3.3 Vectorized Dynamic Beam Allocation

Post and Vilar (2018) describe an algorithm that divides the beam among hypotheses that have generated different numbers of positive constraints. For a beam of size k and with C positive constraint tokens, the algorithm produces a set of candidate extensions of the k hypotheses from the beam. They assemble these extensions from three sources: (a) the top-k best-scoring tokens across all hypotheses in the beam (without respect to constraints); (b) the set of tokens that advance the constraint trie for each hypothesis; and (c) the best-scoring extension of each hypothesis.[3] After constructing this candidate list, they whittle it down to a list of size k and use it to construct the beam at the next time step. This way, the algorithm ensures that portions of the beam are devoted to candidates having met different number of constraints, and thereby that progress is made towards meeting all the constraints as decoding proceeds.

However, their implementation used a procedural approach which is incompatible with batching; that is, constraints for input segments within a batch are processed sequentially, so increasing the batch size does not produce any speed gains. We replace the procedural approach with a vectorized one, which uses GPU operations to quickly assemble the list of candidates and allocate them to the beam such that we do benefit from batching.

A sketch of our algorithm follows. We assemble candidates from the same three sources described above. Sets (a) and (c) already use fast GPU operations. These operations can be done efficiently even batch-wise. Set (b) is less amenable to vectorization, but can be assembled by querying each hypothesis for its unmet constraints. We now use a sorting-based algorithm to parallelize the divvying

---

[3] The difference between (a) and (c) is that the items constituting (a) typically come from different extensions of the top hypotheses, whereas (c) ensures that one extension of each hypothesis is in the candidates list.

Constraints	Speed (sent/sec)				BLEU	
	batch size 1		batch size 20			
	Baseline	+MST,VDBA	Baseline	+MST,VDBA	Baseline	+MST,VDBA
none	4.78	4.84	**17.92**	17.51	40.9	40.9
phr4	0.75	0.89	0.93	**4.71**	47.8	**49.2**
rand3	0.78	0.80	0.87	**4.59**	43.0	**43.2**

Table 1: Comparison between the baseline implementation (SOCKEYE 1.18.57, commit 59180f3) and our approach with multi-state tries (MST) and vectorized Dynamic Beam Allocation (VDBA) in placing different constraints randomly extracted from the reference. All runs use a beam size of 10. The pruning threshold was set to 0 for no constraints ("none") and 30 for "phr4" and "rand3". Decoding speed is measured on an NVIDIA GTX 1080 Ti in sentences per second (the higher the better). Output quality is measured using SacreBLEU (the higher the better).

up of the beam to hypotheses having met different numbers of constraints.

We do this by assembling a matrix with all the candidates for all sentences in the batch (Fig. 3). This matrix contains a column for each candidate, including the sentence number, the number of unmet constraints for that hypothesis, its sequence score, the hypothesis it extends, and the next vocabulary ID. With this matrix, we can quickly select the k hypothesis extensions for the next timestep using a multi-key sort. The first key is the sentence number. Next, it is the number of unmet constraints in each hypothesis. We then make use of a "step" row, which assigns increasing indices *within* each group of hypotheses with the same number of unmet constraints. Sorting on this row as the third key establishes a round-robin assignment of the k-sized beam to items having met different numbers of constraints. In the end, we select the top k items (in the example, $k = 7$ and the selected columns are in gray).

3.4 Evaluation

We use SOCKEYE (Hieber et al., 2017)[4] for our evaluations. We trained a 6-layer German–English Transformer using the default settings on the WMT'18 training data and the `newstest2018` test set for evaluation (Bojar et al., 2018). Following Post and Vilar (2018), we compare decoding results in an unconstrained setting and with two sets of positive constraints: "rand3", which selects 3 random words from the reference, and "phr4", which selects a single 4-word phrase. We report decoding speed (in sentences per second) and BLEU score (Papineni et al., 2002), as measured by SacreBLEU (Post, 2018). The results are shown in Table 1.

Our approach is faster than existing approaches when decoding with positive constraints and produces the same or higher BLEU scores, which we take as a sign of more fluent and natural hypotheses under constraints. Without batching, there is no speedup, but at a batch size of 20, we see roughly a 5× speedup.

4 Improved Monolingual Rewriter

Inspired by the approach described in PARABANK (Hu et al., 2019), we trained a more powerful English monolingual rewriter by using a multi-head self-attention NMT model, Transformer (Vaswani et al., 2017). We used a 6-layer encoder and decoder with a model size of 512 and 8 attention heads. The encoder and decoder embeddings share the same weight. Unlike PARABANK, which trained a rewriter on a subset of 50M paraphrase pairs out of its collection, we trained on *all* of the paraphrastic pairs in PARABANK originated from CzEng[5] that: (1) have a regression score over 0.50; (2) only consist of ASCII characters after punctuation normalization; and (3) have a reference/paraphrase token Jaccard index between 0.25 and 0.65.

We retain 141,381,887 paraphrastic pairs, out of over 220 million, as training data after applying these filters. To ensure output quality, we only use back-translated paraphrases as source.

PARABANK is a real-cased resource. We mark all words that have first-character capitalization and convert them to lowercase. The marking is

---

[4] `https://github.com/awslabs/sockeye/`

[5] PARABANK generated paraphrases from two large bilingual corpora, CzEng (Bojar et al., 2016a) and GigaFrEn (Callison-Burch et al., 2009). We picked paraphrases from only CzEng, the larger one of the two.

used as a source factor (Sennrich and Haddow, 2016) to the encoder. This helps us to decrease the vocabulary size of the the training data.

We learn a shared byte-pair encoding (BPE) over the entire training data with 30,000 BPE operations (Sennrich et al., 2016), keeping all vocabulary items with a frequency over 50 in the post-BPE data. We follow Sennrich and Haddow (2016) and use "BIOE" tagging to annotate BPE segmentation and broadcast the casing factor accordingly. The encoder uses both source factors.

The model is trained on 2 NVIDIA GTX 1080Ti's until convergence (5 days).

Rewriter Evaluation We randomly sampled 100 instances from both MNLI matched and mismatched development set. Each instance consists of 4 sentences: premise, entailed, contradicting, and neutral. We use the following 3 different rewriters to rewrite all 800 sentences: (1) an LSTM-based rewriter trained on PARABANK alpha; following (Hu et al., 2019); (2) a Transformer-based rewriter trained on PARABANK alpha; and (3) a Transformer-based rewriter trained on full PARABANK with the filters and improvements described here.

Inspired by the interface of EASL (Sakaguchi and Van Durme, 2018), we ask crowd-workers to give each paraphrase a score between 0 and 100 depending its semantically similarity to the original, reference sentence. Independently, we provide options for flagging ungrammatical or nonsensical sentences. Paraphrases are judged by up to 3 different workers, with 11 workers participating. We randomly include an attention check consisting of reference sentence itself.[6]

The result is shown in Table 2. Switching the rewriter architecture from LSTM to Transformer improves the human-judged semantic similarity by 5.1% and fluency by 6.5%. The improvements described here leads to a gain of 9.6% in semantic similarity and 10.2% in fluency overall.

This improved Transformer-based rewriter is subsequently used for data augmentation.

	Similarity	STD	Fluency
LSTM alpha	74.5	25.0	80.7%
Transf. alpha	78.3	22.9	87.2%
Transf. Full	**81.7**	**20.9**	**90.9%**

Table 2: Comparison between three monolingual rewriting systems. Systems will "alpha" are trained on PARABANK alpha, which the other one is trained on the full data. Similarity is the mean human-judged semantic similarity score; the higher the better. STD described the standard deviation of similarity. Fluency is the percentage of paraphrases judged to be both grammatical and meaningful.

5 Paraphrastic Data Augmentation

We demonstrate the utility of our improved lexically-constrained decoding via data augmentation with some simple rewriting heuristics and two augmentation strategies. First, the model could be trained on the augmented (training) data. Orthogonally, predictions can be made on the all of the augmented (evaluation) data, which can then be *aggregated*. We show experimental results on natural language inference (NLI, Section 5.1), question answering (QA, Section 5.2), and NMT (Section 5.3) tasks.

These results are merely indicative of the potential in data augmentation via constrained paraphrasing, and are by no means a thorough investigation of strategies that yield the best improvements. Such an investigation, however, could be enabled by our algorithmic improvements and practitioners' domain expertise.

5.1 Natural Language Inference

Natural language inference is the task of determining entailment. Two sentences, a *premise* p and a *hypothesis* h, are labelled with ENTAILMENT, CONTRADICTION, or NEUTRAL depending on whether p logically entails, contradicts, or does not interact with h. MultiNLI (MNLI) (Williams et al., 2018) is a large, multi-genre dataset for natural language inference. The dataset is also divided into *matched* and *mismatched* portions based on whether the source of the evaluation data matches the source of the training set. Recent models rely on contextual sentence encoders pretrained on vast amounts of English monolingual text (Peters et al., 2018; Devlin et al., 2018).

We train and evaluate a model on MNLI, and find that data augmentation leads to improvements exceeding and complementary to those by ELMo, possibly due to improved lexical diversity during training and at inference.

---

[6] Only workers who pass the test at least 90% of the time and contribute at least 9 judgments are included in the result.

Model We use the model described in Bowman et al. (2019)[7] with the default parameters. They train a sentence representation model (possibly on top of ELMo) on the MNLI training set and subsequently train a clean task-specific model for each task (for this model, MNLI again). The task-specific MNLI model roughly follows BiDAF (Seo et al., 2016), followed by an MLP.

We also train a model without the ELMo contextual layers to compare contextual sentence representations against data augmentation. Since there is minor variance between different random seeds,[8] we train each model twice and evaluate the best-performing model on the development set.

Paraphrase Generation We generate paraphrases for our data augmentation experiments by negatively constraining on the most content-bearing token of each input sequence, as determined by inverse document frequency (IDF). For a given input sequence s we calculate the IDF of each token $t_i \in \mathrm{s}$ as $\log \frac{|D|}{|d \in D : t_i \in d|}$ where D is the set of all English sentences in the train set. This relatively simple lexical constraint tends to force the decoder to rewrite the input sequence using different (but semantically related) words while maintaining fluency. In practice, we observed an average unigram precision of 67.6%; i.e., 32.4% of tokens in paraphrases were not contained in their corresponding inputs.

Additional results using a positively constrained rewriter in Appendix A.

Data Setup We first rewrite all premises P to P' and all hypotheses H to H', then for each $p_i \in P, h_i \in H$, we include all four examples, (p_i, h_i), (p_i, h'_i), (p'_i, h_i), and (p'_i, h'_i) into the training set, always preserving the original corresponding gold label. We include two copies of the original dataset in training to increase its weight. The original MNLI dataset contains 393K training pairs, and 20K in each dev and test, while the augmented dataset consists of 1.96M training pairs, and 79K in dev and test.

At test time, we rewrite the test sentence pairs. A trained model can also make predictions on each of three rewritten sentence pairs. Together with the original prediction, these four can then be aggregated by assigning weights to each prediction source. In our experiments, we perform this weighted aggregation (+Agg) for each model, tuning on the development set (Appendix B).

	Dev.	Test. (m/mm)
Baseline	74.8	74.7 (74.8/74.6)
+Agg.	75.0	74.9 (74.9/74.8)
+Train	75.4	75.2 (75.0/75.3)
+Train+Agg.	75.6	75.4 (75.1/75.7)
+ELMo	75.8	75.0 (75.1/75.0)
+Agg.	75.9	75.2 (75.3/75.1)
+Train	76.4	75.6 (75.6/75.6)
+Train+Agg.	**76.7**	**75.8 (75.9/75.7)**

Table 3: F1 scores on MNLI. +Train denotes training on augmented data; +Agg. denotes using a weighted aggregation. Scores on the development set are a weighted average between the matched (m) and mismatched (mm) portions of the dataset, while the test set scores are additionally broken down into each category.

Experimental Results We find in Table 3 that data augmentation helps during training and inference. Not only are the total gains from augmentation comparable to those from ELMo, they are apparent even in the presence of the contextual sentence encoder. This suggests that the gains from data augmentation through rewrites complement recent gains from contextual sentence encoders.

The fairest external comparison is with Bowman et al. (2019), as our model is identical. Their best models achieve 76.2 F1 on development and 75.4 F1 on test. On the development set, they see a gain of 0.6 points by using multi-task training and external datasets. On that set, we report a total gain of up to 0.9 points purely through data augmentation. With respect to absolute test set scores, our best model outperforms theirs by 0.4, showing that rewriter-based data augmentation can be a powerful method for NLP tasks.

Analysis NLI systems have been shown to be brittle when the input is perturbed (Alzantot et al., 2018). Even when the premise or hypothesis is changed in a way that preserves the entailment semantics, the NLI system may make an incorrect prediction where it was previously correct. We present evidence showing that data augmentation for NLI reduces the brittleness of our model.

To demonstrate the brittleness of the baseline models, we analyze how predictions change. The model trained on the *original un-augmented*

[8] Bowman et al. (2019) found the variance to be 0.2

	P', H	P, H'	P', H'	+Agg.
No change	88.51	84.23	81.95	96.20
$- \rightarrow +$	4.23	5.33	6.08	1.75
$+ \rightarrow -$	5.84	8.44	9.67	1.49
$-_1 \rightarrow -_2$	1.42	2.00	2.30	0.57
No change	88.20	83.26	80.68	96.00
$- \rightarrow +$	4.03	5.45	6.11	1.80
$+ \rightarrow -$	6.42	9.22	10.78	1.72
$-_1 \rightarrow -_2$	1.35	2.08	2.42	0.47

Table 4: Percentage of changed predictions on the MNLI development set using the baseline model without (top) and with (bottom) ELMo. $- \rightarrow +$ (correct after rewrite), $+ \rightarrow -$ (originally correct), and $-_1 \rightarrow -_2$ (different incorrect) are changes after rewriting. +Agg. denotes the predictions after weighted aggregation.

P: Visit at sundown or out of season to get the full flavor of the setting
H: The setting is better to visit at sundown or during low season
H': It is better to visit at sunset or during low season

Gold: Entailed
P, H: Predict Entailed
P, H': Predict Neutral

P: I had rejected it as absurd , nevertheless it persisted
H: It persisted even after I rejected it as an absurdity
H': It went on even after I turned it down as an absurdity

Gold: Entailed
P, H: Predict Entailed
P, H': Predict Contradiction

Figure 4: Cases where the baseline system changes its prediction on rewritten examples.

dataset is evaluated on the original development set and each of the rewritten development sets, and we investigate the differences. Table 4 shows how often original predictions are different from the corresponding predictions on the rewritten development sets; predictions can be (1) unchanged, (2) newly correct, (3) newly incorrect, or (4) changed but still incorrect, while Figure 4 shows how even relatively modest, semantically valid paraphrases can cause the NLI model change incorrectly.

Given a perfect rewriter that always generates semantically equivalent paraphrases and a perfect NLI model robust to perturbations, we would expect no change in predictions between the original development set and the rewritten ones. However, this is not what we observe; Table 4 shows that rewriting leads to a greater percentage of newly incorrect predictions than newly correct predictions.

We believe that the higher percentage of newly incorrect predictions on the rewritten development sets demonstrates the brittleness of the NLI system rather than semantic dissimilarity that may be introduced by the rewriter. We note that the aggregated predictions shows the opposite pattern: we see a higher percentage of newly *correct* predictions than incorrect ones. If the paraphrases were largely semantically dissimilar we would not expect any gain by combining predictions.

Given both the numerical boost seen by aggregation and the above examples, we hypothesize that the rewriter does not frequently change entailment semantics. Because the semantics remain similar, and because the paraphrases were generated with constraints designed to introduce lexical diversity, we believe that the label-preserving data augmentation improves the NLI model by making it more tolerant of minor lexical differences, better able to generalize, and less inclined to memorize.

5.2 Question Answering

We apply our paraphrastic rewriter to the task of question answer sentence selection to see if augmenting with paraphrases leads to improvements. The task is defined as follows: Given a question q and a set of candidate sentences $\{c_i\}$, select the candidates which answer q.

Model We adapt a popular neural architecture for NLI, InferSent (Conneau et al., 2017), to our QA sentence selection task. In InferSent, the questions and answers (originally the premises and hypotheses) are embedded using an uncontextualized word embedding (e.g. GloVe), which we also experiment with ELMo (Peters et al., 2018) to incorporate recent advancements in large-scale contextualized pre-training. Bidirectional LSTMs (Graves and Schmidhuber, 2005) are run atop of these contextualized embeddings and a max-pooling layer is used to generate a feature vector for both the question and the answer. Following various matching methods (Mou et al., 2016) and a multi-layer feed-forward neural network, the model produces a final score.

We train the system following the method proposed by Rao et al. (2016), utilizing a ranking loss (Weston and Watkins, 1999) that contrasts positive answers against negative ones.

Paraphrase Generation We augment each answer candidate sentence with exactly 1 paraphrase in the dataset using the following heuristics: (1) named entities shared between a specific answer and its corresponding question are retained as positive constraints; (2) correct answer spans are retained as positive constraints; (3) words with the top-k IDFs (inverse document frequencies; hence "important" words) that are not positive constraints are selected as negative constraints to promote the lexical diversity of the paraphrases.[9]

Data Setup We augment the raw TREC-QA dataset (Wang et al., 2007) under the following orthogonal strategies: (1) augmenting the training set with the paraphrases generated via the approach described above; (2) augmenting the answer candidates at evaluation time, and choosing the max score among the paraphrases as the score (aggregation by *voting*).

Experimental Results We evaluate our models using average precision (MAP) and mean reciprocal rank (MRR). Model selection is done with early stopping to choose the epoch with the maximum MAP score. Note that the "Baseline (+ELMo)" settings below falls back to the standard QA selection task, and our score under ELMo is comparable to earlier state-of-the-art results, e.g. by Rao et al. (2016).

	MAP	MRR
Baseline	71.42	75.16
+Voting	72.94	77.17
+Train	71.57	74.63
+Train +Voting	73.96	80.77
+ELMo	77.49	81.86
+Voting	**80.61**	**85.65**
+Train	75.58	80.30
+Train +Voting	77.86	84.34

Table 5: Experimental results on QA selection.

It is shown that augmenting at evaluation time (aggregation by voting) result in stable improvement (around +2~3% MAP and +2~6% MRR for both scenarios that either augments the training data or not)—this shows that increasing the paraphrastic diversity of the answer candidates could potentially make the system more robust. However augmenting the training set does not yield such improvements—we speculate that this may introduce some noise to the training data.

5.3 Machine Translation

We apply our paraphrastic rewriter to the WMT 2016 Turkish-English translation task (Bojar et al., 2016b). We see no improvement in English to Turkish translation, but see a 1.1 BLEU improvement when training an initial NMT system on half paraphrased and half original data, and continued training on the original data. Full details of the experiments are in Appendix C. This was the highest concentration of standard data we experimented with, and future work will explore additional ways of data augmentation using paraphrases.

6 Conclusion

Lexically-constrained sequence decoding provides control over whether certain tokens or token sequences appear in the output. Motivated by applications such as large-scale MT, we improved the speed for constrained decoding significantly by proposing a vectorized dynamic beam allocation algorithm. We also added multi-state trie representations for robustness to corner cases.

Also reliant on the efficiency of constrained decoding is data augmentation via rewriting, where one might need to explore a variety of strategies with task-specific constraints on development data. We trained an improved monolingual sentential rewriter and used it to rewrite data for NLP tasks. We experimented with augmenting training data, aggregating predictions on rewritten test data, and both. Using a few simple constraint heuristics, we showed improvements additive to ELMo in NLI and QA, and in MT. The rewriter, along with the augmented data files, can be found at `http://nlp.jhu.edu/parabank`. We hope this will enable future exploration of augmentation strategies for a variety of NLP tasks.

Acknowledgments

Thanks to Michael Denkowski, who first suggested using a trie to represent constraints in a group discussion. This research was supported in part by DARPA AIDA and DARPA LORELEI.

---

[9] Stopwords and tokens with non-letter characters (e.g. *with*, *42*, *n't*) are excluded. $k \in \{2, 3, 4\}$ is a hyperparameter we tune – we found out that generally $k = 2$ works the best.

Abstract

In this paper, we propose an effective deep learning framework for inducing courteous behavior in customer care responses. The interaction between a customer and the customer care representative contributes substantially to the overall customer experience. Thus, it is imperative for customer care agents and chatbots engaging with humans to be personal, cordial and emphatic to ensure customer satisfaction and retention. Our system aims at automatically transforming neutral customer care responses into courteous replies. Along with stylistic transfer (of courtesy), our system ensures that responses are coherent with the conversation history, and generates courteous expressions consistent with the emotional state of the customer. Our technique is based on a reinforced pointer-generator model for the sequence to sequence task. The model is also conditioned on a hierarchically encoded and emotionally aware conversational context. We use real interactions on Twitter between customer care professionals and aggrieved customers to create a large conversational dataset having both forms of agent responses: generic and courteous. We perform quantitative and qualitative analyses on established and task-specific metrics, both automatic and human evaluation based. Our evaluation shows that the proposed models can generate emotionally-appropriate courteous expressions while preserving the content. Experimental results also prove that our proposed approach performs better than the baseline models.

1 Introduction

With the advancement of artificial intelligence (AI) and natural language processing (NLP), automatic systems have made immense impact on human lives by assisting them in their everyday works. Human-computer interaction is pervasive in many applications such as chatbots, personal assistants and many more. Natural language generation (NLG) component of such systems is an important aspect of every human computer interaction. Thus research in recent years have been on modulating biases, styles and control in text generation to enhance these interactions.

Customer care is an essential tool used by companies to provide guidance, assistance and in building stable customer relations. The ease of access, ease in following-up and immediacy of social media has made it a strong platform for companies and applications to interact with their customers. In this platform, we see the usage of courteous and emphatic language, which is the center of our current study. For the growth of any company or application it is necessary for the customer care agents to be cordial and amicable to the customer. Thus along with handling queries, it is important for agents to provide customer satisfaction by greeting, empathizing, appreciating feedback, apologizing at the right time, and thus build a strong relation with the customer. In Table 1, we showcase different situations in which an agent can behave courteously, thereby providing a good customer experience.

In this work, we focus on proposing an effective deep learning framework to enhance the existing NLG systems by converting their replies to courteous ones, by staying conversationally grounded, and emotionally aware of the user. For any Natural Language Generation (NLG) module (generic or task oriented), courteous response can play an important role in keeping the user engaged with the system. Also, it will make the system more human-like while generating responses. Inducing courteous behavior in responses can be fused with any existing NLG system to give them humanly essence and simultaneously make users

more comfortable in using these systems leading to an increase in user association with the brand or product. This would eventually lead to customer satisfaction with an increase in customer retention. Moreover, such language conditioning shall ensure that responses are more human-like. Thus, the major motivation behind this task is to create systems that are able to converse with humans efficiently and generate replies in accordance with the emotions of the customer. Courteousness is a virtue of humans and to be able to make a machine behave courteously is a challenging task.

Unlike a generic NLG system that focuses in generating responses, our system adds courteous nature and emotional sense to the replies, thereby, making the responses interesting and engaging to the users. Such systems have high applications in many areas/companies that employ chatbots to deal with the customers. We thus propose a novel research direction of inducing courteous behavior in the natural language responses for the customer care domain whilst being contextually consistent. The key contributions of our work are summarized as follows:

(i) Creation of a high quality and a large conversational dataset, Courteously Yours Customer Care Dataset (CYCCD) prepared from the actual conversations on Twitter. We provide both forms of agent responses: generic and courteous.

(ii) Proposal of a strong benchmark model based on a context and emotionally aware reinforced pointer-generator approach which demonstrates very strong performance (both on quantitative and qualitative analyses) on established and task-specific metrics, both automatic and human evaluation based.

The rest of the paper is structured as follows: In section 2, we discuss the related works. In Section 3 we explain the proposed methodology followed by the dataset description in section 4. Experimental details, evaluation metrics and results are presented in section 5 and 6 respectively. In section 7, we present the concluding remarks followed by future directions.

2 Related Work

Natural language generation (NLG) module has been gaining importance in wide applications such as dialogue systems (Vinyals and Le, 2015; Shen et al., 2018; Wu et al., 2018; Serban et al., 2017a; Raghu et al., 2018; Zhang et al., 2018; Li et al., 2016), question answering systems (Reddy et al., 2017; Duan et al., 2017), and many other natural language interfaces. To help the users achieve their desired goals, response generation provides the medium through which a conversational agent is able to communicate with its user. In (Serban et al., 2017b), the authors have proposed an hierarchical encoder-decoder model for capturing the dependencies in the utterances of a dialogue. Conditional auto-encoders have been employed in (Zhao et al., 2017), that generates diverse replies by capturing discourse-level information in the encoder. Our work differentiates from these previous works in dialogue generation in a way that we embellish the appropriate response content with courteous phrases and sentences, according to the conversation. Hence, our system is an accompaniment to any standalone natural language generation system to enhance its acceptability, usefulness and user-friendliness.

Emotion classification and analysis (Herzig et al., 2016) in customer support dialogue is important for better understanding of the customer and to provide better customer support. Lately, a number of works have been done on controlled text generation (Hu et al., 2017; Li et al., 2017; Subramanian et al., 2017; Fedus et al., 2018; Peng et al., 2018) in order to generate responses with desired attributes. Emotion aware text generation (Zhou and Wang, 2018; Zhou et al., 2018; Huang et al., 2018) have gained popularity as it generates responses depending on a specific emotion. Previous works in conditioned text generation have worked on inducing specific biases and behaviors (Herzig et al., 2017) while generation (like emotion, style, and personality trait). Our work is different in the sense that it can encompass different emotional states (like joy, excitement, sadness, disappointment) and traits (like friendliness, apologetic, thankfulness, empathy), as is the demand of the situation.

Style transfer has been an emerging field in natural language processing (NLP). A couple of works have been done in changing the style of an input text and designing the output text according to some particular styles. In (Rao and Tetreault, 2018), a dataset has been introduced for formality style transfer. Unsupervised text style transfer has encouraged in transforming a given text without parallel data (Shen et al., 2017; Carlson et al., 2017; Fu et al., 2018; Li et al., 2018; Niu and Bansal, 2018). Overall our system is novel as it is motivated by the need for inducing specific behavior and style in an existing NLG systems (neural, or template-based) as a means of post editing, by simultaneously being emotionally and contextually consistent. We have successfully demonstrated this behavior through empirical analysis for a specific application of customer care.

3 Methodology

Given the Conversation History (previous few exchanges in the dialog), and the Generic Response, the task is to generate the Courteous Response. The architectural diagram of our proposed model is in Figure 1.

3.1 Conversational History Representation

The conversation history C is a sequence of utterances $(u_1, u_2, \ldots, u_D)$ and each utterance u_d is a sequence of words $w_1, w_2, \ldots, w_N$ which are represented by their embeddings. For encoding the emotional states associated with these utterances, we use the output distribution from DeepMoji (Felbo et al., 2017) which is pre-trained on the emoji prediction task.

Let the utterance u_d be a sequence of sentences $s_1, s_2, \ldots, s_N$, where the n^{th} sentence has an emotional embedding $e_{n,d}$. Then the emotional representation of the utterance is:

$$e_d[i] = \max_n e_{n,d}[i] \tag{1}$$

The first bi-directional layer over any utterance u_d yields the hidden states $h^1_{1d}, h^1_{2d}, \ldots, h^1_{Nd}$, where N is the word length of the utterance. The final representation of any utterance r_d is given by the concatenation of the emotional representation as well as the last hidden state of the Bi-directional Long Short Term Memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) encoder.

$$r_d = [e_d \cdot h^1_{Nd}] \tag{2}$$

The second hierarchical layer Bi-LSTM encodes the utterance representations $r_1, r_2, \ldots, r_D$ as hidden states $h^2_1, h^2_2, \ldots, h^2_D$. The last hidden state h^2_D is the representative of the conversational history, and is renamed as the conversational context vector c.

3.2 Encoder states

Another single layer unidirectional LSTM network encodes the generic response word embedding sequence to obtain the encoder hidden states h_i.

3.3 Decoder states and Attention calculation

At the decoder time step t, the decoder LSTM state s_t is used to calculate the attention distribution over the encoder states α^t:

$$e^t_i = v^T \tanh(W_h h_i + W_s s_t + b_{\text{attn}}) \tag{3}$$
$$\alpha^t = \text{softmax}(e^t) \tag{4}$$

where v, W_h, W_s and b_{attn} are trainable parameters.

This attention distribution helps to identify the relevant encoder states necessary for the current decoding step. The representation of the encoder for this time step is an attention weighted sum of its states, called the context vector:

$$h^*_t = \sum\nolimits_i \alpha^t_i h_i \tag{5}$$

The LSTM state s_t is updated using s_{t-1}, the previous time step's context vector h^*_{t-1}, word embedding of the previously generated word $w_{emb}(y_{t-1})$, and the conversation context vector c.

$$s_t = LSTM(s_{t-1}, W_p[w_{emb}(y_{t-1}), h^*_{t-1}, c] + \tilde{b}) \tag{6}$$

where, W_p and $\tilde{b}$ are the trainable parameters.

3.4 Output distribution calculation

To aid the copying of words from the generic response while generating the courteous response, we use the mechanism similar to (See et al., 2017). For the pointer generator network, the model computes two distributions, one over the

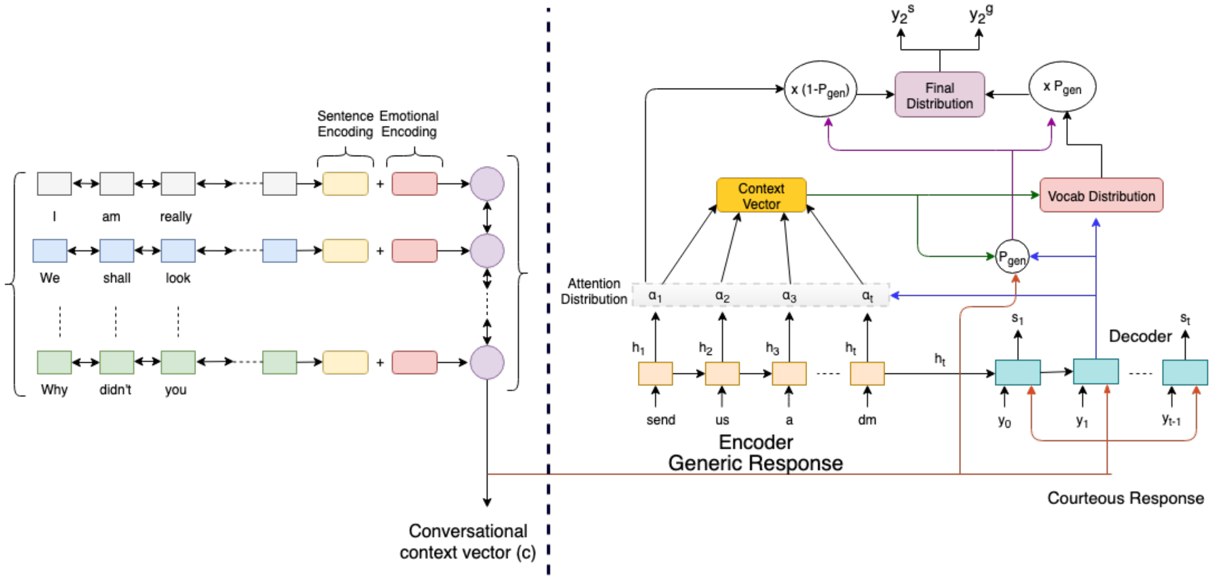

Figure 1: Architectural Diagram of the Proposed Model. Inputs to the model: Conversation History (left), Generic Response (centre) Output: Courteous Response (right). The Conversation History is encoded by hierarchical BiLSTM to a Conversational Context vector c. The encoder encodes the Generic Response into hidden states h_i. Response tokens are decoded one at a time. Attention α_i, and vocabulary distributions (p_{vocab}) are computed, and combined using p_{gen} to produce output distribution. Sampling it yields y_i^s and taking its argmax yields y_i^g.

encoder words (α^t) and one over the vocabulary (p_{vocab}).

$$p_{vocab} = \text{softmax}(W'(W[s_t, h_t^*] + b) + b') \quad (7)$$

where W, W', b and b' are the trainable parameters.

The trade-off between the two distributions is computed dynamically in the form of the *generation probability* $p_{gen} \in [0, 1]$ from the context vector h_t^*, the decoder state s_t, the decoder input x_t, and conversational context vector c:

$$p_{gen} = \sigma(w_{h^*}^T h_t^* + w_s^T s_t + w_x^T x_t + w_c^T c + b_{\text{gen}}) \quad (8)$$

where vectors w_{h^*}, w_s, w_x, w_c and scalar b_{gen} are trainable parameters and σ is the sigmoid function.

The final distribution over the union of the vocabulary words and the words of the generic response is calculated by:

$$P(w) = p_{gen} p_{vocab}(w) + (1 - p_{gen}) \sum\nolimits_{i:w_i=w} \alpha_i^t \quad (9)$$

3.5 Model training

We use the joint reinforcement learning (RL) and machine learning (ML) training as used in (Paulus et al., 2017). If $\tilde{y} = \{\tilde{y}_1, \tilde{y}_2, \ldots, \tilde{y}_{n'}\}$ is the gold output tokens for given generic response tokens x_1 and conversation history x_2, the maximum-likelihood objective using teacher forcing is given by:

$$L_{ML} = -\sum_{t=1}^{n'} \log p(\tilde{y}_t | \tilde{y}_1, \ldots, \tilde{y}_{t-1}, x_1, x_2) \quad (10)$$

Along with training with the maximum likelihood error, we also use reinforcement learning to learn from maximizing discrete metrics that are task specific (which we design as the rewards). We use the self-critical policy gradient algorithm proposed in (Rennie et al., 2017).

Here the REINFORCE (Williams, 1992) algorithm is baselined with the reward obtained by the inference time algorithm (which performs greedy decoding), without the need for training a critic network for estimating value functions. During training, two output sequences are produced: y^s, obtained by sampling $p(y_t^s | y_1^s, \ldots, y_{t-1}^s, x)$ probability distribution, and y^g, the baseline output, obtained by greedily maximizing the output probability distribution at each time step.

$$L_{RL} = (r(y^g) - r(y^s)) \sum_{t=1}^{n'} \log p(y_t^s | y_1^s, \ldots, y_{t-1}^s, x_1, x_2) \quad (11)$$

Our reward function $r(y)$, used for evaluating y against the gold standard output is

$$r(y, \tilde{y}) = \lambda_1 \cdot m1(y, \tilde{y}) + \lambda_2 \cdot m2(y, \tilde{y}) \quad (12)$$

It is the weighted mean of the two terms:

(i) BLEU metric $m1$: Ensures the content matching between the reference and the decoded outputs.

(ii) Emotional accuracy $m2$: Measured by the cosine similarity of the emoji distributions of the gold and generated responses (using pretrained DeepMoji). It ensures that the emotional states of the generated courteous behavior is consistent with the gold.

We first pre-train using the maximum likelihood (ML) objective (Eq. 10) and then using a mixed objective function with a reduced learning rate:

$$L_{mixed} = \eta L_{RL} + (1 - \eta) L_{ML}, \quad (13)$$

3.6 Baselines

We develop the following models:

1. **Model-1**: This is a Seq2Seq model with attention (Luong et al., 2015) and decoder conditioned on the conversational context vector c (without concatenating emotional embedding i.e. instead of Eq. 2, $r_d = h^1_{Nd}$)
2. **Model-2**: This model is developed using Model-1 along with the copying mechanism of Pointer Generator Network.
3. **Model-3**: This model is developed using Model-2 along with emotional embeddings in the conversational context vector as in E.g., 2.

Table 2: Dataset Statistics

4 Dataset

In this section we describe the details of the dataset that we create for our experiments.

4.1 Dataset source and description

We use the data of the interactions between customers and professional customer care agents of companies on their Twitter handles. We source the requisite Twitter data from the dataset made available on Kaggle by Thought vector [1]. Tweets have labels of company names, anonymized user ids, time stamps, and response tweet ids - essential for reconstructing conversations, and nuanced analyses. We filter out conversations having multiple responses to a single tweet, and those starting by a tweet by a company. This was done to ensure correct conversation flow and to acquire suggestion / complaint based exchanges, respectively.

4.2 Process for data creation

As there exists no dataset with generic and courteous versions of utterances we create our own dataset. We prepare responses of generic styles by filtering out courteous sentences, phrases and expressions from the actual responses. We presume actual responses as the courteous form of response.

An example conversation:

Customer utterance (conversation history): *y'all just came to my house like last week and I'm having problems with my internet again smh*

Tweet by the Customer Care professional: *Oh no that's not good. I can help! What is happening with your internet?*

We use this conversation to prepare the courteous and the generic response

1. **Courteous response**: *Oh no that's not good. I can help! What is happening with your internet?*
2. **Generic response**: *What is happening with your internet?*

As we want to filter out courteous phrases / sentences from a given customer care tweet, we segment the tweet into sentences. Purely courteous (and non-informative) sentences must be removed, purely informative sentences must be retained, and informative sentences with courteous expressions must be transformed (to remove only the courteous part from the sentence). We define these three forms of sentences as:

(i) *Courteous sentences*: Sentences which do not contain any information/ suggestions, and are purely non-informative. These may include personalized greetings and expression of appreciation, apology, empathy, assurance, or enthusiasm. Example: *Sorry to hear about the trouble!*

(ii) *Informative sentences without courteous expressions*: These sentences contain the actual content of the tweet and are generally assertions, instructions, imperatives or suggestions. Example: *Simply visit url_name to see availability in that area!*

---

[1] https://www.kaggle.com/thoughtvector/customer-support-on-twitter

(iii) *Hybrid-Informative sentences with courteous expressions*: These are the sentences of the second type also containing some expressions of the first type. Example: ***We appreciate the feedback,*** *we'll pass this along to the appropriate team.*

4.3 Scaling up for large data creation

We annotate sentences in isolation by grouping similar sentences together to speed up annotations and then reconstruct the generic sentences by post-processing rules. We follow the following procedure to prepare the dataset for each company separately:

1. *Sentence segmentation*: We first extract the tweets from customer care agents. Each tweet is segmented into sentences to eventually identify three forms of the sentences.

2. *Clustering*: As expressions and sentences used by professionals of a company often follow similar patterns. Grouping similar sentences together before annotation would therefore significantly make the process faster. The vector-semantic representations of sentences are obtained using the sentence encoder(Conneau et al., 2017) trained on the SNLI corpus(Bowman et al., 2015). We use the K-Means clustering(Aggarwal and Zhai, 2012)(k = 300) to cluster these sentences.

3. *Annotations*: Three annotators proficient in the English language were assigned to annotate the sentences into the three categories: *purely courteous, purely informative, hybrid*. For sentences having both informative and courteous clauses/expressions (hybrid), they were asked to manually prepare the generic sentence by removing the courteous part. Also they were asked to identify non English conversations (and filter them). We observe the multi-rater Kappa agreement ratio of approximately 80%, which may be considered as reliable.

4. *Preparing generic responses*: Now let us assume we have a courteous response S with n sentences $s_1, s_2, \ldots, s_n$. We obtain the generic response by removing the courteous sentences, retaining the informative sentences, and replacing the hybrid sentences with the prepared generic equivalents.

We divide the conversation into train, validation and test sets as given in Table 2. Each training example is of the form: conversational history (last three utterances), generic response and courteous response.

5 Experiments

Implementation Details: We use a vocabulary of size 30k for the task (as the range of courteous expressions is limited, and informative contents can be copied even if they are out-of-vocabulary-OOV). We use 256 dimensional hidden states and 128 dimensional word embeddings (not pre-trained). We use AdaGrad as the optimizer with gradient clipping (magnitude 2). We train with batches of size 16, and use the same size for beam search decoding. We monitor smoothened running loss on the validation set for early stopping and finding the best models for decoding. We use η = 0.99 (similar to (Paulus et al., 2017)) for the joint loss. For the reward function the values of λ_1 and λ_2 are 0.75 and 0.25, respectively.

Automatic Evaluation: For automatic evaluation, in addition to the standard metrics like BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and perplexity, we also use two task-specific metrics:

1. Content preservation (CP): We want to measure how much of the informative content from the original generic response(X) is reflected in the generated courteous response(Y). We use a measure similar to ROUGE-L recall.

$$CP = LCS(X, Y)/len(X) \tag{14}$$

where LCS is the longest common subsequence.

2. Emotional accuracy (EA): To measure the consonance between the generated courteous expressions (source of emotion) and the gold, we find the cosine similarity between the MojiTalk emoji distributions of the two responses (X_e and Y_e).

$$EA = X_e \cdot Y_e/(|X_e||Y_e|) \tag{15}$$

Human Evaluation: In order to understand the quality of the responses we adopt human evaluation to compare the performance of different models. We randomly sample 500 responses from the test set for human evaluation. Given a generic response along with conversation history, three human annotators with post-graduate exposure were assigned to evaluate the courteous responses generated by the different models for the three metrics:

1. Fluency (F): The courteous response is grammatically correct and is free of any errors.

2. Content Adequacy (CA): The generated response contains the information present in the generic form of the response and there is no loss of information while adding the courteous part to the responses.

3. Courtesy Appropriateness (CoA): The courtesy part added to the generic responses is in accordance to the conversation history.

The scoring scheme for fluency and content adequacy is 0: incorrect or incomplete, 1: moderately correct, 2: correct, whereas for courtesy appropriateness the scoring scheme is -1: inappropriate, 0: non-courteous, 1: appropriate, respectively. We computed the Fleiss' kappa (Fleiss, 1971) for the above metrics to measure inter-rater consistency. The kappa score for fluency is 0.75 and courtesy appropriateness is 0.77 indicating "substantial agreement" and the score is 0.67 for content adequacy denoting "considerable agreement".

6 Results and Analysis

Automatic evaluation results: Results of the different models are presented in Table 3. The proposed model performs significantly better than the other baselines for all the evaluation metrics and the improvement in each model is statistically significant compared to the other models.[2]. The attention based sequence to sequence model (Model 1) is a decent baseline with good scores (56.80 BLEU). The Pointer generator model (Model 2) is aided by the copying mechanism. Thus, it is better modeled to include portions of the content from the generic response into the courteous response. This is corroborated by the increased score in CP (+9.33%). Its emotional accuracy is slightly reduced from Model 1 (-0.45%), probably because of eagerness to copy rather than generate. The advantage of the emotional embedding in Model 3 over Model 2 is reflected with the increased scores(+3.77%), because of its ability to better understand the emotional states and generate more appropriate courteous responses. The perplexity values are slightly reduced in Model 3 and Model 4, apparently because of the emotion embedding confusing the actual content from the conversation history. The final model performs decently better than other models. The reinforcement learning objective helps it to improve upon the desired metrics rather than just learn to be accurate at the token level.

Our Model	10.05	44.90	44.60	13.85	38.48	47.67	14.11	41.11	44.78

Table 4: Human evaluation results for Fluency, Content Adequacy and Courtesy Appropriateness (All values are in percentages.)

Human evaluation results: In Table 4, we present the results of human evaluation. In case of fluency, our proposed model and the third model show similar performance, whereas Models 1 and 2 are relatively less fluent. Model 2 shows great improvement with respect to Model 1 as it is able to copy the content from the input. Also, for content adequacy our proposed model has been able to generate 38.48% moderate replies that have adequate amount of information in it while it generates around 47.67% correct responses that contain all the information present in the input. For courtesy appropriateness, Model 1 and Model 2 show lower performance while our proposed model has been able to capture the courteous behavior. As score 1 is given to the responses that are courteous as well as the nature of courteousness is in accordance to the conversation, it can be seen that our model achieves 44.78% performance level which is higher than the other models. From this evaluation, we can infer that the responses generated by our model are not only adequate in terms of information preservation, but also able to induce the courteous behavior by making the responses interesting and informative.

Error Analysis: We further analyse the outputs generated from our proposed model to perform a detailed qualitative analysis of the responses. In Table 5, we present few examples of the responses generated by the different models given the generic input. Some common forms of mistakes include:

1. Unknown Tokens: As Model 1 does not have the copying mechanism, the number of unknown

Table 5: Examples of Courteous Responses Generated by the Different Models

tokens is predicted the most in this. Also often the model predicts 'end of sequence' token just after the 'out of vocabulary' token, thus leaving sequences incomplete.

2. Wrong copying: Sometimes pointer network makes mistakes while copying (being influenced by language model): Gold: .. *which store in gillingham did you visit ?*; Predicted: .. *which store in belgium did you visit ?*

3. Mistakes in emotion identification: These mistakes are more prominent in Models 1 and 2 (they don't have emotional embeddings), where the generated courteous phrases denote mistakes in identifying the emotional state of the customer. For example, Gold: *you're very welcome, hope the kids have an amazing halloween !*; Predicted: *we apologize for the inconvenience. hope the kids have an amazing halloween !*

4. Extra information: Models 1, 2, 3 sometimes generate extra informative sentences than in the generic response: Gold: *please send us a dm*; Predicted: *please send us a dm please let us know if you did not receive it*

5. Contextually wrong courteous phrases: These mistakes are common across models while generating courteous phrases with content in them: Gold: *we want to help, reply by dm and ..*; Predicted: *im sorry you havent received it. please reply by dm and ..*

6. Difference in phrases: Generated responses differ from reference responses in their use of (equivalent) courteous phrases, and are hence wrongly penalized by some metrics.

7 Conclusion and Future Work

In this paper, we propose a new research problem of accentuating customer care responses with courteous behavior. Incorporation of courteousness is important for attaining user satisfaction and to improve the performance of the application leading to user retention. We successfully prepare a large benchmark corpus, created from the actual showcasing of courteous behavior by human professionals on Twitter. Our developed models appropriately model the dialogue history and are informed of the past emotional states through emotional embeddings. We have used both automatic and human based metrics for evaluating the performance of our model. In qualitative and quantitative analyses of the generated responses, we observe contextually correct courteous behavior and content preservation, along with minor inaccuracies as discussed in the error analysis section. Overall the performance of our model shows the variations in responses with the other models keeping the information and courtesy nature of the generated responses intact.

In future, along with the opportunity of extending the architectural designs and training methodologies to enhance the performance of our systems, we look forward to designing a specific component to enhance the natural language generation component of an end to end chatbot, by including appropriate mechanisms to interact with all its components (memory, database, and the dialog manager). Moreover, studies will be conducted on courtesy transfer for the other domains, and also transfer learning from one domain to the another (like customer care to hospitality).

Abstract

Metaphor generation attempts to replicate human creativity with language, which is an attractive but challengeable text generation task. Previous efforts mainly focus on template-based or rule-based methods and result in a lack of linguistic subtlety. In order to create novel metaphors, we propose a neural approach to metaphor generation and explore the shared inferential structure of a metaphorical usage and a literal usage of a verb. Our approach does not require any manually annotated metaphors for training. We extract the metaphorically used verbs with their metaphorical senses in an unsupervised way and train a neural language model from wiki corpus. Then we generate metaphors conveying the assigned metaphorical senses with an improved decoding algorithm. Automatic metrics and human evaluations demonstrate that our approach can generate metaphors with good readability and creativity.

1 Introduction

Metaphor is a kind of language filled with vitality and elasticity. It employs words in a way that deviates from their normal meaning to represent another concept (Li and Sporleder, 2010). Using metaphor allows us to express not just information but also real feelings and complex attitudes. There is a clear need in computational metaphor generation whose insightful results can be used in many applications from entertainment to education (Veale, 2016). Besides, a unified metaphor annotation procedure and creation of a large publicly available metaphor corpus are in great demands. Such resources make it possible to interpretate the identified metaphorical expressions and enhance the performance on other Natural Language Processing (NLP) applications (Shutova, 2010).

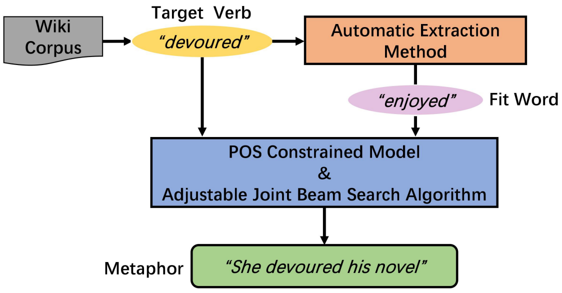

Figure 1: The Metaphor Generation Process

Although metaphor has a long history of academic studies in both philosophy and linguistics (Genesereth, 1980; G. and M., 1985), it still remains a tough problem for the NLP community. As the metaphor is hardly to be well-defined and modeled, little work focuses on the metaphor generation. Most of the previous efforts rely on hand-coded knowledge (Martin, 1990; Feldman and Narayanan, 2004; Agerri et al., 2007) , which heavily constrains the diversity of generated metaphors.

The end-to-end approach presented to sequence learning has been proved effective on the generation tasks like machine translation (Sutskever et al., 2014), abstractive summarization (Tan et al., 2017), product review generation (Zang and Wan, 2017) and multi-label classification (Yang et al., 2018). The approach is able to train a language model which can generate fluent and creative sentences with sufficient corpus. Unfortunately, in spite of the industrious exploration of the metaphor corpus, the annotated data available now is still far from training a good language model. To the best of our knowledge, there has been no work combining metaphor generation with the end-to-end approach.

In this paper, we propose a neural approach for metaphor generation trained with Wiki corpus rather than the limited annotated metaphor corpus, which assures the quality of the language model. The approach is shown in Figure 1. Relevant sta-

Minneapolis, Minnesota, June 2 - June 7, 2019.

tistics demonstrate that the most frequent type of metaphor is expressed by a verb (Martin, 2006; Steen, 2010). In this paper, we focus on generating verb-oriented metaphors. We use an unsupervised method to extract the metaphorically used verbs in Wiki corpus. A metaphorical pair consists of a target verb (e.g. "devoured") and a fit word (e.g. "enjoyed"). And it is used to model the metaphorical usage of the target verb. According to Narayanan (1997), a metaphorical usage and a literal usage share inferential structure. We follow this intuition to find an intersection between the metaphorical usage and the literal usage of a word. For example, in "she devoured (enjoyed) his novels", the literal sense of "enjoyed" represents the contextual sense of "devoured" in such contexts. But the similarity between "enjoyed" and "devoured" is low, which means the target verb "devoured" is merely used in such sense and can be seen as a metaphorically used verb.

For metaphor generation, we first propose a POS constrained language model to generate a sentence containing a given verb and use an elaborately designed algorithm to consider its fit word simultaneously while decoding. For a profound exploration, we introduce automatic metrics as well as manual ways to evaluate the generation results. Experimental results demonstrate that our approach is capable of generating fluent and seemly metaphors. All the generated metaphors are novel and do not exist in the corpus.

To summarise, the contributions of our work are as follows[1]:

- As far as we know, our work is the first endeavor to adopt the end-to-end framework on metaphor generation. Besides, the proposed method does not require any manually labeled metaphor corpus.

- We automatically extract the verbs and their fit words in the corpus in an unsupervised way and use them (e.g. "devoured", "enjoyed") to model the metaphorical senses of the verbs for the generation process. We further explore the semantic shift of a verb by changing the adjustable factors.

- Both automatic metrics and human evaluation results demonstrate the efficacy of our model. Our model outperforms the baseline models on 3 aspects significantly[2].

2 Related Work

Metaphor is highly frequent in language and its computational processing is indispensable for real-world NLP applications addressing semantic tasks. Automatic processing of metaphor can be clearly divided into two subtasks: metaphor identification and metaphor interpretation (Shutova, 2010), little research has been devoted to the metaphor generation. In this subsection, we briefly review some prior work on metaphor generation.

Jones (1992) aims to generate a specific class of metaphors: Transparently-Motivated Metaphor, which is based on universal groundings that are often linked to bodily experience. Abe et al. (2006), Terai and Nakagawa (2010) generate metaphors in the form of "A (target) like B (vehicle)". They firstly compute the probabilistic relationship between concepts and words with a statistical analysis of language data and then select candidates to fill in the template. From a given mapping between the concepts of two domains, Hervás et al. (2007) present an approach to the application of metaphors for referring to concepts in an automatically generated text. Mason (2004) obtains domain-specific selectional preferences of verbs from large corpora and maps their common nominal arguments in other domains. The corresponding metaphorical mappings are achieved by such systematic variations and can generate simple conceptual metaphors in the form of: "A is (a) B". Ovchinnikova et al. (2014) also rely on characteristic predicate but use general propositions instead of the verb and adjective phrases. As some metaphors' target domain is lexically divorced from the source, Lederer (2016) identifies constellations of source-domain triggers in limited source domains. To make the metaphor generators more comprehensible and forceful, Veale (2016) presents a knowledge-base to generate XYZ metaphors such as "Bruce Wayne is the Donald Trump of Gotham City".

Previous methods make groundbreaking explorations on metaphor generation. However, these approaches mainly focus on modeling the phrase-level metaphor expressions and the generation process depends on the templates, which causes the lack of linguistic subtlety to some extent and

---

[1] https://github.com/ArleneYuZhiwei/Metaphor-Generation

[2] Based on two-tailed paired t-test with $p<0.05$.

they are not able to build a large publicly available metaphor corpus for further study. Our approach focuses on generating sentence-level metaphor in a template-free way.

3 Our Approach

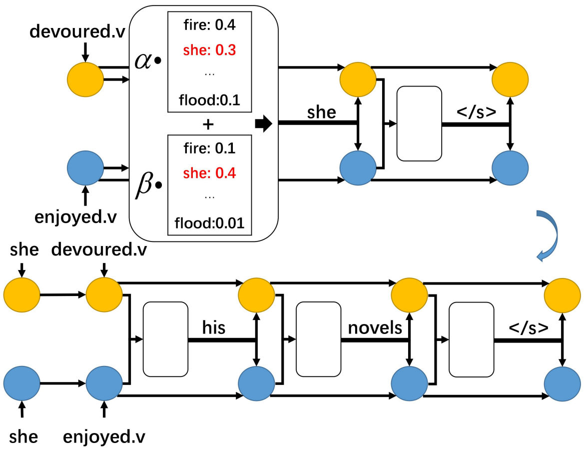

Figure 2: Adjustable Joint Model. Top: A metaphorical pair (e.g. "*devoured*" and "*enjoyed*") are given to the backward model, to generate the backward sequence. Bottom: Input the reversed backward sequence to the forward model, to generate the forward sequence. The inputs and outputs of the forward model are concatenated to form a metaphor.

Metaphors are ubiquitous in the normal corpus but lack of annotation. First, we extract the metaphorical pair which consists of a target word (e.g. "devoured") and its fit word (e.g. "enjoyed") automatically. Then we adopt an end-to-end neural framework to train a POS constrained language model which can generate a sentence containing the assigned verb. For metaphor inference, we apply an adjustable joint beam search algorithm to the decoding phase. In this way, the target verb is metaphorically used in the generated sentence. The proposed model is named Adjustable Joint Model and is shown in Figure 2.

3.1 Automatic Extraction of Metaphor Pairs

Our automatic extraction method is based on the hypotheses as follows:

H1. A metaphorical word is employed in the sentence to represent another concept and deviates from its normal meaning (Wilks, 1978; Li and Sporleder, 2010; Mao et al., 2018).

H2. The metaphorical senses of words occur with relatively lower frequency in the corpus than their literal senses do (Cameron, 2003; Martin, 2006; Mao et al., 2018).

Algorithm 1 Automatic Extraction

```
Require: $S$: the corpus, a set of sentences containing the target words
Require: $T$: the set of target words in $S$
Require: $M$: a trained CBOW model. $v_a^i$ denotes the input vector of word $a$. $v_a^o$ denotes the output vector of word $a$. $v_{context}^i$ denotes the average input vectors of the words in the $context$.
Require: $\varepsilon$: the threshold that determines the metaphoricity.
$Inflect(C)$ gets the inflections of each word in the set $C$. $Sim(x, y)$ calculates the cosine similarity between two vectors $x, y$.
$P = \emptyset$
For any sentence $s \in S$ and the contained target word $t \in T$
$context$ = the set consists of the words in $s$ excluding $t$
$syn$ = the set consists of the synonyms of $t$
$hyp$ = the set consists of the hypernyms of $t$
$candidates = Inflect(syn \cup hyp \cup t)$
$w = \underset{k}{argmax} Sim(v_k^o, v_{context}^i), k \in candidates$
$sim = Sim(v_w^i, v_t^i)$
if $sim < \varepsilon$ then:
    $P \leftarrow P \cup (t, w)$
return $P$
```

As metaphors begin their lives with marked rhetorical effects, whose comprehension requires a special imaginative leap (Nunberg, 1987), it is intuitive to assume that a metaphorical word can be distinguished from the literal one in the corpus with the violation of semantic constraints within a context. It has been proved that the dissimilarity between neural embeddings of the two words in a phrase is indicative of identifying the metaphoricity of the phrase (Shutova et al., 2016; Rei et al., 2017). Thus we find the semantic violation in the corpus based on word embeddings. The word embeddings are obtained by using Continuous Bag-of-Words Model(CBOW) (Mikolov et al., 2013).

Inspired by Mao et al. (2018), we use a fit word to model the contextual sense of the target word. To find a fit word for the target word t, we construct a candidate word set $candidates$ which consists of the target word as well as its synonyms and direct hypernyms extracted from WordNet(Miller, 1998). The target word may have several senses. Each of these senses has a set of corresponding synonyms and hypernyms. We extract the synonyms and hypernyms of all the verb senses. We augment the set with the inflections of the items in it. The word in the $candidates$ which has the highest similarity with the given context represents the contextual sense of the target verb in the sentence.

For example, "*i am afraid this spells trouble*" is a sentence in the corpus and the target word t is "*spells*". The word (e.g. "*means*") in $candidates$ has the highest similarity with the given context (e.g. "*i am afraid this [ ] trouble.*"), and is the fit word of t.

We then compute the similarity between the target verb (e.g. "*spells*") and its fit word (e.g. "*means*") . If the similarity is less than or equal to a threshold $\varepsilon = 0.6$[3], we extract the metaphorical word together with the fit word to form a metaphorical pair. The extraction process is described in Algorithm 1.

Follow the previous work (Nalisnick et al., 2016; Mao et al., 2018), we use OUT-IN vectors to measure the similarity between a fit word and its given context, use IN-IN vectors to measure the similarity between two words in a metaphorical pair[4] .

3.2 POS Constrained Language Model

Our goal is to generate a sentence containing a metaphorically used verb. However, the vanilla end-to-end model cannot guarantee the target word appearing in the generated sequence all the time, letting alone the appearance of a word with a specific part-of-speech. To solve this problem, we present a neural language model which can ensure an assigned verb to appear in the generated sentence. Our design is inspired by the asynchronous forward/backward generation model proposed by (Mou et al., 2016).

The POS constrained language model is trained end-to-end. Given a target verb as input, the model first generates the backward sequence starting from the target word w_t at position t of the sentence and ending up with "</s>" at position 0 of the sentence. n is the position of the last word in the sentence. $p(w_t^1)$ denotes the probability of the backward sequence. Then we reverse the output of the backward sequence as the input to the forward model. And it generates the rest part of the sentence accordingly. $p(w_t^n)$ denotes the probability of the forward sequence. The generated sentence is a connection of the input and output of the forward model whose probability can be decomposed as:

$$p(\overleftarrow{w_t^1}||\overrightarrow{w_t^n})=p(w_t)\prod_{i=1}^{t-1}p^{(bw)}(\overleftarrow{w_{t-i}}|\cdot)\prod_{i=1}^{n-t}p^{(fw)}(\overrightarrow{w_{t+i}}|\cdot), \tag{1}$$

where $p(\cdot||\cdot)$ means the probability of a particular backward/forward sequence. $p^{(bw)}(\overleftarrow{w_t}|\cdot)$ or $p^{(fw)}(\overrightarrow{w_t}|\cdot)$ indicates the probability of w_t given previous sequence $\cdot$ in the backward or forward model respectively. So far, the model is able to generate a sentence containing an assigned word. But the target word is not used as a verb in the generated sequence all the time.

We regard a word with various parts-of-speech as a polyseme. If the word is used with a specific part-of-speech which we are concerned about, we label it with the specific part-of-speech tag, otherwise, the word remains unchanged. In our case, we use a POS tagger (Bird et al., 2009) to label all the words in the metaphorical pairs we extracted into two categories: verb and the other. For instance, "*spells*" is labeled as "*spells.v*" in the corpus if it is used as a verb otherwise "*spells*". We train the POS constrained model with the labeled corpus, and we generate sentences like "*she spells.v her husband at the wheel*" rather than "*he whispered spells as he moved his hands.*" when given "*spells.v*" as input.

3.3 Adjustable Joint Beam Search

In the end-to-end model, the goal of the decoder is to find a sequence $\hat{y}$ which maximizes the conditional probability given by a specific model θ and an input sequence x:

$$\hat{y} = argmax_{y \in \mathcal{Y}} p_\theta(y|x), \tag{2}$$

where $\mathcal{Y}$ is a set of all the possible sequences in the output space. It is impracticable to explore the whole space. Models decompose this problem into a sequence of time steps. The original beam search algorithm produces a probability distribution at each time step over the vocabulary V. And the log function is applied on the probability distribution to get the score distribution. Instead of simply choosing the token with the highest score, the beam search algorithm keeps top k candidates from a large matrix of dimensions $k \times |V|$ which expands the search space, where k denotes

---

[3] Keep in line with Mao et al. (2018)

[4] IN vectors are input vectors of a trained CBOW model. OUT vectors are output vectors of a trained CBOW model.

Algorithm 2 Adjustable Joint Beam Search

```
Require: $k$ : beam size
Require: $\alpha$, $\beta$: adjustment factors
Require: $L$ : maximum sequence length
Require: $w_1, w_2$ : input words
$Decoder-Init(w_i, n)$ copies the initial state of the decoder $n$ times when inputting $w_i$ to the decoder.
$Decoder-Step(beam)$ calculates the score distributions on the beam.
$Top-K(scores, b)$ selects $b$ candidates with highest scores in the score distribution and returns corresponding beam ids ($beam.id$) and word ids ($beam.indices$).
$t = 0; l = k; n = k/2$
$beam1 \leftarrow Decoder-Init(w_1, n)$
$beam2 \leftarrow Decoder-Init(w_2, n)$
while $l > 0$ and $t < L$ do
    $scores1 = Decoder-Step(beam1)$
    $scores2 = Decoder-Step(beam2)$
    $scores = \alpha \cdot scores1 + \beta \cdot scores2$
    $beam1 = Top-K(scores, n)$
    $beam2.ids \leftarrow beam1.ids + n$
    $beam2.indices \leftarrow beam1.indices$
    $t = t + 1$
    $n_e$ ←number of ("</s>") selected in $beam1$ and $beam2$.
    $l = l - n_e$
return $beam1, beam2$
```

the beam size. When "</s>" is selected among the highest scoring candidates the beam is reduced by one. When the beam is zero, the beam search algorithm stops (Lowerre, 1976; Post and Vilar, 2018).

As the metaphorical usage of the verb is represented by the metaphorical pair. We need to generate a sentence for the target verb where the contextual sense of the target word equals to the literal sense of its fit word, which means both target word and its fit word should be suitable in the generated sentence. Given two different verbs in a metaphorical pair as inputs (e.g. "*devoured*.v", "*enjoyed*.v"), we hope to generate a same context for them. However, the original beam search algorithm can hardly choose the same candidates at each time step for them. Yu et al. (2018) propose the joint beam search algorithm for pun generation. The algorithm selects candidates for the two inputs according to the joint score distribution on all beam while decoding. Nevertheless, the semantic distance between the metaphorical sense and the literal sense of the target verb is not the same with the distance between the metaphorical sense and contextual sense of the target word. In addition, the frequencies of the words in each metaphorical pair differ, and there is no reason to believe that two words in a metaphorical pair have the same influence on generating metaphors. Therefore, we use the adjustment factors α, β to modify the weights of the score distributions for two inputs. The proposed adjustable joint beam search algorithm is described in Algorithm 2.

Different from the original beam search algorithm, to start the adjustable joint beam search algorithm, the initial states of the decoder are copied $k/2$ times for each input. At each time step, candidates are chosen from a weighed summation of the score distributions from two sets of the beam. The beam for the next time step is filled by taking the states corresponding to the selected beam ids and word ids. Half of the chosen words are duplicate but come from distinct beam, which means the outputs are one-to-one correspondent for the two distinct inputs. Although the corresponding two sequences select the same word at each time step, they have distinct hidden states, and thus their score distributions are different. The decoder finally outputs k sentences in parallel and the corresponding two sentences are the same except for the input words. We find an intersection between a metaphorical usage and a literal usage of a verb by this means. To avoid that the generated sentence is semantically inclined to the word in a metaphorical pair whose frequency is relatively higher and take the second hypothesis (**H2**) into consideration, we calculate the adjustment factors as follows:

$$\alpha = \sigma\left(1 - \frac{wf(word1)}{wf(word1) + wf(word2)}\right), \quad (3)$$

$$\beta = \sigma\left(1 - \frac{wf(word2)}{wf(word1) + wf(word2)}\right), \quad (4)$$

where $wf(a)$ denotes the frequency of the word a in the corpus. As metaphorical senses of words occur with relatively lower frequency in the corpus, we adjust the weights negatively correlated to the word frequency. And we use σ, the sigmoid function which is differentiable and widely used in the neural network models, to smooth the adjustment factors.

4 Experiments

4.1 Data Preprocessing

Adequate data is a prerequisite condition for training a good language model. It is unrealistic to achieve the goal based on the limited annotated metaphor corpus. In this paper, we use the English Wikipedia corpus to train the POS constrained language model. The corpus is split into sentences whose maximum length is 50 words. We lowercase and tokenize the sentences. All the numeric tokens are replaced with "#". We automatically extract 2812 metaphorical pairs from the corpus, and label words in them into two forms: "*word.v*" and "*word*". We use 461,685 sentences as the training set. We keep 120,000 most frequently occurring words and replace other words with the "<*unk*>" token. We call this processed corpus a **normal corpus**. For comparison, we extract the metaphors in the normal corpus using an unsupervised metaphor identification approach (Mao et al., 2018) and build a **metaphor corpus** with 310,908 sentences. We keep the same vocabulary size. To explore the influence of a fine-grained sense in the metaphor generation task, we use a Word Sense Disambiguation (WSD) tool[5] to label the verbs in the normal corpus. As the polysemes are regarded as different words which obviously increases the vocabulary size, we keep 165,000 most frequently occurring words. And this corpus is named **sense corpus**.

4.2 Compared Models

Since there has been no neural model applied on metaphor generation and the previous template-based models can not generate such verb-oriented metaphors, we implement six neural models for comparison and explore the intrinsic characteristics of metaphor generation. Models are trained on the **normal corpus**, unless otherwise specified.

Normal Model: This model is a basic end-to-end framework whose inputs are verbs and outputs are sentences. We use the teacher forcing algorithm (Williams and Zipser, 1989) while training. The input of the encoder is a verb, and the reference for the decoder is a sentence containing the verb.

POS constrained Model: This model combines the basic end-to-end framework with the POS constrained language model. The model can generate a sentence containing a given verb.

Fit Word Model: The model is trained in the same way as the POS constrained model. The input is a fit word, and we directly replace the fit word in the generated sentence with the corresponding target word.

Metaphor Based Model: The model is the same as the POS constrained model but trained on the **metaphor corpus**.

Uncommon Sense Model: Based on the second hypothesis(**H2**), metaphorical sense appears less common in the corpus than literal sense. It is intuitive to associate the metaphorical sense of the target word with a low-frequency sense. We keep the senses of a target word which appear in the corpus more than 9 times in a sense list. Then we choose the sense with the lowest frequency in the sense list as the metaphorical sense of the target verb. This model generates sentences similarly to the POS constrained model, except that it is trained on the **sense corpus.**

Adjustable Joint Model: The training process is exactly the same as the POS constrained model's, but we use the adjustable joint beam search algorithm while decoding.

4.3 Automatic Evaluation

We extract the metaphorical pairs automatically in the normal corpus and conduct experiments. The automatic evaluation results are shown in Table 1.

Model	l.ave	w.num	ppl.
Normal	10.34	16029	97.84
POS constrained	10.51	16361	133.24
Fit Word	10.70	16666	154.49
Metaphor Based	9.37	14526	**61.88**
Uncommon Sense	7.45	11569	96.52
Adjustable Joint	**11.35**	**16887**	97.03

Table 1: Automatic evaluation results for generated metaphors based on the automatically extracted verbs.

Each target verb may form distinct metaphorical pairs with different fit words. Both the normal model and the POS constrained model generate the same sentences for the same target verbs while the fit word model generates the same sentences for the same fit words. Taking the metaphorical pairs into consideration, adjustable joint model can generate various sentences when the target words are the same but used in diffe-

---

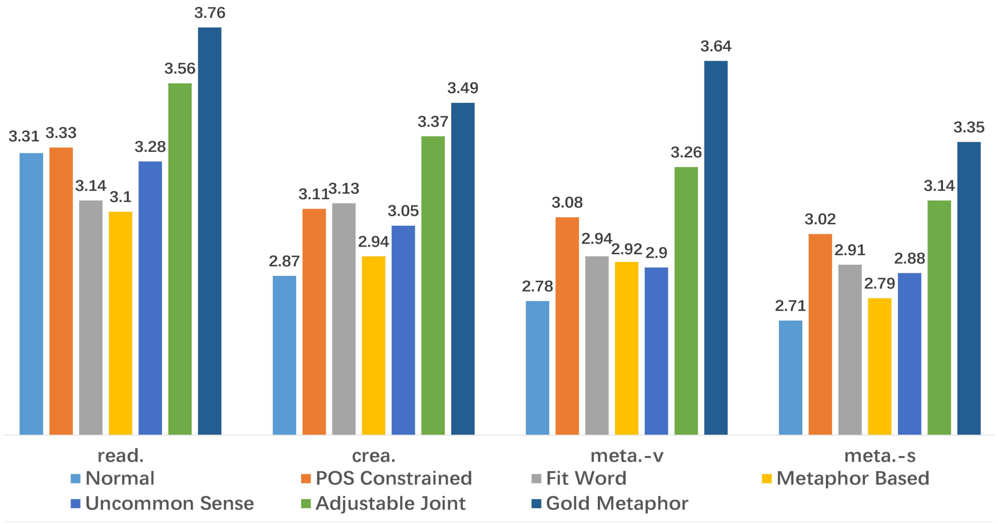

Figure 3: Results of human evaluation.

rent senses. For a fair quantitative analysis, each model generates 1555 sentences for distinct target verbs. **Length-average (l.ave)** is the average length of the generated sentences of each model. **Word.number(w.num)** is the total number of the distinct words in the generated sentences, and the adjustable joint model decodes words with the highest diversity compared to the other models. We use the language modeling toolkit SRILM[6] to evaluate the **perplexity scores (ppl.)**. Theoretically, the normal model should generate more fluent sentences without considering the constraint that a given word must appear in the outputs, however the ppl. is calculated as Eq 5 shows:

$$ppl = 10^{\wedge}\left(\frac{-logP(T)}{s.num + w.num - OOVs}\right), \qquad (5)$$

where $P(T)$ denotes the probabilities of all the sentences, $s.num$ denotes the total number of the sentences. $OOVs$ denotes the number of out-of-vocabulary words. The outputs of the metaphor based models tend to be shorter which results in a higher $P(T)$ and thus a low ppl. Although the adjustable joint model generates sentences with lexical constraints, it chooses the candidates with the highest joint score at each time step and uses more distinct words, and thus it obtains a high $P(T)$ as well as a large $w.num$. It achieves a relatively low ppl. What's more, all the sentences generated by the adjustable joint model are novel and do not exist in the corpus according to the duplicate checking . The fit word model decodes according to the fit words and then the fit words in the sentences are replaced by their target words directly, which results in a higher ppl. Since the amount of the training data corresponding to the inputs of the uncommon sense model is the least, the generated sentences are not so fluent.

4.4 Human Evaluation

For a thorough comparison, we select 80 gold metaphors with high confidence (>0.6) from the data set proposed by (Mohammad et al., 2016). Each verb in the data set was annotated for metaphoricity by 10 annotators and we use the verbs in the selected metaphors as the target words. As metaphor is such a creative and delicate language that automatic evaluation is not adequate. We ask native English speakers on Amazon Mechanical Turk to evaluate all the sentences generated by the neural models and corresponding gold metaphors in four aspects. Each sentence is scored from 1 to 5 by 5 judges. **Readability(read.)** indicates whether the sentence is fluent and consistent with the rules of grammar. **Creativity(crea.)** indicates whether the sentence is distinct and creative. **Metaphorical or Literal Usage of the Verb(meta.-v)** indicates whether the target word is used literally or metaphorically. 1 denotes that the usage of the verb is definitely literal and 5 denotes the verb is obviously metaphorically used. We display typical properties of metaphorical and literal senses as follows: literal usages tend to be more basic, straightforward meaning, more physical and closely tied to our senses; Metaphorical usages tend to be more abstract, more vague and often surprising, someti-

Model	Generated Sentences
Target Verb: *absorbed*	Fit Word: *learn*
Normal	*it is absorbed by the united states .*
POS constrained	*it absorbed the united states in the early century .*
Fit Word	*they absorbed that they are able to find themselves .*
Metaphor Based	*they absorb water from the water to be used as a result of the disease .*
Uncommon Sense	*he absorbed more than a few hundred feet .*
Adjustable Joint	***he absorbed his studies at the university of birmingham .***
Gold Metaphor	*he absorbed the knowledge or beliefs of his tribe .*
Target Verb: *pour*	Fit Word: *crowd*
Normal	*while drinking , he is able to kill him .*
POS constrained	*being poured , the band was released by the band .*
Fit Word	*they poured for the first time , and the team was the first to win the championship .*
Metaphor Based	*it was poured in # and # .*
Uncommon Sense	*she poured the police and her husband .*
Adjustable Joint	***millions of trees poured out of the area .***
Gold Metaphor	*People were pouring out of the theater.*

Table 2: Examples of generated sentences.

mes bring in imagery from a different domain. The aspects above are rated according to comparison. **Metaphoricity of the sentence(meta.-s)** indicates whether the sentence is a metaphor. The score ratings are defined as: 1. not a metaphor at all; 2. pathetic metaphor; 3. not-so-bad metaphor; 4. interesting metaphor; 5. gold metaphor.

Results are shown in Figure 3. The metaphor based model generates shorter sentences which results in a low **ppl.**, but it replicates some words at times, which makes it difficult for human to interpret. The fit word model replaces the fit words with the target words directly and may break the grammatical collocations. Although the adjustable joint model ensures the intersection sense of two words in the metaphorical pair to appear in one sentence, the generated utterance is still readable. As for the **crea.**, without any lexical constraint, the normal model always generates the sentences which are similar to the relatively high-frequency sentences in the corpus and results in the lack of novelty. In contrast, the target words are used in its less used literal senses in the uncommon sense model and the results seem to be kind of creative. The adjustable joint model performs closely to the gold metaphor on the **crea.**, which proves its ability in modeling the creative usage of the verbs. **meta.-v** directly reveals the capability of modeling the metaphorical senses of the target verb. The normal model is uncompetitive as it can not even ensure the appearance of the target verb. The difference between the POS constrained model and the uncommon sense model inspires us that although the metaphorical senses of the words occur with relatively lower frequency in the corpus than their literal senses, the metaphorical senses cannot be easily defined as the most uncommon senses of the target verbs, and thus the exploration on modeling the metaphorical senses is essential. As for the **meta.-s**, it reveals the comprehensiveness of the sentence-level metaphor generation and reminds us of modeling the metaphors in a more thoughtful perspective. The adjustable joint model outperforms the other models on the 3 aspects (**crea.**, **meta.-v**, **meta.-s**) significantly with paired t-test with $p < 0.05$.

4.5 Case Study

To illustrate concretely, we show some examples generated by different models in Table 2. Both the normal model and the POS constrained model generate sentences without considering the senses of the verbs and tend to generate monotonous sentences. And the fit word model generates sentences which are suitable for the fit word but inappropriate for the target word. For example, "*they crowed for the first time*" is fluent while "*they poured for the first time*" is strange. Other models decoding with a sense constraint generate sentences conveying the assigned senses to different degree. However, the uncommon sense model is fine-grained and the training corpus is annotated with WSD tools which results in not only the lack of corpora for some senses but also a sense-label error, as there are no WSD tools that could tag the senses of the verbs with a high precision (> 0.6) (Luo et al., 2018b,a). To solve these problems, we use the extracted metaphorical pairs to depict a metaphorical sense and the generated metaphors are readable.

We also explore the shared inferential structure of a metaphorical usage and a literal usage of a verb by changing the adjustable factors. Table 2 demonstrates the semantic shift of the verb. The POS constrained model can be seen as a special adjustable joint model whose adjustable factors are $\alpha = 1, \beta = 0$ and it generates sentences only considering the target words. In this way the target words are literally used. For contrast, the fit word model with a special setting of the adjustable factors $\alpha = 0, \beta = 1$ generates sentences completely dependent on the fit words, which may result in sentences that are not semantically appropriate. When α, β are caculated by Eq 3 and Eq 4, the generated sentences covey the metaphorical senses of verbs.

5 Conclusion

We make an exploration on verb-oriented metaphor generation and propose a neural approach on automatic metaphor generation. The approach identifies metaphorically used verbs in the normal corpus and extracts the metaphorical pairs in the sentences. We propose a POS constrained model to ensure the appearance of the given verbs and decode with the adjustable joint beam search algorithm, which takes the metaphorical senses of the given verbs into consideration. We generate metaphors which are not only fluent and readable but also creative. However, we can only generate metaphors based on the verbs whose metaphorical senses can be found in the corpus. For future work, we will explore techniques to generate metaphors without extracting its fit words in the corpus and improve the quality of generated metaphors.

Incorporating Context and External Knowledge for Pronoun Coreference Resolution

Hongming Zhang♣[*], **Yan Song**♠, **and Yangqiu Song**♣

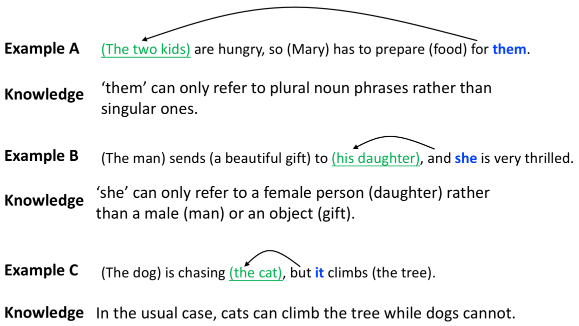
Abstract

Linking pronominal expressions to the correct references requires, in many cases, better analysis of the contextual information and external knowledge. In this paper, we propose a two-layer model for pronoun coreference resolution that leverages both context and external knowledge, where a knowledge attention mechanism is designed to ensure the model leveraging the appropriate source of external knowledge based on different context. Experimental results demonstrate the validity and effectiveness of our model, where it outperforms state-of-the-art models by a large margin.

1 Introduction

The question of how human beings resolve pronouns has long been of interest to both linguistics and natural language processing (NLP) communities, for the reason that pronoun itself has weak semantic meaning (Ehrlich, 1981) and brings challenges in natural language understanding. To explore solutions for that question, pronoun coreference resolution (Hobbs, 1978) was proposed. As an important yet vital sub-task of the general coreference resolution task, pronoun coreference resolution is to find the correct reference for a given pronominal anaphor in the context and has been shown to be crucial for a series of downstream tasks (Mitkov, 2014), including machine translation (Mitkov et al., 1995), summarization (Steinberger et al., 2007), information extraction (Edens et al., 2003), and dialog systems (Strube and Müller, 2003).

Conventionally, people design rules (Hobbs, 1978; Nasukawa, 1994; Mitkov, 1998) or use features (Ng, 2005; Charniak and Elsner, 2009; Li et al., 2011) to resolve the pronoun coreferences. These methods heavily rely on the coverage and quality of the manually defined rules and features. Until recently, end-to-end solution (Lee et al., 2017) was proposed towards solving the general coreference problem, where deep learning models were used to better capture contextual information. However, training such models on annotated corpora can be biased and normally does not consider external knowledge.



Example A (The two kids) are hungry, so (Mary) has to prepare (food) for **them**.

Knowledge 'them' can only refer to plural noun phrases rather than singular ones.

Example B (The man) sends (a beautiful gift) to (his daughter), and **she** is very thrilled.

Knowledge 'she' can only refer to a female person (daughter) rather than a male (man) or an object (gift).

Example C (The dog) is chasing (the cat), but **it** climbs (the tree).

Knowledge In the usual case, cats can climb the tree while dogs cannot.

Figure 1: Pronoun coreference examples, where each example requires different knowledge for its resolution. Blue bold font refers to the target pronoun, where the correct noun reference and other candidates are marked by green underline and brackets, respectively.

Despite the great efforts made in this area in the past few decades (Hobbs, 1978; Mitkov, 1998; Ng, 2005; Rahman and Ng, 2009), pronoun coreference resolution remains challenging. The reason behind is that the correct resolution of pronouns can be influenced by many factors (Ehrlich, 1981); many resolution decisions require reasoning upon different contextual and external knowledge (Rahman and Ng, 2011), which is also proved in other NLP tasks (Song et al., 2017, 2018; Zhang et al., 2018). Figure 1 demonstrates such requirement with three examples, where Example A depends on the plurality knowledge that 'them' refers to plural noun phrases; Example B illustrates the gender requirement of pronouns where 'she' can

Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

only refer to a female person (girl); Example C requires a more general type of knowledge[1] that 'cats can climb trees but a dog normally does not'. All of these knowledge are difficult to be learned from training data. Considering the importance of both contextual information and external human knowledge, how to jointly leverage them becomes an important question for pronoun coreference resolution.

In this paper, we propose a two-layer model to address the question while solving two challenges of incorporating external knowledge into deep models for pronoun coreference resolution, where the challenges include: first, different cases have their knowledge preference, i.e., some knowledge is exclusively important for certain cases, which requires the model to be flexible in selecting appropriate knowledge per case; second, the availability of knowledge resources is limited and such resources normally contain noise, which requires the model to be robust in learning from them.

Consequently, in our model, the first layer predicts the relations between candidate noun phrases and the target pronoun based on the contextual information learned by neural networks. The second layer compares the candidates pair-wisely, in which we propose a knowledge attention module to focus on appropriate knowledge based on the given context. Moreover, a softmax pruning is placed in between the two layers to select high confident candidates. The architecture ensures the model being able to leverage both context and external knowledge. Especially, compared with conventional approaches that simply treat external knowledge as rules or features, our model is not only more flexible and effective but also interpretable as it reflects which knowledge source has the higher weight in order to make the decision. Experiments are conducted on a widely used evaluation dataset, where the results prove that the proposed model outperforms all baseline models by a great margin.[2]

Above all, to summarize, this paper makes the following contributions:

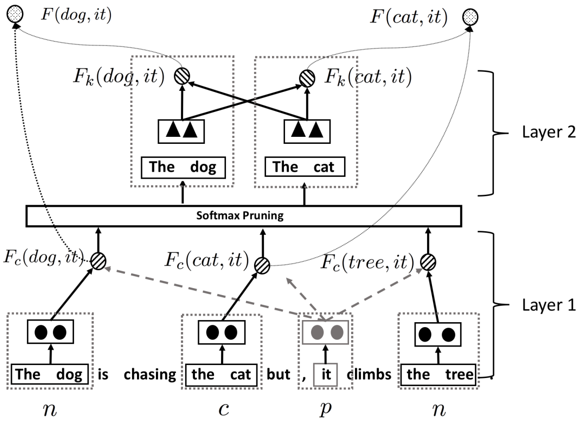

Figure 2: The architecture of the two-layer model for pronoun coreference resolution. The first layer encodes the contextual information for computing F_c. The second layer leverages external knowledge to score F_k. A pruning layer is applied in between the two layers to control computational complexity. The dashed boxes in the first and second layer refer to span representation and knowledge scoring, respectively.

1. We propose a two-layer neural model to combine contextual information and external knowledge for the pronoun coreference resolution task.
2. We propose a knowledge attention mechanism that allows the model to select salient knowledge for different context, which predicts more precisely and can be interpretable through the learned attention scores.
3. With our proposed model, the performance of pronoun coreference resolution is boosted by a great margin over the state-of-the-art models.

2 The Task

Following the conventional setting (Hobbs, 1978), the task of pronoun coreference resolution is defined as: for a pronoun p and a candidate noun phrase set $\mathcal{N}$, the goal is to identify the correct non-pronominal references set[3] $\mathcal{C}$. the objective is to maximize the following objective function:

$$\mathcal{J} = \frac{\sum_{c\in\mathcal{C}} e^{F(c,p)}}{\sum_{n\in\mathcal{N}} e^{F(n,p)}}, \tag{1}$$

where c is the correct reference and n the candidate noun phrase. $F(\cdot)$ refers to the overall coreference scoring function for each n regarding p. Following (Mitkov, 1998), all non-pronominal noun phrases in the recent three sentences of the pronoun p are selected to form N.

Particularly in our setting, we want to leverage both the local contextual information and external

---

[1] This is normally as selectional preference (SP) (Hobbs, 1978), which is defined as given a predicate (verb), a human has the preference for its argument (subject in this example).

[2] All code and data are available at:`https://github.com/HKUST-KnowComp/Pronoun-Coref`.

[3] It is possible that a pronoun has multiple references.

knowledge in this task, thus for each n and p, $F(.)$ is decomposed into two components:

$$F(n,p) = F_c(n,p) + F_k(n,p), \quad (2)$$

where $F_c(n,p)$ is the scoring function that predicts the relation between n and p based on the contextual information; $F_k(n,p)$ is the scoring function that predicts the relation between n and p based on the external knowledge. There could be multiple ways to compute F_c and F_k, where a solution proposed in this paper is described as follows.

3 The Model

The architecture of our model is shown in Figure 2, where we use two layers to incorporate contextual information and external knowledge. Specifically, the first layer takes the representations of different n and the p as input and predict the relationship between each pair of n and p, so as to compute F_c. The second layer leverages the external knowledge to compute F_k, which consists of pair-wise knowledge score f_k among all candidate n. To enhance the efficiency of the model, a softmax pruning module is applied to select high confident candidates into the second layer. The details of the aforementioned components are described in the following subsections.

3.1 Encoding Contextual Information

Before F_c is computed, the contextual information is encoded through a span[4] representation (SR) module in the first layer of the model. Following Lee et al. (2017), we adopt the standard bidirectional LSTM (biLSTM) (Hochreiter and Schmidhuber, 1997) and the attention mechanism (Bahdanau et al., 2015) to generate the span representation, as shown in Figure 3. Given that the initial word representations in a span n_i are $\mathbf{x}_1, ..., \mathbf{x}_T$,

we denote their representations $\mathbf{x}_1^*, ..., \mathbf{x}_T^*$ after encoded by the biLSTM. Then we obtain the inner-span attention by

$$a_t = \frac{e^{\alpha_t}}{\sum_{k=1}^{T} e^{\alpha_k}}, \quad (3)$$

where α_t is computed via a standard feed-forward neural network[5] $\alpha_t = NN_\alpha(\mathbf{x}_t^*)$. Thus, we have the weighted embedding of each span $\hat{x}_i$ through

$$\hat{\mathbf{x}}_i = \sum_{k=1}^{T} a_k \cdot \mathbf{x}_k. \quad (4)$$

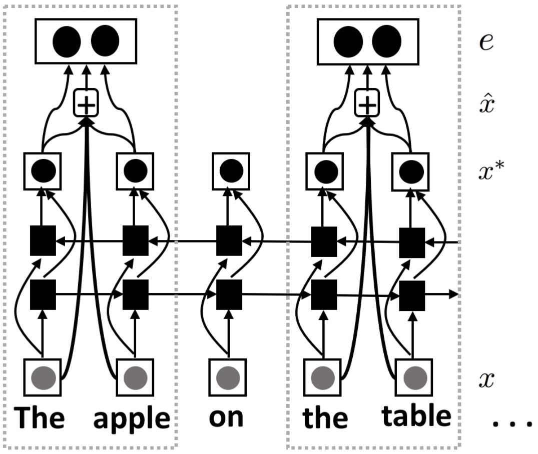

Figure 3: The structure of span representation. Bidirectional LSTM and inner-span attention mechanism are employed to capture the contextual information.

Afterwards, we concatenate the starting ($\mathbf{x}_{start}^*$) and ending ($\mathbf{x}_{end}^*$) embedding of each span, as well as its weighted embedding ($\hat{\mathbf{x}}_i$) and the length feature ($\phi(i)$) to form its final representation e:

$$\mathbf{e}_i = [\mathbf{x}_{start}^*, \mathbf{x}_{end}^*, \hat{\mathbf{x}}_i, \phi(i)]. \quad (5)$$

Once the span representation of $n \in \mathcal{N}$ and p are obtained, we compute F_c for each n with a standard feed-forward neural network:

$$F_c(n,p) = NN_c([\mathbf{e}_n, \mathbf{e}_p, \mathbf{e}_n \odot \mathbf{e}_p]), \quad (6)$$

where $\odot$ is the element-wise multiplication.

3.2 Processing External Knowledge

In the second layer of our model, external knowledge is leveraged to evaluate all candidate n so as to give them reasonable F_k scores. In doing so, each candidate is represented as a group of features from different knowledge sources, e.g., 'the cat' can be represented as a singular noun, unknown gender creature, and a regular subject of the predicate verb 'climb'. For each candidate, we conduct a series of pair-wise comparisons between it and all other ones to result in its F_k score. An attention mechanism is proposed to perform the comparison and selectively use the knowledge features. Consider there exists noise in external knowledge, especially when it is automatically

---

[4] Both noun phrases and the pronoun are treated as spans.

[5] We use NN to present feed-forward neural networks throughout this paper.

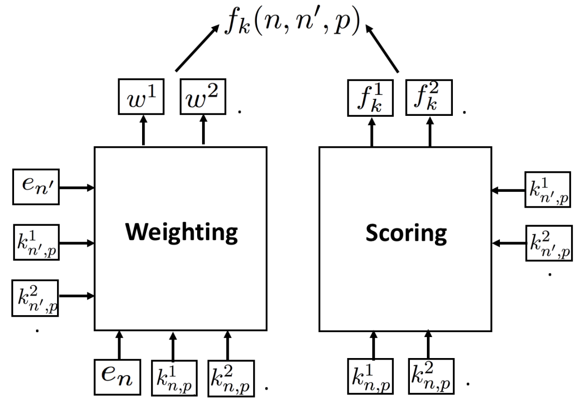

Figure 4: The structure of the knowledge attention module. For each feature k_i from knowledge source i, the the weighting component predict its weight w^i and the scoring component computes its knowledge score f_k^i. Then a weighted sum is obtained for f_k.

generated, such attention mechanism ensures that, for each candidate, reliable and useful knowledge is utilized rather than ineffective ones. The details of the knowledge attention module and the overall scoring are described as follows.

Knowledge Attention Figure 4 demonstrates the structure of the knowledge attention module, where there are two components: (1) weighting: assigning weights to different knowledge features regarding their importance in the comparison; (2) scoring: valuing a candidate against another one based on their features from different knowledge sources. Assuming that there are m knowledge sources input to our model, each candidate can be represented by m different features, which are encoded as embeddings. Therefore, two candidates n and n' regarding p have their knowledge feature embeddings $\mathbf{k}^1_{n,p}, \mathbf{k}^2_{n,p}, ..., \mathbf{k}^m_{n,p}$ and $\mathbf{k}^1_{n',p}, \mathbf{k}^2_{n',p}, ..., \mathbf{k}^m_{n',p}$, respectively. The weighting component receives all features $\mathbf{k}$ for n and n', and the span representations $\mathbf{e}_n$ and $\mathbf{e}_{n'}$ as input, where $\mathbf{e}_n$ and $\mathbf{e}_{n'}$ help selecting appropriate knowledge based on the context. As a result, for a candidate pair (n, n') and a knowledge source i, its knowledge attention score is computed via

$$\beta_i(n,n',p) = NN_{ka}([\mathbf{o}^i_{n,p}, \mathbf{o}^i_{n',p}, \mathbf{o}^i_{n,p} \odot \mathbf{o}^i_{n',p}]), \tag{7}$$

where $\mathbf{o}^i_{n,p} = [\mathbf{e}_n, \mathbf{k}^i_{n,p}]$ and $\mathbf{o}^i_{n',p} = [\mathbf{e}_{n'}, \mathbf{k}^i_{n',p}]$ are the concatenation of span representation and external knowledge embedding for candidate n and n' respectively. The weight for features from different knowledge sources is thus computed via

$$w_i = \frac{e^{\beta_i}}{\sum_{j=1}^{m} e^{\beta_j}}. \tag{8}$$

Similar to the weighting component, for each feature i, we compute its score $f_k^i(n,n',p)$ for n against n' in the scoring component through

$$f_k^i(n,n',p) = NN_{ks}([\mathbf{k}^i_{n,p}, \mathbf{k}^i_{n',p}, \mathbf{k}^i_{n,p} \odot \mathbf{k}^i_{n',p}]). \tag{9}$$

where it is worth noting that we exclude $\mathbf{e}$ in this component for the reason that, in practice, the dimension of $\mathbf{e}$ is normally much higher than $\mathbf{k}$. As a result, it could dominate the computation if $\mathbf{e}$ and $\mathbf{k}$ is concatenated.[6]

Once the weights and scores are obtained, we have a weighted knowledge score for n against n':

$$f_k(n,n',p) = \sum_{i=1}^{m} w_i \cdot f_k^i(n,n',p). \tag{10}$$

Overall Knowledge Score After all pairs of n and n' are processed by the attention module, the overall knowledge score for n is computed through the averaged $f_k(n,n',p)$ over all n':

$$F_k(n,p) = \frac{\sum_{n' \in \mathcal{N}_o} f_k(n,n',p)}{|\mathcal{N}_o|}, \tag{11}$$

where $\mathcal{N}_o = \mathcal{N} - n$ for each n.

3.3 Softmax Pruning

Normally, there could be many noun phrases that serve as the candidates for the target pronoun. One potential obstacle in the pair-wise comparison of candidate noun phrases in our model is the squared complexity $O(|\mathcal{N}|^2)$ with respect to the size of $\mathcal{N}$. To filter out low confident candidates so as to make the model more efficient, we use a softmax-pruning module between the two layers in our model to select candidates for the next step. The module takes F_c as input for each n, uses a softmax computation:

$$\hat{F}_c(n,p) = \frac{e^{F_c(n,p)}}{\sum_{n_i \in \mathcal{N}} e^{F_c(n_i,p)}}. \tag{12}$$

where candidates with higher $\hat{F}_c$ are kept, based on a threshold t predefined as the pruning standard. Therefore, if candidates have similar F_c

---

[6] We do not have this concern for the weighting component because the softmax (c.f. Eq. 8) actually amplifies the difference of β even if they are not much differentiated.

type	train	dev	test	all
Third Personal	21,828	2,518	3,530	27,876
Possessive	7,749	1,007	1,037	9,793
All	29,577	3,525	4,567	37,669

Table 1: Statistics of the evaluation dataset. Number of selected pronouns are reported.

scores, the module allow more of them to proceed to the second layer. Compared with other conventional pruning methods (Lee et al., 2017, 2018) that generally keep a fixed number of candidates, our pruning strategy is more efficient and flexible.

4 Experiment Settings

4.1 Data

The CoNLL-2012 shared task (Pradhan et al., 2012) corpus is used as the evaluation dataset, which is selected from the Ontonotes 5.0[7]. Following conventional approaches (Ng, 2005; Li et al., 2011), for each pronoun in the document, we consider candidate n from the previous two sentences and the current sentence. For pronouns, we consider two types of them following Ng (2005), i.e., third personal pronoun (*she*, *her*, *he*, *him*, *them*, *they*, *it*) and possessive pronoun (*his*, *hers*, *its*, *their*, *theirs*). Table 1 reports the number of the two type pronouns and the overall statistics for the experimental dataset. According to our selection range of candidate n, on average, each pronoun has 4.6 candidates and 1.3 correct references.

4.2 Knowledge Types

In this study, we use two types of knowledge in our experiments. The first type is linguistic features, i.e., plurality and animacy & gender. We employ the Stanford parser[8], which generates plurality, animacy, and gender markups for all the noun phrases, to annotate our data. Specifically, the plurality feature denotes each n and p to be singular or plural. For each candidate n, if its plurality status is the same as the target pronoun, we label it 1, otherwise 0. The animacy & gender (AG) feature denotes whether a n or p is a living object, and being male, female, or neutral if it is alive. For each candidate n, if its AG feature matches the target pronoun's, we label it 1, otherwise 0.

The second type is the selectional preference (SP) knowledge. For this knowledge, we create a knowledge base by counting how many times a predicate-argument tuple appears in a corpus and use the resulted number to represent the preference strength. Specifically, we use the English Wikipedia[9] as the base corpus for such counting. Then we parse the entire corpus through the Stanford parser and record all dependency edges in the format of *(predicate, argument, relation, number)*, where predicate is the governor and argument the dependent in the original parsed dependency edge[10]. Later for sentences in the training and test data, we firstly parse each sentence and find out the dependency edge linking p and its corresponding predicate. Then for each candidate[11] n in a sentence, we check the previously created SP knowledge base and find out how many times it appears as the argument of different predicates with the same dependency relation (i.e., *nsubj* and *dobj*). The resulted frequency is grouped into the following buckets [1, 2, 3, 4, 5-7, 8-15, 16-31, 32-63, 64+] and we use the bucket id as the final SP knowledge. Thus in the previous example:

The dog is chasing *the cat* but **it** climbs *the tree*.

Its parsing result indicates that '**it**' is the subject of the verb 'climb'. Then for '*the dog*', '*the cat*', and '*the tree*', we check their associations with 'climb' in the knowledge base and group them in the buckets to form the SP knowledge features.

4.3 Baselines

Several baselines are compared in this work. The first two are conventional unsupervised ones:

- **Recent Candidate**, which simply selects the most recent noun phrase that appears in front of the target pronoun.
- **Deterministic** model (Raghunathan et al., 2010), which proposes one multi-pass seive model with human designed rules for the coreference resolution task.

Besides the unsupervised models, we also compare with three representative supervised ones:

- **Statistical** model, proposed by Clark and Manning (2015), uses human-designed entity-level

---

[7] https://catalog.ldc.upenn.edu/LDC2013T19

[8] https://stanfordnlp.github.io/CoreNLP/

[9] https://dumps.wikimedia.org/enwiki/

[10] In Stanford parser results, when a verb is a linking verb (e.g., am, is), an 'nsubj' edge is created between its predicative and subject. Thus for this case the predicative is treated as the predicate for the subject (argument) in our study.

[11] If a noun phrase contains multiple words, we use the parsed result to locate its keyword and use it to represent the entire noun phrase.

Model	Third Personal Pronoun			Possessive Pronoun			All		
	P	R	F1	P	R	F1	P	R	F1
Recent Candidate	50.7	40.0	44.7	64.1	45.5	53.2	54.4	41.6	47.2
Deterministic (Raghunathan et al., 2010)	68.7	59.4	63.7	51.8	64.8	57.6	62.3	61.0	61.7
Statistical (Clark and Manning, 2015)	69.1	62.6	65.7	58.0	65.3	61.5	65.3	63.4	64.3
Deep-RL (Clark and Manning, 2016)	72.1	68.5	70.3	62.9	74.5	68.2	68.9	70.3	69.6
End2end (Lee et al., 2018)	75.1	83.7	79.2	73.9	82.1	77.8	74.8	83.2	78.8
Feature Concatenation	73.5	88.3	80.2	72.5	87.3	79.2	73.2	87.9	79.9
The Complete Model	75.4	87.9	**81.2**	74.9	87.2	**80.6**	75.2	87.7	**81.0**

Table 2: Pronoun coreference resolution performance of different models on the evaluation dataset. Precision (P), recall (R), and F1 score are reported, with the best one in each F1 column marked bold.

features between clusters and mentions for coreference resolution.

- **Deep-RL** model, proposed by Clark and Manning (2016), a reinforcement learning method to directly optimize the coreference matrix instead of the traditional loss function.
- **End2end** is the current state-of-the-art coreference model (Lee et al., 2018), which performs in an end-to-end manner and leverages both the contextual information and a pre-trained language model (Peters et al., 2018).

Note that the Deterministic, Statistical, and Deep-RL models are included in the Stanford CoreNLP toolkit[12], and experiments are conducted with their provided code. For End2end, we use their released code[13] and replace its mention detection component with gold mentions for the fair comparison.

To clearly show the effectiveness of the proposed model, we also present a variation of our model as an extra baseline to illustrate the effect of different knowledge incorporation manner:

- **Feature Concatenation**, a simplified version of the complete model that removes the second knowledge processing layer, but directly treats all external knowledge embeddings as features and concatenates them to span representations.

4.4 Implementation

Following previous work (Lee et al., 2018), we use the concatenation of the 300d GloVe embeddings (Pennington et al., 2014) and the ELMo (Peters et al., 2018) embeddings as the initial word representations. Out-of-vocabulary words are initialized with zero vectors. Hyper-parameters are set as follows. The hidden state of the LSTM module is set to 200, and all the feed-forward networks in our model have two 150-dimension hidden layers. The default pruning threshold t for softmax pruning is set to 10^{-7}. All linguistic features (plurality and AG) and external knowledge (SP) are encoded as 20-dimension embeddings.

For model training, we use cross-entropy as the loss function and Adam (Kingma and Ba, 2015) as the optimizer. All the aforementioned hyper-parameters are initialized randomly, and we apply dropout rate 0.2 to all hidden layers in the model. Our model treats a candidate as the correct reference if its predicted overall score $F(n, p)$ is larger than 0. The model training is performed with up to 100 epochs, and the best one is selected based on its performance on the development set.

5 Experimental Results

Table 2 compares the performance of our model with all baselines. Overall, our model performs the best with respect to all evaluation metrics. Several findings are also observed from the results. First, manually defined knowledge and features are not enough to cover rich contextual information. Deep learning models (e.g., End2end and our proposed models), which leverage text representations for context, outperform other approaches by a great margin, especially on the recall. Second, external knowledge is highly helpful in this task, which is supported by that our model outperforms the End2end model significantly.

Moreover, the comparison between the two variants of our models is also interesting, where the final two-layer model outperforms the Feature Concatenation model. It proves that simply treating external knowledge as the feature, even though they are from the same sources, is not as effective as learning them in a joint framework. The reason

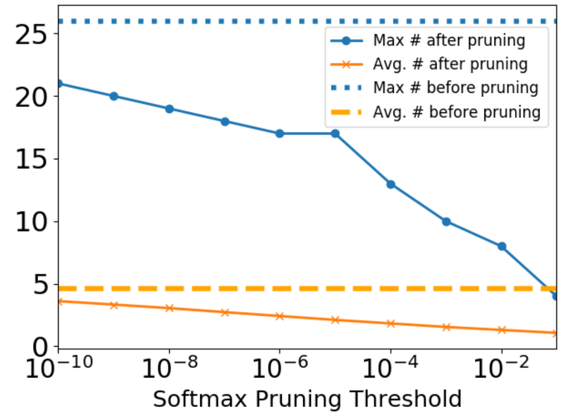

Figure 5: Effect of different thresholds on candidate numbers. Max and Average number of candidates after pruning are represented with solid lines in blue and orange, respectively. Two dashed lines indicate the max and the average number of candidates before pruning.

	F1	ΔF1
The Complete Model	81.0	-
–Plurality knowledge	80.7	-0.3
–AG knowledge	80.5	-0.5
–SP knowledge	80.4	-0.6
–Knowledge Attention	80.1	-0.9

Table 3: Performance of our model with removing different knowledge sources and knowledge attention.

behind this result is mainly from the noise in the knowledge source, e.g., parsing error, incorrectly identified relations, etc. For example, the plurality of 17% noun phrases are wrongly labeled in the test data. As a comparison, our knowledge attention might contribute to alleviate such noise when incorporating all knowledge sources.

Effect of Different Knowledge To illustrate the importance of different knowledge sources and the knowledge attention mechanism, we ablate various components of our model and report the corresponding F1 scores on the test data. The results are shown in Table 3, which clearly show the necessity of the knowledge. Interestingly, AG contributes the most among all knowledge types, which indicates that potentially more cases in the evaluation dataset demand on the AG knowledge than others. More importantly, the results also prove the effectiveness of the knowledge attention module, which contributes to the performance gap between our model and the Feature Concatenation one.

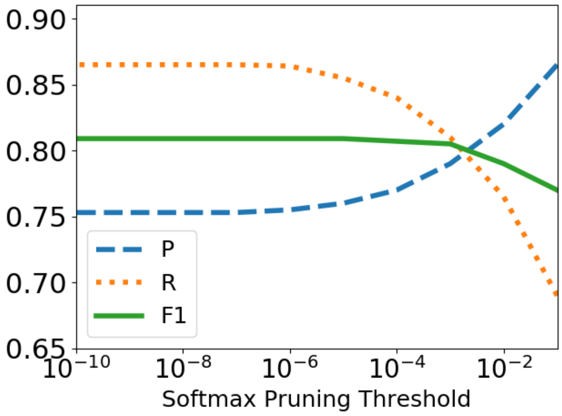

Figure 6: Effect of different pruning thresholds on model performance. With the threshold increasing, the precision increases while the recall and F1 drop.

Effect of Different Pruning Thresholds We try different thresholds t for the softmax pruning in selecting reliable candidates. The effects of different thresholds on reducing candidates and overall performance are shown in Figure 5 and 6 respectively. Along with the increase of t, both the max and the average number of pruned candidates drop quickly, so that the space complexity of the model can be reduced accordingly. Particularly, there are as much as 80% candidates can be filtered out when $t = 10^{-1}$. Meanwhile, when referring to Figure 6, it is observed that the model performs stable with the decreasing of candidate numbers. Not surprisingly, the precision rises when reducing candidate numbers, yet the recall drops dramatically, eventually results in the drop of F1. With the above observations, the reason we set $t = 10^{-7}$ as the default threshold is straightforward: on this value, one-third candidates are pruned with almost no influence on the model performance in terms of precision, recall, and the F1 score.

6 Case Study

To further demonstrate the effectiveness of incorporating knowledge into pronoun coreference resolution, two examples are provided for detailed analysis. The prediction results of the End2end model and our complete model are shown in Table 4. There are different challenges in both examples. In Example A, 'Jesus', 'man', and 'my son' are all similar (male) noun phrases matching the target pronoun '*He*'. The End2end model predicts all of them to be correct references because their context provides limited help in dis-

	Example A	Example B
Sentences	... (A large group of people) met (Jesus). (A man in the group) shouted to him: "(Teacher), please come and look at (my son). **He** is the only child I have" ...	... (My neighbor) told me that there was (an accident), and everyone else was intact, except (his father), who was in (hospital) for fractures. I comforted him first and asked (my friend) to rush me to (the hospital). (My neighbor) showed me the police report at (the hospital), which indicated **it** was all my neighbor's fault. ...
Pronoun	**He**	**it**
Candidate NPs	A large group of people, Jesus, A man in the group, Teacher, my son.	My friend, an accident, his father, hospital, my friend, the hospital, My neighbor, the hospital.
End2end	Jesus, A man in the group, my son	None
Our Model	my son	an accident

Table 4: The comparison of End2end and our model on two examples drawn from the test data. Pronouns are marked as blue bold font. Correct references are indicated in green underline font and other candidates are indicated with brackets. 'None' refers to that none of the candidates is predicated as the correct reference.

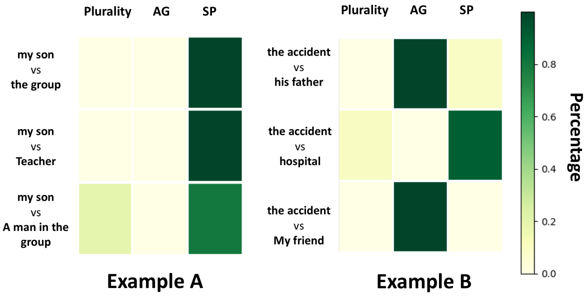

Figure 7: Heatmaps of knowledge attention for two examples, where in each example the knowledge attention weights of the correct references against other candidates are illustrated. Darker color refers to higher weight on the corresponding knowledge type.

tinguishing them. In Example B, the distance between 'an accident' and the pronoun 'it' is too far. As a result, the 'None' result from the End2end model indicates that the contextual information is not enough to make the decision. As a comparison, in our model, integrating external knowledge can help to solve such challenges, e.g., for Example A, SP knowledge helps when Plurality and AG cannot distinguish all candidates.

To clearly illustrate how our model leverages the external knowledge, we visualize the knowledge attention of the correct reference against other candidates[14] via heatmaps in Figure 7. Two interesting observations are drawn from the visualization. First, given two candidates, if they are significantly different in one feature, our model tends to pay more attention to that feature. Take AG as an example, in Example A, the AG features of all candidates consistently match the pronoun 'he' (all male/neutral). Thus the comparison between 'my son' and all candidates pay no attention to the AG feature. While in Example B, the target pronoun 'it' cannot describe human, thus 'father' and 'friend' are 0 on the AG feature while 'hospital' and 'accident' are 1. As a result, the attention module emphasizes AG more than other knowledge types. Second, The importance of SP is clearly shown in these examples. In example A, Plurality and AG features cannot help, the attention module weights higher on SP because 'son' appears 100 times as the argument of the parsed predicate 'child' in the SP knowledge base, while other candidates appear much less at that position. In example B, as mentioned above, once AG helps filtering 'hospital' and 'accident', SP plays an important role in distinguishing them because 'accident' appears 26 times in the SP knowledge base as the argument of the 'fault' from the results of the parser, while 'hospital' never appears at that position.

7 Related Work

Coreference resolution is a core task for natural language understanding, where it detects mention span and identifies coreference relations among them. As demonstrated in (Lee et al., 2017), mention detection and coreference prediction are the two major focuses of the task. Different from the general coreference task, pronoun coreference resolution has its unique challenge since the semantics of pronouns are often not as clear as normal noun phrases, in general, how to leverage the context and external knowledge to resolve the coreference for pronouns becomes its focus (Hobbs,

---

[14] Only candidates entered the second layer are considered.

1978; Rahman and Ng, 2011; Emami et al., 2018).

In previous work, external knowledge including manually defined rules (Hobbs, 1978; Ng, 2005), such as number/gender requirement of different pronouns, and world knowledge (Rahman and Ng, 2011), such as selectional preference (Wilks, 1975; Zhang and Song, 2018), have been proved to be helpful for pronoun coreference resolution. Recently, with the development of deep learning, Lee et al. (2017) proposed an end-to-end model that learns contextual information with an LSTM module and proved that such knowledge is helpful for coreference resolution when the context is properly encoded. The aforementioned two types of knowledge have their own advantages: the contextual information covers diverse text expressions that are difficult to be predefined while the external knowledge is usually more precisely constructed and able to provide extra information beyond the training data. Different from previous work, we explore the possibility of joining the two types of knowledge for pronoun coreference resolution rather than use only one of them. To the best of our knowledge, this is the first attempt that uses deep learning model to incorporate contextual information and external knowledge for pronoun coreference resolution.

8 Conclusion

In this paper, we proposed a two-layer model for pronoun coreference resolution, where the first layer encodes contextual information and the second layer leverages external knowledge. Particularly, a knowledge attention mechanism is proposed to selectively leverage features from different knowledge sources. As an enhancement to existing methods, the proposed model combines the advantage of conventional feature-based models and deep learning models, so that context and external knowledge can be synchronously and effectively used for this task. Experimental results and case studies demonstrate the superiority of the proposed model to state-of-the-art baselines. Since the proposed model adopted an extensible structure, one possible future work is to explore the best way to enhance it with more complicated knowledge resources such as knowledge graphs.

Abstract

Commonsense reasoning is fundamental to natural language understanding. While traditional methods rely heavily on human-crafted features and knowledge bases, we explore learning commonsense knowledge from a large amount of raw text via unsupervised learning. We propose two neural network models based on the Deep Structured Semantic Models (DSSM) framework to tackle two classic commonsense reasoning tasks, Winograd Schema challenges (WSC) and Pronoun Disambiguation (PDP). Evaluation shows that the proposed models effectively capture contextual information in the sentence and coreference information between pronouns and nouns, and achieve significant improvement over previous state-of-the-art approaches.

1 Introduction

Commonsense reasoning is concerned with simulating the human ability to make presumptions about the type and essence of ordinary situations they encounter every day (Davis and Marcus, 2015). It is one of the key challenges in natural language understanding, and has drawn increasing attention in recent years (Levesque et al., 2011; Roemmele et al., 2011; Zhang et al., 2017; Rashkin et al., 2018a,b; Zellers et al., 2018; Trinh and Le, 2018). However, due to the lack of labeled training data or comprehensive hand-crafted knowledge bases, commonsense reasoning tasks such as Winograd Schema Challenge (Levesque et al., 2011) are still far from being solved.

In this work, we propose two effective unsupervised models for commonsense reasoning, and evaluate them on two classic commonsense reasoning tasks: Winograd Schema Challenge (WSC) and Pronoun Disambiguation Problems (PDP). Compared to other commonsense reasoning tasks, WSC and PDP better approximate real human reasoning, and can be more easily solved by native English-speaking adults (Levesque et al., 2011). In addition, they are also technically challenging. For example, the best reported result on WSC is only 20 percentage points better than random guess in accuracy (Radford et al., 2019).

1. *The city councilmen refused the demonstrators a permit because **they** feared violence.*

   Who feared violence?

   A. **The city councilmen** B. The demonstrators

2. *The city councilmen refused the demonstrators a permit because **they** advocated violence.*

   Who advocated violence?

   A. The city councilmen B. **The demonstrators**

Table 1: Examples from Winograd Schema Challenge (WSC). The task is to identify the reference of the pronoun in bold.

Table 1 shows two examples from WSC. In order to resolve the co-reference in these two examples, one cannot predict what "***they***" refers to unless she is equipped with the commonsense knowledge that "*demonstrators usually cause violence and city councilmen usually fear violence*".

As no labeled training data is available for these tasks, previous approaches are based on either hand-crafted knowledge bases or large-scale language models. For example, Liu et al. (2017) used existing knowledge bases such as ConceptNet (Liu and Singh, 2004) and WordNet (Miller, 1995) for external supervision to train word embeddings and solve the WSC challenge. Recently, Trinh and Le (2018) first used raw text from books/news to train a neural Language Model (LM), and then em-

---

Proceedings of NAACL-HLT 2019, pages 882–891
Minneapolis, Minnesota, June 2 - June 7, 2019.

ployed the trained model to compare the probabilities of the sequences, where the pronouns are replaced by each of the candidate references, and to pick the candidate that leads to the highest probability as the answer.

Because none of the existing hand-crafted knowledge bases is comprehensive enough to cover all the world knowledge[1], we focus on building unsupervised models that can learn commonsense knowledge directly from unlimited raw text. Different from the neural language models, our models are optimized for co-reference resolution and achieve much better results on both the PDP and WSC tasks.

In this work we formulate the two commonsense reasoning tasks in WSC and PDP as a pairwise ranking problem. As the first example in Table 1, we want to develop a pair-wise scoring model $\text{Score}_\theta(x_i, y)$ that scores the correct antecedent-pronoun pair ("*councilmen*", "*they*") higher than the incorrect one ("*demonstrators*", "*they*"). These scores depend to a large degree upon the contextual information of the pronoun (e.g., they) and the candidate antecedent (e.g., councilmen). In other words, it requires to capture the semantic meaning of the pronoun and the candidate antecedent based on the sentences where they occur, respectively.

To tackle this issue, we propose two models based on the framework of Deep Structured Similarity Model (DSSM) (Huang et al., 2013), as shown in Figure 1(a). Formally, let S^x be the sentence containing the candidate antecedent x_i and S^y the sentence containing the pronoun y which we're interested in. DSSM measures the semantic similarity of a pair of inputs (x_i, y) by 1) mapping x_i and y, together with their context information, into two vectors in a semantic space using deep neural networks f_1 and f_2, parameterized by θ; and 2) computing cosine similarity[2] between them. In our case, we need to learn a task-specific semantic space where the distance between two vectors measures how likely they co-refer. Commonsense knowledge such as "demonstrators usually cause violence" can be implicitly captured in the semantic space through DSSM, which is trained on a large amount of raw text.

DSSM requires labeled pairs for training.Since there is no labeled data for our tasks, we propose two unsupervised DSSMs, or UDSSMs. As shown in Figure 1(b) and 1(c), $(\mathbf{S}^x, \mathbf{S}^y)$ are encoded into contextual representations by deep neural networks f_1 and f_2; then we compute pair-wise their co-reference scores.

In what follows, we will describe two assumptions we propose to harvest training data from raw text. **Assumption I: A pronoun refers to one of its preceding nouns in the same sentence.** The sentences generated by this assumption will be used for training UDSSM-I. Some examples will be shown in the "data generation" section. **Assumption II: In a sentence, pronouns of the same gender and plurality are more likely to refer to the same antecedent than other pronouns.** Similarly, the sentences following the assumption will be used for training UDSSM-II.

Note that the two models, UDSSM-I and UDSSM-II are trained on different types of pairwise training data, thus the model structures are different, as illustrated in Figure 1(b) and 1(c), respectively. Experiments demonstrated that our methods outperform stat-of-the-art performance on the tasks of WSC and PDP.

2 Related Work

As a key component of natural language understanding, commonsense reasoning has been included in an increasing number of tasks for evaluation: COPA (Roemmele et al., 2011) assesses commonsense causal reasoning by selecting an alternative, which has a more plausible causal relation with the given premise. Story Cloze Test (ROCStories, Mostafazadeh et al. 2016) evaluates story understanding, story generation, and script learning by choosing the most sensible ending to a short story. JOCI (Zhang et al., 2017) generalizes the natural language inference (NLI) framework (Cooper et al., 1996; Dagan et al., 2006; Bowman et al., 2015; Williams et al., 2018) and evaluates commonsense inference by predicting the ordinal likelihood of a hypothesis given a context. Event2Mind (Rashkin et al., 2018b) models stereotypical intents and reactions of people, described in short free-form text. SWAG (Zellers et al., 2018) frames commonsense inference as multiple-choice questions for follow-up events given some context. ReCoRD (Zhang et al., 2018)

---

[1] We don't believe it is possible to construct such a knowledge base given that the world is changing constantly.

[2] DSSMs can be applied to a wide range of tasks depending on the definition of (x, y). For example, (x, y) is a query-document pair for Web search ranking, a document pair in recommendation, a question-answer pair in QA, and so on. See Chapter 2 of (Gao et al., 2018) for a survey.

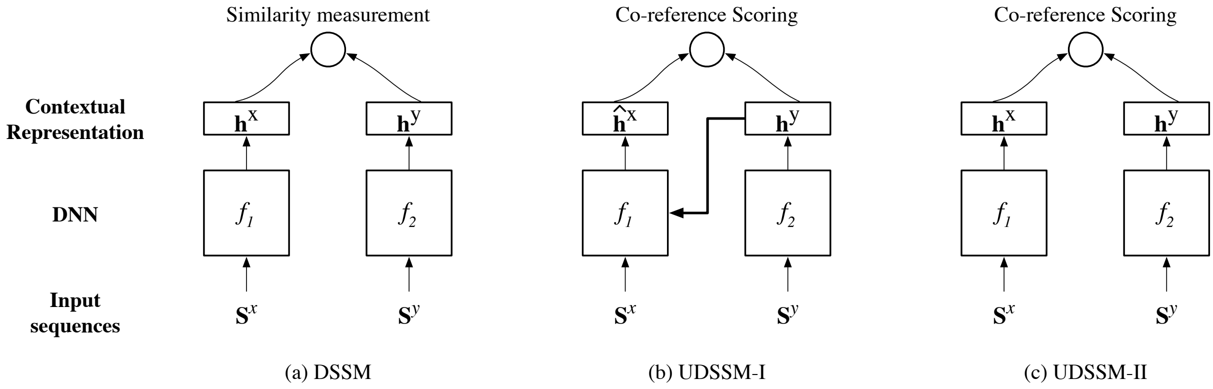

Figure 1: An overview of (a) the general framework of Deep Structured Semantic Model (DSSM) and our two unsupervised models based on DSSM: (b) UDSSM-I and (c) UDSSM-II. Compared with DSSM, both UDSSM-I and UDSSM-II compute co-reference scores instead of similarity.

evaluates a machine's ability of commonsense reasoning in reading comprehension.

Among all these commonsense reasoning tasks, the Winograd Schema Challenge (WSC) and Pronoun Disambiguation Problems (PDP) (Levesque et al., 2011) are known as the most challenging tasks for commonsense reasoning. Although both tasks are based on pronoun disambiguation, a subtask of coreference resolution (Soon et al., 2001; Ng and Cardie, 2002; Peng et al., 2016), PDP and WSC differ from normal pronoun disambiguation due to their unique properties, which are based on commonsense, selecting the most likely antecedent from both candidates in the directly preceding context.

Previous efforts on solving the Winograd Schema Challenge and Pronoun Disambiguation Problems mostly rely on human-labeled data, sophisticated rules, hand-crafted features, or external knowledge bases (Peng et al., 2015; Bailey et al., 2015; Schüller, 2014). Rahman and Ng (2012) hired workers to annotate supervised training data and designed 70K hand-crafted features. Sharma et al. (2015); Schüller (2014); Bailey et al. (2015); Liu et al. (2017) utilized expensive knowledge bases in their reasoning processes. Recently, Trinh and Le 2018 applied neural language models trained with a massive amount of unlabeled data to the Winograd Schema Challenge and improved the performance by a large margin. In contrast, our unsupervised method based on DSSM significantly outperforms the previous state-of-the-art method, with the advantage of capturing more contextual information in the data.

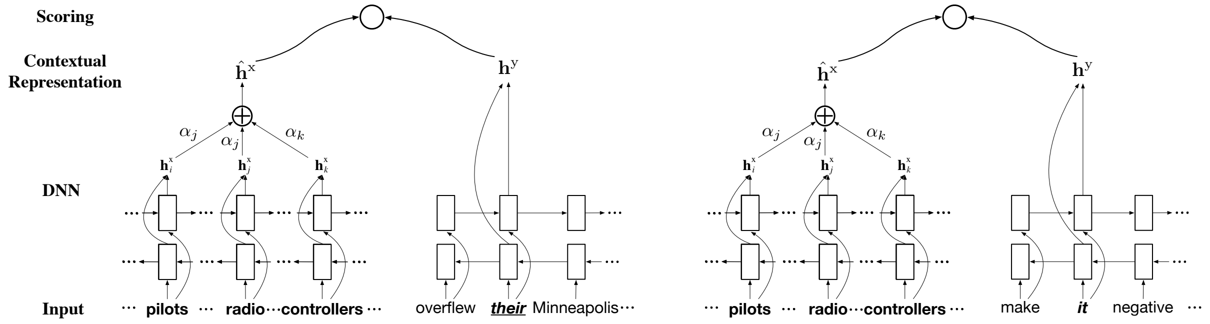
3 Approach

As shown in Figure 1, we propose two unsupervised deep structured semantic models (**UDSSM-I** and **UDSSM-II**), which consist of two components: DNN encoding and co-reference scoring. For the model UDSSM-I, the co-referred word pairs are automatically learned through an attention mechanism, where the attention weights are the co-reference scores for word pairs. For the second model UDSSM-II, we will directly optimize the co-reference score during training. After all, we will get the co-reference scoring function, $\text{Score}_\theta(x_i, y)$, to compare the candidate answers in the tasks of PDP/WSC. Next, we will show the details of our models trained in an unsupervised way.

In the following sections, we will use uppercase symbols in bold, e.g., $\mathbf{S}^\text{x}$, to represent matrices. Lowercase symbols in bold, e.g., $\mathbf{h}^\text{x}$, represent vectors. A regular uppercase symbol, e.g., S^x, represents a lexical sequence. A regular lowercase symbol, e.g., x_i or y, represents a token.

3.1 UDSSM-I Model

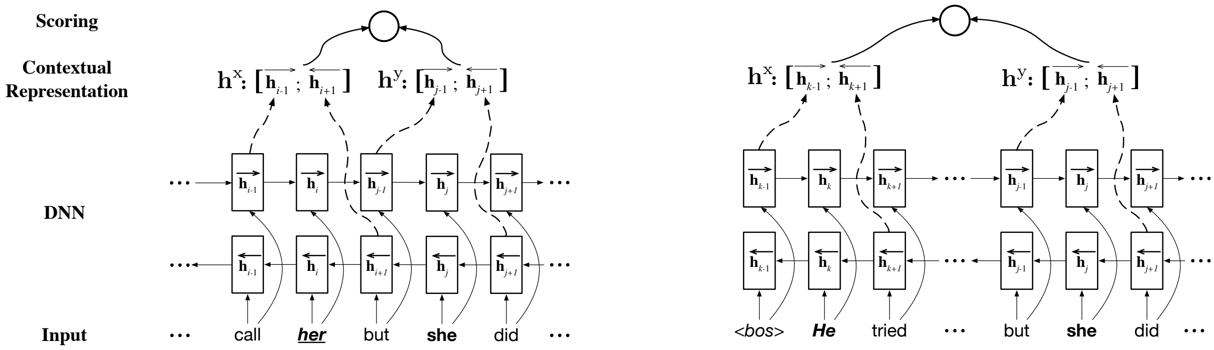
This model is developed based on Assumption I. Its architecture is shown in Figure 2. The sentences generated based on this assumption contain a pronoun y and a set of its preceding nouns $\{x_i, x_j ...\}$, which includes the referred word by pronoun. For example, the sentence in Figure 2. As there is no clear label for the co-referred word pairs under this assumption, our model will rank the set of nouns $\{x_i, x_j ...\}$ which contains the noun that the pronoun y refers to higher than the set which does not. And the co-reference score between words will not be optimized directly during



(a) Positive example

(b) Negative example

Figure 2: The procedure of using UDSSM-I to compute the co-reference scores of a positive example and a negative example respectively. The positive example is generated from the sentence '*Two **Northwest Airlines pilots** failed to make **radio contact** with **ground controllers** for more than an hour and overflew **their** Minneapolis destination by 150 miles before discovering the mistake and turning around.*". The negative one replaces the second sequence with one sequence from different sentence.



(a) Positive example

(b) Negative example

Figure 3: The procedure of using UDSSM-II to compute the co-reference scores of a positive example and a negative example respectively. Both examples are generated from the sentence "*He tried twice to call her but she did not answer the phone*".

training, but is learned indirectly through the attention mechanism. We will describe in turn how the training data is generated from raw text, the model architecture, and the co-reference scoring function for the final prediction on the tasks of PDP/WSC.

3.1.1 Data Generation

The main challenge of PDP/WSC tasks is that it has no labeled training data. Here we introduce a simple method to collect unsupervised training data by leveraging some linguistic patterns. Following Assumption 1, the first hypothesis we make is that "the pronoun refers to one of the preceding nouns", which is a common phenomenon in well-written stories or news. In this way, we generate (S^{x}, S^{y}) pairs from raw text as follows:

- Parse the sentences in the raw text to obtain entity names, nouns and pronouns.
- Pick sentences that contain at least one pronoun and multiple nouns preceding it.
- Split each sentence into two sub-sentences to form a positive pair (S^{x}, S^{y}), where S^{x} is the first sub-sentence with identified nouns and entity names while S^{y} is the second sub-sentence with a pronoun.
- One or more negative pairs are generated from (S^{x}, S^{y}) by replacing S^{y} with $S^{\mathrm{y}_{neg}}$ randomly sampled from other positive pairs.

We split the sentence with pronouns and nouns into two sub-sequences separated by the previous word of the pronoun. Therefore, the example sentence in the Figure 2 can be split into two sub-sentences as shown below:

- S^{x}: " **Two Northwest Airlines pilots** failed to make **radio contact** with **ground controllers** for more than an hour and"

- S^{y}: "overflew **their** Minneapolis destination by 150 miles before discovering the mistake and turning around".

As the sentences are collected from raw text, the co-reference words are not given. Our proposed UDSSM-I model will learn the co-reference scoring function through attention mechanism based on the generated sequence pairs. Next, we will introduce the details of this model.

3.1.2 Model Architecture

This method takes the pair of sequences, (S^{x}, S^{y}), as inputs, and computes similarity between the sequences collected from the same sentence. As we hypothesize that one of the nouns in the first sequence and the pronoun in the second are co-referred, we only use the contextual representations of nouns and pronoun to represent the sequences. To obtain the contextual representation, we first use a bi-directional LSTM to process these sequences [3]:

$$\mathbf{H}^{\mathrm{x}} = \text{Bi-LSTM}(\mathbf{S}^{\mathrm{x}}), \mathbf{H}^{\mathrm{y}} = \text{Bi-LSTM}(\mathbf{S}^{\mathrm{y}}), \tag{1}$$

where $\mathbf{S}^{\mathrm{x}} \in \mathbb{R}^{d \times X}$, $\mathbf{S}^{\mathrm{y}} \in \mathbb{R}^{d \times Y}$ are the word embeddings of the two sequences. d is the dimension of the word embeddings. X, Y are the lengths of the two sequences. $\mathbf{H}^{\mathrm{x}} \in \mathbb{R}^{l \times X}$ and $\mathbf{H}^{\mathrm{y}} \in \mathbb{R}^{l \times Y}$ are the hidden states of bi-directional LSTM. Our model is task-specifically constructed, so we directly use the hidden state of the first pronoun in the second sequence as its representation:

$$f_2(S^y) = \mathbf{h}^{\mathrm{y}} = \mathbf{h}^{\mathrm{y}}_2, \tag{2}$$

where $\mathbf{h}^{\mathrm{y}}_2 \in \mathbb{R}^{\mathrm{l}}$ is the second[4] vector from $\mathbf{H}^{\mathrm{y}}$ and it represents the contextual information of the pronoun. Next, we will get the representation of the first sequence. As there are multiple nouns in the first sequence and the pronoun usually refers to only one of them, we use the weighted sum of all the LSTM hidden states of the nouns to represent the sequence, $\hat{\mathbf{h}}^{\mathrm{x}} \in \mathbf{R}^{l}$, as follows:

$$\begin{aligned}
\mathbf{H}^{\mathrm{n}} &= [\mathbf{h}^{\mathrm{x}}_i; \mathbf{h}^{\mathrm{x}}_j; ...] \\
\alpha &= \text{SoftMax}\left((\mathbf{W}^{\mathrm{g}}\mathbf{H}^{\mathrm{n}} + \mathbf{b}^{\mathrm{g}} \otimes \mathbf{e}_N)^{\mathrm{T}}\mathbf{h}^{\mathrm{y}}\right), \\
f_1(S^x) &= \hat{\mathbf{h}}^{\mathrm{x}} = \mathbf{H}^{\mathrm{n}}\alpha,
\end{aligned} \tag{3}$$

where $i, j...$ are the positions of the nouns in the sequence S^x and $[;]$ is the concatenation of two vectors. $\mathbf{H}^{\mathrm{n}} \in \mathbb{R}^{l \times N}$ are all the hidden states of the nouns[5] in $\mathbf{H}^{\mathrm{x}}$ in the sequence. N is the number of nouns in the sequence. $\alpha \in \mathbb{R}^{N}$ is the weights assigned for the different nouns and $\hat{\mathbf{h}}^{\mathrm{x}} \in \mathbb{R}^{l}$ is the weighted sum of all the hidden states of the nouns. $\mathbf{W}^{\mathrm{g}} \in \mathbb{R}^{l \times l}$ and $\mathbf{b}^{\mathrm{g}} \in \mathbb{R}^{l}$ are the parameters to learn; $\mathbf{e}_N \in \mathbb{R}^{\mathrm{N}}$ is a vector of all 1s and it is used to repeat the bias vector N times into the matrix. Then we will maximize the similarity of the contextual representations of ($\hat{\mathbf{h}}^{\mathrm{x}}, \mathbf{h}^{\mathrm{y}}$). Meanwhile, we also need some negative samples $\mathbf{h}^{\mathrm{y}_{neg}}_k$ for $\hat{\mathbf{h}}^{\mathrm{x}}$. Then our loss function for this method is constructed:

$$L = -\log\left(\frac{\exp\left(\hat{\mathbf{h}}^{\mathrm{x}}\mathbf{h}^{\mathrm{y}}\right)}{\exp\left(\hat{\mathbf{h}}^{\mathrm{x}}\mathbf{h}^{\mathrm{y}}\right) + \sum_k^K \exp\left(\hat{\mathbf{h}}^{\mathrm{x}}\mathbf{h}^{\mathrm{y}_{neg}}_k\right)}\right), \tag{4}$$

where $\mathbf{h}^{\mathrm{y}_{neg}}_k \in \mathbb{R}^{l}$ is the randomly sampled hidden state of pronoun from the sequences not in the same sentence with S^y.

3.1.3 Co-reference Scoring Function

Overall, the model tries to make the co-reference states similar to each other. The co-reference scoring function is defined:

$$\text{Score}_\theta(x_i, y) = g(\mathbf{h}^{\mathrm{x}}_i, \mathbf{h}^{\mathrm{y}}) = (\mathbf{W}^{\mathrm{g}}\mathbf{h}^{\mathrm{x}}_i + \mathbf{b}^{\mathrm{g}})^{\mathrm{T}}\mathbf{h}^{\mathrm{y}}, \tag{5}$$

where the candidate located at the i-th position is represented by its LSTM hidden state $\mathbf{h}^{\mathrm{x}}_i$ and the pronoun in the snippet is represented by $\mathbf{h}^{\mathrm{y}}$. And the output value of this function for each candidate will be used for the final prediction. Next, we will introduce the other unsupervised method.

3.2 UDSSM-II Model

This model is developed based on Assumption II. Its architecture is shown in Figure 3. As the model is similar to the previous one, we will introduce the details in a similar way.

3.2.1 Data Generation

The second assumption is that "the pronoun pairs in a single sentence are co-reference words if they are of the same gender and plurality; otherwise they are not." Based on this assumption, we can directly construct the co-reference training pairs as follows:

---

[3] We use two different LSTMs to process the sequences S^{x} and S^{Y} here. This is to make the negative sampling in Eqn. (4) more efficient, so that we can directly use the other representations in the same batch as negative ones.

[4] We assign the word just before the pronoun to the second sequence, so the pronoun always appears in the second position of the sequence.

[5] We use the toolkit of spaCy in Python for POS and NER, and we will remove the sequences that contain less than 2 nouns.

- Parse the raw sentences to identify pronouns.
- Pick sentences that contain at least two pronouns.
- The sub-sequence pair with pronouns of the same gender and plurality is labeled as a positive pair; otherwise it is labeled as negative.
- Replace the corresponding pronoun pairs with a special token "**@Ponoun**".

Take the following sentence as an example: "**He** tried twice to call **her** but **she** did not answer the phone." There are three pronouns detected in the sentence, and we assume that the words **her** and **she** are co-reference words, while pairs (**she**, **He**) and (**her**, **He**) are not. Thus we can obtain three training examples from the given sentence. However, in the PDP and WSC tasks, models are asked to compute the co-reference scores between pronoun and candidate nouns, instead of two pronouns. Therefore, we replace the first pronoun in the sentence with a place holder; i.e., a negative training pair is generated by splitting the raw sentence into the following two sub-sequences:

- S^{x}: " **@Ponoun** tried twice to call her"
- S^{y}: "but **she** did not answer the phone."
- label: Negative

and the positive training pair can be generated by the same way:

- S^{x}: " He tried twice to call **@Ponoun**"
- S^{y}: "but **she** did not answer the phone."
- label: Positive

Thus, we could directly train the encoder and co-reference scoring components through the generated training pairs.

3.2.2 Model Architecture

The previous method, UDSSM-I, follows the task setting of PDP/WSC, and builds the model based on the similarity of the representations between nouns and the pronoun. As there is no signal indicating the exact alignment between co-reference words, the model tries to learn it based on the co-occurrence information from large scale unlabelled corpus. For the method of UDSSM-II, each representation pair $(\mathbf{h}^{\text{x}}, \mathbf{h}^{\text{y}})$ has a clear signal, r, indicating whether they are co-referred or not. For simplicity, we do not have to split the sentence into two parts. We first use LSTM to process the sentence as follows:

$$\overrightarrow{\mathbf{H}} = \overrightarrow{\text{LSTM}}([\mathbf{S}^{\text{x}}; \mathbf{S}^{\text{y}}]), \overleftarrow{\mathbf{H}} = \overleftarrow{\text{LSTM}}([\mathbf{S}^{\text{x}}; \mathbf{S}^{\text{y}}]), \quad (6)$$

where we can concatenate the word embeddings, $[\mathbf{S}^{\text{x}}; \mathbf{S}^{\text{y}}]$, of two sequences collected under Assumption II. $\overrightarrow{\text{LSTM}}$ and $\overleftarrow{\text{LSTM}}$ are built in different directions, and $\overrightarrow{\mathbf{H}}$, $\overleftarrow{\mathbf{H}}$ are the hidden states of the corresponding LSTM. Suppose that the pronoun pair in the sentence are located at the i-th and j-th positions as shown in the bottom part of Figure 3(a). We use the hidden states around the pronouns as their contextual representations as follows:

$$f_1(S^x) = \mathbf{h}^{\text{x}} = \begin{bmatrix} \overrightarrow{\mathbf{h}_{i-1}} \\ \overleftarrow{\mathbf{h}_{i+1}} \end{bmatrix}, f_2(S^y) = \mathbf{h}^{\text{y}} = \begin{bmatrix} \overrightarrow{\mathbf{h}_{j-1}} \\ \overleftarrow{\mathbf{h}_{j+1}} \end{bmatrix}, \quad (7)$$

where $\begin{bmatrix} \cdot \\ \cdot \end{bmatrix}$ is the concatenation of all the vectors inside it. Then we further concatenate these representation pair:

$$\mathbf{h}^c = \begin{bmatrix} \mathbf{h}^{\text{x}} \\ \mathbf{h}^{\text{y}} \end{bmatrix}, \quad (8)$$

where $\mathbf{h}^c \in \mathbb{R}^{4l}$, and it will be the input of loss function with cross entropy as follows:

$$\begin{aligned} L &= -r \log\left(\frac{\exp(\mathbf{w}^p \mathbf{h}^c)}{\exp(\mathbf{w}^p \mathbf{h}^c) + \exp(\mathbf{w}^n \mathbf{h}^c)}\right) \\ &- (1-r) \log\left(\frac{\exp(\mathbf{w}^n \mathbf{h}^c)}{\exp(\mathbf{w}^p \mathbf{h}^c) + \exp(\mathbf{w}^n \mathbf{h}^c)}\right), \end{aligned}$$

where $r \in \{0, 1\}$ indicates whether the pronouns at the m-th and n-th positions should be considered co-reference or not. $\mathbf{w}^p \in \mathbb{R}^{4l}$ and $\mathbf{w}^n \in \mathbb{R}^{4l}$ are the parameters to learn.

3.2.3 Co-reference Scoring Function

Similar to the Eqn.(5), for each candidate, we use co-reference scoring function $\text{Score}_\theta(x_i, y)$ for the answer selection:

$$\text{Score}_\theta(x_i, y) = g(\mathbf{h}_i^{\text{x}}, \mathbf{h}^{\text{y}}) = \mathbf{w}^p \begin{bmatrix} \overrightarrow{\mathbf{h}_{i-1}} \\ \overleftarrow{\mathbf{h}_{i+1}} \\ \overrightarrow{\mathbf{h}_{j-1}} \\ \overleftarrow{\mathbf{h}_{j+1}} \end{bmatrix}, \quad (9)$$

where i is the position of the candidate in the sentence and j is the position of the pronoun.

	PDP	WSC

Table 2: The experiment results on PDP and WSC datasets. We compare our models to Goolge LM trained on the same corpus [6].

4 Experiments

In this section, we will introduce the datasets to train and evaluate our models for commonsense reasoning, the hyper-parameters of our model, and the analysis of our results.

4.1 Datasets

Training Corpus We make use of the raw text from Gutenberg [7], a corpus offerring over 57,000 free eBooks, and 1 Billion Word [8], a corpus of news, to train our model. We first ignore the sentences that contain less than 10 tokens or longer than 50 tokens. Then, for the model UDSSM-I, we collect all the sentences with the pronoun before which there're at least two nouns. For UDSSM-II, we collect all the sentences with at least 2 pronouns. In total, we collect around 4 million training pairs from each corpus for our proposed method respectively, and we split 5% as validation set.

Evaluation Dataset We evaluate our model on the commonsense reasoning datasets, Pronoun Disambiguation Problems (PDP) [9] and Winograd Schema challenges (WSC) [10], which include 60 and 285 questions respectively. Both of the tasks are constructed for testing commonsense reasoning and all the questions from these challenges are obvious for human beings to solve with commonsense knowledge, but hard for machines to solve with statistical techniques.

4.2 Experimental Setting

We use the same setting for both our models. The hidden state dimension of a single-directional LSTM is set to be 300. We use 300 dimensional GloVe embeddings [11] for initialization. We use Adamax to optimise the model, set learning rate to be 0.002, dropout rate on all layers are tuned from [0, 0.1, 0.2] and the batch size from [30, 50, 100, 200]. For the model UDSSM-I, in one batch, we treat all sequence pairs not from the same sentence as negative cases. And it takes around 30 hours on a single K40 GPU to train our models, which are much faster than training a large LM (Jozefowicz et al., 2016) taking weeks on multiple GPUs.

---

[6] The best models reported in the works of Radford et al. (2019) and Trinh and Le (2018) are trained on a much larger corpus from Common Crawl.

[11] `https://github.com/stanfordnlp/GloVe`

4.3 Experimental Results

The experiment results are shown in Table 2. Most of the performance in the top of the Table 2 are the models trained with external knowledge bases, such as Cause-Effect (Liu et al., 2016), WordNet (Miller, 1995), ConceptNet (Liu and Singh, 2004) knowledge bases. Unsupervised Semantic Similarity Method (USSM) (Liu et al., 2017) is based on the skip-gram model (Mikolov et al., 2013) to train word embeddings and the embeddings of all the words connected by knowledge bases are optimized to be closer. Neural Knowledge Activated Method (NKAM) (Liu et al., 2017) trained a binary classification model based on whether the word pairs appear in the knowledge base. One limitation of these methods is that they rely heavily on the external knowledge bases. Another limitation is that they just linearly aggregate the embeddings of the words in the context, and that's hard to integrate the word order information. Instead, our model with LSTM can better represent the contextual information. Besides, our model don't need any external knowledge bases, and achieve a significant improvement on both of the datasets.

We further compare our models with the unsupervised baselines, ELMo (Peters et al., 2018) which selects the candidate based on the cosine similarity of the hidden states of noun and pronoun. Another unsupervised baseline, Google Language Model for commonsense reasoning (Trinh and Le, 2018), which compares the perplexities of the new sentences by replacing the pronoun with candidates. To make a fair comparison to Trinh and Le (2018)'s work, we also train our single model on the corpus of Gutenberg only. We can see that both of our methods get significant improvement on the PDP dataset, and our UDSSM-II can achieve much better performance on the WSC dataset. We also report our ensemble model (nine models with different hyperparameters) trained with both corpus of Gutenberg and 1 Billion Word, and it also achieve better performance than Google Language Model trained with the same corpus.

Finally, we also compare to the pre-trained Coreference Resolution Tool (Clark and Manning, 2016a,b)[12], and we can see that it doesn't adapt to our commonsense reasoning tasks and can't tell the difference between each pair of sentences from WSC. In this way, our model can get much better performance.

4.4 Analysis

WSC 1:	**Paul** tried to call George on the phone, but **he** wasn't successful.
Ours 1:	**He** tried to call 911 using her cell phone but that **he** could n't get the phone to work.
WSC 2:	Paul tried to call **George** on the phone, but **he** was n't available .
Ours 2:	He tried twice to call **her** but **she** did not answer the phone .

Table 3: Comparison of the data from WSC and our training data. Our sentences are retrieved from the UDSSM-II training dataset based on the BM25 value for analysis. The pseudo labels in our training data can help identify the co-references in WSC.

In this subsection, we will conduct further analysis on the reason that our models work, the benefit of our models comparing to a baseline, and the limitation of our proposed models.

We have a further analysis on the pair-wise sentences, which we collected for training, to check how our model can work. We find that some reasoning problems can somehow be converted to the paraphrase problem. For example, in Table 3, we make use of Lucene Index[13] with BM25 to retrieve the similar sentences to the WSC sentences from our training dataset, and make a comparison. We can see that these pairs are somehow paraphrased each other respectively. For the first pair, the contextual representations of "Paul" and "he" in WSC could be similar to the contextual representations of "he" in our training sentence. As these representations are used to compute the co-reference score, the final scores would be similar. The pseudo label "positive" for our first sentence will make the positive probability of the golden co-references "Paul" and "he" in WSC higher. And for the second pair in Table 3, the pseudo label of positive in our second sentence will make the positive probability of the golden co-references "George" and "he" in WSC 2 higher. In this way, these kinds of co-reference patterns from training data can be directly mapped to solve the Winograd Schema Challenges.

---

[12] `https://github.com/huggingface/neuralcoref`

[13] `http://lucene.apache.org/pylucene/`

Here's another example from PDP demonstrating the benefit of our method: "Always before, Larry had helped Dad with his work. But *he* could not help him now, for Dad said that ". Trinh and Le (2018) failed on this one, probably because language models are not good at solving long distance dependence, and tends to predict that "he " refers to "his" in the near context rather the correct answer "Larry". And our model can give the correct prediction.

We further analysis the predictions of our model. We find that some specific commonsense knowledge are still hard to learn, such as the following pairs:

- The trophy doesn't fit into the brown **suitcase** because **it** is too small.
- The **trophy** doesn't fit into the brown suitcase because **it** is too large.

To solve this problem, the model should learn the knowledge to compare the size of the objects. However, all of our models trained with different hyper-parameters select the same candidate as the co-referred word for "it" in both sentences. To solve the problem, broader data need to collect for learning more commonsense knowledge.

5 Conclusion

In conclusion, to overcome the lack of human labeled data, we proposed two unsupervised deep structured semantic models (UDSSM) for commonsense reasoning. We evaluated our models on the commonsense reasoning tasks of Pronoun Disambiguation Problems (PDP) and Winograd Schema Challenge (Levesque et al., 2011), where the questions are quite easy for human to answer, but quite challenging for the machine. Without using any hand-craft knowledge base, our model achieved stat-of-the-art performance on the two tasks.

In the future work, we will use Transformer, which is proved to be more powerful than LSTM, as the encoder of our unsupervised deep structured semantic models, and we will collect a larger corpus from Common Crawl to train our model.

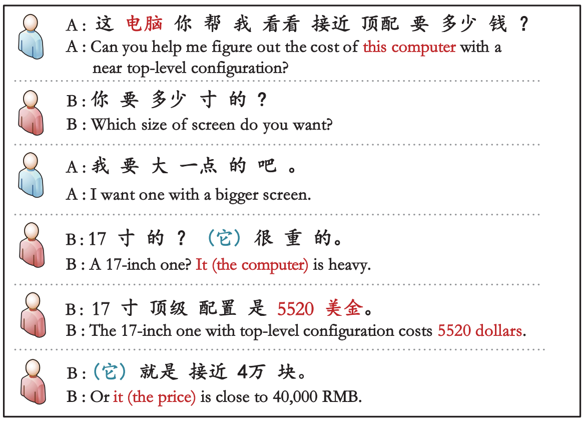
Abstract

Pronouns are often dropped in Chinese sentences, and this happens more frequently in conversational genres as their referents can be easily understood from context. Recovering dropped pronouns is essential to applications such as Information Extraction where the referents of these dropped pronouns need to be resolved, or Machine Translation when Chinese is the source language. In this work, we present a novel end-to-end neural network model to recover dropped pronouns in conversational data. Our model is based on a structured attention mechanism that models the referents of dropped pronouns utilizing both sentence-level and word-level information. Results on three different conversational genres show that our approach achieves a significant improvement over the current state of the art.

1 Introduction

Chinese is a pro-drop language, meaning that it is not always necessary to have an overt pronoun when the referent is clear from the context. This is in contrast with a non-pro-drop language like English, where an overt pronoun is always needed. For example, Kim (2000) shows that an overt subject is used only in 64% of the cases in Chinese while that percentage is over 96% in English.

Even in pro-drop languages like Chinese, pronouns are omitted to different degrees in different genres. Pronouns are dropped more often in informal conversational genres than in formal genres like newswire. Recovering these dropped pronouns (DPs) is important to applications such as Machine Translation where dropped pronouns need to be made explicit when Chinese is translated into a target language (Wang et al., 2016a,b, 2018) or Information Extraction where relations might involve entities referred to by these DPs.



A : 这 电脑 你 帮 我 看看 接近 顶配 要 多少 钱 ?
A : Can you help me figure out the cost of this computer with a near top-level configuration?

B : 你 要 多少 寸 的 ?
B : Which size of screen do you want?

A : 我 要 大 一点 的 吧 。
A : I want one with a bigger screen.

B : 17 寸 的 ? （它） 很 重 的。
B : A 17-inch one? It (the computer) is heavy.

B : 17 寸 顶级 配置 是 5520 美金。
B : The 17-inch one with top-level configuration costs 5520 dollars.

B : （它） 就是 接近 4万 块。
B : Or it (the price) is close to 40,000 RMB.

Figure 1: An example conversation between two people. The first dropped pronoun refers to "this computer" in the first sentence and is translated into "it" in English. It needs to be recovered from the wider context.

More concretely, recovering DPs involves i) first locating the position in a sentence where a pronoun is dropped, and ii) determining the type of the pronoun that is dropped. This is illustrated in Figure 1, where the recovered dropped pronouns are in parenthesis. Both instances of dropped pronouns can be replaced with the overt pronoun 它 ("it"), but they refer to different things in the conversation. Dropped pronoun recovery is different from zero pronoun (ZP) resolution (Chen and Ng, 2015; Yin et al., 2017, 2018) where the focus is on resolving an anaphoric pronoun to its antecedent, assuming the position of the zero pronoun is already determined. Here we do not attempt to resolve the dropped pronoun to its referent. Dropped pronoun recovery can thus be viewed as the first step of zero pronoun resolution, but this task is also important in its own right. In applications like machine translation, dropped pronouns only need to be identified and translated correctly but they do not need to be resolved.

Traditionally dropped pronoun recovery has

Minneapolis, Minnesota, June 2 - June 7, 2019.

been formulated as a sequence labeling problem where each word in the sentence receives a tag that indicates whether the word has a dropped pronoun before it and which pronoun is dropped. Yang et al. (2015) leverages lexical, contextual and syntactic features to detect DPs before each word from a predefined list of pronouns. Giannella et al. (2017) utilizes a linear-chain conditional random field (CRF) classifier to simultaneously predict the position as well as the person number of a dropped pronoun based on lexical and syntactic information. These featured-based methods require labor-intensive feature engineering.

In contrast, Zhang et al. (2016) uses a multi-layer perceptron based neural network model to recover dropped pronouns, which eliminates the need for feature engineering. The input to their model is a context embedding constructed by concatenating the embeddings of word tokens in a fixed-length window. However, the referent of a dropped pronoun that provides crucial information to determine the identity of a pronoun is typically found outside the local context of the dropped pronoun, and thus cannot be effectively modeled with a window-based multi-layer perceptron model. For example, in Figure 1 the referent of the first dropped pronoun, the third person singular pronoun 它 (“it”) is 电脑 (“computer”), which appears in the very first utterance, several utterances before the pro-drop sentence. Therefore, long-distance contextual information needs to be captured in order to determine the type of the dropped pronoun.

In this paper, we describe a novel Neural Dropped Pronoun Recovery framework, named NDPR that can model the referent information in a much larger context. The model makes use of contextual information at two levels of granularity: the sentence level and the word level. An illustration of the NDPR framework is given in Figure 2. The referent modeling process is implemented with a structured attention mechanism. For each word token in the pro-drop sentence, the model attends to the utterance in which the referent of the dropped pronoun is mentioned by sentence attention and then zeros in to the referent by word attention. The resulting referent representation is combined with the representation of the dropped pronoun to make the final prediction on the location and type of the dropped pronoun. We demonstrate the effectiveness of our proposed model on three Chinese conversational datasets and results show that our approach outperforms the current state of the art by a fairly large margin.

We also perform ablation studies to explore the contribution of the different components of our model. We show that word-level attention is more effective in recovering *concrete* pronouns because it serves as a matching mechanism that matches the representation of the dropped pronoun against that of the DP referent. In contrast, sentence-level attention can be considered as an auxiliary tool for word-level attention to improve model accuracy by filtering out irrelevant referents. All code is available at `https://github.com/ningningyang/NDPR`.

Our contributions are summarized as follows:

- We propose a novel attention-based neural network to recover dropped pronouns in Chinese conversational data by modeling their referent.
- We evaluate our system on three conversational genres and show that our model consistently outperforms the state of the art by a large margin on all three datasets.
- We also present experimental results that demonstrate the effectiveness of various components in our framework and analyze some mistakes made by our model on each dataset.

2 Related Work

2.1 Dropped pronoun recovery.

Dropped pronoun detection originates from Empty Category (EC) detection and resolution, a task aimed to recover certain dropped elements in syntactic treebanks (Chung and Gildea, 2010; Cai et al., 2011; Xue and Yang, 2013). Dropped pronoun recovery was first proposed as an independent task in (Yang et al., 2015), which leveraged a set of specially designed features to recover DPs in Chinese text messages. Giannella et al. (2017) employed a linear-chain CRF classifier to jointly determine the position and person number of dropped pronouns in Chinese SMS messages using hand-crafted features. These traditional feature-based methods require heavy feature engineering. Zhang et al. (2016) for the first time utilized a multi-layer perceptron model to recover dropped pronouns. Each word is expressed as a concatenation of embeddings of word tokens in a fixed-length window. This method can not resolve the cases when

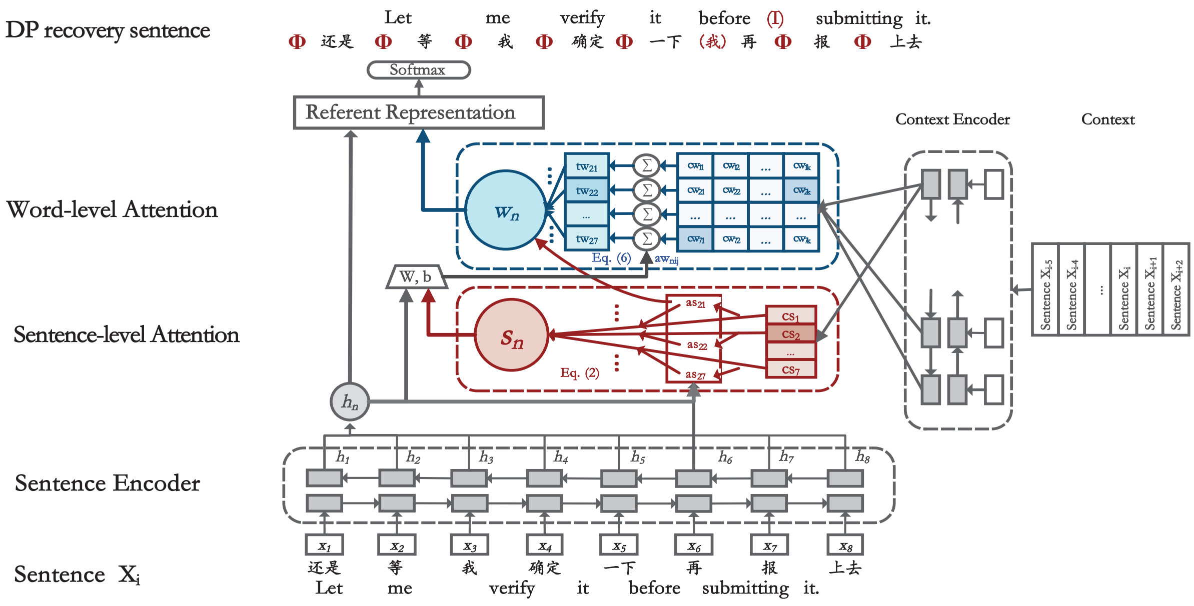

Figure 2: Neural Dropped Pronoun Recovery Framework.

referents are outside the local context, which is a common occurrence in conversational data. There has also been some work that attempts to recover dropped pronoun in pro-drop languages to help Machine Translation (Wang et al., 2016a,b, 2018). There are some inherent differences between their work and ours. In their work, they attempt to create training data by projecting pronouns from another language to Chinese, and the specific location of a dropped pronoun may not matter as much as long as it is translated correctly when Chinese is the source language. In contrast, we focus on recovering DPs from conversational context, and determining the correct position of a dropped pronoun is critical part of the task.

2.2 Zero pronoun resolution.

A line of research that is closely related to our task is zero pronoun (ZP) resolution, which aims to resolve Chinese pronouns to their antecedents. Converse and Palmer (2006) presented a rule-based method to resolve ZP by utilizing the Hobbs algorithm (Hobbs, 1978). Learning-based anaphoric resolution approaches have also been extensively explored. Zhao and Ng (2007) and Kong and Zhou (2010) proposed systems that perform ZP resolution by integrating syntactic features and position information in a system based on decision trees and context-sensitive convolution tree kernels. With the powerful learning capacity of neural networks, recent work focuses on learning representations to resolve zero pronouns or common noun phrases (Ng, 2007; Yin et al., 2017, 2018). The DP recovery task explored in our work focuses on determining the position and type of dropped pronoun without attempting to resolve it to an antecedent.

2.3 Attention and memory network.

The attention mechanism is first proposed for neural machine translation (Bahdanau et al., 2014) and has been attempted in a variety of natural language processing tasks (Bahdanau et al., 2014; Hermann et al., 2015). Kim (2017) extended the basic attention mechanism to incorporate structural biases by combining graphical models with neural networks. Yang et al. (2016) proposed a word and sentence-level hierarchical attention network for document classification. Xing et al. (2018) also presented a hierarchical recurrent attention network (HRAN) to model the hierarchy of conversation context in order to generate multi-turn responses in chatbots. In contrast with these bottom-up mechanisms, our model adopts a top-down structured attention mechanism to construct the representation for a DP. Our model attempts to identify utterances which contain the referent of a DP, and then focus in on the representation of the referent itself. Our model draws inspiration from the memory network and its variants (Weston et al., 2015; Sukhbaatar et al., 2015; Henaff et al., 2017; Miller et al., 2016), where an external memory component is used to store and update knowledge.

3 Approach

Following (Yang et al., 2015), we formulate DP recovery as a sequential tagging problem. Given an input sentence $X = (x_1, x_2, ..., x_s)$ and its contextual utterances $\boldsymbol{C} = (X_1, ..., X_m)$, our task is to model $P(Y|X, \boldsymbol{C})$ and predict a set of labels $Y = (y_1, y_2, ..., y_s)$. Each element of Y indicates whether a pronoun is dropped and which type it should be before each word in the sentence X. The NDPR model consists of three components: (1) Input Layer; (2) Referent Modeling Layer; (3) Output Layer. We describe them in detail below.

3.1 Input Layer

This layer converts the raw inputs X and $\boldsymbol{C}$ into distributed representations.

3.1.1 Sentence X

During the encoding process, the input sentence of length s, is transformed into a sequence of d-dimensional word embeddings at first, and then fed into two different kinds of bidirectional recurrent neural networks (RNN) (Elman, 1991):

- **BiGRU** (Bahdanau et al., 2014): Each word $x_n, n \in \{1, ..., s\}$ of the sentence is represented as a concatenation of forward and backward hidden states as: $\boldsymbol{h_n} = [\overleftarrow{\boldsymbol{h}}_{\boldsymbol{n}}, \overrightarrow{\boldsymbol{h}}_{\boldsymbol{n}}]$. We aim to express DP by the hidden state of the first word after DP.
- **PC-BiGRU** (Yin et al., 2017): Pronoun-centered BiGRU (PC-BiGRU) also contains two independent GRU networks. For each word $x_n, n \in \{1, ..., s\}$, the forward GRU_f encodes the preceding context of DP from left to right as $\overrightarrow{\boldsymbol{h}}_{\boldsymbol{n-1}}$, and the backward GRU_b models the succeeding context as $\overleftarrow{\boldsymbol{h}}_{\boldsymbol{n}}$ in the reverse direction. Final hidden state of DP is also concatenated as $\boldsymbol{h_n} = [\overleftarrow{\boldsymbol{h}}_{\boldsymbol{n}}, \overrightarrow{\boldsymbol{h}}_{\boldsymbol{n-1}}]$. The intuition of this structure is to express DP by the last word before DP and the first word after DP.

3.1.2 Context C

The context provides the necessary background information to recover DPs. In our work, we utilize five utterances preceding the one the DP is in and two utterances following current input sentence X as context **C**. The size of **C** is determined empirically since our statistics show that 97% of the dropped pronouns can be inferred based on information in the 7 sentences surrounding the sentence in which the dropped pronoun occurs. The context **C** passes through the same encoder as X, yielding two kinds of memories: (1) sentence-level memory: concatenated final states of the forward and backward GRU for each contextual utterance $i = \{1, ..., m\}$ as $\boldsymbol{cs_i} = [\overleftarrow{\boldsymbol{cs}}_{\boldsymbol{i}}, \overrightarrow{\boldsymbol{cs}}_{\boldsymbol{i}}]$, holding sentence level background knowledge. (2) word-level memory: a set of concatenated hidden states at each time step $j = \{1, ..., k\}$ as $\boldsymbol{cw_{i,j}} = [\overleftarrow{\boldsymbol{cw}}_{\boldsymbol{i,j}}, \overrightarrow{\boldsymbol{cw}}_{\boldsymbol{i,j}}]$, expressing the contextual information of words in memory.

3.2 Referent Modeling layer

The referent modeling layer models the interaction between the input sentence X and its context $\boldsymbol{C}$ and outputs representation of DP referents. The relevant information for predicting the dropped pronoun is retrieved by a two-step attention-based inference mechanism in which the intermediate results of sentence-level attention is utilized to support subsequent word-level inference.

3.2.1 Identify utterances mentioning DP

This operation aims to figure out which utterances mention the intended referent of DP. We compute the relevance between the hidden states $\boldsymbol{h_n}$ representing the DP and its sentence level contextual representation $\boldsymbol{cs_i}$, resulting in $rs_{n,i}$. After passing it through softmax, we obtain a sentence-level attention distribution $as_{n,i}$ as:

$$rs_{n,i} = \boldsymbol{h_n^T cs_i} \tag{1}$$

$$as_{n,i} = \frac{e^{rs_{n,i}}}{\sum_{i=1}^{m} e^{rs_{n,i}}} \tag{2}$$

We then conclude sentence-level background information $\boldsymbol{s_n}$ of DP as a weighted sum of contextual utterance representations:

$$\boldsymbol{s_n} = \sum_{i=1}^{m} as_{n,i} \cdot \boldsymbol{cs_i} \tag{3}$$

3.2.2 Update DP representation

This operation updates representation of the DP by combining the original DP information $\boldsymbol{h_n}$ with sentence-level background knowledge $\boldsymbol{s_n}$ through a linear transformation as:

$$\boldsymbol{hs_n} = \boldsymbol{W^{2d \times 4d}}[\boldsymbol{h_n}, \boldsymbol{s_n}] + \boldsymbol{b^{2d}}, \tag{4}$$

The updated DP state $\boldsymbol{hs_n}$ will be used in subsequent word level inference.

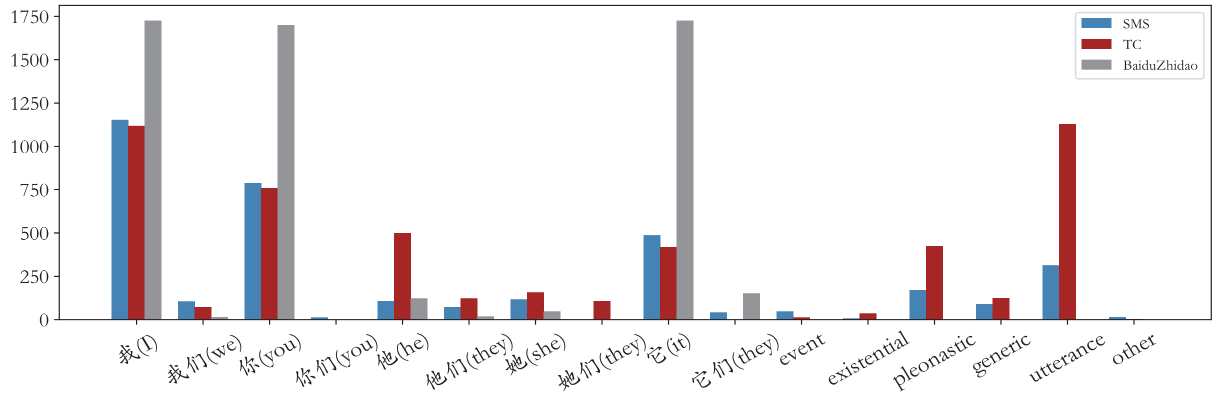

Figure 3: Counts of each type of dropped pronouns in different conversational data sets. Pronouns have a more balanced distribution in Chinese SMS and telephone conversation(TC). For BaiduZhidao, only concrete pronouns are annotated and the distribution of these pronouns is extremely uneven.

3.2.3 Identify DP referents

This operation aims to capture the word sequence that represents the intended referent of the DP. We cast the updated DP state $\boldsymbol{hs_n}$ onto the space of contextual words $\boldsymbol{cw_{i,j}}$ by measuring the similarity $rw_{n,i,j}$ between them. The casting operation also serves as a regularization measure to restrict the inference space. The similarities are fed into the softmax function to give a word-level attention distribution $aw_{n,i,j}$ for each contextual word as:

$$rw_{n,i,j} = \boldsymbol{W^{1\times 2d}}(\boldsymbol{hs_n} \odot \boldsymbol{cw_{i,j}}) + b^1 \qquad (5)$$

$$aw_{n,i,j} = \frac{e^{rw_{n,i,j}}}{\sum_{j=1}^{k} e^{rw_{n,i,j}}}, \qquad (6)$$

The attention distribution $aw_{n,i,j}$ also provides an interpretation for DP recovery results based on the words it attends to.

Finally, we derive the word-level representation $\boldsymbol{w_n}$ from word states $\boldsymbol{cw_{i,j}}$. Word-level attention $aw_{n,i,j}$ is used to compute a weighted sum of contextual word states $\boldsymbol{cw_{i,j}}$ of each utterance, yielding the referent representation $\boldsymbol{tw_{n,i}}$. Then, sentence-level attention as_i further filters out irrelevant referents, yielding the final referent representation $\boldsymbol{w_n}$ as:

$$\boldsymbol{tw_{n,i}} = \sum_{j=1}^{k} aw_{n,i,j} \cdot \boldsymbol{cw_{i,j}} \qquad (7)$$

$$\boldsymbol{w_n} = \sum_{i=1}^{m} as_{n,i} \cdot \boldsymbol{tw_{n,i}} \qquad (8)$$

3.3 Output Layer and Training Objective

The output layer predicts the recovery result based on DP state $\boldsymbol{h_n}$ and referent representation $\boldsymbol{w_n}$. We feed the concatenation of these two parts into a 2-layer fully connected softmax classifier to give a categorical probability distribution over 17 candidate pronouns as:

$$\boldsymbol{\alpha_n} = tanh(\boldsymbol{W_1} \cdot [\boldsymbol{h_n}; \boldsymbol{w_n}] + \boldsymbol{b}) \qquad (9)$$

$$P(y_n|x_n,\boldsymbol{C}) = softmax(\boldsymbol{W_2} \cdot \boldsymbol{\alpha_n} + \boldsymbol{b}) \qquad (10)$$

We train our model by minimizing cross-entropy between the predicted label distributions and the annotated labels for all sentences. The training objective is defined as:

$$loss = -\sum_{l\in N}\sum_{n=1}^{s}\delta(y_n|x_n,\boldsymbol{C})\log(P(y_n|x_n,\boldsymbol{C})), \qquad (11)$$

where N represents all training instances, s represents the number of words in each sentence; $\delta(y_n|x_n,c)$ represents the annotated label of x_n.

4 Datasets and Experimental Setup

4.1 Datasets

We perform experiments on three Chinese conversational datasets.

- Chinese text message (SMS) data, which consists of 684 SMS/Chat files. We use the same dataset split as (Yang et al., 2015), which reserves 16.7% of the training set as a held-out development set to tune the hyper-parameters and evaluate the model on a separate test set.

- OntoNotes Release 5.0, which is used in the CoNLL 2012 Shared Task. We use a portion of OntoNotes 5.0 that consists of transcripts of Chinese telephone conversation (TC) speech. The 9,507-sentence subset of OntoNotes only has coreference annotations for anaphoric zero pronouns. In order to formulate the task as an end-to-end sequence labeling task, we annotate all the dropped pronouns following annotation guidelines described in (Yang et al., 2015).
- BaiduZhidao, which is a question answering dialogue dataset used in (Zhang et al., 2016). It contains 11,160 sentences that are annotated with 10 types of concrete dropped pronouns.

Figure 3 shows the statistics of each type of pronouns in the three data sets. According to (Yang et al., 2015), 5 out of 15 types of dropped pronouns in the SMS data set are *abstract pronouns* that do not correspond to any actual pronoun in Chinese. These can refer to an event (Event), the previous utterance (Previous Utterance), or an generic or unspecific entity (Generic). The other two abstract pronouns are used to indicate the subject of an existential construction (Existential) or a pleonastic subject (Pleonastic). The other ten types of Chinese pronouns are classified as concrete pronouns. The same 15 types of pronouns are used to annotate the TC data. We can see that the BaiDuZhidao data set only has concrete pronouns.

4.2 Evaluation metrics

We use the same evaluation metrics as (Yang et al., 2015): precision (P), recall (R) and F-score (F).

4.3 Training details

Our model is implemented with Tensorflow. The vocabulary is generated from the training set, which contains 17,199 word types. Out-of-vocabulary (OOV) words are represented as UNK. The BiGRU encoder uses a hidden layer of 150 units. To train the model, we use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.0003. We train the model for 8 epochs and select the model with the highest F-score on the development set for testing. Dropout rate is set at 0.2 on the fully connected layers. We use uniform initialization for the weight matrices and zero initialization for biases.

4.4 Baseline Methods and Model Variations

We compare our proposed NDPR framework with three baselines and implement two parallel experiments:

- **MEPR**: This model is provided by Yang (2015), which uses a maximum entropy (ME) classifier with hand-crafted features to recover dropped pronouns.
- **NRM**: This model is proposed by Zhang (2016), which uses two independent multi-layer perceptrons to locate the position of dropped pronouns and determine the type of dropped pronouns.
- **BiGRU**: This model encodes each word in the target sentence with a bidirectional GRU. The output representation of the BiGRU encoder is used to predict the type of the dropped pronoun. This method can be seen as a degenerate variant of our NDPR model without the attention mechanism.
- **NDPR**: This model uses the BiGRU encoder with both sentence-level and word-level attention. The word embeddings are initialized with pre-trained 300-D Zhihu QA vectors (Li et al., 2018) and fine-tuned when training the DP recovery model.
- **NDPR-rand**: Same as NDPR except that the word embeddings are randomly initialized.
- **NDPR-PC-BiGRU**: Same as NDPR but the encoder of utterance X is replaced with PC-BiGRU.

We also perform two ablation experiments to explore the effectiveness of sentence-level attention and word-level attention:

- **NDPR-S**: Same as NDPR but the referent modeling layer only utilizes sentence-level attention. The output layer makes prediction with only DP state $\boldsymbol{h_n}$ and sentence level information $\boldsymbol{s_n}$.
- **NDPR-W**: Same as NDPR but the referent modeling layer only utilizes word-level attention. The output layer makes prediction with only DP state $\boldsymbol{h_n}$ and word-level information $\boldsymbol{w_n}$.

5 Results and Discussion

5.1 Main Results

Table 1 shows experimental results of three baseline systems and variants of our proposed NDPR

Model	Chinese SMS			TC of OntoNotes			BaiduZhidao		
	P(%)	R(%)	F	P(%)	R(%)	F	P(%)	R(%)	F
MEPR (Yang et al., 2015)	37.27	45.57	38.76	-	-	-	-	-	-
NRM* (Zhang et al., 2016)	37.11	44.07	39.03	23.12	26.09	22.80	26.87	49.44	34.54
BiGRU	40.18	45.32	42.67	25.64	36.82	30.93	29.35	42.38	35.83
NDPR-rand	46.47	43.23	43.58	28.98	41.50	33.38	35.44	43.82	37.79
NDPR-PC-BiGRU	46.34	46.21	46.27	36.69	40.12	38.33	38.42	48.01	41.68
NDPR-W	46.78	**46.61**	45.76	38.67	41.56	39.64	38.60	**50.12**	**43.36**
NDPR-S	46.99	46.32	44.89	37.40	40.32	38.81	39.32	46.40	41.53
NDPR	**49.39**	44.89	**46.39**	**39.63**	**43.09**	**39.77**	**41.04**	46.55	42.94

Table 1: Results in terms of precision, recall and F-score on 16 types of pronouns produced by the baseline systems and variants of our proposed NDPR model. For NRM* (Zhang et al., 2016), we implement the proposed model as described in the paper.

Tag	NDPR-S	NDPR-W	NDPR
他们 (masculine they)	17.05	23.28	**24.44**
她 (she)	32.35	33.72	**35.14**
previous utterance	84.90	86.08	**87.55**
他 (he)	29.05	31.20	**34.92**
它 (it)	25.00	26.67	**26.95**
她们 (feminine they)	0	0	**40.00**
我 (I)	50.66	50.90	**52.98**
我们 (we)	31.49	33.57	**34.81**
你 (singular you)	42.88	44.15	**44.31**
pleonastic	25.89	22.29	**28.46**
generic	11.61	11.08	**16.83**
event	6.15	0	**16.27**
existential	34.17	30.84	**38.71**
你们 (plural you)	0	0	**5.41**
它们 (inanimate they)	16.00	**19.15**	13.89

Table 2: F-scores of our proposed model NDPR and its two variants (NDPR-S, NDPR-W) for concrete and abstract pronouns on the Chinese SMS test set.

model on Chinese SMS, TC section of OntoNotes, and BaiduZhidao. We can see that our proposed model and its variants outperform the baseline methods on all these datasets by different margins. Our best model, NDPR, outperforms MEPR by 7.63% in terms of F-score on the Chinese SMS dataset, and outperforms NRM by 16.97% and 8.40% on the OntoNotes and BaiduZhidao datasets respectively. Compared with the degenerate variant model BiGRU, our NDPR model also performs better on all three datasets, which demonstrate the effectiveness of referent modeling mechanism composed of sentence-level and word-level attention.

The experimental results also show that all components of our model have made a positive contribution, which is evidenced by the fact that the full model NDPR outperforms the other variants by a small margin. The results also show that pretrained word embeddings have had a positive impact on the model, as shown by the higher accuracy of the NDPR model over the NDPR-rand model, where the word embeddings are randomly initialized.

PC-BiGRU encoder seems to perform worse than vanilla BiGRU encoder, as shown by the slightly lower F-score of the NDPR-PC-BiGRU model. But it alleviates what we call the local pronoun repetition problem, the situation where a DP is recovered redundantly in a sentence before a verb and its adverbial modifier. We attribute this to that PC-BiGRU uses the context state h_{n-1} of the last word before DP instead of h_n, which makes the model pay more attention to the preceding modifier.

For the BaiduZhidao dataset, the NDPR-W model actually performs better than NDPR model, as indicated by the higher F-score for NDPR-W in the last column of Table 1. We attribute this to the fact that there are only concrete pronouns in this dataset. The combination of “我 (I)”, “你 (singular you)” and “它 (it)” accounts for 94.47% of the overall dropped pronoun population, for which the referent can be easily determined by word-level attention. Moreover, the fewer conversation turns in this data set mean there are few irrelevant referents that need to be filtered out by sentence-level attention.

5.2 Ablation Study

In this section, we dive a bit deeper and look at the impact of the attention mechanism on concrete and

Pro-drop sentence: A: (她)(she) 是 用的 锤头 还是 扳手?
A: What did (she) use, a hammer or wrench?

A: 你 终于 出现 了 。
You finally showed up.
B: 你 别 乱说 。
Don't talk nonsense.
A: 啊 哈哈 。
Haha.
B: 最近 我 的 电脑 它 让 我 女儿(daughter) 搞坏 了
My daughter broke my computer recently.
A: 哈哈 她(she) 还 有 这 功能 她(she) 不 简单
Haha. She can even do that. She is not to be under-estimated.
B: 嗯 , 破坏力 很 强 。
Yes, very destructive.
B: 她(she) 用 了 一 根 手指 。
She just used a finger.

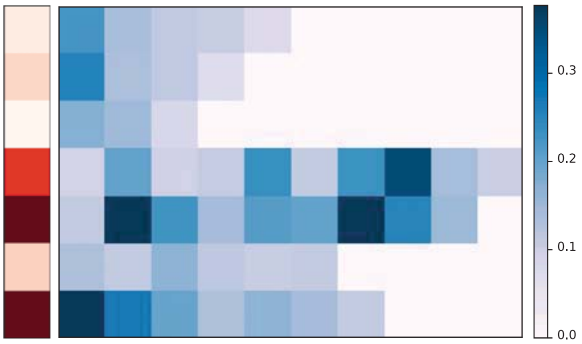

Figure 4: Visualization of attention in the NDPR model. The red pattern on the left shows the distribution of sentence-level attention and the blue pattern on the right shows the distribution of word-level attention. Darker color indicates higher attention weight.

Chinese SMS

Context : A: 我还以为你大过年要搬家呢！
A: I thought you would make a move during the Spring Festival.
A: 我希望你能在报社附近找个房子。
A: I hope you can rent a house near the newspaper office.
B: 嗯，我能接上最好了。
B: Well, it is best if the new house is ready.
Gold : B: (event) 不行就只能搬回去了。
B: I have to move back if the new house is not accessible.
NDPR: B: (我) 不行就只能搬回去了。
B: I have to move back if I can not.

Context : A: 我可以从上海直飞到纽约吗？
A: Can I take a direct flight from Shanghai to New York?
Gold : B: (generic) 直飞都没有
B: There is no direct flight.
NDPR : B: (我) 直飞都没有。
B: I can not flight directly.

TC of OntoNotes

Gold : (你) 有空，(你) 有空 (你) 可能还会到北京去，是吧？
You may go to Beijing again when you are free, you are free, right?
NDPR : (你) 有空，(我) 有空 (我) 可能还会到北京去，是吧？
I may go to Beijing again when you are free, I am free, right?

BaiduZhidao

Context : A: 医院开的那些退烧药有用吗？
A: Are those antipyretics prescribed by the hospital useful?
Gold : B: (它们) 都有什么成分？
B: What are the ingredients of them?
NDPR : B: (它) 都有什么成分？
B: What are the ingredients of it?

Figure 5: Example errors made by NDPR on different conversational datasets.

abstract pronouns, respectively. Table 2 shows the F-scores of three variants of our proposed model for each type of pronouns on the entire Chinese SMS test set. The best results among these three variants are in boldface, and the better results between NDPR-S and NDPR-W are underlined.

We can see that for all types of concrete pronouns, the NDPR-W model outperforms the NDPR-S model by a significant margin. In general, the referent of concrete dropped pronoun is usually realized in the form of a phrase that consists of one or more word, and they can be accurately captured by word-level attention. The NDPR model that incorporates both word-level and sentence-level attention further improves upon NDPR-W, with the lone exception of 它们 (“they”). We believe the reason is that the sentence-level encoder cannot adequately represent the interaction between the multiple referents for plural pronouns like 它们 and only add noise to the representation.

However, this observation does not hold for abstract dropped pronouns. The NDPR-W performs comparably or slightly worse on four out of the five types of abstract pronouns. This is consistent with the fact that the referent of abstract pronouns like “Event” is often an entire sentence. The full NDPR model still outperforms both NDPR-W and NDPR-S for all abstract pronouns.

5.3 Attention Visualization

Intuitively, sentence-level attention models the interaction between the dropped pronoun and each context utterance. The utterance containing the referent of the dropped pronoun should receive more attention. Similarly, word-level attention models the interaction between each word in the context and the dropped pronoun. Thus words that describe the referent of the pronoun should receive more attention if the model works as intended. Figure 4 shows a instance of attention distribution produced by our model.

In this example, the model correctly gives higher attention weights to three utterances that contain words that indicate the referent of the pronoun. At word level, the model also gives higher attention weights to the specific words that indicate the referent of the dropped pronoun. For example, words such as 她 (“she”) and 女儿 (“daughter”) have received higher weights, as indicated by the darker color. This suggests that in this case the model attends to the right utterances and words and works as we have expected.

5.4 Error Analysis

Figure 5 shows some typical mistakes made by our model on each genre. For the Chinese SMS dataset, the distribution of different types of pronouns is relatively balanced (See Table 3), and our model does a better job on concrete pronouns but stumbles on abstract pronouns like "event" and "generic" as shown in Table 2 as it is harder to attend to the correct parts of the context in these cases.

The TC data of OntoNotes is a transcription of telephone conversations where there are often repetitions, and our model struggles when people repeat what they said. If the same pronoun is mentioned repeatedly, our model can not capture this interaction, since each pronoun is recover independently. This suggests that one future improvement might involve using a sequence-based decoder.

In the BaiduZhidao dataset, only concrete pronouns are annotated as shown in Figure 3. Pronouns like 它 ("it") and 它们 ("they") account for a large proportion of all dropped pronouns. For these two categories, the performance of our proposed method is hit-and-miss, which can be attributed to the absence of pronoun resolution common sense.

6 Conclusions

We have proposed an end-to-end neural network architecture that attempts to model the interaction between the dropped pronoun and its referent in order to recover dropped pronouns in Chinese conversational data. Our model is based on sentence-level and word-level attention and results show that our model consistently outperforms baseline methods when evaluated on three separate datasets. We further investigate the effectiveness of different components of our model by performing ablation experiments and demonstrate the interpretability of our model using attention visualization.

The Problem with Probabilistic DAG Automata for Semantic Graphs

Abstract

Semantic representations in the form of directed acyclic graphs (DAGs) have been introduced in recent years, and to model them, we need probabilistic models of DAGs. One model that has attracted some attention is the DAG automaton, but it has not been studied as a probabilistic model. We show that some DAG automata cannot be made into useful probabilistic models by the nearly universal strategy of assigning weights to transitions. The problem affects single-rooted, multi-rooted, and unbounded-degree variants of DAG automata, and appears to be pervasive. It does not affect planar variants, but these are problematic for other reasons.

1 Introduction

Abstract Meaning Representation (AMR; Banarescu et al. 2013) has prompted a flurry of interest in probabilistic models for semantic parsing. AMR annotations are directed acyclic graphs (DAGs), but most probabilistic models view them as strings (e.g. van Noord and Bos, 2017) or trees (e.g. Flanigan et al., 2016), removing their ability to represent coreference—one of the very aspects of meaning that motivates AMR. Could we we instead use probabilistic models of DAGs?

To answer this question, we must define probability distributions over sets of DAGs. For inspiration, consider probability distributions over sets of strings or trees, which can be defined by weighted finite automata (e.g. Mohri et al., 2008; May et al., 2010): a finite automaton generates a set of strings or trees—called a language—and if we assume that probabilities factor over its transitions, then any finite automaton can be weighted to define a probability distribution over this language. This assumption underlies powerful dynamic programming algorithms like the Viterbi, forward-backward, and inside-outside algorithms.

What is the equivalent of weighted finite automata for DAGs? There are several candidates (Chiang et al., 2013; Björklund et al., 2016; Gilroy et al., 2017), but one appealing contender is the *DAG automaton* (Quernheim and Knight, 2012) which generalises finite tree automata to DAGs explicitly for modeling semantic graphs. These DAG automata generalise an older formalism called *planar DAG automata* (Kamimura and Slutzki, 1981) by adding weights and removing the planarity constraint, and have attracted further study (Blum and Drewes, 2016; Drewes, 2017), in particular by Chiang et al. (2018), who generalised classic dynamic programming algorithms to DAG automata. But while Quernheim and Knight (2012) clearly intend for their weights to define probabilities, they stop short of claiming that they do, instead ending their paper with an open problem: "*Investigate a reasonable probabilistic model.*"

We investigate probabilistic DAG automata and prove a surprising result: **For some DAG automata, it is impossible to assign weights that define non-trivial probability distributions**. We exhibit a very simple DAG automaton that generates an infinite language of graphs, and for which the only valid probability distribution that can be defined by weighting transitions is one in which the support is a single DAG, with all other graphs receiving a probability of zero.

Our proof relies on the fact that a non-planar DAG automaton generates DAGs so prolifically that their number grows factorially in their size, rather than exponentially as in other automata. It holds for DAG automata that allow multiple roots or nodes of unbounded degree. But it breaks down when applied to the planar DAGs of Kamimura and Slutzki (1981), which are nevertheless too restrictive to model semantic graphs. Our result does

Proceedings of NAACL-HLT 2019, pages 902–911
Minneapolis, Minnesota, June 2 - June 7, 2019.

not mean that it is impossible to define a probability distribution for the language that a DAG automaton generates. But it does mean that this distribution does not factor over the automaton's transitions, so crucial dynamic programming algorithms do not generalise to DAG automata that are expressive enough to model semantic graphs.

2 DAGs, DAG Automata, and Probability

We are interested in AMR graphs like the one below for "Rahul bakes his cake" (Figure 1, left), which represents entities and events as nodes, and relationships between them as edges. Both nodes and edges have labels, representing the type of an entity, event, or relationship. But the graphs we model will only have labels on nodes. These node-labeled graphs can simulate edge labels using a node with one incoming and one outgoing edge, as in the graph on the right of Figure 1.

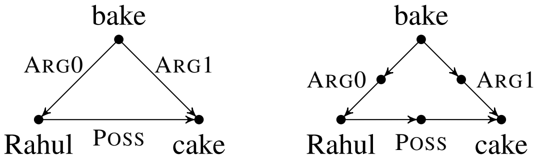

Figure 1: A graph with both node and edge labels (left) and an equivalent graph with only node labels (right).

Definition 1. *A node-labeled directed* ***graph*** *over a label set* Σ *is a tuple* $G = (V, E, lab, src, tar)$ *where* V *is a finite set of nodes,* E *is a finite set of edges,* $lab\colon V \to \Sigma$ *is a function assigning labels to nodes,* $src\colon E \to V$ *is a function assigning a source node to every edge, and* $tar\colon E \to V$ *is a function assigning a target node to every edge.*

Sometimes we will discuss the set of edges coming into or going out of a node, so we define functions IN: $V \to E^*$ and OUT: $V \to E^*$.

$$\textsc{In}(v) = \{e \mid \text{tar}(e) = v\}$$
$$\textsc{Out}(v) = \{e \mid \text{src}(e) = v\}$$

A node with no incoming edges is called a **root**, and a node with no outgoing edges is called a **leaf**. The **degree** of a node is the number of edges connected to it, so the degree of v is $|\textsc{In}(v) \cup \textsc{Out}(v)|$.

A **path** in a directed graph from node v to node v' is a sequence of edges $(e_1, \ldots, e_n)$ where $\text{src}(e_1) = v$, $\text{tar}(e_n) = v'$ and $\text{src}(e_{i+1}) = \text{tar}(e_i)$ for all i from 1 to $n-1$. A **cycle** in a directed graph is any path in which the first and last nodes are the same (i.e., $v = v'$). A directed graph without any cycles is a **directed acyclic graph (DAG)**.

A DAG is **connected** if every pair of its nodes is connected by a sequence of edges, not necessarily directed. Because DAGs do not contain cycles, they must always have at least one root and one leaf, but they can have multiple roots and multiple leaves. However, our results apply in different ways to single-rooted and multi-rooted DAG languages, so, given a label set Σ, we distinguish between the set of all connected DAGs with a single root, $\mathcal{G}^1_\Sigma$; and those with one or more roots, $\mathcal{G}^*_\Sigma$.

2.1 DAG Automata

Finite automata generate strings by transitioning from state to state. Top-down tree automata generalise string finite automata by transitioning from a state to an ordered sequence of states, generating trees top-down from root to leaves; while bottom-up tree automata transition from an ordered sequence of states to a single state, generating trees bottom-up from leaves to root. The planar DAG automata of Kamimura and Slutzki (1981) generalise tree automata, transitioning from one ordered sequence of states to another ordered sequence of states (Section 4). Finally, the DAG automata of Quernheim and Knight (2012) transition from *multisets* of states to multisets of states, rather than from sequences to sequences, and this allows them to generate non-planar DAGs. We summarise the differences in Table 1 below.

Automaton	Transitions	Example
string	one-to-one	$p \to p'$
top-down tree	one-to-many	$p \to (p', q')$
bottom-up tree	many-to-one	$(p', q') \to p$
planar DAG	many-to-many	$(p, q) \to (p', q')$
non-planar DAG	many-to-many	$\{p, q\} \to \{p', q'\}$

Table 1: The forms of transitions in different automata.

For the remainder of this section and the next, we will focus only on non-planar DAG automata, and when we refer to DAG automata, we mean this type. To formally define them, we need a notation for multisets—sets that can contain repeated elements. A **multiset** is a pair (S, m) where S is a finite set and $m : S \to \mathbb{N}$ is a count function—that is, $m(x)$ counts the number of times x appears in the multiset. The set of all finite multisets over S is $M(S)$. When we write multisets, we will often simply enumerate their elements. For example, $\{p, q, q\}$ is the multiset containing one p and two

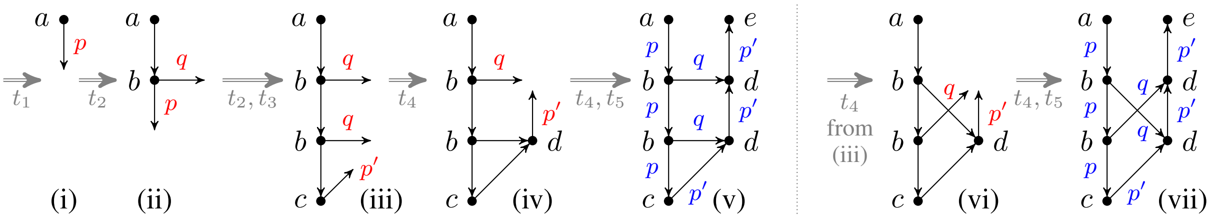

Figure 2: Two derivations using the automaton of Example 1. Parts (i), (ii), and (iii) are common to both derivations. Parts (iv) and (v) represent one completion, while (vi) and (vii) represent an alternative completion. Grey double edges denote derivation steps, labeled with the corresponding transition(s); red edge labels on partial graphs (i–iv) and (vi) denote frontier states; blue edge labels on complete graphs (v) and (vii) denote an accepting run.

q's, and since multisets are unordered, it can also be written $\{q, p, q\}$ or $\{q, q, p\}$. We write $\emptyset$ for a multiset containing no elements.

Definition 2. *A **DAG automaton** is a triple* $A = (Q, \Sigma, T)$ *where* Q *is a finite set of states;* Σ *is a finite set of node labels; and* T *is a finite set of transitions of the form* $\alpha \xrightarrow{\sigma} \beta$ *where* $\sigma \in \Sigma$ *is a node label,* $\alpha \in M(Q)$ *is the left-hand side, and* $\beta \in M(Q)$ *is the right-hand side.*

Example 1. Let $A = (Q, \Sigma, T)$ be a DAG automaton where $Q = \{p, p', q\}$, $\Sigma = \{a, b, c, d, e\}$ and the transitions in T are as follows:

$$\emptyset \xrightarrow{a} \{p\} \quad (t_1)$$
$$\{p\} \xrightarrow{b} \{p, q\} \quad (t_2)$$
$$\{p\} \xrightarrow{c} \{p'\} \quad (t_3)$$
$$\{p', q\} \xrightarrow{d} \{p'\} \quad (t_4)$$
$$\{p'\} \xrightarrow{e} \emptyset \quad (t_5)$$

2.1.1 Generating Single-rooted DAGs

A DAG automaton generates a graph from root to leaves. To illustrate this, we'll focus on the case where a DAG is allowed to have only a single root, and return to the multi-rooted case in Section 3.1. To generate the root, the DAG automaton can choose any transition with $\emptyset$ on its left-hand side—these transitions behave like transitions from the start state in a finite automaton on strings, and always generate roots. In our example, the only available transition is t_1, which generates a node labeled a with a dangling outgoing edge in state p, as in Figure 2(i). The set of all such dangling edges is the **frontier** of a partially-generated DAG.

While there are edges on the frontier, the DAG automation must choose and apply a transition whose left-hand side matches some subset of them. In our example, the automaton can choose either t_2 or t_3, each matching the available p edge. The edges associated with the matched states are attached to a new node with new outgoing frontier edges specified by the transition, and the matched states are removed from the frontier. If our automaton chooses t_2, it arrives at the configuration in Figure 2(ii), with a new node labeled b, new edges on the frontier labeled p and q, and the incoming p state forgotten. Once again, it must choose between t_2 and t_3—it cannot use the q state because that state can only be used by t_4, which also requires a p' on the frontier. So each time it applies t_2, the choice between t_2 and t_3 repeats.

If the automaton applies t_2 again and then t_3, as it has done in Figure 2(iii), it will face a new set of choices, between t_4 and t_5. But notice that choosing t_5 will leave the q states stranded, leaving a partially derived DAG. We consider a run of the automaton successful only when the frontier is empty, so this choice leads to a dead end.

If the automaton chooses t_4, it has an additional choice: it can combine p' with *either* of the available q states. If it combines with the lowermost q, it arrives at the graph in Figure 2(iv), and it can then apply t_4 to consume the remaining q, followed by t_5, which has $\emptyset$ on its right-hand side. Transitions to $\emptyset$ behave like transitions to a final state in a finite automaton, and generate leaf nodes, so we arrive at the complete graph in Figure 2(v). If the p' state in Figure 2(iii) had instead combined with the upper q, a different DAG would result, as shown in Figure 2(vi-vii).

The DAGs in Figure 2(v) and Figure 2(vii) are planar, which means they can be drawn without crossing edges.[1] But this DAG automaton can also produce non-planar DAGs like the one in Figure 3. To see that it is non-planar, we first *contract* each dotted edge by removing it and fusing its endpoints into a single node. This gives us the *minor*

---

[1] While the graph in Figure 2(vii) is drawn with crossing $b-d$ edges, one of these edges can be redrawn so that they do not cross.

subgraph $K_{3,3}$, and any graph with a $K_{3,3}$ minor is non-planar (Wagner, 1937).

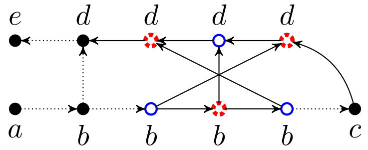

Figure 3: A non-planar graph that can be generated by the automaton of Example 1. When the dotted edges are contracted, we obtain $K_{3,3}$, the complete (undirected) bipartite graph over two sets of three nodes. One set is denoted by hollow blue nodes (○), the other by dotted red nodes (⁘).

2.1.2 Recognising DAGs and DAG Languages

We define the language generated by a DAG automaton in terms of recognition, which asks if an input DAG could have been generated by an input automaton. We recognise a DAG by finding a run of the automaton that could have generated it. To guess a run on a DAG, we guess a state for each of its edges, and then ask whether those states simulate a valid sequence of transitions.

A **run** of a DAG automaton $A = (Q, \Sigma, T)$ on a DAG $G = (V, E, \text{lab}, \text{src}, \text{tar})$ is a mapping $\rho : E \rightarrow Q$ from edges of G to automaton states Q. We extend ρ to multisets by saying $\rho(\{e_1, \ldots, e_n\}) = \{\rho(e_1), \ldots, \rho(e_n)\}$, and we call a run **accepting** if for all $v \in V$ there is a corresponding transition $\rho(\textsc{In}(v)) \xrightarrow{\text{lab}(v)} \rho(\textsc{Out}(v))$ in T. DAG G is **recognised** by automaton A if there is an accepting run of A on G.

Example 2. The DAGs in Figure 2(v) and 2(vii) are recognised by the automaton in Example 1. The only accepting run for each DAG is denoted by the blue edge labels.

The **single-rooted language** $L_s(A)$ of a DAG automaton A is $\{G \in \mathcal{G}^1_\Sigma \mid A \text{ recognizes } G\}$.

2.2 Probability and Weighted DAG Automata

Definition 3. *Given a language L of DAGs, a **probability distribution** over L is any function $p : L \rightarrow \mathbb{R}$ meeting two requirements:*

(R1) *Every DAG must have a probability between 0 and 1, inclusive. Formally, we require that for all $G \in L$, $p(G) \in [0, 1]$.*

(R2) *The probabilities of all DAGs must sum to one. Formally, we require $\sum_{G \in L} p(G) = 1$.*

R1 and R2 suffice to define a probability distribution, but in practice we need something stronger than R1: all DAGs must receive a *non-zero* weight, since in practical applications, objects with probability zero are effectively not in the language.

Definition 4. *A probability distribution p has **full support** of L if and only if it meets condition R1'.*

(R1') *Every DAG must have a probability greater than 0 and less than or equal to 1. Formally, we require that for all $G \in L$, $p(G) \in (0, 1]$.*

While there are many ways to define a function that meets requirements R1' and R2, probability distributions in natural language processing are widely defined in terms of weighted automata or grammars, so we adapt a common definition of weighted grammars (Booth and Thompson, 1973) to DAG automata.

Definition 5. *A **weighted DAG automaton** is a pair (A, w) where $A = (Q, \Sigma, T)$ is a DAG automaton and $w : T \rightarrow \mathbb{R}$ is a function that assigns real-valued weights to the transitions of A.*

Since weights are functions of transitions, we will write them on transitions following the node label and a slash (/). For example, if $p \xrightarrow{a} q$ is a transition and 2 is its weight, we write $p \xrightarrow{a/2} q$.

Example 3. Let (A, w) be a weighted DAG automaton with $A = (Q, \Sigma, T)$, where $Q = \{p, q\}$, $\Sigma = \{a, b, c\}$, and the weighted transitions of T are as follows:

$$\emptyset \xrightarrow{a/0.5} \{p, q\} \quad (t'_1)$$

$$\{p\} \xrightarrow{b/0.5} \{p\} \quad (t'_2)$$

$$\{p, q\} \xrightarrow{c/1} \emptyset \quad (t'_3)$$

We use the weights on transitions to weight runs.

Definition 6. *Given a weighted DAG automaton (A, w) and a DAG $G = (V, E, lab, src, tar)$ with an accepting run ρ, we extend w to compute the **weight of the run** $w(\rho)$ by multiplying the weights of all of its transitions:*

$$w(\rho) = \prod_{v \in V} w(\rho(\textsc{In}(v)) \xrightarrow{lab(v)} \rho(\textsc{Out}(v)))$$

Example 4. The DAG automaton of Example 3 generates the DAG in Figure 4, shown with its only accepting run in blue and the weighted transitions that generated it in grey. The weight of the accepting run is $0.5 \times 0.5 \times 0.5 \times 1 = 0.125$.

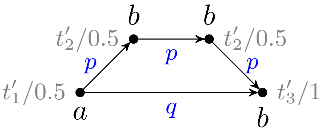

Figure 4: A DAG generated by the automaton in Example 3. Blue edge labels denote an accepting run; grey node labels denote weighted transitions used in the run.

Let $R_A(G)$ be the set of all accepting runs of a DAG G using the automaton A. We extend w to calculate the weight of a DAG G as the sum of the weights of all the runs that produce it:

$$w(G) = \sum_{\rho \in R_A(G)} w(\rho).$$

While all weighted DAG automata assign real values to DAGs, not all weighted DAG automata define probability distributions. To do so, they must also satisfy requirements R1 and R2.

Definition 7. *A weighted automaton (A, w) over language $L(A)$ is **probabilistic** if and only if function $w : L(A) \to \mathbb{R}$ is a probability distribution.*

Example 5. Consider the weighted automaton in Example 3. Every DAG generated by this automaton must use t'_1 and t'_3 exactly once, and can use t'_2 any number of times. If we let G_n be the DAG that uses t'_2 exactly n times, then the language L defined by this automaton is $\bigcup_{n \in \mathbb{N}} G_n$. Since $w(G_n) = w(t'_1)w(t'_2)^n w(t'_3)$ and $w(t'_1)$, $w(t'_2)$ and $w(t'_3)$ are positive, w satisfies R1 and:

$$\sum_{G \in L} w(G) = \sum_{n=0}^{\infty} w(G_n) = \sum_{n=0}^{\infty} w(t'_1)w(t'_2)^n w(t'_3)$$
$$= \sum_{n=0}^{\infty} 0.5^{n+1} = 1$$

Thus w also satisfies R2 and the weighted automaton in Example 3 is probabilistic.

Definition 8. *A probabilistic automaton (A, w) over language $L(A)$ is **probabilistic with full support** if and only if w has full support of $L(A)$.*

For every finite automaton over strings or trees, there is a weighting of its transitions that makes it probabilistic (Booth and Thompson, 1973), and it is easy to show that it can be made probabilistic with full support. For example, string finite automata have full support if for every state the sum of weights on its outgoing transitions is 1 and each weight is greater than 0.[2] But as we will show, this is not always possible for DAG automata.

3 Non-probabilistic DAG Automata

We will exhibit a DAG automaton that generates factorially many DAGs for a given number of nodes, and we will show that for any nontrivial assignment of weights, this factorial growth rate causes the weight of all DAGs to sum to infinity.

Theorem 1. *Let $\mathcal{A}$ be the automaton defined in Example 1. There is no w that makes $(\mathcal{A}, w)$ probabilistic with full support over $L_s(\mathcal{A})$.*

Proof. In any run of the automaton, transition t_1 is applied exactly once to generate the single root, placing a p on the frontier. This gives a choice between t_2 and t_3. If the automaton chooses t_2, it keeps one p on the frontier and adds a q, and must then repeat the same choice. Suppose it chooses t_2 exactly n times in succession, and then chooses t_3. Then the frontier will contain n edges in state q and one in state p'. The only way to consume all of the frontier states is to apply transition t_4 exactly n times, consuming a q at each step, and then apply t_5 to consume p' and complete the derivation. Hence in any accepting run, t_1, t_3 and t_5 are each applied once, and t_2 and t_4 are each applied n times, for some $n \geq 0$. Since transitions map uniquely to node labels, it follows that every DAG in $L_s(\mathcal{A})$ will have exactly one node each labeled a, c, and e; and n nodes each labeled b and d.

When the automaton applies t_4 for the first time, it has n choices of q states to consume, each distinguished by its unique path from the root. The second application of t_4 has $n-1$ choices of q, and the ith application of t_4 has $n-(i-1)$ choices. Therefore, there are $n!$ different ways to consume the q states, each producing a unique DAG.

Let $f(n)$ be the weight of a run where t_2 has been applied n times, and to simplify our notation, let $B = w(t_1)w(t_3)w(t_5)$, and $C = w(t_2)w(t_4)$. Let $c(n)$ be the number of unique runs where t_2 has been applied n times. By the above:

$$f(n) = w(t_1)w(t_2)^n w(t_3)w(t_4)^n w(t_5) = BC^n$$
$$c(n) = n!$$

Now we claim that any DAG in $L_s(\mathcal{A})$ has exactly one accepting run, because the mapping of

---

[2] Assuming no epsilon transitions, in our notation for DAG automata restricted to strings this would include transitions to $\emptyset$, which correspond to states with a final probability of 1 (Mohri et al., 2008).

node labels to transitions also uniquely determines the state of each edge in an accepting run. For example, a b node must result from a t_2 transition and a d node from a t_4 transition, and since the output states of t_2 and input states of t_4 share only a q, any edge from a b node to a d node must be labeled q in any accepting run. Now let $G \in L_s(\mathcal{A})$ be a DAG with n nodes labeled b. Since G has only one accepting run, we have:

$$w(G) = f(n)$$

Let L_n be the set of all DAGs in $L_s(\mathcal{A})$ with n nodes labeled b. Then $L_s(\mathcal{A}) = \bigcup_{n=0}^{\infty} L_n$ and:

$$\begin{aligned}\sum_{G \in L_s(\mathcal{A})} w(G) = \sum_{n=0}^{\infty} \sum_{G \in L_n} w(G) &= \sum_{n=0}^{\infty} c(n) f(n) \\ &= \sum_{n=0}^{\infty} (n!)(BC^n)\end{aligned}$$

Hence for $(\mathcal{A}, w)$ to be probabilistic with full support, R1' and R2 require us to choose B and C so that, respectively, $BC^n \in (0, 1]$ for all n and $\sum_{n=0}^{\infty} n!BC^n = 1$. Note that this does not constrain the component weights of B or C to be in $(0, 1]$—they can be any real numbers. But since R1' requires BC^n to be positive for all n, both B and C must also be positive. If either were 0, then BC^n would be 0 for $n > 0$; if either were negative, then BC^n would be negative for some or all values of n.

Now we show that any choice of positive C causes $\sum_{G \in L_s(\mathcal{A})} w(G)$ to diverge. Given an infinite series of the form $\sum_{n=0}^{\infty} a_n$, the **ratio test** (D'Alembert, 1768) considers the ratio between adjacent terms in the limit, $\lim_{n \to \infty} \frac{|a_{n+1}|}{|a_n|}$. If this ratio is greater than 1, the series diverges; if less than 1 the series converges; if exactly 1 the test is inconclusive. In our case:

$$\lim_{n \to \infty} \frac{|(n+1)!BC^{n+1}|}{|n!BC^n|} = \lim_{n \to \infty} (n+1)|C| = \infty.$$

Hence $\sum_{G \in L_s(\mathcal{A})}$ diverges for any choice of C, equivalently for any choice of weights. So there is no w for which $(\mathcal{A}, w)$ is probabilistic with full support over $L_s(\mathcal{A})$. $\square$

Note that any automaton recognising $L_s(\mathcal{A})$ must accept factorially many DAGs in the number of nodes. Our proof implies that there is *no* probabilistic DAG automaton for language $L_s(\mathcal{A})$, since no matter how we design its transitions—each of which must be isomorphic to one in $\mathcal{A}$ apart from the identities of the states—the factorial will eventually overwhelm the constant factor corresponding to C in our proof, no matter how small it is.

Theorem 1 does not rule out *all* probabilistic variants of $\mathcal{A}$. It requires R1'—if we only require the weaker R1, then a solution of B=1 and C=0 makes the automaton probabilistic. But this trivial distribution is not very useful: it assigns all of its mass to the singleton language {  }.

Theorem 1 also does not mean that it is impossible to define a probability distribution over $L_s(\mathcal{A})$ with full support. If, for every DAG G with n nodes labeled b, we let $p(G) = \frac{1}{2^{n+1} n!}$, then:

$$\sum_{G \in L_s(\mathcal{A})} w(G) = \sum_{n=0}^{\infty} \frac{1}{2^{n+1} n!} n! = \sum_{n=0}^{\infty} \frac{1}{2^{n+1}} = 1$$

But this distribution does not factor over transitions, so it cannot be used with the dynamic programming algorithms of Chiang et al. (2018).

A natural way to define distributions using a DAG automaton is to define two conditional probabilities: one over the choice of nodes to rewrite, given a frontier; and one over the choice of transition, given the chosen nodes. The latter factors over transitions, but the former does not, so it also cannot use the algorithms of Chiang et al. (2018).[3]

Theorem 1 only applies to single-rooted, non-planar DAG automata of bounded degree. Next we ask whether it extends to other DAG automata, including those that recognise multi-rooted DAGs, DAGs of unbounded degree, and planar DAGs.

3.1 Multi-rooted DAGs

What happens when we consider DAG languages that allow multiple roots? In one reasonable interpretation of AMRbank, over three quarters of the DAGs have multiple roots (Kuhlmann and Oepen, 2016), so we want a model that permits this.[4]

Section 2.1.1 explained how a DAG automaton can be constrained to generate single-rooted languages, by restricting start transitions (i.e. those

---

[3] In this model, the subproblems of a natural dynamic program depend on the set of possible frontiers, rather than subsets of nodes as in the algorithms of Chiang et al. (2018). We do not know whether this could be made efficient.

[4] AMR annotations are single-rooted, but they achieve this by duplicating edges: every edge type, like ARG0, has an inverse type, like ARG0-OF. The number cited here assumes edges of the second type are converted to the first type by reversing their direction.

with $\emptyset$ on the left-hand side) to a single use at the start of a derivation. To generate DAGs with multiple roots, we simply allow start transitions to be applied at any time. We still require the resulting DAGs to be connected. For an automaton A, we define its **multi-rooted language** $L_m(A)$ as $\{G \in \mathcal{G}^*_\Sigma | A \text{ recognises } G\}$.

Although one automaton can define both single- and multi-rooted DAG languages, these languages are incomparable. Drewes (2017) uses a construction very similar to the one in Theorem 1 to show that single-rooted languages have very expressive path languages, which he argues are too expressive for modeling semantics.[5] Since the constructions are so similar, it natural to wonder if the problem that single-rooted automata have with probabilities is related to their problem with expressivity, and whether it likewise disappears when we allow multiple roots. We now show that multi-rooted languages have the same problem with probability, because any multi-rooted language contains the single-rooted language as a sublanguage.

Corollary 1. *Let $\mathcal{A}$ be the automaton defined in Example 1. There is no w that makes $(\mathcal{A}, w)$ probabilistic with full support over $L_m(\mathcal{A})$.*

Proof. By their definitions, $L_s(\mathcal{A}) \subset L_m(\mathcal{A})$, so:

$$\sum_{G \in L_m(\mathcal{A})} w(G) = \sum_{G \in L_s(\mathcal{A})} w(G) + \sum_{G \in L_m(\mathcal{A}) \setminus L_s(\mathcal{A})} w(G)$$

The first term is ∞ by Theorem 1 and the second is positive by R1', so the sum diverges. Hence there is no w for which $(\mathcal{A}, w)$ is probabilistic with full support over $L_m(\mathcal{A})$. $\square$

3.2 DAGs of Unbounded Degree

The maximum degree of any node in any DAG recognised by a DAG automaton is bounded by the maximum number of states in any transition, because any transition $\alpha \xrightarrow{\sigma} \beta$ generates a node with $|\alpha|$ incoming edges and $|\beta|$ outgoing edges. So, the families of DAG languages we have considered all have bounded degree.

DAG languages with unbounded degree could be useful to model phenomena like coreference in meaning representations, and they have been studied by Quernheim and Knight (2012) and Chiang et al. (2018). These families generalise and strictly contain the family of bounded-degree DAG languages, so they too, include DAG automata that cannot be made probabilistic.

3.3 Implications for semantic DAGs

We introduced DAG automata as a tool for modeling the meaning of natural language, but the DAG automaton in Theorem 1 is very artificial, so it's natural to ask whether it has any real relevance to natural language. We will argue informally that this example illustrates a pervasive problem with DAG automata—specifically, we conjecture that the factorial growth we observe in Theorem 1 arises under very mild conditions that arise naturally in models of AMR.

Consider object control in a sentence like "I help Ruby help you" and its AMR in Figure 5.

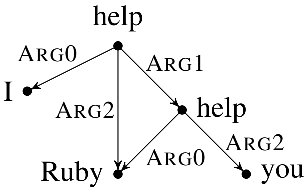

Figure 5: The AMR for "I help Ruby help you".

We can extend the control structure unboundedly with additional helpers, as in "I help Briony help Kim-Joy help Ruby help you", and this leads to unboundedly long repetitive graphs like the one in Figure 6. These graphs can be cut to separate the sequence of "help" predicates from their arguments, as illustrated by the dashed blue line.

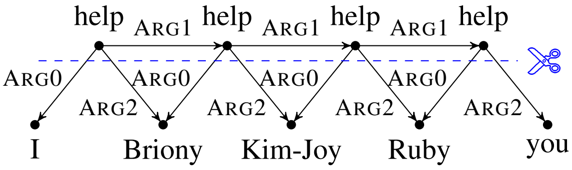

Figure 6: The AMR for "I help Briony help Kim-Joy help Ruby help you" shown with a cut.

Let a **cut** be a set of edges such that removing them splits the graph into two connected subgraphs: one containing the root, and the other containing all the leaves. Any cut in a complete graph

---

[5] The **path language** of a DAG is the set of strings that label a path from a root to a leaf, and the path language of a DAG language is the set of all such strings over all DAGs. For example, the path language of the DAG in Figure 2(v) is $\{abde, abbdde, abbcdde\}$. Berglund et al. (2017) show that path languages of multi-rooted DAG automata are regular, while those of single-rooted DAG automata characterised by a partially blind multi-counter automaton.

could have been the frontier of a partially-derived graph. What if the number of edges in a cut—or **cut-width**—can be unbounded, as in the language of AMR graphs that model object control?

Since a DAG automaton can have only a finite number of states, there is some state that can occur unboundedly many times in a graph cut. All edges in a cut with this state can be rewired by permuting their target nodes, and the resulting graph will still be recognised by the automaton, since the rewiring would not change the multiset of states into or out of any node. If each possible rewiring results in a unique graph then the number of recognised graphs will be factorial in the number of source nodes for these edges, and the argument of Theorem 1 can be generalised to show that no weighting of any DAG automaton over the graph language makes it probabilistic with full support. For example, in the graph above, all possible rewirings of the ARG2 edges result in a unique graph.[6] Although edge labels are not states, their translation into node labels implies that they can only be associated to a finite number of transitions, hence to a finite number of states in any corresponding DAG automaton. A full investigation of conditions under which Theorem 1 generalises is beyond the scope of this paper.

Conjecture 1. *Under mild conditions, if language* $L(A)$ *of a DAG automaton* A *has unbounded cut-width, there is no* w *that makes* (A, w) *probabilistic with full support.*

4 Planar DAG Automata

The fundamental problem with trying to assign probabilities to non-planar DAG automata is the factorial growth in the number of DAGs with respect to the number of nodes. Does this problem occur in planar DAG automata?

Planar DAG automata are similar to the DAG automata of Section 2 but with an important difference: they transition between *ordered* sequences of states rather than unordered multisets of states. We write these sequences in parentheses, and their order matters: (p, q) differs from (q, p). We write ϵ for the empty sequence. When a planar DAG automaton generates DAGs, it keeps a strict order over the set of frontier states at all times. A transition whose left-hand side is (p, q) can only be applied to adjacent states p and q in the frontier, with p preceding q. The matched states are replaced in the frontier by the sequence of states in the transition's right-hand side, maintaining order.

Example 6. Consider a planar DAG automaton with the following transitions:

$$\begin{array}{rcl} \epsilon \xrightarrow{a} (p) & & (t''_1) \\ (p) \xrightarrow{b} (p, q) & & (t''_2) \\ (p) \xrightarrow{c} (p') & & (t''_3) \end{array} \qquad \begin{array}{rcl} (p', q) \xrightarrow{d} (p') & & (t''_4) \\ (p') \xrightarrow{e} \epsilon & & (t''_5) \end{array}$$

In the non-planar case, n applications of t_2 can generate $n!$ unique DAGs, but n applications of the corresponding transition t''_2 in this automaton can only generate one DAG. To see this, consider the partially derived DAG on the left of Figure 7, with its frontier drawn in order from left to right. The p' state can only combine with the q state immediately to its right, and since dead-ends are not allowed, the only possible choice is to apply t''_4 twice followed by t''_5, so the DAG on the right is the only possible completion of the derivation.

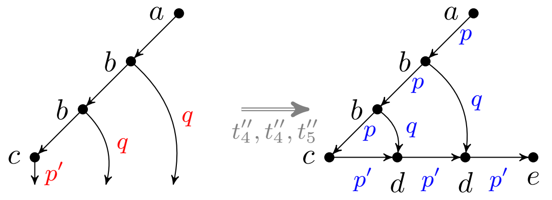

Figure 7: A partial derivation using the planar DAG automaton of Example 6 (left; red edge labels denote frontier states) and its only possible completion (right; blue edge labels denote an accepting run).

This automaton is probabilistic when $w(t''_1) = w(t''_2) = 1/2$, $w(t''_3) = w(t''_4) = w(t''_5) = 1$, and indeed the argument in Theorem 1 does not apply to planar automata since the number of applicable transitions is linear in the size of the frontier. But planar DAG automata have other problems that make them unsuitable for modeling AMR.

The first problem is that there are natural language constructions that naturally produce non-planar DAGs in AMR. For example, consider the sentence "Four contestants mixed, baked and ate cake." Its AMR, shown in Figure 8, is not planar because it has a $K_{3,3}$ minor, and it is easy to see from this example that any coordination of three predicates sharing two arguments produces this structure. In the first release of AMR, 117 out of 12844 DAGs are non-planar.

The second problem is that planar DAG au-

---

[6] This is also a problem linguistically, since many of the rewired graphs no longer model object control.

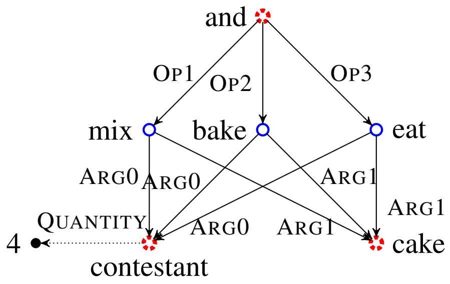

Figure 8: An AMR for the sentence "Four contestants mixed, baked and ate a cake". As in Figure 3, contracting the dotted edge yields a $K_{3,3}$ minor, with one set denoted by hollow blue nodes (○), the other by dotted red nodes (◌).

tomata model Type-0 string derivations by design (Kamimura and Slutzki, 1981). This seems more expressive than needed to model natural language and means that many important decision problems are undecidable—for example, emptiness, which is decidable in polynomial time for non-planar DAG automata (Chiang et al., 2018).

5 Conclusions

Table 2 summarises the properties of several different variants of DAG automata. It has been argued that all of these properties are desirable for probabilistic models of meaning representations (Drewes, 2017). Since none of the variants supports all properties, this suggests that no variant of the DAG automaton is a good candidate for modeling meaning representations. We believe other formalisms may be more suitable, including several subfamilies of hyperedge replacement grammars (Drewes et al., 1997) that have recently been proposed (Björklund et al., 2016; Matheja et al., 2015; Gilroy et al., 2017).

	non-planar				planar
bounded degree	yes		no		yes
roots	1	1+	1	1+	1
probabilistic	no	no	no	no	?
decidable	yes	yes	yes	yes	no
regular paths	no	yes	no	yes	no

A Systematic Study of Leveraging Subword Information for Learning Word Representations

Yi Zhu, Ivan Vulić, and **Anna Korhonen**
Language Technology Lab
University of Cambridge
`{yz568, iv250, alk23}@cam.ac.uk`

Abstract

The use of subword-level information (e.g., characters, character n-grams, morphemes) has become ubiquitous in modern word representation learning. Its importance is attested especially for morphologically rich languages which generate a large number of rare words. Despite a steadily increasing interest in such *subword-informed word representations*, their systematic comparative analysis across typologically diverse languages and different tasks is still missing. In this work, we deliver such a study focusing on the variation of two crucial components required for subword-level integration into word representation models: 1) *segmentation of words* into subword units, and 2) *subword composition functions* to obtain final word representations. We propose a general framework for learning subword-informed word representations that allows for easy experimentation with different segmentation and composition components, also including more advanced techniques based on position embeddings and self-attention. Using the unified framework, we run experiments over a large number of subword-informed word representation configurations (60 in total) on 3 tasks (general and rare word similarity, dependency parsing, fine-grained entity typing) for 5 languages representing 3 language types. Our main results clearly indicate that there is no "one-size-fits-all" configuration, as performance is both language- and task-dependent. We also show that configurations based on unsupervised segmentation (e.g., BPE, Morfessor) are sometimes comparable to or even outperform the ones based on supervised word segmentation.

1 Introduction

Word representations are central to a wide variety of NLP tasks (Collobert et al., 2011; Chen and Manning, 2014; Jia and Liang, 2016; Ammar et al., 2016; Goldberg, 2017; Peters et al., 2018; Kudo, 2018, *inter alia*). Standard word representation models are based on the distributional hypothesis (Harris, 1954) and induce representations from large unlabeled corpora using word co-occurrence statistics (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014). However, as pointed out by recent work (Bojanowski et al., 2017; Vania and Lopez, 2017; Pinter et al., 2017; Chaudhary et al., 2018; Zhao et al., 2018), mapping a finite set of word types into corresponding word representations limits the capacity of these models to learn beyond distributional information, which leads to several fundamental limitations.

The standard approaches ignore the internal structure of words, that is, the syntactic or semantic composition from subwords or morphemes to words, and are incapable of parameter sharing at the level of subword units. Assigning only a single vector to each word causes the data sparsity problem, especially in resource-poor settings where huge amounts of training data cannot be guaranteed. The issue is also prominent for morphologically rich languages (e.g., Finnish) with productive morphological systems that generate a large number of infrequent/rare words (Gerz et al., 2018). Although potentially useful information on word relationships is hidden in their internal *subword-level structure*,[1] subword-agnostic word representation models do not take these structure features into account and are effectively unable to represent rare words accurately, or unseen words at all.

Therefore, there has been a surge of interest in *subword-informed* word representation architectures aiming to address these gaps. A large number of architectures has been proposed in related research, and they can be clustered over the two main axes (Lazaridou et al., 2013; Luong et al., 2013;

---

[1] For example, nouns in Finnish have 15 cases and 3 plural forms; Spanish verbs may contain over 40 inflected forms, sharing the lemma and taking up standard suffixes.

Proceedings of NAACL-HLT 2019, pages 912–932
Minneapolis, Minnesota, June 2 - June 7, 2019.

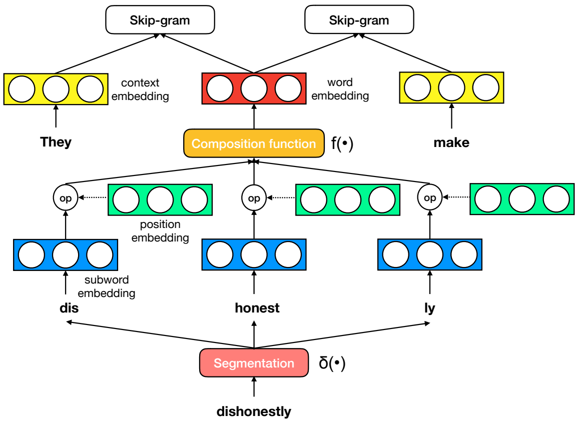

Figure 1: Illustration of the general framework for learning subword-informed word representations, with the focus on two crucial components: 1) segmentation of words and 2) subword embedding composition. By varying the two components, and optionally including or excluding position embeddings from the computations, we obtain a wide spectrum of different subword-informed configurations used in the study (see §2). Our word-level representation model in this work is skip-gram (on the top layer of the figure), but it can be replaced by any other distributional word-level model.

Qiu et al., 2014; Cotterell and Schütze, 2015; Wieting et al., 2016; Avraham and Goldberg, 2017; Vania and Lopez, 2017; Pinter et al., 2017; Cotterell and Schütze, 2018). First, the models differ in the chosen method for *segmenting words into subwords*. The methods range from fully supervised approaches (Cotterell and Schütze, 2015) to e.g. unsupervised approaches based on BPE (Heinzerling and Strube, 2018). Second, another crucial aspect is the *subword composition function* used to obtain word embeddings from the embeddings of each word's constituent subword units. Despite a steadily increasing interest in such subword-informed word representations, their systematic comparative analysis across the two main axes, as well as across typologically diverse languages and different tasks is still missing.[2]

In this work, we conduct a systematic study of a variety of subword-informed word representation architectures that all can be described by a general framework illustrated by Figure 1. The framework enables straightforward experimentation with prominent word segmentation methods (e.g., BPE, Morfessor, supervised segmentation systems) as well as subword composition functions (e.g., addition, self-attention), resulting in a large number of different *subword-informed configurations*.[3]

Our study aims at providing answers to the following crucial questions: **Q1)** How generalizable are subword-informed models across typologically diverse languages and across different downstream tasks? Do different languages and tasks require different configurations to reach peak performances or is there a single best-performing configuration? **Q2)** How important is it to choose an appropriate segmentation and composition method? How effective are more generally applicable unsupervised segmentation methods? Is it always better to resort to a supervised method, if available? **Q3)** Is there a difference in performance with and without the full word representation? Can more advanced techniques based on position embeddings and self-attention yield better task performance?

We evaluate subword-informed word representation configurations originating from the general framework in three different tasks using standard benchmarks and evaluation protocols: 1) general and rare word similarity and relatedness, 2) dependency parsing, and 3) fine-grained entity typing for 5 languages representing 3 language families (fusional, introflexive, agglutinative). We show that different tasks and languages indeed require diverse subword-informed configurations to reach peak performance: this calls for a more careful language- and task-dependent tuning of configuration components. We also show that more sophisticated configurations are particularly useful for representing rare words, and that unsupervised segmentation methods can be competitive to supervised segmentation in tasks such as parsing or fine-grained entity typing. We hope that this paper will provide useful points of comparison and comprehensive guidance for developing next-generation subword-informed word representation models for typologically diverse languages.

2 Methodology

The general framework for learning subword-informed word representations, illustrated by Figure 1, is introduced in §2.1. We then describe its main components: segmentation of words into subword units (§2.2), subword and position embeddings (§2.3), and subword embedding composition

---

[2] A preliminary study of Vania and Lopez (2017) limits its focus on the use of subwords in the language modeling task.

[3] Following a similar work on subword-agnostic word embedding learning (Levy et al., 2015), our system design choices resulting in different configurations can be seen as a set of hyper-parameters that also have to be carefully tuned for each language and each application task.

functions (§2.4), along with all the configurations for these components used in our evaluation.

2.1 General Framework

Formally, given a word w, its word embedding $\mathbf{w}$ can be computed by the composition of its subword embeddings as follows:

$$\mathbf{w} = f_{\mathbf{\Theta}}(\delta(w), \mathbf{W}_s, \mathbf{W}_p), \quad (1)$$

where $\delta(w)$ is a deterministic function that segments w into an ordered sequence of its constituent subword units $S_w = (s_{w_i})_1^n$, with $s_{w_i} \in \mathcal{S}$ being a subword type from the subword vocabulary $\mathcal{S}$ of size $|\mathcal{S}|$. Optionally, some segmentation methods can also generate a sequence of the corresponding morphotactic tags $T_w = (t_{w_i})_1^n$. Alone or together with T_w, S_w is embedded into a sequence of subword representations $\mathbf{S}_w = (\mathbf{s}_{w_i})_1^n$ from the subword embedding matrix $\mathbf{W}_s \in \mathbb{R}^{|\mathcal{S}|\times d}$, where d is the dimensionality of subword embeddings. Another optional step is to obtain a sequence of position embeddings $\mathbf{P}_w = (\mathbf{p}_{w_i})_1^n$: they are taken from the position embedding matrix $\mathbf{W}_p \in \mathbb{R}^{p\times d}$, where p is the maximum number of the unique positions. $\mathbf{P}_w$ can interact with $\mathbf{S}_w$ to compute the final representations for subwords $\mathbf{R}_w = (\mathbf{r}_{w_i})_1^n$ (Vaswani et al., 2017). $f_{\mathbf{\Theta}}$ is a composition function taking $\mathbf{R}_w$ as input and outputting a single vector $\mathbf{w}$ as the word embedding of w.

For the distributional "word-level" training, similar to prior work (Bojanowski et al., 2017), we adopt the standard skip-gram with negative sampling (SGNS) (Mikolov et al., 2013) with bag-of-words contexts. However, we note that other distributional models can also be used under the same framework. Again, following Bojanowski et al. (2017), we calculate the word embedding $\mathbf{w}_t \in \mathbb{R}^d$ for each target word w_t using the formulation from Eq. (1), and parametrize context words with another word embedding matrix $\mathbf{W}_c \in \mathbb{R}^{|\mathcal{V}|\times d}$, where $|\mathcal{V}|$ is the size of word vocabulary $\mathcal{V}$.

2.2 Segmentation of Words into Subwords

We consider three well-known segmentation methods for the function δ, briefly outlined here.

Supervised Morphological Segmentation We use CHIPMUNK (Cotterell et al., 2015) as a representative supervised segmentation system, proven to provide a good trade-off between accuracy and speed.[4] It is based on semi-Markov conditional random fields (Sarawagi and Cohen, 2005). For each word, apart from generating S_w, it also outputs the corresponding morphotactic tags T_w.[5] In §2.3 we discuss how to incorporate information from T_w into subword representations.

δ	δ(*dishonestly*)
CHIPMUNK	(*dis*, *honest*, *ly*) (*prefix*, *root*, *suffix*)
Morfessor	(*dishonest*, *ly*)
BPE	(*dish*, *on*, *est*, *ly*)

Table 1: Segmentations of the word *dishonestly*.

Morfessor Morfessor (Smit et al., 2014) denotes a family of generative probabilistic models for unsupervised morphological segmentation used, among other applications, to learn morphologically-aware word embeddings (Luong et al., 2013).

BPE Byte Pair Encoding (BPE; Gage (1994)) is a simple data compression algorithm. It has become a de facto standard for providing subword information in neural machine translation (Sennrich et al., 2016). The input word is initially split into a sequence of characters, with each unique character denoted as a byte. BPE then iteratively replaces the most common pair of consecutive bytes with a new byte that does not occur within the data, and the number of iterations can be set in advance to control the granularity of the byte combinations.

An example output for all three methods is shown in Table 1. Note that a standard practice in subword-informed models is to also insert the entire word token into S_w (Bojanowski et al., 2017).[6] This is, however, again an optional step and we evaluate configurations with and without the inclusion of the word token in S_w.

2.3 Subword and Position Embeddings

The next step is to encode S_w (or the tuple (S_w, T_w) for CHIPMUNK) to construct a sequence of subword representations $\mathbf{S}_w$. Each row of the subword embedding matrix $\mathbf{W}_s$ is simply defined as the embedding of a unique subword. For CHIPMUNK, we define each row in $\mathbf{W}_s$ as the concatenation of the subword s and its predicted tag t. We also test

---

[4] `http://cistern.cis.lmu.de/chipmunk`

[5] In our experiments, we use only basic information on affixes such as prefixes and suffixes, and leave the integration of fine-grained information such as inflectional and derivational affixes as future work.

[6] We only do the insertion if $|S_w| > 1$. For CHIPMUNK, a generic tag `word` is added to the sequence T_w.

CHIPMUNK configurations without the use of T_w to analyze its contribution.[7]

After generating $\mathbf{S}_w$, an optional step is to have a *learnable* position embedding sequence $\mathbf{P}_w$ further operate on $\mathbf{S}_w$ to encode the order information. Similar to $\mathbf{W}_s$, the definition of the position embedding matrix $\mathbf{W}_p$ also varies: for Morfessor and BPE, we use the absolute positions of subwords in the sequence S_w, whereas for CHIPMUNK morphotactic tags are encoded directly as positions.

Finally, following prior work (Gehring et al., 2017; Mikolov et al., 2018), we use addition and element-wise multiplication between each subword vector $\mathbf{s}$ from $\mathbf{S}_w$ and the corresponding position vector $\mathbf{p}$ from $\mathbf{P}_w$ to compute each entry $\mathbf{r}$ for the final sequence of subword vectors $\mathbf{R}_w$:

$$\mathbf{r} = \mathbf{s} + \mathbf{p} \quad \text{or} \quad \mathbf{r} = \mathbf{s} \odot \mathbf{p}. \tag{2}$$

2.4 Composition Functions

A composition function f_Θ is then applied to the sequence of subword embeddings $\mathbf{R}_w$ to compute the final word embedding $\mathbf{w}$. We investigate three composition functions: 1) addition, 2) single-head and 3) multi-head self-attention (Vaswani et al., 2017; Lin et al., 2017).[8] Addition is used in the original `fastText` model of Bojanowski et al. (2017), and remains a strong baseline for many tasks. However, addition treats each subword with the same importance, ignoring semantic composition and interactions among the word's constituent subwords. Therefore, we propose to use a self-attention mechanism, that is, a learnable weighted addition as the composition function on subword sequences. To the best of our knowledge, we are the first to apply a self-attention mechanism to the problem of subword composition.

Composition Based on Self-Attention Our self-attention mechanism is inspired by Lin et al. (2017). It is essentially a multilayer feed-forward neural network without bias term, which generates a weight matrix for the variable length input $\mathbf{R}_w$:

$$\mathbf{H}_w = tanh(\mathbf{W}_{h_1}\mathbf{R}_w^T) \tag{3}$$

$$\mathbf{A}_w = softmax(\mathbf{W}_{h_2}\mathbf{H}_w) \tag{4}$$

Component	Option	Label
Segmentation	CHIPMUNK	*sms*
	Morfessor	*morf*
	BPE	*bpe*
Morphotactic tag	concatenated with subword (only *sms*)	*st*
Word token	exclusion	*w-*
	inclusion	*w+*
Position embedding	exclusion	*p-*
	additive	*pp*
	multiplicative	*mp*
Composition function	addition	*add*
	single head attention	*att*
	multi-head attention	*mtx*

Table 2: Different components used to construct subword-informed configurations, and their labels.

Each row of $\mathbf{A}_w$ is a weight vector for rows of $\mathbf{R}_w$, which models different aspects of semantic compositions and interactions. For the single-head self-attention, $\mathbf{A}_w$ degenerates to a row vector as the final attention vector $\mathbf{a}_w$. For the multi-head self-attention, we average the rows of $\mathbf{A}_w$ to generate $\mathbf{a}_w$.[9] Finally, $\mathbf{w}$ is computed as the weighted addition of subword embeddings from $\mathbf{R}_w$: $\mathbf{w} = \sum_{w_1}^{w_n} a_{w_i}\mathbf{r}_{w_i}$.

3 Experimental Setup

We train different subword-informed model configurations on 5 languages representing 3 morphological language types: English (EN), German (DE), Finnish (FI), Turkish (TR) and Hebrew (HE), see Table 3. We then evaluate the resulting subword-informed word embeddings in three distinct tasks: 1) general and rare word similarity and relatedness, 2) syntactic parsing, and 3) fine-grained entity typing. The three tasks have been selected in particular as they require different degrees of syntactic and semantic information to be stored in the input word embeddings, ranging from a purely semantic task (word similarity) over a hybrid syntactic-semantic task of entity typing to syntactic parsing.

Subword-Informed Configurations We train a large number of subword-informed configurations by varying the segmentation method δ (§2.2), subword embeddings $\mathbf{W}_s$, the inclusion of position embeddings $\mathbf{W}_p$ and the operations on $\mathbf{W}_s$ (§2.3), and the composition functions f_Θ (§2.4). The configurations are based on the following variations of

---

[7] The extra information on tags should lead to a more expressive model resolving subword ambiguities. For instance, the subword *post* in *postwar* and noun *post* are intrinsically different: the former is the prefix and the later is the root.

[8] Using more complex compositions based on CNNs and RNNs is also possible, but we have not observed improvement in our evaluation tasks with such compositions, which is also in line with findings from recent work (Li et al., 2018).

[9] We have also experimented with adding an extra transformation layer over attention matrix to generate the attention vector, but without any performance gains.

constituent components: (1) For the segmentation δ, we test a supervised morphological system CHIPMUNK (*sms*), Morfessor (*morf*) and BPE (*bpe*). A word token can be optionally inserted into the subword sequence S_w for all three segmentation methods (*ww*) or left out (*w-*); (2) We can only embed the subword s for *morf* and *bpe*, while with *sms* we can optionally embed the concatenation of the subword and its morphotactic tag $s:t$ (*st*);[10] (3) We test subword embedding learning without position embeddings (*p-*), or we integrate them using addition (*pp*) or element-wise multiplication (*mp*); (4) For the composition function function f_Θ, we experiment with addition (*add*), single head self-attention (*att*), and multi-head self-attention (*mtx*). Table 2 provides an overview of all components used to construct a variety of subword-informed configurations used in our evaluation.

The variations of components from Table 2 yield 24 different configurations in total for *sms*, and 18 for *morf* and *bpe*. We use pretrained CHIPMUNK models for all test languages except for Hebrew, as Hebrew lacks gold segmentation data. Following Vania and Lopez (2017), we use the default parameters for Morfessor, and 10k merge operations for BPE across languages. We use available BPE models pre-trained on Wikipedia by Heinzerling and Strube (2018).[11]

Two well-known word representation models, which can also be described by the general framework from Figure 1, are used as insightful baselines: the subword-agnostic SGNS model (Mikolov et al., 2013) and `fastText` (FT)[12] (Bojanowski et al., 2017). FT computes the target word embedding using addition as the composition function, while the segmentation is straightforward: the model simply generates all character n-grams of length 3 to 6 and adds them to S_w along with the full word.

Training Setup Our training data for all languages is Wikipedia. We lowercase all text and replace all digits with a generic tag #. The statistics of the training corpora are provided in Table 3.

Typology	Language	#tokens	#types
Fusional	English (EN)	600M	900K
	German (DE)	200M	940K
Agglutinative	Finnish (FI)	66M	600K
	Turkish (TR)	52M	300K
Introflexive	Hebrew (HE)	90M	410K

Table 3: Statistics of our Wikipedia training corpora. For faster training, we use one third of the entire Wikipedia corpus for EN and DE.

All subword-informed variants are trained on the same data and share the same parameters for the SGNS model.[13] Further, we use ADAGRAD (Duchi et al., 2011) with a linearly decaying learning rate, and do a grid search of learning rate and batch size for each δ on the German[14] WordSim-353 data set (WS; Leviant and Reichart (2015)). The hyperparameters are then fixed for all other languages and evaluation runs. Finally, we set the learning rate to 0.05 for *sms* and *bpe*, and 0.075 for *morf*, and the batch size to 1024 for all the settings.

3.1 Evaluation Tasks

Word Similarity and Relatedness These standard intrinsic evaluation tasks test the semantics of word representations (Pennington et al., 2014; Bojanowski et al., 2017). The evaluations are performed using the Spearman's rank correlation score between the average of human judgement similarity scores for word pairs and the cosine similarity between two word embeddings constituting each word pair. We use Multilingual SimLex-999 (SIMLEX; Hill et al. (2015); Leviant and Reichart (2015); Mrkšić et al. (2017)) for English, German and Hebrew, each containing 999 word pairs annotated for true semantic similarity. We further evaluate embeddings on FinnSim-300 (FS300) produced by Venekoski and Vankka (2017) for Finnish and AnlamVer (AN; Ercan and Yıldız (2018)) for Turkish. We also run experiments on the WordSim-353 test set (WS; Finkelstein et al. (2002)), and its portions oriented towards true similarity (WS-SIM) and broader relatedness (WS-REL) portion for English and German.

Finally, to analyze the importance of subword information for learning embeddings of rare words, we evaluate on the recently released CARD-660 dataset (CARD; Pilehvar et al. (2018)) for English, annotated for true semantic similarity.

---

[10] Once *st* is applied, we do not use position embeddings anymore, because the morphotactic tags are already encoded in subword embeddings, i.e., *st* and *pp* are mutually exclusive.

[11] `https://github.com/bheinzerling/bpemb`

[12] `https://github.com/facebookresearch/fastText`

[13] We rely on the standard choices: 300-dimensional subword and word embeddings, 5 training epochs, the context window size is 5, 5 negative samples, the subsampling rate of 10^{-5}, and the minimum word frequency is 5.

[14] German has moderate morphological complexity among the five languages, so we think the hyperparameters tuned on it could be applicable to other languages.

Table 5: Results on the dependency parsing task. The two best configurations are selected according to LAS.

Dependency Parsing Next, we use the syntactic dependency parsing task to analyze the importance of subword information for syntactically-driven downstream applications. For all test languages, we rely on the standard Universal Dependencies treebanks (UD v2.2; Nivre et al. (2016)). We use subword-informed word embeddings from different configurations to initialize the deep biaffine parser of Dozat and Manning (2017) which has shown competitive performance in shared tasks (Dozat et al., 2017) and among other parsing models (Ma and Hovy, 2017; Shi et al., 2017; Ma et al., 2018).[15] We use default settings for the biaffine parser for all experimental runs

Fine-Grained Entity Typing The task is to map entities, which could comprise more than one entity token, to predefined entity types (Yaghoobzadeh and Schütze, 2015). It is a suitable semi-semantic task to test our subword models, as the subwords of entities usually carry some semantic information from which the entity types can be inferred. For example, *Lincolnshire* will belong to `/location/county` as *-shire* is a suffix that strongly indicates a location. We rely on an entity typing dataset of Heinzerling and Strube (2018) built for over 250 languages by obtaining entity mentions from Wikidata (Vrandečić and Krötzsch, 2014) and their associated FIGER-based entity types (Ling and Weld, 2012): there only exists a one-to-one mapping between the entity and one of the 112 FIGER types.

We randomly sample the data to obtain a train/dev/test split with the size of 60k/20k/20k for all languages. For evaluation we extend the RNN-based model of Heinzerling and Strube (2018), where they stacked all the subwords of entity tokens into a flattened sequence: we use the hierarchical embedding composition instead. For each entity token, we first compute its word embeddings with our subword configurations,[16] then feed the word embeddings of entity tokens to a bidirectional LSTM with 2 hidden layers of size 512, followed by a projection layer which predicts the entity type.

---

[15] `https://github.com/tdozat/Parser-v2`

[16] Although it is true that case information can be very important to the task, we conform to Heinzerling and Strube (2018) lowercasing all letters.

4 Results and Analysis

To get a better grasp of the overall performance without overloading the tables, we focus on reporting two best configurations and the worst configuration for each task and language from the total of 60 configurations, except for Hebrew with 36 configurations, where there is no gold segmentation data for training *sms* model. We also analyze the effects of different configurations on different tasks based on language typology. The entire analysis revolves around the key questions Q1-Q3 posed in the introduction. The reader is encouraged to refer to the supplementary material for the complete results.

Tables 4, 5, and 6 summarize the main results on word similarity and relatedness, dependency parsing and entity typing, respectively. In addition, the comparisons of different configurations across tasks and language types are shown in Figure 2 (as well as Figure 3 to 7 in the supplementary material). There, we center the comparison around two crucial components: segmentation and composition. The value in each pixel block is the percentage rank of the row configuration minus that of column configuration. We compute such percentage ranks by performing three levels of averaging over: 1) all related datasets for the same task; 2) all sub-configurations that entail the configuration in question; 3) all languages from the same language types.

Q1. Tasks and Languages Regarding the absolute performance of our subword-informed configurations, we notice that they outperform SGNS and FT in 3/5 languages on average, and for 8/13 datasets on word similarity and relatedness. The gains are more prominent over the subword-agnostic SGNS model and for morphologically richer languages such as Finnish and Turkish. The results on the two other tasks are also very competitive, with strong performance reported especially on the entity typing task. This clearly indicates the importance of integrating subword-level information into word vectors. A finer-grained comparative analysis shows that best-performing configurations vary greatly across different languages.

The comparative analysis across tasks also suggests that there is no single configuration that outperforms the others in all three tasks, although certain patterns in the results emerge. For instance, the supervised segmentation (*sms*) is very useful for word similarity and relatedness (seen in Figure 4). This result is quite intuitive: *sms* is trained according to the readily available gold standard morphological segmentations. However, *sms* is less useful for entity typing, where almost all best-performing configurations are based on *morf* (see also Figure 4). This result is also interpretable: *morf* is a conservative segmenter that captures longer subwords, and is not distracted by short and nonsensical subwords (like *bpe*) that have no contribution to the prediction.[17] The worst configurations on word similarity are based on *bpe*: its aggressive segmentation often results in non-interpretable or nonsensical subwords which are unable to recover useful semantic information. Due to the same reason, the results in all three tasks indicate that the best configurations with *bpe* are always coupled with *ww*, and the worst are obtained with *w-* (i.e., without the inclusion of the full word).

The results on parsing reveal similar performances for a spectrum of heterogeneous configurations. In other words, while the chosen configuration is still important, its impact on performance of state-of-the-art dependency parsers (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017) is decreased, as such parsers are heavily parametrized multi-component methods (e.g., besides word embeddings they rely on biLSTMs, intra-sentence attention, character representations).[18] Therefore, a larger space of subword-informed configurations for word representations leads to optimal or near-optimal results. However, *sms* seems to yield highest scores on average in agglutinative languages (see also Figure 2).

Figure 2 clearly demonstrates that, apart from entity typing heatmaps (the third row) which show very similar trends over different language types, the patterns for different tasks and language types tend to vary in general. Similarly, other figures in the supplementary material also show diverging trends across languages representing different language types.

---

[17] For example, *sms* and *bpe* both split "Valberg" (`/location/city`) and "Robert Valberg" (`/person/actor`) with a suffix "berg". Since "berg" could represent both a place or a person, it is not useful alone as a suffix to predict the correct entity type, whereas *morf* does not split the word and makes the prediction solely based on surrounding entity tokens.

[18] We also experimented with removing token features such as POS tags and character embeddings in some settings, but we observed similar trends in the final results.

	Best	2nd Best	Worst	`sgns`	`ft`

Table 6: Test accuracy, the evaluation metric used by Heinzerling and Strube (2018), on the fine-grained entity typing task. The results are averaged over 5 runs with random seeds.

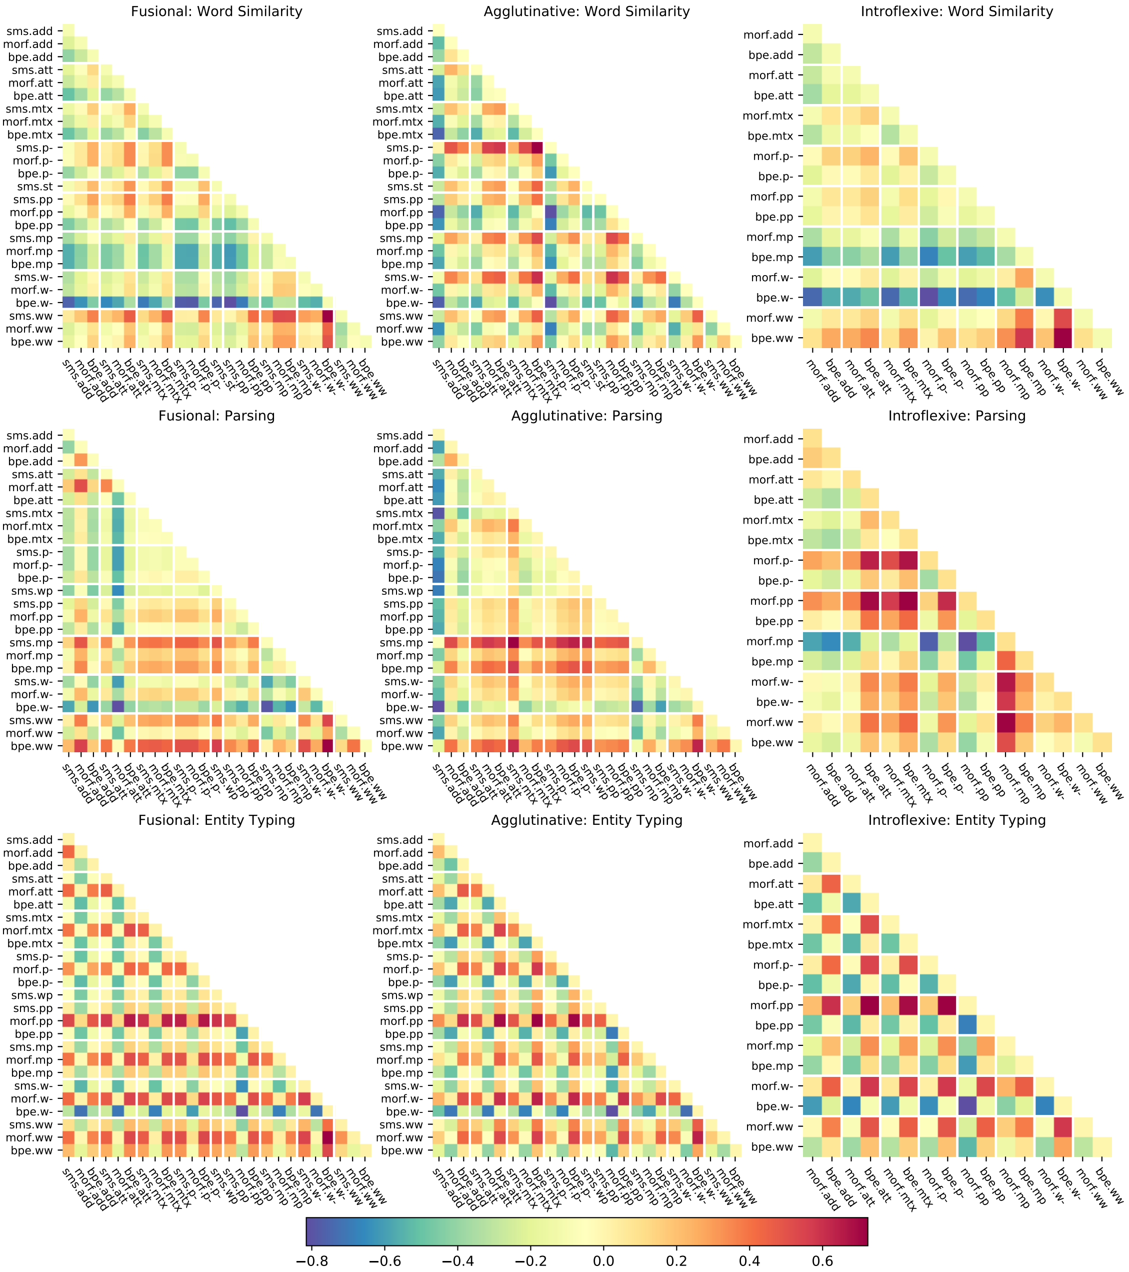

Figure 2: Comparisons of different configurations across tasks grouped by language types. The value in each pixel block is the percentage rank of the row configuration minus that of column configuration. For example, in word similarity for fusional language, the rank for the row *sms.ww* is 0.787 and 0.071 for column *bpe.w-*, and the block value is 0.716. The higher the value, the better the performance of the row compared to the column configuration.

Q2 and Q3. Configurations As mentioned, different tasks reach high scores with different segmentation and composition components. The crucial components for word similarity are *sms* and *ww*, and *sms* is generally better than *morf* and *bpe* in fusional and agglutinative languages (see Figure 4 and 7). The presence of *ww* is desired in this task as also found by Bojanowski et al. (2017): it enhances the information provided by the segmentation. As discussed before, the best configurations with *bpe* are always coupled with *ww*, and the worst with *w-*. *ww* is less important for the more conservative *morf* where the information stored in *ww* can be fully recovered from the generated subwords. Interestingly, *pp* and *mp* do not have positive effects on this task for fusional and introflexive languages, but they seem to resonate well with agglutinative languages, and they are useful for the two other tasks (seen in Figure 6). In general, position embeddings have shown potential benefits in all tasks, where they selectively emphasize or filter subwords according to their positions. *pp* is extremely useful in entity typing for all languages, because it indicates the root position.

Concerning composition functions, *add* still remains an extremely robust choice across tasks and languages. Surprisingly, the more sophisticated self-attention composition prevails only on a handful of datasets: compare the results with *add* vs. *att* and *mtx*. In fact, the worst configurations mostly use *att* and *mtx* (see also Figure 5). In sum, our results suggest that, when unsure, *add* is by far the most robust choice for the subword composition function. Further, morphotactic tags encoded in subword embeddings (*st*) seem to be only effective combined with self-attention in word similarity and relatedness. These findings call for further investigation in future work, along with the inclusion of finer-grained morphotactic tags into the proposed modeling framework.

Further Discussion A recurring theme of this study is that subword-informed configurations are largely task- and language-dependent. We can extract multiple examples from the reported results affirming this conjecture. For instance, in fusional and agglutinative languages *mp* is critical to the model on dependency parsing, while for Hebrew, an introflexive language, *mp* is among the most detrimental components on the same task. Further, for Turkish word similarity *bpe.ww* outperforms *sms.ww*: due to affix concatenation in Turkish, *sms* produces many affixes with only syntactic functions that bring noise to the task. Interestingly, SGNS performs well in Hebrew on parsing and word similarity: it shows that it is still difficult for linear segmentation methods to capture non-concatenative morphology.

Finally, fine-tuning subword-informed representations seems especially beneficial for rare word semantics: our best configuration outperforms FT by 0.111 on CARD, and even surpasses all the state-of-the-art models on the rare word similarity task, as reported by Pilehvar et al. (2018). We hope that our findings on the CARD dataset will motivate further work on building more accurate representations for rare and unseen words (Bhatia et al., 2016; Herbelot and Baroni, 2017; Schick and Schütze, 2018) by learning more effective and more informed components of subword-informed configurations.

5 Conclusion

We have presented a general framework for learning subword-informed word representations which has been used to perform a systematic analysis of 60 different subword-aware configurations for 5 typologically diverse languages across 3 diverse tasks. The large space of presented results has allowed us to analyze the main properties of subword-informed representation learning: we have demonstrated that different components of the framework such as segmentation and composition methods, or the use of position embeddings, have to be carefully tuned to yield improved performance across different tasks and languages. We hope that this study will guide the development of new subword-informed word representation architectures. Code is available at: `https://github.com/cambridgeltl/sw_study`.

A Supplemental Material

In this supplementary material we present the full results of different configurations of our subword-informed representations and baseline models in three tasks across five languages. For details and notations of different model configurations, please refer to the original paper.

Since `fastText` (FT) package cannot generate each subword embedding for a given word, we also implemented our own version (`our_ft`) within the same subword-informed training framework. We trained `our_ft` on all the five languages with the same training corpus, and kept the same hyperparameters as FT package except that we used 1024 as batch size for faster training. We show that our implementation yields comparable results with the original FT in word similarity and relatedness and parsing across languages. For entity typing, we experimented with the extended hierarchical composition architecture described in the paper on `our_ft`, i.e., using subword embeddings to compute word representations and updating subword embeddings of `our_ft` during training, and only use word embeddings as input for SGNS and FT and directly update them. Additionally, we also experimented with some of our model configurations with character n-grams as our segmentation methods, but did not observe performance gains. Due to its large parameter space (usually 2-4 times larger than SGNS) and the computational limits, we leave it as our future work.

Table 7, 8 and 9 show the results of word similarity and relatedness based on different segmentation methods, and Table 10, 11 and 12 for the results of dependency parsing. Table 13 shows the accuracy on development and test set for entity typing across all five languages. Figure 3 shows the configuration comparisons in languages with available datasets for word relatedness. Figure 4 to 7 show the results on all downstream tasks across languages when each test data point is categorized according to some specific component. Specifically, Figure 4 shows the results when only different segmentation methods are considered, and Figure 5, 6 and 7 show the results on varying composition functions, position embedding types and whether including the word token embedding, respectively.

Abstract

Pre-trained word vectors are ubiquitous in Natural Language Processing applications. In this paper, we show how training word embeddings jointly with bigram and even trigram embeddings, results in improved unigram embeddings. We claim that training word embeddings along with higher n-gram embeddings helps in the removal of the contextual information from the unigrams, resulting in better stand-alone word embeddings. We empirically show the validity of our hypothesis by outperforming other competing word representation models by a significant margin on a wide variety of tasks. We make our models publicly available.

1 Introduction

Distributed word representations are essential building blocks of modern NLP systems. Used as features in downstream applications, they often enhance generalization of models trained on a limited amount of data. They do so by capturing relevant distributional information about words from large volumes of unlabeled text.

Efficient methods to learn word vectors have been introduced in the past, most of them based on the distributional hypothesis of Harris (1954); Firth (1957): *"a word is characterized by the company it keeps"*. While a standard approach relies on global corpus statistics (Pennington et al., 2014) formulated as a matrix factorization using mean square reconstruction loss, other widely used methods are the bilinear word2vec architectures introduced by Mikolov et al. (2013a): While skip-gram aims to predict nearby words from a given word, CBOW predicts a target word from its set of context words.

Recently, significant improvements in the quality of the word embeddings were obtained by augmenting word-context pairs with sub-word information in the form of character n-grams (Bojanowski et al., 2017), especially for morphologically rich languages. Nevertheless, to the best of our knowledge, no method has been introduced leveraging collocations of words with higher order word n-grams such as bigrams or trigrams as well as character n-grams together.

In this paper, we show how using higher order word n-grams along with unigrams during training can significantly improve the quality of obtained word embeddings. The addition furthermore helps to disentangle contextual information present in the training data from the unigrams and results in overall better distributed word representations.

To validate our claim, we train two modifications of CBOW augmented with word-n-gram information during training. One is a recent sentence embedding method, Sent2Vec (Pagliardini et al., 2018), which we repurpose to obtain word vectors. The second method we propose is a modification of CBOW enriched with character n-gram information (Bojanowski et al., 2017) that we again augment with word n-gram information. In both cases, we compare the resulting vectors with the most widely used word embedding methods on word similarity and analogy tasks and show significant quality improvements. The code used to train the models presented in this paper as well as the models themselves are made available to the public[1].

2 Model Description

Before introducing our model, we recapitulate fundamental existing word embeddings methods.

CBOW and skip-gram models. Continuous bag-of-words (CBOW) and skip-gram models are

standard log-bilinear models for obtaining word embeddings based on word-context pair information (Mikolov et al., 2013a). Context here refers to a symmetric window centered on the target word w_t, containing the surrounding tokens at a distance less than some window size ws: $C_t = \{w_k \,|\, k \in [t - \mathsf{ws}, t + \mathsf{ws}]\}$. The CBOW model tries to predict the target word given its context, maximizing the likelihood $\prod_{t=1}^{T} p(w_t|C_t)$, whereas skip-gram learns by predicting the context for a given target word maximizing $\prod_{t=1}^{T} p(C_t|w_t)$. To model those probabilities, a softmax activation is used on top of the inner product between a target vector $\mathbf{u}_{w_t}$ and its context vector $\frac{1}{|C_t|}\sum_{w \in C_t} \mathbf{v}_w$.

To overcome the computational bottleneck of the softmax for large vocabulary, negative sampling or noise contrastive estimation are well-established (Mikolov et al., 2013b), with the idea of employing simpler pairwise binary classifier loss functions to differentiate between the valid context C_t and fake contexts N_{C_t} sampled at random. While generating target-context pairs, both CBOW and skip-gram also use input word subsampling, discarding higher-frequency words with higher probability during training, in order to prevent the model from overfitting the most frequent tokens. Standard CBOW also uses a dynamic context window size: for each subsampled target word w, the size of its associated context window is sampled uniformly between 1 and ws (Mikolov et al., 2013b).

Adding character n-grams. Bojanowski et al. (2017) have augmented CBOW and skip-gram by adding character n-grams to the context representations. Word vectors are expressed as the sum of its unigram and average of its character n-gram embeddings W_w:

$$\mathbf{v} := \mathbf{v}_w + \frac{1}{|W_w|} \sum_{c \in W_w} \mathbf{v}_c$$

Character n-grams are hashed to an index in the embedding matrix . The training remains the same as for CBOW and skip-gram. This approach greatly improves the performances of CBOW and skip-gram on morpho-syntactic tasks. For the rest of the paper, we will refer to the CBOW and skip-gram methods enriched with subword-information as *CBOW-char* and *skip-gram-char* respectively.

GloVe. Instead of training online on local window contexts, GloVe vectors (Pennington et al., 2014) are trained using global co-occurrence statistics by factorizing the word-context co-occurrence matrix.

Ngram2vec. In order to leverage the performance of word vectors, training of word vectors using the skip-gram objective function with negative sampling is augmented with n-gram co-occurrence information (Zhao et al., 2017).

2.1 Improving unigram embeddings by adding higher order word-n-grams to contexts

CBOW-char with word n-grams. We propose to augment CBOW-char to additionally use word n-gram context vectors (in addition to char n-grams and the context word itself). More precisely, during training, the context vector for a given word w_t is given by the average of all word-n-grams N_t, all char-n-grams, and all unigrams in the span of the current context window C_t:

$$\mathbf{v} := \frac{\sum_{w \in C_t} \mathbf{v}_w + \sum_{n \in N_t} \mathbf{v}_n + \sum_{w \in C_t} \sum_{c \in W_w} \mathbf{v}_c}{|C_t| + |N_t| + \sum_{w \in C_t} |W_w|} \tag{1}$$

For a given sentence, we apply input subsampling and a sliding context window as for standard CBOW. In addition, we keep the mapping from the subsampled sentence to the original sentence for the purpose of extracting word n-grams from the original sequence of words, within the span of the context window. Word n-grams are added to the context using the hashing trick in the same way char-n-grams are handled. We use two different hashing index ranges to ensure there is no collision between char n-gram and word n-gram representations.

Sent2Vec for word embeddings. Initially implemented for sentence embeddings, Sent2Vec (Pagliardini et al., 2018) can be seen as a derivative of word2vec's CBOW. The key differences between CBOW and Sent2Vec are the removal of the input subsampling, considering the entire sentence as context, as well as the addition of word-n-grams.

Here, word and n-grams embeddings from an entire sentence are averaged to form the corresponding sentence (context) embedding.

For both proposed CBOW-char and Sent2Vec models, we employ dropout on word n-grams during training. For both models, word embeddings are obtained by simply discarding the higher order n-gram embeddings after training.

Table 1: Impact of using word n-grams: Models are compared using Spearman correlation measures for word similarity tasks and accuracy for word analogy tasks. Top performances on each dataset are shown in bold. An underline shows the best model(s) restricted to each architecture type. The abbreviations uni., bi., and tri. stand for unigrams, bigrams, and trigrams respectively.

3 Experimental Setup

3.1 Training

We train all competing models on a wikipedia dump of 69 million sentences containing 1.7 billion words, following (Pagliardini et al., 2018).

Sentences are tokenized using the Stanford NLP library (Manning et al., 2014). All algorithms are implemented using a modified version of the fasttext (Bojanowski et al., 2017; Joulin et al., 2017) and sent2vec (Pagliardini et al., 2018) libraries respectively. Detailed training hyperparameters for all models included in the comparison are provided in Table 3 in the supplementary material. During training, we save models checkpoints at 20 equidistant intervals and found out that the best performance for CBOW models occurs around $60-80\%$ of the total training. As a result, we also indicate the checkpoint at which we stop training the CBOW models. We use 300-dimension vectors for all our word embedding models. For the Ngram2vec model, learning source and target embeddings for all the n-grams upto bigrams was the best performing model and is included in the comparison.

For each method, we extensively tuned hyperparameters starting from the recommended values. For each model, we select the parameters which give the best averaged results on our word-similarity and analogy tasks. After selecting the best hyperparameters, we train 5 models for each method, using a different random seed. The reported results are given as mean and standard deviation for those five models.

3.2 Evaluation

In order to evaluate our model, we use six datasets covering pair-wise word-similarity tasks and two datasets covering word-analogy tasks.

Word-similarity tasks. Word-similarity tasks consist of word pairs along with their human annotated similarity scores. To evaluate the performance of our models on pair-wise word-similarity tasks, we use *WordSim353* (353 word-pairs) (Finkelstein et al., 2002) divided into two datasets, *WordSim Similarity* (203 word-pairs) and

Table 2: Improvement over existing methods: Models are compared using Spearman correlation measures for word similarity tasks and accuracy for word analogy tasks. Top performance(s) on each dataset is(are) shown in bold. The abbreviations uni., bi., and tri. stand for unigrams, bigrams, and trigrams respectively.

WordSim Relatedness (252 word-pairs) (Agirre et al., 2009); *MEN* (3000 word-pairs) (Bruni et al., 2012); *Mechanical Turk* dataset (Radinsky et al., 2011) (287 word-pairs); *Rare words dataset* (2034 word-pairs) (Luong et al., 2013); and *SimLex-999* (999 word-pairs) (Hill et al., 2015) dataset.

To calculate the similarity between two words, we use the cosine similarity between their word representations. The similarity scores then, are compared to the human ratings using Spearman's ρ (Spearman, 1904) correlation scores.

Word-analogy tasks. Word analogy tasks pose analogy relations of the form "x is to y as $x^\star$ is to $y^\star$", where y is hidden and must be guessed from the dataset vocabulary.

We use the *MSR* (Mikolov et al., 2013c) and the *Google* (Mikolov et al., 2013a) analogy datasets. The *MSR* dataset contains 8000 syntactic analogy quadruplets while the *Google* set has 8869 semantic and 10675 syntactic relations.

To calculate the missing word in the relation, we use the 3CosMul method (Levy and Goldberg, 2014):

$$y^\star := \arg \max_{z \in \mathcal{V} \setminus \{x, y, x^\star\}} \frac{cos(\mathbf{v}_z, \mathbf{v}_y) \cdot cos(\mathbf{v}_z, \mathbf{v}_{x^\star})}{cos(\mathbf{v}_z, \mathbf{v}_x) + \varepsilon} \tag{2}$$

where $\varepsilon = 0.0001$ is used to prevent division by 0 and $\mathcal{V}$ is the dataset vocabulary.

We remove all the out of vocabulary words and are left with 6946 syntactic relations for the *MSR* dataset and 1959 word-pairs for the *Rare Words* dataset. All other datasets do not have any out of vocabulary words.

4 Results

Impact of word n-grams. In Table 1, we evaluate the impact of adding contextual word n-grams to two CBOW variations: CBOW-char and Sent2Vec. By adding n-gram information, we consistently observe a boost in the Spearman correlation on the word similarity tasks. On the few datasets where we do not observe an improvement, the results for word-n-gram augmented methods are within standard deviation reach. The *Rare Words* dataset for Sent2Vec is the only exception, despite getting some improvement for CBOW-char based methods. This observation can be attributed to the fact that character ngrams are shared between unigrams, enhancing generalization to infrequent words. Without char n-grams, the model might underfit those rare words, even more so with word n-grams.

We also see that the boost obtained by adding n-grams on word-similarity tasks is much larger for Sent2Vec models as compared to the CBOW-char ones possibly due to the fact that during training, Sent2Vec models use a much larger context and hence can use much more n-gram information for obtaining a better context representation.

For analogy tasks, we see an improvement in the augmented CBOW-char methods for morpho-syntactic analogy datasets with little or no gain for semantic analogy datasets. Yet, for Sent2Vec models, the gain is the other way around. This observation indicates the strong role played by character n-grams in boosting the performance on the syntactic tasks as well as restricting the word n-grams from improving the performance on semantic analogies.

Comparison with competing methods. In Table 2, we compare word n-gram augmented methods with the most prominent word embedding models. We obtain state-of-the-art results for standalone unigram embeddings on most of the datasets confirming our hypothesis. The *Mechanical Turk* dataset is the only exception.

We notice that Sent2Vec trigrams model dominates the word-similarity tasks as well as the semantic analogy tasks. However, character n-grams are quite helpful when it comes to syntactic analogy tasks underlining the importance of subword information. We also note that the Ngram2vec model outperforms our augmented CBOW-char model in some of the tasks but is always inferior to Sent2Vec in those cases.

5 Conclusion and Future Work

We empirically show how augmenting the context representations using higher-order word n-grams improves the quality of word representations. The empirical success also calls for a new theoretical model on the composite effect of training higher order n-grams simultaneously with unigrams. Also, the success of Sent2Vec on word-level tasks, a method originally geared towards obtaining general purposed sentence embeddings, hints towards the additional benefits of using compositional methods for obtaining sentence/phrase representations.

A Training parameters for selected models

Training parameters for all models except GloVe and Ngram2vec are provided in Table 3. For the GloVe model , the minimum word count is set to 10; the window size is set to 10; we use 10 epochs for training; X_{max}, the weighting parameter for the word-context pairs is set to 100; all other parameters are set to default. For Ngram2vec, the minimum word count is set to 10; the window size is set to 5; both source and target vectors are trained for unigrams and bigrams; overlap between the target word and source n-grams is allowed. All other features are set to default. To train the Ngram2vec models, we use the library provided by (Zhao et al., 2017)[2].

Abstract

Leveraging domain knowledge is an effective strategy for enhancing the quality of inferred low-dimensional representations of documents by topic models. In this paper, we develop *topic modeling with knowledge graph embedding* (TMKGE), a Bayesian nonparametric model to employ knowledge graph (KG) embedding in the context of topic modeling, for extracting more coherent topics. Specifically, we build a hierarchical Dirichlet process (HDP) based model to flexibly borrow information from KG to improve the interpretability of topics. An efficient online variational inference method based on a stick-breaking construction of HDP is developed for TMKGE, making TMKGE suitable for large document corpora and KGs. Experiments on three public datasets illustrate the superior performance of TMKGE in terms of topic coherence and document classification accuracy, compared to state-of-the-art topic modeling methods.

1 Introduction

Topic models, such as Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 2017) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003), play significant roles in helping machines interpret text documents. Topic models consider documents as a bag of words. Given the word information, topic models formulate documents as mixtures of latent topics, where these topics are generated via the multinomial distributions over words. Bayesian methods are utilized to extract topical structures from the document-word frequency representations of the text corpus. Without supervision, however, it is found that the topics generated from these models are often not interpretable (Chang et al., 2009; Mimno et al., 2011). In recent studies, incorporating knowledge of different forms as a supervision has become a powerful strategy for discovering meaningful topics (Andrzejewski et al., 2009).

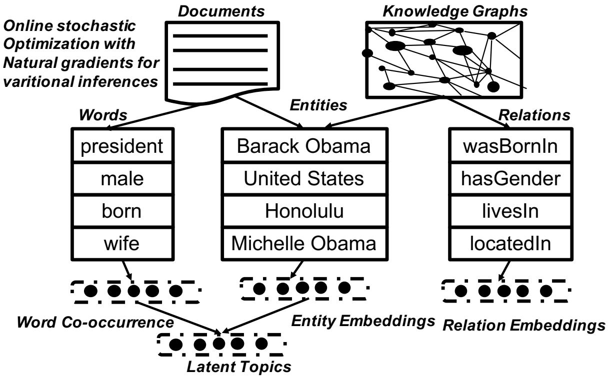

Figure 1: An overview of the proposed TMKGE framework. Entities are shared by both documents and knowledge graphs. Entity embeddings generated by *TransE* a knowledge graph embedding package are passed into TMKGE to generate hidden topics.

Most conventional approaches take prior domain knowledge into account to improve the topic coherence (Andrzejewski et al., 2009; Andrzejewski and Zhu, 2009; Hu et al., 2014; Jagarlamudi et al., 2012; Doshi-Velez et al., 2015). One commonly used domain knowledge is based on word correlations (Andrzejewski et al., 2009; Chen et al., 2013; Chen and Liu, 2014). For example, *must-links* and *cannot-links* among words are generated by domain experts to help topic modeling (Andrzejewski et al., 2009). Another useful form of knowledge for topic discoveries is based on word semantics (Andrzejewski and Zhu, 2009; Chemudugunta et al., 2008; Hu et al., 2014; Jagarlamudi et al., 2012; Doshi-Velez et al., 2015). In particular, word embedding (Pennington et al., 2014; Goldberg and Levy, 2014), in which bag of words are transformed into vector representations so that contexts are embedded into those word vectors, are used as semantic regularities to enhance topic models (Nguyen et al., 2015; Li et al., 2016; Das et al., 2015; Batmanghelich et al., 2016).

Proceedings of NAACL-HLT 2019, pages 940–950
Minneapolis, Minnesota, June 2 - June 7, 2019.

Knowledge graph (KG) embedding (Bordes et al., 2013) learns a low-dimensional continuous vector space for entities and relations to preserve the inherent structure of KGs. Yao et al. (2017) proposes KGE-LDA to incorporate embeddings of KGs into topic models to extract better topic representations for documents and shows promising performance. However, KGE-LDA forces words and entities to have identical latent representations, which is a rather restrictive assumption that prevents the topic model from recovering correct underlying latent structures of the data, especially in scenarios where only partial KGs are available.

This paper develops *topic modeling with knowledge graph embedding* (TMKGE), a hierarchical Dirichlet process (HDP) based model to extract more coherent topics by taking advantage of the KG structure. Unlike KGE-LDA, the proposed TMKGE allows for more flexible sharing of information between words and entities, by using a multinomial distribution to model the words and a multivariate Gaussian mixture to model the entities. With this approach, we introduce two proportional vectors, one for words and one for entities. In contrast, KGE-LDA only uses one, shared by both words and entities. Similar to HDP, TMKGE includes a collection of Dirichlet processes (DPs) at both corpus and document levels. The atoms of corpus-level DP form the base measure for document levels DPs of words and entities. Therefore, the atoms of corpus-level DP can represent word topics, entity mixture components, or both of them. Figure 1 provides an overview of TMKGE, where two sources of inputs, bag of words and KG embedding, extracted from corpus and KGs respectively, are passed into TMKGE.

As a nonparametric model, TMKGE does not assume a fix number of topics or entity mixture components as constraints. Instead, it learns the number of topics and entity mixture components automatically from the data. Furthermore, an efficient online variational inference algorithm is developed, based on Sethuraman's stick-breaking construction of HDP (Sethuraman, 1994). We in fact construct stick-breaking inference in a minibatch fashion (Wang et al., 2011; Bleier, 2013), to derive a more efficient and scalable coordinate-accent variational inference for TMKGE.

Summary of contributions: TMKGE is a Bayesian nonparametric model to extract more coherent topics by taking advantage of knowledge graph structures. We introduce two proportional vectors for more flexible sharing of information between words and entities. We derive an efficient and scalable parameter estimation algorithm via online variational inference. Finally, we empirically demonstrate the effectiveness of TMKGE in topic discovering and document classification.

2 Background and Related Work

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a popular probabilistic model that learns latent topics from documents and words, by using Dirichlet priors to regularize the topic distributions. The generated topics from LDA models, however, are often not interpretable (Chang et al., 2009; Mimno et al., 2011), in part because LDA models are unsupervised without using prior knowledge or external resources.

In recent years, prior knowledge are leveraged to guide the process of topic modeling (Andrzejewski and Zhu, 2009; Hu et al., 2014; Jagarlamudi et al., 2012; Doshi-Velez et al., 2015). For example, the deep forest LDA (DF-LDA) model (Andrzejewski et al., 2009) is proposed to incorporate *must-links* and *cannot-links* among words into topic modeling. One weakness of the DF-LDA model is that the link information is domain-dependent. Later, general knowledge based LDA is introduced to leverage must-links from multiple domains (Chen et al., 2013). More recently, MetaLDA (Zhao et al., 2017) proposes to improve topic modeling by incorporating diverse meta information as priors for both document hyperparameter α and word hyperparameter β.

Besides the word correlations, word semantics are also utilized as one type of useful knowledge for topic modeling (Chemudugunta et al., 2008; Hu et al., 2014; Jagarlamudi et al., 2012). Word embeddings, as a low-dimensional continuous vectors of words (Mikolov et al., 2013; Bengio et al., 2003; Pennington et al., 2014) are regarded to be an efficient representations of word semantics. Latent Feature Topic Modeling (LFTM) is proposed to use pre-trained word embeddings in topic modeling (Nguyen et al., 2015). It incorporates the embedding of a word and its topics into the traditional multinomial distribution over words as the probability function of topic modeling. TopicVec extends LFTM by combining a word and its local contextual words together into the conventional multinomial distribution over words. It also learns embedding representations for topics (Li et al., 2016). Gaussian-LDA goes further to improve topic modeling (Das et al., 2015) by taking into considerations the continuous nature of word embeddings. Shi et al. (2017) constructs a more unified framework, STE (skip-gram topic embedding) to address the problem of polysemy. Li et al. (2019) proposes a unified framework TMSA (Topic Modeling and Sparse Autoencoder) to improve topic discovery and word embedding simultaneously via a mutual learning mechanism.

Hu et al. (2016) proposes topic-based embeddings for learning from large knowledge graphs (KGE). KGE learns low-dimensional continuous vector space for both entities and relations to preserve the inherent structure of knowledge graphs. A Bayesian method is introduced by considering the embeddings of entities and relations as topics. Later, Yao et al. (2017) proposes knowledge graph embedding LDA (KGE-LDA) to encode entity embeddings learned from knowledge graphs into LDA and show that knowledge graph embeddings boost topic discoveries. Inspired by this work, we explore to utilize entity embeddings to encode prior knowledge for topic modeling.

3 Method

This section presents the TMKGE model and an efficient online variational inference for learning its parameters. We first provide a review of hierarchical Dirichlet process (HDP) (Teh et al., 2005).

3.1 Preliminaries of HDP

Dirichlet process (DP) (MacEachern and Müller, 1998) $G \sim \text{DP}(\gamma_0, G_0)$, with a base measure G_0 and a concentration parameter $\gamma_0 > 0$, is the distribution of a random probability measure G over a measurable space $(\Omega, \mathcal{B})$, such that for any measurable disjoint partition $(A_1, ..., A_Q)$ of Ω,

$$(G(A_1), ..., G(A_Q)) \sim \text{Dir}(\gamma_0 G_0(A_1), ..., \gamma_0 G_0(A_Q))$$

where “Dir” denotes a Dirichlet distribution.

Hierarchical Dirichlet process (HDP) (Teh et al., 2005), introduced for dealing with multiple (D) groups of data, is a distribution over a set of random probability measures over $(\Omega, \mathcal{B})$: one probability measure $G_d \sim \text{DP}(\alpha_0, G_0)$ for each group $d \in \{1, 2, ..., D\}$, and a global probability measure $G_0 \sim \text{DP}(\gamma_0, H)$ with a base measure H.

Stick-breaking construction Teh et al. (2005) shows that the draws from G_0 and G_d can be expressed as weighted sums of point masses:

$$G_0 = \sum_{k=0}^{\infty} \beta_k \delta_{\phi_k}, \qquad G_d = \sum_{k=0}^{\infty} \pi_{dk} \delta_{\phi_k}.$$

A more convenient stick-breaking construction, especially for deriving closed-form variational inference (Wang et al., 2011), is Sethuraman (1994)’s construction, which proceeds as follows. First, the global-level DP draw is represented as

$$\beta'_k \sim \text{Beta}(1, \gamma_0), \qquad \beta_k = \beta'_k \prod_{\ell=1}^{k-1} (1 - \beta'_\ell),$$

Note that the distribution for $\boldsymbol{\beta} = \{\beta_k\}_{k=1}^{\infty}$ is also commonly written as $\boldsymbol{\beta} \sim \text{GEM}(\gamma_0)$ (Pitman, 2002). Subsequently, the group-level draws are constructed as

$$\begin{aligned} \psi_{dt} \sim & G_0, \qquad \pi'_{dt} = \text{Beta}(1, \alpha_0), \\ \pi_{dt} = & \pi'_{dt} \prod_{\ell=1}^{t-1} (1 - \pi'_{d\ell}), \qquad G_d = \sum_{t=1}^{\infty} \pi_{dt} \delta_{\psi_{dt}}. \end{aligned} \tag{1}$$

Alternatively, the group-level atoms $\{\psi_{dt}\}_{t=1}^{\infty}$ can be represented as $\psi_{dt} = \phi_{c_{dt}}$, where the auxiliary indicator variables c_{dt} are independently drawn from a multinomial $\text{Mult}(\boldsymbol{\beta})$.

Teh et al. (2008) also proposes a collapsed inference method as an alternative of stick-breaking inference. However, following Fox et al. (2011), we stick to the uncollapsed HDP model considering our truncated Dirichlet process has more computational efficiency and is simple to implement.

3.2 The TMKGE Model

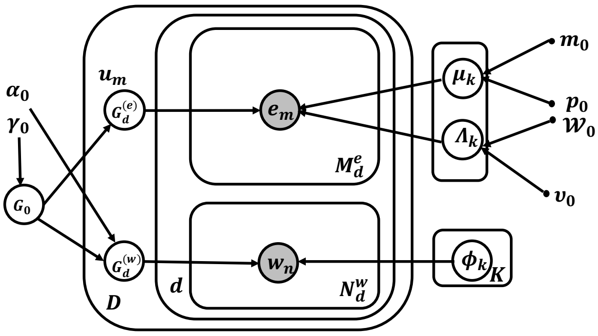

Figure 2: Graphical representation of the TMKGE framework. There are two components, the lower of which is the one for words and the upper of which is the one for entities. Both components share the Dirichlet process as priors. Since entities are represented with knowledge graph embeddings, therefore, each entity is generated with Gaussian priors while the one for words is still generated with Dirichlet priors.

Figure 2 is the graphical representation of TMKGE. Let D denote the number of documents in the corpus, where each document $d \in \{1, 2, ..., D\}$ contains $N_d^{(w)}$ words and $N_d^{(e)}$ entities. Throughout this work, superscripts (w) and (e) indicate word and entity related parameters, respectively. In each document d, the n-th word is represented by w_{dn}, where each word belongs to a vocabulary of size V, i.e., $w_{dn} \in \{1, 2, ..., V\}$. Furthermore, the P-dimensional embedding of the m-th entity is $\boldsymbol{e}_{dm}$, where the total number of unique entities in the corpus is E. We assume that entity embeddings are obtained from the "complete" knowledge graph, and hence they contain information independent of the corpus. In this paper, we use TransE (Bordes et al., 2013), a simple and effective tool for knowledge encoding, to calculate the embeddings of entities extracted from the documents. We should mention that we remove the normalization step of TransE and thus the output vectors ($\boldsymbol{e}_{dm}$) do not have unit ℓ_2 norm.

TMKGE builds upon HDP for joint modeling of word topics and entity mixtures. At the corpus level, word topics and entity mixtures correspond to atoms of a Dirichlet process $G_0 \sim \text{DP}(\gamma_0, H)$. At the document level, word topics and entity mixture components are atoms of independent DPs, with shared base measure G_0. Mathematically, for document d, we have

$$G_d^{(w)} \sim \text{DP}(\alpha_0, G_0), \qquad G_d^{(e)} \sim \text{DP}(\alpha_0, G_0),$$

where $G_d^{(w)}$ and $G_d^{(e)}$ are word and entity related DPs. Sethuraman's construction in (1) yields

$$G_d^{(w)} = \sum_{t=1}^{\infty} \pi_{dt}^{(w)} \delta_{\psi_{dt}^{(w)}}, \qquad G_d^{(e)} = \sum_{t=1}^{\infty} \pi_{dt}^{(e)} \delta_{\psi_{dt}^{(e)}}. \qquad (2)$$

These DPs are then used to assign words and entities to topics and mixture components, respectively. In document d, let $z_{dn}^{(w)}$ denote the topic assigned to the n-th word, and $z_{dm}^{(e)}$ denote the mixture component assigned to the m-th entity. Using the mixing proportions of DPs in (2), we have

$$p(z_{dn}^{(w)} = t) = \pi_{dt}^{(w)}, \qquad p(z_{dn}^{(e)} = t) = \pi_{dt}^{(e)}.$$

For simplicity, we use index t to denote both word and entity related atoms, although they can correspond to different atoms of the global DPs.

The mixing proportions of corpus-level DP are used to map the document atoms to the shared global atoms. More precisely, we introduce the word and entity atoms mapping auxiliary variables $\boldsymbol{c}_d^{(w)} = \{c_{dt}^{(w)}\}_{t=1}^{\infty}$ and $\boldsymbol{c}_d^{(e)} = \{c_{dt}^{(e)}\}_{t=1}^{\infty}$. The mapping probabilities then can be expressed as

$$p(c_{dt}^{(w)} = k) = \beta_k, \qquad p(c_{dt}^{(e)} = k) = \beta_k.$$

TMKGE allows flexible sharing of information between knowledge graphs and documents. This is an important advantage, as in practice only partial relational information are available, and thus strictly forcing the topics and entity mixtures to share components may lead to reducing the power of model to correctly recover the latent structure of the data. Furthermore, the nonparametric nature of the model enables the automatic discovery of number of atoms for both words and entities, at document and corpus levels.

Each atom of corpus DP (G_0) corresponds to a set of parameters for both words and entities. Atom k contains topic-word Dirichlet distribution $\boldsymbol{\phi}_k = (\phi_{k1}, ..., \phi_{kV})^T$, and entity Gaussian mixture parameters $\{\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k\}$. Given $\boldsymbol{\phi}_k$ and topic assignment variables, the generative process for n-th word of document d is

$$\begin{aligned} z_{dn}^{(w)} &\sim \text{Mult}(\boldsymbol{\pi}_d^{(w)}), \\ (w_{dn} | z_{dn}^{(w)} = t, c_{dt}^{(w)} = k, \boldsymbol{\phi}_k) &\sim \text{Mult}(\boldsymbol{\phi}_k). \end{aligned}$$

In a similar fashion, the generative process of m-th entity of document d is

$$\begin{aligned} z_{dm}^{(e)} &\sim \text{Mult}(\boldsymbol{\pi}_d^{(e)}), \\ (\boldsymbol{e}_{dm} | z_{dm}^{(e)} = t, c_{dt}^{(e)} = k, \boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k) &\sim \text{N}(\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k^{-1}), \end{aligned}$$

where $\boldsymbol{\mu}_k$ and $\boldsymbol{\Lambda}_k$ are the mean vector and precision matrix of multivariate Gaussian distribution.

Furthermore, we impose conjugate priors on both word and entity components parameters as:

$$\begin{aligned} \boldsymbol{\phi}_k &\sim \text{Dir}(\eta, ..., \eta), \qquad \boldsymbol{\mu}_k \sim \text{N}\big(\boldsymbol{m}_0, (\rho_0 \boldsymbol{\Lambda}_k)^{-1}\big), \\ \boldsymbol{\Lambda}_k &\sim \text{Wishart}(\nu_0, \boldsymbol{W}_0). \end{aligned}$$

3.3 Online Variational Inference

In this section, inspired by (Wang et al., 2011), we propose an online variational inference algorithm for efficient learning of TMKGE model parameters. We use a fully factorized variational distribution based on stick-breaking construction, and perform online mean-field variational inference.

In addition to topic parameters $\boldsymbol{\phi}_k$ and entity mixture parameters $\{\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k\}$, other parameters of interest are corpus-level stick proportions $\boldsymbol{\beta}' = \{\beta'_k\}_{k=1}^{\infty}$, document-level stick proportions for words $\boldsymbol{\pi}_d'^{(w)} = \{\pi_{dt}'^{(w)}\}_{t=1}^{\infty}$ and entities $\boldsymbol{\pi}_d'^{(e)} = \{\pi_{dt}'^{(e)}\}_{t=1}^{\infty}$, topic assignments for words

$\boldsymbol{z}_d^{(w)} = \{z_{dn}^{(w)}\}_{n=1}^{N_d^{(w)}}$, mixture assignments for entities $\boldsymbol{z}_d^{(e)} = \{z_{dm}^{(e)}\}_{m=1}^{N_d^{(e)}}$, and mapping variables $\boldsymbol{c}_d^{(w)}$ and $\boldsymbol{c}_d^{(e)}$. Denote $\Theta^{(w)}$ and $\Theta^{(e)}$ respectively the word and entity related parameters. Then the variational distribution factorizes as

$$q(\boldsymbol{\beta}', \Theta^{(w)}, \Theta^{(e)}) = q(\boldsymbol{\beta}')q(\Theta^{(w)})q(\Theta^{(e)}).$$

For corpus-level stick proportions, we assume a Beta distribution:

$$q(\boldsymbol{\beta}') = \prod_{k=1}^{K-1} \text{Beta}(\beta'_k | u_k, v_k),$$

where the number of global atoms is truncated at K, thereby $q(\beta'_K = 1) = 1$. For the word related parameters $\Theta^{(w)}$, we have

$$\begin{aligned} q(\Theta^{(w)}) &= q(\boldsymbol{c}^{(w)})q(\boldsymbol{z}^{(w)})q(\boldsymbol{\pi}'^{(w)})q(\boldsymbol{\phi}), \\ q(\boldsymbol{c}^{(w)}) &= \prod_{d=1}^{D} \prod_{t=1}^{T-1} \text{Mult}(\boldsymbol{\varphi}_{dt}^{(w)}), \\ q(\boldsymbol{z}^{(w)}) &= \prod_{d=1}^{D} \prod_{n=1}^{N_d^{(w)}} \text{Mult}(\varsigma_{dt}^{(w)}), \\ q(\boldsymbol{\pi}'^{(w)}) &= \prod_{d=1}^{D} \prod_{t=1}^{T-1} \text{Beta}(\pi'_{dt} | a_{dt}^{(w)}, b_{dt}^{(w)}), \\ q(\boldsymbol{\phi}) &= \prod_{k=1}^{K} \text{Dir}(\boldsymbol{\lambda}_k). \end{aligned}$$

The variational distributions for entity related parameters have a similar form to the above distributions, except the Gaussian mixture parameters, which are expressed as follows:

$$q(\boldsymbol{\mu}_k) = \text{N}\big(\boldsymbol{m}_k, (\rho_k \boldsymbol{\Lambda}_k)^{-1}\big), \quad q(\boldsymbol{\Lambda}_k) = \text{Wishart}(\nu_k, \boldsymbol{W}_k).$$

In standard variational inference theory, the evidence lower bound (ELBO), which is the lower bound to the marginal log likelihood of the observed data, is maximized to find the best variational approximation to the true intractable posterior. Given the modeling framework of TMKGE, the ELBO can be written as

$$\begin{aligned} \mathcal{L}(q) = \sum_d \Bigg\{ &\mathbb{E}\Big[\log\Big(p(\boldsymbol{w}_d | \boldsymbol{c}_d^{(w)}, \boldsymbol{z}_d^{(w)}, \boldsymbol{\phi}) p(\boldsymbol{c}_d^{(w)} | \boldsymbol{\beta}') \\ &\times p(\boldsymbol{z}_d^{(w)} | \boldsymbol{\pi}'^{(w)}_d) p(\boldsymbol{e}_d | \boldsymbol{c}_d^{(e)}, \boldsymbol{z}_d^{(e)}, \boldsymbol{\mu}, \boldsymbol{\Lambda}) \\ &\times p(\boldsymbol{c}_d^{(e)} | \boldsymbol{\beta}') p(\boldsymbol{z}_d^{(e)} | \boldsymbol{\pi}'^{(e)}_d) p(\boldsymbol{\pi}'^{(w)}_d | \alpha_0) p(\boldsymbol{\pi}'^{(e)}_d | \alpha_0)\Big)\Big] \\ &+ H\big(q(\boldsymbol{c}_d^{(w)})\big) + H\big(q(\boldsymbol{z}_d^{(w)})\big) + H\big(q(\boldsymbol{\pi}'^{(w)}_d)\big) \\ &+ H\big(q(\boldsymbol{c}_d^{(e)})\big) + H\big(q(\boldsymbol{z}_d^{(e)})\big) + H\big(q(\boldsymbol{\pi}'^{(e)}_d)\big) \Bigg\} \\ &+ \mathbb{E}\Big[\log\Big(p(\boldsymbol{\beta}')p(\boldsymbol{\phi})p(\boldsymbol{\mu}, \boldsymbol{\Lambda})\Big)\Big] + H\big(q(\boldsymbol{\beta}')\big) \\ &+ H\big(q(\boldsymbol{\phi})\big) + H\big(q(\boldsymbol{\mu}, \boldsymbol{\Lambda})\big), \end{aligned}$$

where $H(\cdot)$ is the entropy term for variational distribution. By taking derivatives of this lower bound with respect to each variational parameter, we derive the coordinate ascent update steps.

We develop an online variational inference for TMKGE, to process large datasets (Wang et al., 2011; Hoffman et al., 2010). Given the existing corpus-level parameters, first a document d is sampled and then its optimal document-level variational parameters are computed. For word related variational parameters, these updates include

$$\begin{aligned} a_{dt}^{(w)} &= 1 + \sum_n \varsigma_{dnt}^{(w)}, \\ b_{dt}^{(w)} &= \alpha_0 + \sum_n \sum_{s=t+1}^{T} \varsigma_{dns}^{(w)}, \\ \varphi_{dtk}^{(w)} &\propto \exp\Big(\sum_n \varsigma_{dns}^{(w)} \mathbb{E}_q\big[\log p(w_{dn}|\boldsymbol{\phi}_k)\big] \mathbb{E}_q\big[\log \beta_k\big]\Big), \\ \varsigma_{dnt}^{(w)} &\propto \exp\Big(\sum_k \varphi_{dtk}^{(w)} \mathbb{E}_q\big[\log p(w_{dn}|\boldsymbol{\phi}_k)\big] \mathbb{E}_q\big[\log \pi_{dt}^{(w)}\big]\Big) \end{aligned} \tag{3}$$

where expectations are with respect to variational distributions and have closed forms. For entity related variational parameters, similar updates can be derived, with the term $\mathbb{E}_q\big[\log p(\boldsymbol{e}_{dm}|\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k)\big]$ replacing $\mathbb{E}_q\big[\log p(w_{dn}|\boldsymbol{\phi}_k)\big]$. Following Wang et al. (2011), for the corpus-level variational parameters, we use the following gradients:

$$\begin{aligned} \partial\lambda_{kv} &= -\lambda_{kv} + \eta + D\sum_t \varphi_{dtk}^{(w)} \big(\sum_n \varsigma_{dnt}^{(w)} I[w_{dn} = v]\big), \\ \partial\boldsymbol{m}_k &= -\boldsymbol{m}_k + \frac{D\sum_{m,t} \varphi_{dtk}^{(e)} \varsigma_{dmt}^{(e)} \boldsymbol{e}_{dm} + \rho_0 \boldsymbol{m}_0}{Dr_k + \rho_0}, \\ \partial\rho_k &= -\rho_k + \rho_0 + Dr_k, \\ \partial\nu_k &= -\nu_k + \nu_0 + Dr_k, \\ \partial\boldsymbol{W}_k &= -\boldsymbol{W}_k + \Big(\boldsymbol{W}_0^{-1} + D\sum_{m,t} \varphi_{dtk}^{(e)} \varsigma_{dmt}^{(e)} \boldsymbol{e}_{dm} \boldsymbol{e}_{dm}^T\Big)^{-1}, \\ \partial u_k &= -u_k + 1 + D\sum_t \big(\varphi_{dtk}^{(w)} + \varphi_{dtk}^{(e)}\big), \\ \partial v_k &= -v_k + \gamma_0 + D\sum_t \sum_{\ell=k+1}^{K} \big(\varphi_{dt\ell}^{(w)} + \varphi_{dt\ell}^{(e)}\big), \end{aligned} \tag{4}$$

where r_k is defined as $\sum_{m,t} \varphi_{dtk}^{(e)} \varsigma_{dmt}^{(e)}$. The corpus-level parameters are then updated using these gradients (among them, the first, the fifth and the sixth are natural gradients while the other four are approximations from the posterior of Gaussian Wishart scale matrix W. It appears difficult to obtain natural gradients for those four.) and a learning rate parameter ϵ_t. For instance, for topic-words distribution parameters we have

$$\boldsymbol{\lambda} \leftarrow \boldsymbol{\lambda} + \epsilon_{t_0} \partial\boldsymbol{\lambda}. \tag{5}$$

Table 1: Topic Coherence of all models on three datasets with different number of top words. A higher PMI score implies a more coherent topic. Improvements of TMKGE over other methods are significant.

The rest of corpus-level variational parameters in (4) can be similarly updated. To ensure that the parameters converge to a stationary point, the learning rate satisfies (Hoffman et al., 2010; Sato, 2001) $\sum_{t_0=1}^{\infty} \epsilon_{t_0} = \infty$ and $\sum_{t_0=1}^{\infty} \epsilon_{t_0}^2 < \infty$.

Following Wang et al. (2011), we use $\epsilon_{t_0} = (\tau_0 + t_0)^{-\kappa}$, where $\kappa \in (0.5, 1]$ and $\tau_0 > 0$. To improve the stability of online variational inference, we use a mini-batch of documents to compute the natural gradients. That is, the contribution of the single document d in (4) is replaced by sum of contributions of documents in the mini-batch $\mathcal{S}$, and the factor D is replaced by $D/|\mathcal{S}|$. The overall scheme of online variational inference for TMKGE is shown in Algorithm 1.

Algorithm 1 Online variational inference for the proposed TMKGE framework.

```
Initialize corpus-level variational parameters.
while Stopping criterion is not met do
    Sample a random document $d$ from the corpus.
    Update $\boldsymbol{a}_d^{(w)}$, $\boldsymbol{b}_d^{(w)}$, $\boldsymbol{\varphi}_d^{(w)}$ and $\boldsymbol{\varsigma}_d^{(w)}$ using (3).
    Update $\boldsymbol{a}_d^{(e)}$, $\boldsymbol{b}_d^{(e)}$, $\boldsymbol{\varphi}_d^{(e)}$ and $\boldsymbol{\varsigma}_d^{(e)}$ similar to (3).
    Compute the natural gradients using (4).
    Set $\epsilon_{t_0} = (\tau_0 + t_0)^{-\kappa}$ and $t_0 \leftarrow t_0 + 1$.
    Update all corpus-level parameters as (5).
end
```

4 Experiments

We evaluate TMKGE on two experimental tasks and compare its performance to those of LDA, HDP and KGE-LDA. For LDA and HDP, we use the online variational inference implementations. More precisely, we will evaluate our framework by the test whether it finds coherent and meaningful topics and the test whether it can achieve good performance in document classification.

We run our experiments on three popular datasets; 20 Newsgroups, NIPS and the Ohsumed corpus. The 20 Newsgroups dataset contains 18,846 documents evenly categorized into 20 different categories.

The NIPS dataset contains 1,740 papers from the NIPS conference. The Ohsumed corpus is from the MEDLINE database. We consider the 13,929 unique Cardiovascular diseases abstracts in the first 20,000 abstracts of the year 1996. Each document in the set has one or more associated categories from the 23 disease categories. The documents belonging to multiple categories are eliminated so that 7,400 documents belonging to only one category remain. The datasets are tokenized with Stanford CoreNLP (Manning et al., 2014). After standard pre-processing (such as removing stop words), there are 20,881 distinct words in the 20 Newsgroups dataset, 14,482 distinct words in the NIPS dataset and 8,446 distinct words in the Ohsumed dataset.

4.1 External knowledge source

The knowledge graph we employ is WordNet (Miller, 1995). WordNet is a large lexical knowledge graph. Entities in WordNet are synonyms which express distinct concepts. Relations in WordNet mainly involve conceptual-semantic and lexical relations. We use a subset of WordNet (WN18) introduced in Bordes et al. (2011) and employed in Yao et al. (2017) as well. WN18 contains 151,442 triplets with 40,943 entities and 18 relations. We link tokenized words to entities in WN18 via NLTK (Bird and Loper, 2004).

Table 2: Example topics learned from three datasets by TMKGE with $K = 300$ and $T = 20$, and KGE-LDA with $K = 30$. The last row for each model is the topic coherence computed using the 4,776,093 Wikipedia documents as reference. Some medical short words: pbl = Peripheral blood leucocyte, meh = Mean erythrocyte hemoglobin.

4.2 Model parameters

In the experiments, for each method, we report the results based on the hyperparameter settings that obtain the best performances. For TMKGE and HDP, we report the results for $K = 300$, $T = 20$ and $K = 100$, $T = 10$ cases. For LDA and KGE-LDA, respectively, we have $K = 100$ and $K = 30$. Throughout this work we fix the dimension of entity embedding as $P = 5$. For online variational inference, we run the algorithms for 1000 iterations, with mini-batch size of 100.

4.3 Topic Coherence

We assess the performance of the proposed TMKGE model based on topic coherence. Topic coherence has been shown to be more consistent with human judgment than other typical topic model metrics such as perplexity (Chang et al., 2009; Newman et al., 2010). We perform both quantitative and qualitative analysis of the topics discovered by TMKGE, and compare its performance to those of LDA, HDP and KGE-LDA.

4.3.1 Quantitative Analysis

We evaluate the coherence of discovered topics by the point-wise mutual information (PMI) Topic Coherence metric. The PMI Topic Coherence is implemented following Newman et al. (2010):

$$PMI(k) = \sum_{j=2}^{N} \sum_{i=1}^{j-1} \log \frac{p(w_i, w_j)}{p(w_i)p(w_j)}$$

where k refers to a topic, N refers to the number of top words of k, $p(w_i)$ is the probability that w_i appears in a document, $p(w_i, w_j)$ is the probability that w_i and w_j co-occur in the same document. A higher PMI score implies a more coherent topic. Following KGE-LDA, 4,776,093 Wikipedia articles are employed for obtaining topic coherence scores. Different from Yao et al. (2017), which used a fixed value of N (the number of top words, e.g. $N = 5$ or $N = 10$), we vary N in a range from 5 to 30. (Lau and Baldwin, 2016) suggests that calculating topic coherence over several different cardinalities and averaging results in a substantially more stable evaluation.

Table 1 shows the average topic coherence for different methods and datasets. We can observe that for the three datasets, TMKGE achieves highest topic coherence in almost all top word sizes. In the few cases which TMKGE does not rank highest, there only exist subtle differences with the top performing result. This shows that knowledge graph embedding improves the coherence of discovered topics. Further, for the top 10 words, the topic coherence of all three datasets are higher than those obtained by KGE-LDA. This shows that topic modeling based on HDP for both entity embedding and words enjoys incomparable advantages over LDA-based modeling.

4.3.2 Qualitative Analysis

Table 2 shows example topics with their PMI scores learned from the three corpora by KGE-LDA and our TMKGE model. For comparison, we report similar topics to those listed in the KGE-LDA paper. It can be seen that TMKGE finds quite closely related words in a topic. For example, for the second column of 20 Newsgroups, topic words from both TMKGE and KGE-LDA are related to computers. However, it can be noted that words from TMKGE focus more on the core words of computer science. In contrast, words from the same topic in KGE-LDA seems to be closer to the brand, such as windows, mac or apple. In addition, topics found from TMKGE are more diverse than those found in KGE-LDA. For 20 Newsgroups, the three topics we list here refer to theology, computer science and middle east respectively while the three topics from KGE-LDA refer to internet, computer and car respectively. Both TMKGE and KGE-LDA discover probability-related and machine learning topics with different top words from NIPS dataset. Roughly speaking, KGE-LDA discovers gene-related, cancer-related and treatment-related topics from Ohsumed corpus. TMKGE discovers more diverse and more specific topics. For example, one topic TMKGE discovers is about Vietnamese veterans, cancer-related and sexual-disease topics. From the perspective of topic coherence, we can also see that TMKGE obtains higher PMI score in most of those topics. The whole trend is consistent with the average PMI score reported in the last section. Overall, TMKGE performs better than other topic models, including LDA, HDP and KGE-LDA in terms of average PMI and also in qualitative case studies.

4.4 Document Classification

We evaluate our proposed method through document classification, we follow the approach in (Li and McCallum, 2006) for document classification.

We have conducted a five-way classification on the `comp` subject of 20 Newsgroups dataset and on the top five most frequent labels of Ohsumed dataset (no labels for nips dataset), where each class of documents is divided into 75% training and 25% testing. For each class, the LDA, HDP and TMKGE models are trained on the training documents, and then the predictive likelihood for the test documents is calculated using the E-step in the variational inference procedure of LDA. A document is classified correctly if its corresponding model produces the highest likelihood.

class	LDA	HDP	KGE-LDA	TMKGE
20 Newsgroup				
pc	68.6	78.9	67.2	**78.9**
os	71.7	80.7	70.7	**82.3**
mac	82.0	**87.1**	68.1	86.5
windows.x	84.0	83.5	64.4	**84.9**
graphics	81.2	81.9	65.4	**83.0**
Ohsumed				
C04	50.6	73.0	59.1	**73.8**
C10	46.2	63.0	54.4	**64.9**
C14	51.5	44.6	33.2	**52.3**
C21	86.5	89.5	83.7	**89.7**
C23	68.2	81.9	75.3	**86.1**

Table 3: Document classification accuracy a five-way classification on the comp subject of 20 Newsgroups dataset and on the top five most frequent labels of ohsumed dataset (no labels for NIPS dataset).

Table 3 presents the average classification accuracy for TMKGE, HDP and LDA over five repeated simulations. The table includes the classification accuracy for KGE-LDA, where the learned topic proportions are used as features for SVM classifier. For the majority of document classes, TMKGE has the best classification accuracy, except for the class `mac`. As shown, the SVM classifier based on KGE-LDA has significantly worst performance. For more complete comparisons, we run experiments on all subjects of 20 Newsgroups and also report experimental results published in Shi et al. (2017) in Table 4. TMKGE achieves the best performance on all models.

Model	Acc (%)	Model	Acc (%)
BOW	79.7	STE-Diff	82.9
Skip-Gram	75.4	LDA	77.5
TWE	81.5	TMSA	83.5
PV	75.4	HDP	82.4
GPU-DMM	48.0	KGE-LDA	70.5
STE-Same	80.4	TMKGE	**88.8**

Table 4: Document classification: all subjects of 20 Newsgroups dataset for more complete comparisons. Clearly shown is the best performances of TMKGE

A few points can be observed from the superior performance of TMKGE. Firstly, it looks the addition of unnormalized knowledge graph embedding into TMKGE as a proportional vector to the word vector boosts the performance. Secondly, the selection of HDP over LDA plays an essential role. This can be indicated from the poor performance of KGE-LDA (which is even worse than BOW). More impressively, TMKGE achieves even much better performances than STE-Diff, TWE and TMSA, all of which involve the integration of word embedding and topic modeling. Impressively, TMKGE shows its supremacy over the state of the art model, TMSA with high margins. This shows that the knowledge graph structure included into the entity embedding conveys more information than pure word embedding. Meanwhile, this also shows that the two proportional vectors generated with online HDP enables the flexible sharing of information between words and entities. Accordingly, more coherent topics are extracted and the classification result are boosted as well.

5 Conclusion

This paper presents TMKGE, a Bayesian nonparametric model based on hierarchical Dirichlet process for incorporation of entity embeddings from external knowledge graphs into topic modeling. The proposed method allows for flexible sharing of information between documents and knowledge graph. Specifically, TMKGE avoids forcing the words and entities to identical latent factors, thus making it a suitable framework for scenarios where only partial relational information are available. Furthermore, as a Bayesian nonparameteric model, TMKGE learns the number of word topics and entity mixture components automatically from the data. We have derived an efficient and scalable online variational inference for TMKGE.

Comprehensive experiments on three different datasets suggest that TMKGE significantly outperforms SOA methods in terms of both topic coherence and document classification accuracy.
