Abstract

The recent surge of text-based online counseling applications enables us to collect and analyze interactions between counselors and clients. A dataset of those interactions can be used to learn to automatically classify the client utterances into categories that help counselors in diagnosing client status and predicting counseling outcome. With proper anonymization, we collect counselor-client dialogues, define meaningful categories of client utterances with professional counselors, and develop a novel neural network model for classifying the client utterances. The central idea of our model, ConvMFiT, is a pre-trained conversation model which consists of a general language model built from an out-of-domain corpus and two role-specific language models built from unlabeled in-domain dialogues. The classification result shows that ConvMFiT outperforms state-of-the-art comparison models. Further, the attention weights in the learned model confirm that the model finds expected linguistic patterns for each category.

1 Introduction

Some mental disorders are known to be treated effectively through psychotherapy. However, people in need of psychotherapy may find it challenging to visit traditional counseling services because of time, money, emotional barriers, and social stigma (Bearse et al., 2013). Recently, technology-mediated psychotherapy services emerged to alleviate these barriers. Mobile-based psychotherapy programs (Mantani et al., 2017), fully automated chatbots (Ly et al., 2017; Fitzpatrick et al., 2017), and intervention through smart devices (Torrado et al., 2017) are examples. Among them, text-based online counseling services with professional counselors are becoming popular because clients can receive these services without traveling to an office and with reduced financial burden compared to traditional face-to-face counseling sessions (Hull, 2015).

In text-based counseling, the communication environment changes from face-to-face counseling sessions. The counselor cannot read nonverbal cues from their clients, and the client uses text messages rather than spoken utterances to deliver their thoughts and feelings, resulting in changes of dynamics in the counseling relationship. Previous studies explored computational approaches to analyzing the dynamic patterns of relationship between the counselor and the client by focusing on the language of counselors (Imel et al., 2015; Althoff et al., 2016), clustering topics of client issues (Dinakar et al., 2014), and looking at therapy outcomes (Howes et al., 2014; Hull, 2015).

Unlike previous studies, we take a computational approach to analyze client responses from the *counselor's perspective*. Client responses in counseling are crucial factors for judging the counseling outcome and for understanding the status of the client. So we build a novel categorization scheme of client utterances, and we base our categorization scheme on the cognitive behavioral theory (CBT), a widely used theory in psychotherapy. Also, in developing the categories, we consider whether they are adequate for the unique text-only communication environment, and appropriate for the annotation of the dialogues as training data. Then using the corpus of text-based counseling sessions annotated according to the categorization scheme, we build a novel conversation model to classify the client utterances.

This paper presents the following contributions:

- First, we build a novel categorization method as a labeling scheme for client utterances in text-based counseling dialogues.

Proceedings of NAACL-HLT 2019, pages 1448–1459
Minneapolis, Minnesota, June 2 - June 7, 2019.

- Second, we propose a new model, Conversation Model Fine-Tuning (ConvMFiT) to classify the utterances. We explicitly integrate pre-trained language-specific word embeddings, language models and a conversation model to take advantage of the pre-trained knowledge in our model.
- Third, we empirically evaluate our model in comparison with other models including a state-of-the-art neural network text classification model. Also, we show typical phrases of counselors and clients for each category by investigating the attention layers.

2 Categorization of Client Utterances

Client responses provide essential clues to understanding the client's internal status which can vary throughout counseling sessions. For example, client's responses describing their problems prevail at the early stage of counseling (Hill, 1978; E. Hill et al., 1983), but as counseling progresses, problem descriptions decrease while insights and discussions of plans continue to increase (Seeman, 1949). Client responses can also help in predicting counseling outcomes. For example, a higher proportion of insights and plans in client utterances indicates a high positive effect of counseling (Hill, 1978; E. Hill et al., 1983).

Categorization Objective. Our final aim is to build a machine learning model to classify the client utterances. Thus, the categorization of the utterances should satisfy the following criteria:

- *Suitable for the text-only environment*: Categories should be detected only using the text response of clients.
- *Available as a labeling scheme*: The number of categories should be small enough for manual annotation by counseling experts.
- *Meaningful to counselors*: Categories should be meaningful for outcome prediction or counseling progress tracking.

Previous studies in psychology proposed nine and fourteen categories for client and counselor verbal responses, respectively, by analyzing transcriptions from traditional face-to-face counseling sessions (Hill, 1978; Hill et al., 1981). But these categories were developed for face-to-face spoken interactions, and we found that for online text-only counseling dialogues, these categories are not directly applicable. Using text without non-verbal cues, a client's responses are inherently different from the transcriptions of verbally spoken responses which include categories such as 'silence' (no response for more than 5 seconds) and 'non-verbal referent' (physically pointing at a person). Another relevant study, derived from text-based counseling sessions with suicidal adolescents proposes 19 categories which we judged to be too many to be practical for manual annotation (Kim, 2010).

The last criterion of "meaningful to counselors" is perhaps the most important. To meet that criterion, we base the categorization process on the *cognitive behavioral theory (CBT)* which is the underlying theory behind psychotherapy counseling. The details of using CBT for the categorization process is explained next.

Categorization Process and Results. In developing the categories, we follow the Consensual Qualitative Research method (Hill et al., 1997). Two professional counselors with clinical experience participated in this qualitative research method to define the categorization.

To begin, we randomly sample ten client cases considering demographic information including age, gender, education, job, and previous counseling experiences. We then start the categorization process with the fundamental components of the CBT which are *events*, *thoughts*, *emotions*, and *behavior* (Hill et al., 1981). The professional counselors annotate every client utterance to with those initial component categories with tags that add detail. For example, if an utterance is annotated as 'emotion', we add 'positive/negative' or concrete label such as 'hope'. If these tags are categorized to be a new category, we add that category to the list until it is saturated. When the number of categories becomes more than 40, we define higher level categories that cover the existing categories.

In the second stage, annotators discuss and merge these categories into five high-level categories. Category 1 is *informative responses to counselors*, and category 2 is *providing factual information and experiences*. Categories 3 and 4 are related to the client factors, *expressing appealing problems* and *psychological changes*. The last category is about the *logistics of the counseling sessions* including scheduling the next session. The categories in detail are as follows:

Characteristic	Informative		Client Factors		Process
Category Name	**Factual Information (Fact.)**	**Anecdotal Experience (Anec.)**	**Appealing Problem (Prob.)**	**Psychological Change (Chan.)**	**Counseling Process (Proc.)**
Explanation	Brief mention of categorical information	Clients experience contributing to the appealing problem	Clients factors related to the appealing problem	Statement at the resolution stage of the appealing problem	Statement of counseling structure and relationship
Examples	• Objective Fact • Living conditions • Demographic information • Limited conditions	• Experience with others • Comments from others • Trauma • Interpersonal situations	• Negative Emotion • Cognitive distortion • Interpersonal problems • Family problems	• Positive Prediction • Expectation, Determination • Coping behaviors • Self-awareness	• A message to counselor • Gratitude, Greetings • Time appointment • Questions about the consultation

Table 1: Final Categorization of client utterances. Five categories are discovered, two for informative giving information to a counselor (Factual information, Anecdotal Experience), two for client factors (appealing problems, psychological change), and the last one for counseling process.

- *Factual information (Fact.)* Informative responses to counselor's utterances, including age, gender, occupation, education, family, previous counseling experience, etc.

- *Anecdotal Experience (Anec.)* Responses describing past incidents and current situations related to the formation of appealing problems. Responses include traumatic experiences, interactions with other people, comments from other people, and other anecdotal experiences.

- *Appealing Problems (Prob.)* Utterances addressing the main appealing problem which is yet to be resolved, including client's internal factors or their behaviors related to the problems. Specifically, the utterances include cognition, emotion, physiological reaction, and diagnostic features of the problem and desire to be changed.

- *Psychological Change (Chan.)* Utterances describing insights, cognition of small and big changes in internal factors or behaviors. That is, an utterance at the point where the appealing problem is being resolved.

- *Counseling Processes (Proc.)* Utterances that include the objective of counseling, requests to the counselor, plans about the counseling sessions, and counseling relationship. This category also covers greetings and making an appointment for the next session.

We summarize the category explanations and examples in Table 1.

3 Dataset

In this section, we explain how counseling dialogues differ from general dialogues, describe the dialogues we collected and annotated, and explain how we preprocessed the data.

3.1 Characteristics of Counseling Dialogues

The counseling dialogues consist of multiple turns taken by a counselor and a client, and each turn can contain multiple utterances. Here we describe two unique characteristics of text-based online counseling conversations compared to general non-goal oriented conversations.

Distinctive roles of speakers. Counseling conversations are goal-oriented with the aim to produce positive counseling outcomes, and the two speakers have distinctive roles. The client gives objective information about themselves and subjective experiences and feelings to the counselor to appeal the problems they are suffering from. Then the counselor establishes a therapeutic relationship with the client and elicits various strategies to induce psychological changes in the client. These distinct roles of the conversational participants distinguish counseling conversations from

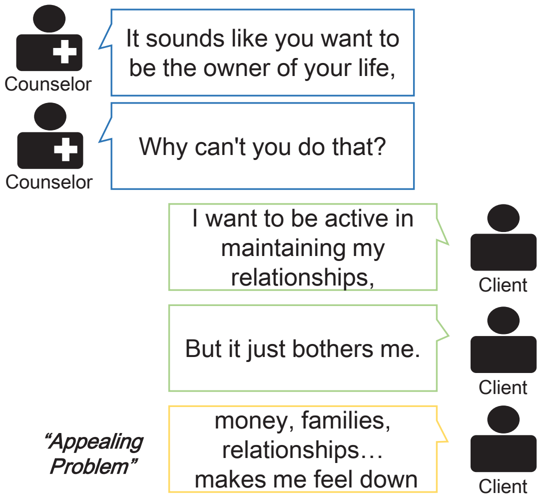

Figure 1: Translated example conversation between a counselor and a client. Each turn can have multiple utterances, and we annotate the client turn at the *utterance*-level. The first two boxes indicate 1) *Counselor's utterance* and the next two are 2) *Client's context utterance*, and the last box is 3) *Client's target utterance*. The annotation for the last client utterance is "appealing problem".

non-goal oriented open-domain response generation modeling.

Multiple utterances in a turn. We define an *utterance* as a single text bubble. Counselors and clients can generate multiple utterances in a turn. Especially in a client turn, various information not to be missed by a counselor may occur across multiple utterances. Thus, we treat every utterance separately, as shown in Fig. 1

3.2 Collected Dataset

Total dialogues. We collect counseling dialogues of clients with their corresponding professional counselors from Korean text-based online counseling platform Trost. [1] Overall, we use 1,448 counseling dialogues which are anonymized before researchers obtain access to the data, by removing personally identifiable information in the dialogues. All meta-data of the dialogues are not provided to the researchers, and named entities such as client's and counselor's names are replaced with random numeric identifiers. The research process including data anonymization and pre-processing is validated by the KAIST Institutional Review Board (IRB).

Labeled Dialogues. We randomly choose and label 100 dialogues with the discovered five categories. Note that we only label client utterances. Based on these categories, five professional counselors annotated their own client's every utterance in the conversations, as shown in Fig. 1. Note that each utterance can have multiple labels if it includes information across multiple categories.

Table. 2 shows the descriptive statistics of our labeled dataset. The first two rows present the average lengths of each utterance of counselors and clients in terms of words and characters, showing there is a small difference between the counselor utterance and the client utterance. On the other hand, the average number of utterances in a single counseling session differs; on average, clients write more utterances than counselors.

	Counselor		Client	
	Mean	Std.	Mean	Std.
# of words	6.26	6.25	5.91	14.62
# of chars	25.71	23.44	24.31	61.10
# of utters	163.2	236.97	238.72	578.49

Table 2: Descriptive statistics of labeled counseling dialogues.

3.3 Preprocessing

We intentionally leave in punctuations and emojis since they can help to infer the categories of the client utterances, treating them as separate tokens. Then we construct triples from the labeled dialogues consisting of 1) counselor's utterances (blue in Fig. 1), 2) client's context utterances (green), and 3) client's target utterances to be categorized. (yellow)

We split the dataset into train, validation, and test sets. Table. 3 shows the number of triples in each set, showing factual information (Fact.) and psychological change (Chan.) categories appear less frequently than the others.

4 Model

We introduce ConvMFiT (Conversation Model Fine-Tuning), fine-tuning pre-trained seq2seq based conversation model to classify the client's utterances.

Background. Our corpus of 100 labeled conversations is not large enough to fully capture the linguistic patterns of the categories without external knowledge. The small size of the dataset is difficult to overcome because the labeling by professional counselors is costly. We found a poten-

---

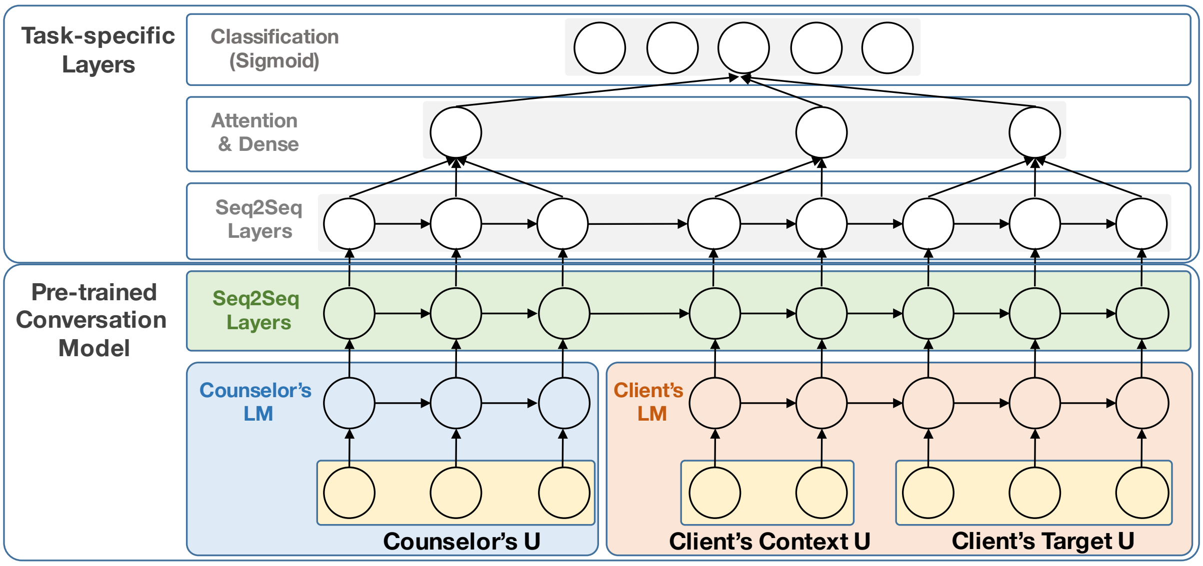

Figure 2: ConvMFiT (Conversation Model Fine-Tuning) model architecture. We use a pre-trained conversation model using seq2seq models. The model is based on pre-trained counselor's and client's language models. (lower colored part) Then, we stack additional task-specific seq2seq layers and classification layers over the conversation model to learn specific features. Between the two layers, attention layer is added to enhance its interpretability.

	Train	Valid	Test	# of labels
Fact.	817	140	172	1129
Anec.	5317	1180	1175	7726
Prob.	4728	1004	981	6713
Chan.	887	211	199	1297
Pros.	4570	964	961	6459
# of triples	14679	3166	3165	21100

Table 3: The number of triples (partner's utterance, client's context utterance, client's target utterance) and corresponding labels for each set. Factual information (Fact.) and psychological change (Chan.) categories have less number of instances compared to the others.

tially effective solution for a small labeled dataset by using pre-trained language models for various NLP tasks (Ramachandran et al., 2017; Howard and Ruder, 2018). Therefore, we focus on transferring knowledge from unlabeled in-domain dialogues as well as a general out-of-domain corpus.

Overview. We illustrate the overall model architecture. We first stack pre-trained seq2seq layers which represent a conversation model (see Fig. 2, lower colored part). Then we stack additional seq2seq layers and classification layers over it to capture task-specific features, and an attention layer is added between the two to enhance the model's interpretability (see Fig. 2, upper white part).

This approach leverages the advantages of using a language model based conversation model for transfer learning. The model can be regarded as an extended version of ULMFiT (Howard and Ruder, 2018) with modifications to fit our task. In ConVMFiT, the model accepts a pre-trained seq2seq conversation model that requires two pre-trained language models, like an encoder and a decoder, learning the dependencies between them on the seq2seq layers. This approach is shown to be effective for machine translation, applying a source language model for the encoder and target language model for the decoder (Ramachandran et al., 2017).

4.1 Model Components

Word Vectors. Counseling dialogues consist of natural Korean text which is morphologically rich, so we train word vectors specifically developed for the Korean language (Park et al., 2018a). We train the vectors over a Korean corpus including out-of-domain general documents, 1) Korean Wikipedia, 2) online news articles, and 3) Sejong Corpus, as well as in-domain unlabeled counseling dialogues. The corpus contains 0.13 billion tokens. To validate the trained vector quality, we check performance on word similarity task (WS353) for Korean (Park et al., 2018a). The Spearmans correlation is 0.682, which is comparable to the state-of-the-art performance. These vectors are used as inputs (see Fig. 2, yellow).

Pre-trained Language Models. We assume that counselors and clients have different language models because they have distinctive roles in the dialogue. Therefore, we train a counselor language model and a client language model separately. We collect counselor utterances in the total dialogue dataset, except dialogues in the test set, to train a counselor language model, and all others are used for training a client language model. Then, We fine-tune the two trained LMs with utterances in the labeled dialogues.

For each model, we train word-level language models by using multilayer LSTMs. We apply various regularization techniques, weight tying (Inan et al., 2017), embedding dropout and variational dropout (Gal and Ghahramani, 2016), which are used to regularize LSTM language models (Inan et al., 2017; Ramachandran et al., 2017; Merity et al., 2018).

We use a 3-layer LSTM model having 300 hidden units for every layer. We set embedding dropout and output dropout for each layer to 0.2, 0.1, respectively. The pre-trained language models generate inputs to seq2seq layer of a conversation model (Fig. 2, blue and red).

Pre-trained Conversation Model. Next, we train a seq2seq conversation model (Vinyals and Le, 2015). We use the pre-trained counselor language model as an encoder, and the client language model as a decoder. The dependency of the decoder on the encoder is trained by seq2seq layers, stacked over the pre-trained models. (Fig. 2, green)

We stack 2-layer LSTMs over the pre-trained counselor and client language models, respectively. The final states of the LSTMs on the counselor language model is used as an initial state of the LSTMs on the client language model. We set the hidden unit size of 300 for every LSTMs and set output dropout to 0.05. The outputs of pre-trained conversation models is used for inputs to seq2seq layers of the task-specific layers.

During training the conversation model, we regularize the parameters of the model by adding cross entropy losses of the pre-trained counselor and client language models to seq2seq cross entropy loss of the conversation model. Three losses are weighted equally. This prevents catastrophic forgetting of the pre-trained language models and is important to achieve high performance (Ramachandran et al., 2017). Also, there is room for improvement of the architecture of a conversation model, which integrates pre-trained language models, to capture dialogue patterns better and thus leads to higher classification performance. We will explore the architecture in future work.

Task-specific layers. By leveraging pre-trained language model based conversation model, we finally add layers for classification. In order to capture task-specific features, we first stack seq2seq layers over the conversation model. Then we add attention mechanism for document classification (Yang et al., 2016). Lastly, we use a sigmoid function as an output layer to predict whether the information is included in utterances because multiple categories can appear in a single utterance. (Fig. 2, gray)

We use a 2-layer LSTM model for the seq2seq layers. We set 300 hidden units for every LSTMs and set output dropout to 0.05. The size of attention layer is set to 500.

4.2 Model Training

Thus the model is trained by three steps: 1) training word vectors and two language models, 2) training seq2seq conversation model with pre-trained LMs, and 3) fine-tuning task-specific classification layers, after removing softmax of the conversation model. In the last step, we compute binary logistic loss between predicted probability for each category and label as a loss function. We use Adam with default parameters for the optimizer, in order to train language models, conversation model, and fine-tuning the classifier. Also, gradual unfreezing is applied while training the model, starting updating parameters from the task-specific layers and unfreezing the next lower frozen layer for each epoch. We unfreeze layers every other epoch until all layers are tuned, and we stop training when the validation loss is minimized. All hyperparameters are tuned over the development set.

5 Experiments

5.1 Comparison Models

We compare our model with baseline models in Table 4. Models 1-5 are classifiers which only use the target client utterance to classify it, and models 6-8 are conversation model-based classifiers considering counselor's utterances and client's context utterances. All models use the same pre-trained word vectors for a fair comparison.

(1) Random Forest, (2) SVM with RBF kernel. We represent an utterance by an average of all word vectors in it, then feed it to the classifier input.

(3) CNN for text classification (Kim, 2014). In the convolution layer, we set the filter size to 1-10, and 30 filters each, then we apply max-over-time pooling. Then, a dense layer and sigmoid activation is applied over the layer.

(4) RNN Bidirectional LSTM is used where the final states for each direction are concatenated to represent the utterances. Then, a dense layer and a sigmoid activation are stacked.

(5) ULMFiT. A pre-trained client language model is used as a universal language model. Details are the same as described in Section 5.3. In addition, 2-LSTM layers and dense layer with sigmoid activations are stacked over the LM for classification. Gradual unfreezing is applied during training (Howard and Ruder, 2018).

(6) Seq2Seq. Like encoder-decoder based conversation model (Vinyals and Le, 2015), three LSTMs are assigned for each Counselor's utterances, client's context/target utterances. The initial states of the client language models are set to the final states of preceding utterances. Then dense & sigmoid layers for classification are stacked over the final state of the client's target utterances.

(7) HRED. Hierarchical encoder-decoder model (HRED) is used as a conversation model (Serban et al., 2016). For the encoder RNN, counselor's utterances and client's context utterances are given as inputs, and their information is stored in context RNN, which delivers it to the decoder accepting client's target utterances. Like (6) Seq2Seq, dense & sigmoid layers for classification are stacked over the final state of the client's target utterances.

5.2 Ablation Study

We conduct an ablation study to investigate the effect of the pre-trained models in Table 5.

(1-4) Adding pre-trained models. Model 1-4 have the same architecture as ConvMFiT, which is Model (8) in Table. 4. Model (1) in Table. 5 initializes every parameter randomly. Model (2) starts training only with pre-trained word vectors. Model (3) leverages counselor and client language models as well, and Model (4) shows the performance of ConvMFiT. As Model (3) and (4) use more than two pre-trained components, gradual unfreezing in applied, unfreezing shallower layers first during training.

(4-1) Task-specific Seq2Seq Layers. Model (4-1) removes task-specific Seq2Seq layers in the model, which leaves only attention and dense layer to capture task-specific features. It may result in an insufficient model capacity to capture relevant features for the task.

(4-2) Effect of Gradual Unfreezing. Model (4-2) is trained without gradual unfreezing, allowing the parameters of every layer in the model change by the gradients from the first epoch.

6 Results

6.1 Classification Performance

We show the performance of our model and comparison models in Table. 4. (1) Random Forests and (2) Support Vector Machines underperform to classify utterances correctly which belong to rarely occurred classes. Compared to (1) and (2), (3) CNN and (4) RNN show better performance since they look at the sequence of words (.416, .431, respectively). RNN shows slightly better performance than CNN. (6) ULMFiT outperforms the others by using a pre-trained client language models (.455).

The client target utterances have their context, and they also depend on the counselor's preceding utterances, so using the preceding counselor utterance as well as the client context utterances helps to improve the classification performance. When integrating the information using simple (6) seq2seq model, it shows better performance (.530) than (5) ULMFiT. (7) HRED adds a higher-level RNN to seq2seq models, but we find there is little performance gain (.001) which makes the model overfit easily.

(8) ConvMFiT employs pre-trained conversation model based on pre-trained LMs and so outperforms all other baseline models (.642). This is because ConvMFiT integrates conversational contexts and the counselor language model, which helps to capture the patterns of client's language better. Also, the improvement is higher for the class (Fact.) and (Chan.) which have small numbers of examples since the ConvMFiT could leverage pre-trained knowledge to classify them.

6.2 Effect of Pre-trained Components

With an ablation study applying pre-trained components step by step to our model, we show the

No.	Dep.	Model	F1 (Fact.)	F1 (Anec.)	F1 (Prob.)	F1 (Chan.)	F1 (Proc.)	Macro Prec	Macro Rec	Macro F1

4-1	O	O	O	O	X	.307	.738	.666	.304	.802	.513	.687	.563
4-2	O	O	O	X	O	.417	.768	.721	.399	.824	.591	.695	.626
4	O	O	O	O	O	**.441**	**.761**	**.726**	**.447**	**.835**	**.602**	**.716**	**.642**

Table 5: Ablation study results. All models use the same architecture of ConvMFiT. Adding pre-trained word vectors (2), counselor and client language models (3), seq2seq layers of conversation model (4) results in a performance improvement. Also, adding task-specific seq2seq layers to ensure the model's sufficient capacity for capturing relevant features (4-1), and applying gradual unfreezing lead to performance improvement (4-2).

sources of performance improvement in Table 5. Model (1) uses the same architecture but no pre-trained models are applied, showing poor performance due to overfitting (.455). The f1 score is lower than that of the simple seq2seq model. Model (2) only uses pre-trained word vectors, and it helps to increase the performance slightly (.494). Also, Model (3) adds two pre-trained LMs with gradual unfreezing, resulting in a substantial performance increase (.626.), so we find pre-trained LMs are essential to the improvement. Lastly, Model (4) adds the dependency between two language models to fully leverage the pre-trained conversation model. This also helps classify utterances better (.642).

In addition, we find only adding attention and dense layers are not sufficient to learn task-specific features, so providing the model more capacity helps improving the performance. Without task-specific seq2seq layers, model (4-1) shows decreased f1 score (.563). Meanwhile, model (4-2) shows careful training scheme affects to the performance as well.

6.3 Qualitative Results

To investigate how linguistic patterns of counselors and clients differ in the various categories, we report qualitative results based on the activation values of the attention layer. To protect the anonymity of the clients, we explore key phrases from utterances rather than publish parts of the conversation in any form.

To this end, we compute the relative importance of n-grams. For any n of n-gram in an utterance of length N where $n < N$, the relative importance r is computed as follows:

$$\left(\prod_{i=1}^{n} a_i - (1/N)^n \right) / (1/N)^n \qquad (1)$$

where a_i is corresponding attention value of a word, $\prod_{i=1}^{n} a_i$ is the product of the values for every words in the n-gram, normalized by the expected attention weights $(1/N)^n$. The normalization term considers the length of utterance since a word in short utterances tends to have high attention value because of $\sum_{i=1}^{N} a_i = 1$.

We name this measure 'relative importance' r meaning that the degree of the n-gram is how much it is attended to compared to the expectation. Based on this, we select examples from 100 top-ranked key phrases for each category and the results are presented in Appendix (Table. 6). All of the presented key phrases are translated to English from Korean.

Factual Information. Clients provide demographic information and previous experience of visits to counselors or psychiatrists. In some case, clients talk more about the motivation of counseling. Since this information is explored in an early stage of counseling sessions, we also find counselor greetings with client's names.

Anecdotal Experience. Clients describe their experiences by using past tense verbs. Usually, utterances include phrases such as 'I thought that', 'I was totally wrong'. Counselors show simple responses 'well..', and reflections.

Appealing Problem. Like anecdotal experience, clients describe their problems, but with using the present tense of verbs. They are appealing their thinking and emotions. Counselors also show simple responses or reflections. Since some clients immediately start pouring out their problems right after counseling sessions starts, so greetings from counselor appear in key phrases.

Psychological Change. Clients obviously report their change of feelings, emotions or thoughts. It includes looking back on the past and then determining to change in the future. Counselors give supportive responses and empathetic understanding.

Counseling Process. Clients and counselors exchange greetings with each other. Also, they discuss making an appointment for the next session. In some cases, counselors respond to client's questions about the logistics of the sessions.

7 Related Work

Researchers have explored psycho-linguistic patterns of people with mental health problems (Gkotsis et al., 2016), depression (Resnik et al., 2015), Asperger's and autism (Ji et al., 2014) and Alzheimer's disease (Orimaye et al., 2014). In addition, these linguistic patterns can be quantified, for example, overall mental health (Loveys et al., 2017; Coppersmith et al., 2014), and schizophrenia (Mitchell et al., 2015).

To aid people with those mental issues, large portion of studies are dedicated to detecting those issues from natural language. Depression (Morales et al., 2017; Jamil et al., 2017; Fraser et al., 2016), anxiety (Shen and Rudzicz, 2017), distress (Desmet et al., 2016), and self-harm risk (Yates et al., 2017) can be effectively detected from narratives or social media postings.

8 Discussion and Conclusion

In this paper, we developed five categories of client utterances and built a labeled corpus of counseling dialogue. Then we developed the ConvMFiT for classifying the client utterances into the five categories, leveraging a pre-trained conversation model. Our model outperformed comparison models, and this is because of transferring knowledge from the pre-trained models. We also explored and showed typical linguistic patterns of counselors and clients for each category.

Our ConvMFiT model will be useful in other classification tasks based on dialogues. ConvMFiT is a seq2seq model for counselor-client conversation, however, another approach would be to model with existing non-goal oriented conversation models incorporating Variational Autoencoder (VAE) (Serban et al., 2017; Park et al., 2018b; Du et al., 2018). We plan to attempt these models in future work.

We expect to apply our trained model to various text-based psychotherapy applications, such as extracting and summarizing counseling dialogues or using the information to build a model addressing the privacy issue of training data. We hope our categorization scheme and our ConvMFiT model become a stepping stone for future computational psychotherapy research.

Ethical Approval

The study reported in this paper was approved by the KAIST Institutional Review Board (#IRB-17-95).

Abstract

Word vectors and Language Models (LMs) pretrained on a large amount of unlabelled data can dramatically improve various Natural Language Processing (NLP) tasks. However, the measure and impact of similarity between pretraining data and target task data are left to intuition. We propose three cost-effective measures to quantify different aspects of similarity between source pretraining and target task data. We demonstrate that these measures are good predictors of the usefulness of pretrained models for Named Entity Recognition (NER) over 30 data pairs. Results also suggest that pretrained LMs are more effective and more predictable than pretrained word vectors, but pretrained word vectors are better when pretraining data is dissimilar.

1 Introduction

Modern neural architectures for NLP are highly effective when provided a large amount of labelled training data (Zhang et al., 2015; Conneau et al., 2017; Bowman et al., 2015). However, a large labelled data set is not always readily accessible due to the high cost of expertise needed for labelling or even due to legal barriers. Researchers working on such tasks usually spend a considerable amount of effort and resources on collecting useful external data *sources* and investigating how to transfer knowledge to their *target* tasks (Qi et al., 2009; Kim et al., 2017). Recent transfer learning techniques make the most of limited labelled data by incorporating word vectors or LMs pretrained on a large amount of unlabelled data. This produces dramatic improvements over a range of NLP tasks where appropriate unlabelled data is available (Peters et al., 2017, 2018; Akbik et al., 2018; Devlin et al., 2019).

However, there is still a lack of systematic study on how to select appropriate data to pretrain word vectors or LMs. We observe a range of heuristic strategies in the literature: (1) collecting a large amount of generic data, e.g., web crawl (Pennington et al., 2014; Mikolov et al., 2018); (2) selecting data from a similar *field* (the subject matter of the content being discussed), e.g., biology (Chiu et al., 2016; Karimi et al., 2017); and, (3) selecting data from a similar *tenor* (the participants in the discourse, their relationships to each other, and their purposes), e.g., Twitter, or online forums (Li et al., 2017; Chronopoulou et al., 2019). In all these settings, the decision is based on heuristics and varies according to the individual's experience. We also conducted a pilot study that suggests that the practitioner's intuition is to prioritise field over tenor (see Section 3).

Our overarching goal is to develop a cost-effective approach that, given a NER data set, nominates the most suitable source data to pretrain word vectors or LMs from several options. Our approach builds on the hypothesis that the more similar the source data is to the target data, the better the pretrained models are, all other aspects (such as source data size) being equal. We propose using target vocabulary covered rate and language model perplexity to select pretraining data. We also introduce a new measure based on the change from word vectors pretrained on source data to word vectors initialized from source data and then trained on target data. Experiments leverage 30 data pairs from five source and six target NER data sets, each selected to provide a range of fields (i.e., biology, computer science, medications, local business) and tenors (i.e., encyclopedia articles, journal articles, experimental protocols, online reviews).

Our contributions can be summarized as below:

- We propose methods to quantitatively measure different aspects of similarity between

Proceedings of NAACL-HLT 2019, pages 1460–1470
Minneapolis, Minnesota, June 2 - June 7, 2019.

source and target data sets and find that these measures are predictive of the impact of pretraining data on final accuracy. To the best of our knowledge, this is the first systematic study to investigate LMs pretrained on various data sources.[1]

- We find that it is important to consider tenor as well as field when selecting pretraining data, contrary to human intuitions.
- We show that models pretrained on a modest amount of similar data outperform pretrained models that take weeks to train over very large generic data.

2 Related Work

Text Similarity Word similarity following the hypothesis that similar words tend to occur in similar contexts (Harris, 1954) is well studied and forms the foundation of neural word embedding architectures. Hill et al. (2015) and Budanitsky and Hirst (2006) evaluate functional similarity (as in *school* versus *college*) and associative similarity (as in *school* versus *teacher*) captured by semantic models, respectively. Pavlick et al. (2015) study sentence-level similarity, using entailment relation, vector embedding and stylistic variation measures. Kusner et al. (2015) propose Word Mover's Distance to measure the similarity between documents and evaluate on document classification tasks. We extend the study of similarity to corpus-level, and focus on its implication on unsupervised pretraining.

Pretrained Word Vectors The effectiveness of pretrained word vectors mainly depends on three factors: source data, training algorithm, and its hyper-parameters. Turian et al. (2010) and Levy et al. (2015) systematically compare count-based distributional models and distributed neural embedding models. They find that both models can improve the performance of downstream tasks. Chiu et al. (2016) identify the most influential hyper-parameters of neural embedding methods. They also investigate the impact of the source data size and find that larger pretraining data do not necessarily produce better word vectors for biomedical NER. Our work regarding pretrained word vectors is conducted using skip-gram model with default hyper-parameter setting (Mikolov et al., 2013), and our focus is on the impact of similarity between source data and target task data on the effectiveness of pretrained word vectors for NER tasks. Our observations are a useful supplement to the literature as a practitioners' guide.

Pretrained Language Models Dai and Le (2015) investigate different methods to transfer knowledge to supervised recurrent neural networks. They establish that a pretrained recurrent LM can improve the generalization ability of the supervised models. They use unlabelled data from Amazon reviews to pretrain the LM and find that it can improve classification accuracy on the Rotten Tomatoes data set. Joshi et al. (2018) empirically showed that, for their vaccination behaviour detection task on twitter data, LMs pretrained on a small amount of movie reviews outperform the ones pretrained on large size of Wikipedia data. Peters et al. (2017) successfully inject the information captured by a bidirectional LM into a sequence tagger, and extend this approach to other NLP tasks (Peters et al., 2018). Our work is based on (Peters et al., 2018) and investigates the impact of pretraining data on the effectiveness of pretrained LMs for downstream NER tasks.

Transfer Learning While our study falls into the paradigm of semi-supervised learning, we distinguish ourselves from other studies in transfer learning. One sub-area of transfer learning is domain adaptation, which aims to learn transferable representation from a source domain and apply it to a target domain (Blitzer et al., 2006; Yang and Eisenstein, 2015). The question in domain adaptation is usually framed as 'Given a source and a target, how to transfer?'. In contrast, the question we address is 'Given a specific target, which source to choose from?'. The other sub-area of transfer learning is transferring from multiple sources (Yin and Schütze, 2015; Li et al., 2018). Our work focuses, instead, on the selection of a single external data source. Our work is inspired by the methodology proposed by Johnson et al. (2018) where they predict a system's accuracy using larger training data from its performance on much smaller pilot data. However, we aim to predict the usefulness of pretrained models for target tasks from the similarity between the source pretraining data and the target task data.

Named Entity Recognition Our work builds on the literature on deep neural networks applied to sequence tagging tasks. Architectures based on

---

[1] Our pretrained word vectors and LMs are publicly available: https://bit.ly/2O0mOOG.

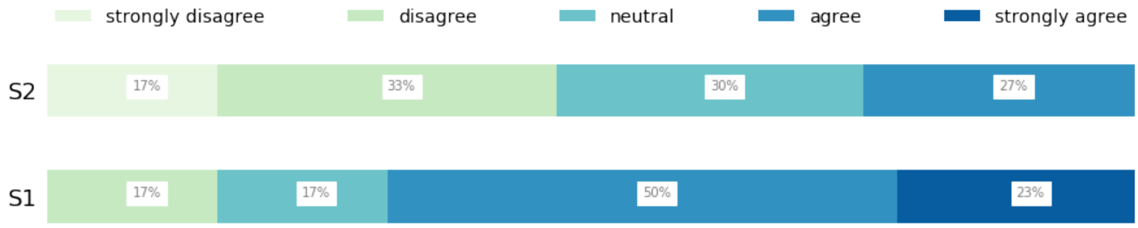

Figure 1: Likert scale ratings from NLP and ML practitioners ($N = 30$) for the statement 'Unsupervised pretraining on S would be useful for supervised named entity recognition learning on T.' Target data T is described as 'Online forum posts about medications,' source data S1 as 'Research papers about biology and health,' and source data S2 as 'Online reviews about restaurants, hotels, barbers, mechanics, etc.'

different combinations of convolutional and recurrent neural networks have achieved state-of-the-art results on many NER tasks. A detailed review and comparison of these methods can be found in (Yang et al., 2018). Our experiments on the usefulness of pretrained word vectors and pretrained LMs for NER tasks are based on one variant proposed by Lample et al. (2016).

3 What Human Intuition Indicates

Results of a survey capturing intuition regarding selection of pretraining data across 30 NLP or machine learning practitioners is shown in Figure 1. Participants were provided short descriptions of the target data set T, and two possible source data sets S1 and S2 as

- T: Online forum posts about medications;
- S1: Research papers about biology and health;
- S2: Online reviews about restaurants, hotels, barbers, mechanics, etc.

We constructed each of these descriptions as 't about f' where t is intended to describe the tenor and f the field. Each participant rated both sources on a five-point Likert, indicating agreement with the statement "Unsupervised pretraining on S would be useful for supervised named entity recognition learning on T". 73% of participants agreed or strongly agreed that S1 would be useful, while only 27% agreed that S2 would be useful. A Wilcoxon signed-rank test indicates that scores are significantly higher for S1 than for S2 ($Z = 43.0, p < 0.001$).

Although small in scale, these results show that intuition varies across practitioners, motivating our work on identifying quantitative measures that are predictive of performance. These results also suggest that practitioners favour field over tenor when selecting pretraining data, which would be detrimental to accuracy of the target NER tasks in later experiments (Section 7.2).

4 Similarity Measures

To measure the similarity between source and target data, we start from identifying linguistic concepts behind these human intuitions. Then, we propose several measures to quantify these attributes which lead to the perception that two data sets are similar.

Researchers who select pretraining data from a similar field believe that, if the source data has a similar field to the target data, they tend to share similar vocabulary. Conversely, vocabularies are different from each other if source and target are from different fields. Imagine data sets about medications and restaurants. Those who select pretraining data from a similar tenor believe that tenor may impact the writing style of text. Imagine the participants in online reviews and scientific papers, their relationships to each other, their purposes and how these affect text style, including punctuation, lexical normalization, politeness, emotiveness and so on (Lee, 2001; Solano-Flores, 2006; Pavlick and Tetreault, 2016).

Below, we detail different measures based on these intuitions to quantify different aspects of similarity between two data sets.

4.1 Target Vocabulary Covered

The first measure is simply the percentage of the target vocabulary that is also present in the source data. An extremely dissimilar example is that of different languages. They have a totally different vocabulary and are considered dissimilar, even if they are written in a similar style and talking about the same subject [2]. We propose *Target Vocabulary Covered (TVC)* as a measure of field, calculated as

$$TVC(D_S, D_T) = \frac{|V_{D_S} \cap V_{D_T}|}{|V_{D_T}|},$$

where V_{D_S} and V_{D_T} are sets of unique tokens in source and target data sets respectively. We also investigate a variant where only content words (nouns, verbs, adjectives) are used to calculate V_{D_S} and V_{D_T}. We denote this variant as *VCcR*.

4.2 Language Model Perplexity

A language model can assign a probability to any sequence of words $< w_1, \cdots, w_N >$ using chain rule of probability:

$$p(w_1, w_2, \cdots, w_N) = \prod_{i=1}^{N} p(w_i | w_1^{w-1}),$$

where N is the length of the sequence and w_1^{i-1} are all words before word w_i. In practice, this equation can be simplified by n-gram models based on Markov Assumption:

$$p(w_1, w_2, \cdots, w_N) = \prod_{i=1}^{N} p(w_i | w_{i-n+1}^{i-1}),$$

where w_{i-n+1}^{i-1} represents only n preceding words of w_i. To make the model generalize better, smoothing techniques can be used to assign non-zero probabilities to unseen events. In this study, we use Kneser-Ney smoothed 5-gram models (Heafield, 2011). To measure the similarity between two data sets using language modeling, we first train the language model on the source data, then evaluate it on the target data using perplexity to represent the degree of similarity. The intuition is that, if the model finds a sentence very unlikely (dissimilar from the data where this language model is trained on), it will assign a low probability and therefore high perplexity. The summed up *perplexity (PPL)* is then:

$$PPL(D_S, D_T) = \sum_{i=1}^{m} P(D_T^i)^{-\frac{1}{N_i}},$$

where m is the number of sentences in the target data set, and $P(D_T^i)$ is the probability assigned by the language model trained on the source data to the i-th sentence from the target data set, whose sentence length is N_i.

PPL is token-based, similar to TVC, but also captures surface structure. We therefore propose PPL as a proxy to measure tenor as well as field.

4.3 Word Vector Variance

Pretrained word vectors capture semantic and syntactic regularities of words (Artetxe et al., 2018). The variance of a word vector that is first trained on the source data and then on the target data can reflect the difference of linguistic regularities between the two data sets.

Intuitively, if the context words around a given word are very different in the source and target data, then the word vector of this word learned from the source will be updated more than those words whose context words are similar between source and target. Therefore, we use *Word Vector Variance (WVV)* as another combined measure of tenor and field.

To calculate word vector variance, we first train word vectors on the source data set using skip-gram model (Mikolov et al., 2013). The trained word vectors are denoted as $WS \in \mathbb{R}^{|V_S| \times d}$, where $|V_S|$ is the vocabulary size of the source data set and d is the vector dimension. Then, we use WS as initial weights of a new skip-gram model, and train this new model on the target data. We denote the final word vectors as WT. The WVV can be calculated as:

$$WVV(D_S, D_T) = \frac{1}{|V_S|} \frac{1}{d} \sum_{i}^{|V_S|} \sum_{j}^{d} (WS_i^j - WT_i^j)^2.$$

The smaller the word vector variance, the more similar context surrounds the same words from the two data sets, and therefore the more similar the two data sets are.

5 Data Sets

Source data sets We use five data sets as source data, covering a range of fields (i.e., clinical, biomedical, local business and Wiki with diverse fields) and tenors (i.e., popular reporting, notes, scholarly publications, online reviews and encyclopedia). To isolate the impact of source size, we sample all source data to approximately 100 million tokens. We also analyze the impact of source data size separately in Section 7.3. The specifications of these source data sets are given in Table 1.

---

[2] Our focus is on transferring through pretrained models using one single source and we do not consider multilingual similarity.

Data set	Description
1BWB	The original one billion word language model benchmark data (Chelba et al., 2013), produced from News Crawl data. It has been randomly shuffled and we use the last 13 out of 100 files.
MIMIC	A clinical database comprising over 58,000 hospital admissions for intensive care unit (ICU) patients (Johnson et al., 2016). We use the first 50,000 notes associated with hospital stays.
PubMed	Around 30 million citations for biomedical literature covering the fields of biomedical and health. We use articles published after October 2017 and utilize their titles and abstracts only.
Wiki	WikiText-103, released by Merity et al. (2016) and consisting of around 28K *Good* or *Featured* articles from Wikipedia. These articles are reviewed by human editors, and they are selected based on the writing quality. We refer to this data set as Wiki.
Yelp	An online forum where customers can write reviews about local businesses. We use data released in round 12 of the Yelp Data set Challenge and select the first 2 out of 6 million reviews.

Table 1: List of the source data sets.

Target data sets Six NER data sets are used as target data: CADEC (Karimi et al., 2015), CoNLL2003 (Sang and Meulder, 2003), CRAFT (Bada et al., 2012), JNLPBA (Collier and Kim, 2004), ScienceIE (Augenstein et al., 2017) and WetLab (Kulkarni et al., 2018). Details of these target data are listed in Table 2. We choose these data sets based on two considerations:

1. NER is a popular structured NLP task. Using NER, we want to observe how the similarity between source and target data may affect the effectiveness of different pretrained word vectors and LMs on downstream tasks.

2. NER is highly sensitive to word representations, because the model needs to make token level decisions. That is, each token needs to be assigned a proper label. Past studies have shown that removing pretrained word vectors from a tagging system results in a large drop in performance (Huang et al., 2015; Lample et al., 2016).

6 Experimental Setup

To investigate the impact of source data on pretrained word vectors and LMs, we pretrain word vectors and LMs on different sources separately, then observe how the effectiveness of these pretrained models varies in different NER data sets.

We use the BiLSTM-CRF model, a state-of-the-art model for sequence tagging tasks, as a supervised model for the target NER task. We follow the architecture proposed in (Lample et al., 2016), except that we use two BiLSTM-layers and employ a CNN network to learn character-level representations (Ma and Hovy, 2016). Micro average F_1 score is used to evaluate the performance of the tagger (Sang and Meulder, 2003).

Word vectors are pretrained using word2vec with its default hyper-parameter setting (Mikolov et al., 2013). In different experiments, we only replace the word embedding weights initialized by word vectors pretrained on different source data, then make these weights trained jointly with other model parameters. The baseline is denoted as *None* in Table 3, where word embedding weights are randomly initialized.

LMs are pretrained using the architecture proposed by Jozefowicz et al. (2016) with hyper-parameters in (Peters et al., 2018). The supervised model used for NER is the same BiLSTM-CRF model mentioned above, and we follow the approach proposed by Peters et al. (2018) to incorporate the pretrained LMs. Note that these pretrained LMs are character-based. Therefore, words in the target data set are first converted into a sequence of characters, and then fed into the LMs. The contextualized representation of each word is generated using the outputs of all layers of the pretrained LMs, then injected to the input of the second BiLSTM layer of the supervised model.

7 Experimental Results

Using proposed similarity measures, we first quantify the similarity between all source-target pairs (Section 7.1), then investigate how these measures can be used to predict the usefulness of pretraining data (Section 7.2). Finally, we take the source data size into consideration, and observe its impact on the effectiveness of pretrained model on both similar and dissimilar source-target settings (Section 7.3).

Data set	Size	Entity Types	Description
CADEC	120,341	Adverse Drug Event, Disease, Drug, Finding, Symptom	Posts taken from AskaPatient, which is a forum where consumers can discuss their experiences with medications.
CoNLL2003	301,418	Person, Organization, Location, Miscellany	Newswire from the Reuters RCV1 corpus.
CRAFT	561,015	Cell, Chemical entity, Biological taxa, Protein, Biomacromolecular sequence, Entrez gene, Biological process and molecular function, Cellular component	Full-length, open-access journal articles about biology.
JNLPBA	593,590	Protein, DNA, RNA, Cell line and Cell type	Abstract of journal articles about biology.
ScienceIE	99,555	Process (including methods, equipment), Task and Material (including corpora, physical materials)	Journal articles about Computer Science, Material Sciences and Physics.
Wetlab	220,618	Action, 9 object-based (Amount, Concentration, Device, Location, Method, Reagent, Speed, Temperature, Time) entity types, 5 measure-based (Numerical, Generic-Measure, Size, pH, Measure-Type) and 3 other (Mention, Modifier, Seal) types	Protocols written by researchers about conducting biology and chemistry experiments.

Table 2: List of the target NER data sets and their specifications. Size is shown in number of tokens.

7.1 Similarity Between Source and Target Data Sets

Different aspects of similarity measured between five source and six target data sets are shown in the left side of Table 3. The language model trained on PubMed achieves lower perplexity when evaluated on CRAFT, JNLPBA and ScienceIE compared to other sources. On one hand, it is expected that PubMed is similar to CRAFT and JNLPBA, since they are all sampled journal articles about biology and health, thus being similar in terms of both field and tenor. On the other hand, although ScienceIE does not have the same field as PubMed (computer science, material and physics versus biology and health), they are similar because they share a similar tenor (scholarly publications).

The measures calculated on CADEC also show that tenor is reflected more than field by PPL and WVV. Source data set Yelp is more similar to CADEC than PubMed and MIMIC from both PPL and WVV perspectives. CADEC is a data set focusing on recognizing drugs, diseases and adverse drug events. The field of CADEC is therefore more similar to PubMed which includes journal articles in health discipline and MIMIC which contains clinical notes. However, CADEC is written by patients, and can be considered as 'drug reviews'. The tenor is therefore closer to the one in Yelp, where customers use informal language to describe their experiences.

All sources are measured against WetLab with relatively high PPL and WVV values. This reflects the fact that the tenor of WetLab (experimental protocols) is different from the tenor of all sources, although WetLab has a similar field (biology) with PubMed which is therefore more similar than other sources. For CoNLL2003, 1BWB which is News Crawl data is the most similar source, while PubMed is the most dissimilar source from PPL perspective, and MIMIC is the most dissimilar one using WVV measure.

Although WVV does not distinguish between different sources as PPL does, it still reflects the same trend as PPL regarding which source is the most similar to a given target data set.

Can these different similarity measures reach a consensus? Similarity results in Table 3 indicate that using different measures can lead to almost the same answer regarding which source is the most similar one to a given target. To further investigate the level of agreement between different similarity measures, we employ inter-method agreement that we ask a fine-grained question on the results in Table 3: given a target and two sources, do similarity measures make the same conclusion as to which source is more similar? Using the five source and six target data sets, we generate a total of 60 binary comparisons. For example, given WetLab, is 1BWB a more similar source than Wiki? PPL shows that 1BWB is more simi-

Table 3: Similarity between source and target data sets (left), and the effectiveness of word vectors and LMs pretrained using different sources for NER (right). Lower PPL or WVV values indicate higher similarity between source and target, while higher TVC and TVcC values indicate higher similarity. *None* rows refer to the models that word embedding weights are randomly initialized with no pretrained LMs. Δ shows absolute improvement. We repeat every NER experiment 5 times, and report mean and standard deviation of test F_1 scores.

lar, while WVV gives an opposite answer. Fleiss's kappa (Fleiss, 1971) (a variant of Cohen's kappa for more than two raters) is a robust metric used to measures inter-rater agreement, since it takes random chance into consideration. We use it to measure the inter-method agreement between the 60 binary comparisons inferred using PPL, WVV and TVC. Our results achieve a Fleiss's kappa of 0.733, which shows a high agreement between conclusions inferred using different measures.

Overall, we find that these similarity measures can reach high level of consensus. To simplify our following discussion, from here on *similar* means low PPL (because of its clear distinction between different sources), unless otherwise stated.

7.2 Impact of Pretraining Data

After we quantify the similarity between source and target data sets, the next question is how these similarity measures can be used to predict the effectiveness of pretrained models for NER tasks.

Results in Table 3 show that, although all pretrained word vectors and LMs can improve the performance of the target model, the improvement varies in different target data sets. In other words, no single source is suitable for all target NER data

	Word vectors	**LMs**
TVC	0.454	0.666
TVcC	0.469	0.739
PPL	-0.398	-0.618
WVV	-0.406	-0.747

Table 4: Correlation coefficients between similarity measures and the effectiveness of pretrained models. The coefficients vary between -1 (negative correlation) and 1 (positive correlation). Zero means no correlation.

sets. Word vectors and LMs pretrained on a source similar to the target outperform the ones pretrained on other sources (except pretrained word vectors for JNLPBA data set).

We also observe that pretrained LMs provide more benefits than pretrained word vectors if source data is similar to the target (see 1BWB-CoNLL2003 and PubMed-JNLPBA data pairs). However, if the source is dissimilar to the target, pretrained word vectors outperform pretrained LMs (see these pairs: MIMIC-CoNLL2003, PubMed-CoNLL2003, MIMIC-CRAFT).

Predictiveness of similarity measures To analyze how proposed similarity measures correlate to the effectiveness of pretrained word vectors and LMs for the target NER tasks, we employ the Pearson correlation analysis to find out the relationships between improvement due to pretrained models and TVC, TVcC, PPL and WVV. The results in Table 4 show that our proposed similarity measures are predictive of the effectiveness of the pretraining data. In terms of pretrained word vectors, VCcR is the most informative factor in predicting the effectiveness of pretrained word vectors given a target data set. It implies that finding a source data set which has large vocabulary intersection with the target data set is a promising first step to generate effective pretrained word vectors. The results regarding the LM performance show that it has a stronger correlation with similarity measures than the one of word vectors, thus more predictable using our proposed measures.

Comparison to publicly available pretrained models Recent literature shows substantial improvements are sometimes possible when pretraining on very large generic corpora. Given that pretrained models are freely available, is it even necessary to pretrain on similar data as proposed above? We compare to publicly available (1) word vectors trained on 6 billion tokens of encyclopaedia articles and news stories about various fields [3] and (2) LMs trained on 5.5 billion tokens of encyclopaedia articles and news stories about various fields [4]. We use the same experimental setup described in Section 6, that pretrained word vectors are used to initialize the weights of word embedding layer, whereas outputs of pretrained LMs are used as input features of the supervised model. We find that word vectors and LMs pretrained on small similar sources can achieve competitive or even better performance than the ones pretrained on larger sources (Table 5). On JNLPBA, ScienceIE and Wetlab, LMs pretrained on the small similar source perform better, while word vectors pretrained on the small similar source perform better on CRAFT, JNLPBA, and ScienceIE.

	Word vectors		**LMs**	
	GloVe	Ours	ELMo	Ours
CADEC	**70.30**	70.27	**71.91**	70.46
CoNLL2003	**90.25**	86.36	**91.34**	89.78
CRAFT	74.22	**75.45**	**75.77**	75.45
JNLPBA	73.19	**73.24**	73.65	**74.29**
ScienceIE	37.10	**37.91**	41.15	**42.07**
WetLab	**79.15**	78.93	79.57	**79.62**

Table 5: Comparison between our best performance pretrained models and the publicly available ones, which are pretrained on much larger corpora.

	ScienceIE		**WetLab**	
	Def	**Opt**	**Def**	**Opt**
1BWB	34.40	34.57	78.66	79.12
MIMIC	31.23	34.14	78.68	78.65
PubMed	**37.91**	**38.86**	**78.93**	**79.28**
Wiki	36.15	35.63	78.45	78.99
Yelp	33.92	34.25	78.48	78.78

Table 6: Impact of hyper-parameter setting on the effectiveness of pretrained word vectors. 'Opt' is hyper-parameter setting proposed in (Chiu et al., 2016), whereas 'Def' is the default setting in word2vec.

These results indicate that a small similar source reduces the computational cost without sacrificing the performance. This is especially important in practice, because collecting data and pretraining models are expensive. For example, a LM pretrained on 1 billion tokens takes three weeks to train on 32 GPUs (Jozefowicz et al., 2016).

Comparison to other hyper-parameter settings Chiu et al. (2016) propose a hyper-parameter combination of skip-gram model that is empirically

---

[3] https://nlp.stanford.edu/projects/glove/

[4] https://allennlp.org/elmo

identified on NER tasks. They find that a narrow context window size can boost the performance since it can capture better word function rather than domain similarity. We use their proposed hyper-parameter setting to train word vectors on different source data, and evaluate these pretrained word vectors on the ScienceIE and WetLab data sets. The reason for hand-picking these two is that benefits of pretrained word vectors on these two sets vary with a large margin. Our results suggest that this hyper-parameter setting can overall (except Wiki-ScienceIE and MIMIC-WetLab pairs) produce better performance compare to the default setting (Table 6). Most importantly we observe that our observation that similar sources generate better pretrained models can still holds with these hyper-parameters: PubMed, which is the most similar source to both target data sets, still outperforms other sources.

7.3 Controlling for source data size

To further investigate how source data size affects pretrained word vectors and LMs for NER tasks, we sample six PubMed subsets of different size. For target data sets, we use CoNLL2003, to which PubMed is the most dissimilar source, and JNLPBA, to which PubMed is the most similar source. We observe that 500 MB of pretraining data appears to be sufficient to calculate similarity, and capping factors out the impact of size (Figure 2). As discussed, VCcR is the most influential factor affecting the usefulness of pretrained word vectors for NER task. Increasing source data size may provide a larger vocabulary intersection with the target data set, but the resulting absolute F_1 score increase is less than 0.5, after the source data has been large enough. We also observe that if source and target data are dissimilar (PubMed-CoNLL2003 pair), pretrained word vectors is a better option than pretrained LMs, no matter how large source data is. However, pretrained LMs outperform pretrained word vectors, if source is similar to target (PubMed-JNLPBA pair).

We leave exploration of the combined effect of size and similarity to future work, but believe size should be considered separately, noting that results here suggest that similarity is more important.

8 Conclusions

We studied whether there are cost-effective methods to identify data sets to pretrain word vectors and LMs that are building blocks of NER models. We proposed using three measures, Target Vocabulary Covered, Language Model Perplexity, and Word Vector Variance, to measure different aspects of similarity between source and target data. We investigated how these measures correlate with the effectiveness of pretrained word vectors and LMs for NER tasks. We found that the effectiveness of pretrained word vectors strongly depends on whether the source data have a high vocabulary intersection with target data, while pretrained LMs can gain more benefits from a similar source. While different NLP tasks may rely on different aspects of language, our study is a step towards systematically guiding researchers on their choice of data for pretraining. As a future study, we will explore how these similarity measures predict performance of pretrained models in other NLP tasks.

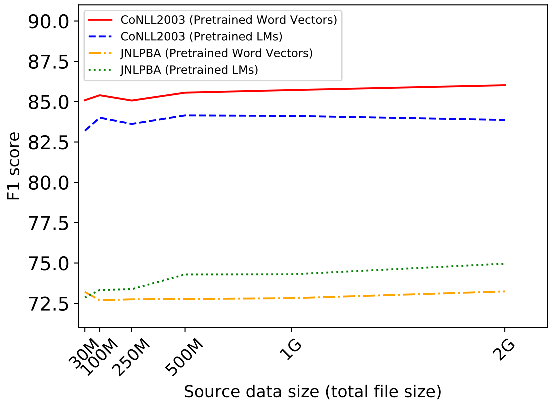

Figure 2: Impact of source data size on the effectiveness of pretrained models for NER.

Acknowledgments

We would like to thank Massimo Piccardi and Mark Dras for their constructive feedback. The authors also thank the members of CSIRO Data61's Language and Social Computing (LASC) team for helpful discussions, as well as anonymous reviewers for their insightful comments.

Abstract

Modern NLP systems require high-quality annotated data. In specialized domains, expert annotations may be prohibitively expensive. An alternative is to rely on crowdsourcing to reduce costs at the risk of introducing noise. In this paper we demonstrate that directly modeling instance difficulty can be used to improve model performance, and to route instances to appropriate annotators. Our difficulty prediction model combines two learned representations: a 'universal' encoder trained on out-of-domain data, and a task-specific encoder. Experiments on a complex biomedical information extraction task using expert and lay annotators show that: (i) simply excluding from the training data instances predicted to be difficult yields a small boost in performance; (ii) using difficulty scores to weight instances during training provides further, consistent gains; (iii) assigning instances predicted to be difficult to domain experts is an effective strategy for task routing. Our experiments confirm the expectation that for specialized tasks expert annotations are higher quality than crowd labels, and hence preferable to obtain if practical. Moreover, augmenting small amounts of expert data with a larger set of lay annotations leads to further improvements in model performance.

1 Introduction

Assembling training corpora of annotated natural language examples in specialized domains such as biomedicine poses considerable challenges. Experts with the requisite domain knowledge to perform high-quality annotation tend to be expensive, while lay annotators may not have the necessary knowledge to provide high-quality annotations. A practical approach for collecting a sufficiently large corpus would be to use crowdsourcing platforms like Amazon Mechanical Turk (MTurk). However, crowd workers in general are likely to provide noisy annotations (Abad and Moschitti, 2016; Plank et al., 2014; Alonso et al., 2015), an issue exacerbated by the technical nature of specialized content. Some of this noise may reflect worker quality and can be modeled (Abad and Moschitti, 2016; Plank et al., 2014; Cohn and Specia, 2013; Nguyen et al., 2017), but for some instances lay people may simply lack the domain knowledge to provide useful annotation.

In this paper we report experiments on the EBM-NLP corpus comprising crowdsourced annotations of medical literature (Nye et al., 2018). We operationalize the concept of annotation difficulty and show how it can be exploited during training to improve information extraction models. We then obtain expert annotations for the abstracts predicted to be most difficult, as well as for a similar number of randomly selected abstracts. The annotation of highly specialized data and the use of lay and expert annotators allow us to examine the following key questions related to lay and expert annotations in specialized domains:

Can we predict item difficulty? We define a training instance as difficult if a lay annotator or an automated model disagree on its labeling. We show that difficulty can be predicted, and that it is distinct from inter-annotator agreement. Further, such predictions can be used during training to improve information extraction models.

Are there systematic differences between expert and lay annotations? We observe decidedly lower agreement between lay workers as compared to domain experts. Lay annotations have high precision but low recall with respect to expert annota-

Proceedings of NAACL-HLT 2019, pages 1471–1480
Minneapolis, Minnesota, June 2 - June 7, 2019.

tions in the new data that we collected. More generally, we expect lay annotations to be lower quality, which may translate to lower precision, recall, or both, compared to expert annotations.

Can one rely solely on lay annotations? Reasonable models can be trained using lay annotations alone, but similar performance can be achieved using markedly less expert data. This suggests that the optimal ratio of expert to crowd annotations for specialized tasks will depend on the cost and availability of domain experts. Expert annotations are preferable whenever its collection is practical. But in real-world settings, a combination of expert and lay annotations is better than using lay data alone.

Does it matter what data is annotated by experts? We demonstrate that a system trained on combined data achieves better predictive performance when experts annotate difficult examples rather than instances selected at i.i.d. random.

Our contributions in this work are summarized as follows. We define a task difficulty prediction task and show how this is related to, but distinct from, inter-worker agreement. We introduce a new model for difficulty prediction combining learned representations induced via a pre-trained 'universal' sentence encoder (Cer et al., 2018), and a sentence encoder learned from scratch for this task. We show that predicting annotation difficulty can be used to improve the task routing and model performance for a biomedical information extraction task. Our results open up a new direction for ensuring corpus quality. We believe that item difficulty prediction will likely be useful in other, non-specialized tasks as well, and that the most effective data collection in specialized domains requires research addressing the fundamental questions we examine here.

2 Related Work

Crowdsourcing annotation is now a well-studied problem (Snow et al., 2008; Abad and Moschitti, 2016; Plank et al., 2014; Alonso et al., 2015). Due to the noise inherent in such annotations, there have also been considerable efforts to develop aggregation models that minimize noise (Abad and Moschitti, 2016; Plank et al., 2014; Cohn and Specia, 2013; Nguyen et al., 2017).

There are also several surveys of crowdsourcing in biomedicine specifically (Good and Su, 2013; Khare et al., 2015; Lee et al., 2017). Some work in this space has contrasted model performance achieved using expert vs. crowd annotated training data (Zhai et al., 2013; Cocos et al., 2017; Dumitrache et al., 2018). Dumitrache *et al.* (2018) concluded that performance is similar under these supervision types, finding no clear advantage from using expert annotators. This differs from our findings, perhaps owing to differences in design. The experts we used already hold advanced medical degrees, for instance, while those in prior work were medical students. Furthermore, the task considered here would appear to be of greater difficulty: even a system trained on $\sim$5k instances performs reasonably, but far from perfect. By contrast, in some of the prior work where experts and crowd annotations were deemed equivalent, a classifier trained on 300 examples can achieve very high accuracy (Cocos et al., 2017).

More relevant to this paper, prior work has investigated methods for 'task routing' in active learning scenarios in which supervision is provided by heterogeneous labelers with varying levels of expertise (Yan et al., 2011; Donmez and Carbonell, 2008; Nguyen et al., 2015; Wallace et al., 2011; Yan et al., 2011). The related question of whether effort is better spent collecting additional annotations for already labeled (but potentially noisily so) examples or novel instances has also been addressed (Sheng et al., 2008). What distinguishes the work here is our focus on providing an operational definition of instance *difficulty*, showing that this can be predicted, and then using this to inform task routing.

3 Application Domain

Our specific application concerns annotating abstracts of articles that describe the conduct and results of randomized controlled trials (RCTs). Experimentation in this domain has become easy with the recent release of the EBM-NLP (Nye et al., 2018) corpus, which includes a reasonably large training dataset annotated via crowdsourcing, and a modest test set labeled by individuals with advanced medical training. More specifically, the training set comprises 4,741 medical article abstracts with crowdsourced annotations indicating snippets (sequences) that describe the Participants (P), Interventions (I), and Outcome (O) elements of the respective RCT, and the test set is composed of 191 abstracts with P, I, O sequence annotations from three medical experts.

Difficult Sentences

[Population]
1. Primary RP were screened and assigned to either the nifedipine SR group (Group N) or the Ginkgo biloba extract group (Group G) in the ratio of 2:1 .
2. A positive correlation was found for all methods in the controls (r=0.83-0.94) and RA patients (r=0.51-0.69).

[Interventions/Comparators]
1. They were all enrolled in mainstream compulsory education.
2. RA patients reported that they were less sedentary and engaged in more higher intensity PA than what was objectively assessed.

[Outcomes]
1. To develop a cycle - based risk prediction model for neutropenic complications (NC) during chemotherapy with doxorubicin (DOX) or a pegy lated liposomal formulation (PLD) for patients with metastatic breast cancer (MBC).
2. The purpose of this study was to evaluate the long-term safety and efficacy of risperidone.

Easy Sentences

[Population]
1. A prospective study in 80 patients was carried out.
2. We studied 200 women aged 35 years and older who had a family history of breast cancer in a first-degree relative.

[Interventions/Comparators]
1. Hormonal contraceptives are used widely but their effects on HIV-1 risk are unclear.
2. In the second group, custom - fit MRI - based pin guides were used.

[Outcomes]
1. Extrapyramidal AEs were reported in 6(8%) patients.
2. The overall progression - free survival rates were similar between the two arms (P=.095).

Table 1: Example sentences are difficult or easy to annotate for crowd workers. The underlined text are reference annotations from domain experts.

Table 1 shows an example of difficult and easy examples according to our definition of difficulty. The underlined text demarcates the (consensus) reference label provided by domain experts. In the difficult examples, crowd workers marked text distinct from these reference annotations; whereas in the easy cases they reproduced them with reasonable fidelity. The difficult sentences usually exhibit complicated structure and feature jargon.

An abstract may contain some ‘easy’ and some ‘difficult’ sentences. We thus perform our analysis at the sentence level. We split abstracts into sentences using spaCy.[1] We excluded sentences that comprise fewer than two tokens, as these are likely an artifact of errors in sentence splitting. In total, this resulted in 57,505 and 2,428 sentences in the train and test set abstracts, respectively.

4 Quantifying Task Difficulty

The test set includes annotations from both crowd workers and domain experts. We treat the latter as ground truth and then define the difficulty of sentences in terms of the observed agreement between expert and lay annotators. Formally, for annotation task t and instance i:

$$\text{Difficulty}_{ti} = \frac{\sum_{j=1}^{n} f(\text{label}_{ij}, y_i)}{n} \quad (1)$$

where f is a scoring function that measures the quality of the label from worker j for sentence i, as compared to a ground truth annotation, y_i. The difficulty score of sentence i is taken as an average over the scores for all n layworkers. We use Spearmans’ correlation coefficient as a scoring function. Specifically, for each sentence we create two vectors comprising counts of how many times each token was annotated by crowd and expert workers, respectively, and calculate the correlation between these. Sentences with no labels are treated as maximally easy; those with *only* either crowd worker or expert label(s) are assumed maximally difficult.

The training set contains only crowdsourced annotations. To label the training data, we use a 10-fold validation like setting. We iteratively retrain the LSTM-CRF-Pattern sequence tagger of Patel *et al.* (2018) on 9 folds of the training data and use that trained model to predict labels for the 10th. In this way we obtain predictions on the full training set. We then use predicted spans as proxy ‘ground truth’ annotations to calculate the diffi-

---

[1] `https://spacy.io/`

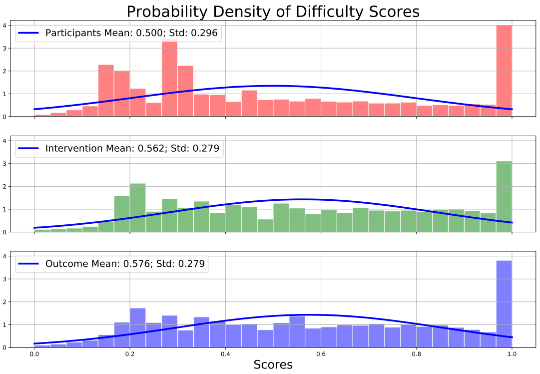

Figure 1: Distributions of difficulty scores over all sentences that contain any span annotations

culty score of sentences as described above; we normalize these to the $[0, 1]$ interval. We validate this approximation by comparing the proxy scores against reference scores over the test set, the Pearson's correlation coefficients are 0.57 for Population, 0.71 for Intervention and 0.68 for Outcome.

There exist many sentences that contain neither manual nor predicted annotations. We treat these as maximally easy sentences (with difficulty scores of 0). Such sentences comprise 51%, 42% and 36% for Population, Interventions and Outcomes data respectively, indicating that it is easier to identify sentences that have no Population spans, but harder to identify sentences that have no Interventions or Outcomes spans. This is intuitive as descriptions of the latter two tend to be more technical and dense with medical jargon.

We show the distribution of the automatically labeled scores for sentences that do contain spans in Figure 1. The mean of the Population (P) sentence scores is significantly lower than that for other types of sentences (I and O), again indicating that they are easier on average to annotate. This aligns with a previous finding that annotating Interventions and Outcomes is more difficult than annotating Participants (Nye et al., 2018).

Many sentences contain spans tagged by the LSTM-CRF-Pattern model, but missed by all crowd workers, resulting in a maximally difficult score (1). Inspection of such sentences revealed that some are truly difficult examples, but others are tagging model errors. In either case, such sentences have confused workers and/or the model, and so we retain them all as 'difficult' sentences.

Content describing the P, I and O, respectively, is quite different. As such, one sentence usually contains (at most) only one of these three content types. We thus treat difficulty prediction for the respective label types as separate tasks.

Workers	P	I	O
crowd workers	0.52	0.43	0.41
domain experts	0.74	0.68	0.57

Table 2: Average inter-worker agreement.

5 Difficulty is not Worker Agreement

Our definition of difficulty is derived from agreement between expert and crowd annotations for the test data, and agreement between a predictive model and crowd annotations in the training data. It is reasonable to ask if these measures are related to inter-annotator agreement, a metric often used in language technology research to identify ambiguous or difficult items. Here we explicitly verify that our definition of difficulty only weakly correlates with inter-annotator agreement.

We calculate inter-worker agreement between crowd and expert annotators using Spearman's correlation coefficient. As shown in Table 2, average agreement between domain experts are considerably higher than agreements between crowd workers for all three label types. This is a clear indication that the crowd annotations are noisier.

Furthermore, we compare the correlation between inter-annotator agreement and difficulty scores in the training data. Given that the majority of sentences do not contain a PICO span, we only include in these calculations those that contain a reference label. Pearson's r are 0.34, 0.30 and 0.31 for P, I and O, respectively, confirming that inter-worker agreement and our proposed difficulty score are quite distinct.

6 Predicting Annotation Difficulty

We treat difficulty prediction as a regression problem, and propose and evaluate neural model variants for the task. We first train RNN (Chung et al., 2014) and CNN (Kim, 2014) models.

We also use the *universal sentence encoder* (USE) (Cer et al., 2018) to induce sentence representations, and train a model using these as features. Following (Cer et al., 2018), we then experiment with an ensemble model that combines the 'universal' and task-specific representations to predict annotation difficulty. We expect these universal embeddings to capture general, high-level semantics, and the task specific representations to capture more granular information. Figure 2 de-

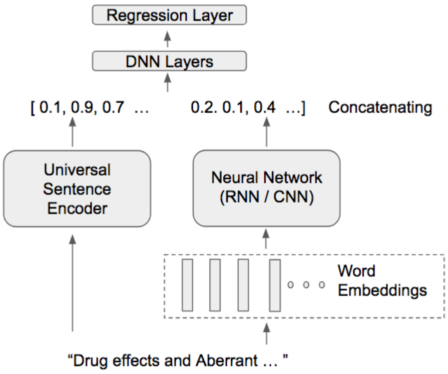

Figure 2: Model architecture.

picts the model architecture. Sentences are fed into both the universal sentence encoder and, separately, a task specific neural encoder, yielding two representations. We concatenate these and pass the combined vector to the regression layer.

6.1 Experimental Setup and Results

We trained models for each label type separately. Word embeddings were initialized to 300d GloVe vectors (Pennington et al., 2014) trained on common crawl data;[2] these are fine-tuned during training. We used the Adam optimizer (Kingma and Ba, 2014) with learning rate and decay set to 0.001 and 0.99, respectively. We used batch sizes of 16.

We used the large version of the universal sentence encoder[3] with a transformer (Vaswani et al., 2017). We did not update the pretrained sentence encoder parameters during training. All hyperparamaters for all models (including hidden layers, hidden sizes, and dropout) were tuned using Vizier (Golovin et al., 2017) via 10-fold cross validation on the training set maximizing for F1.[4]

As a baseline, we also trained a linear Support-Vector Regression (Fan et al., 2008) model on n-gram features (n ranges from 1 to 3).[5]

Table 3 reports Pearson correlation coefficients between the predictions with each of the neural models and the ground truth difficulty scores. Rows 1-4 correspond to individual models, and row 5 reports the ensemble performance. Columns correspond to label type. Results from all models outperform the baseline SVR model: Pearson's correlation coefficients range from 0.550 to 0.622. The regression correlations are the lowest.

	P	I	O
NGRAM+SVR	0.455	0.311	0.541
RNN	0.521	0.555	0.601
CNN	0.470	0.522	0.550
USE	0.492	0.518	0.580
USE+RNN	0.550	0.604	0.622

Table 3: Pearson correlation coefficients of sentence difficulty predictions.

The RNN model realizes the strongest performance among the stand-alone (non-ensemble) models, outperforming variants that exploit CNN and USE representations. Combining the RNN and USE further improves results. We hypothesize that this is due to complementary sentence information encoded in universal representations.

For all models, correlations for Intervention and Outcomes are higher than for Population, which is expected given the difficulty distributions in Figure 1. In these, the sentences are more uniformly distributed, with a fair number of difficult and easier sentences. By contrast, in Population there are a greater number of easy sentences and considerably fewer difficult sentences, which makes the difficulty ranking task particularly challenging.

7 Better IE with Difficulty Prediction

We next present experiments in which we attempt to use the predicted difficulty during training to improve models for information extraction of descriptions of Population, Interventions and Outcomes from medical article abstracts. We investigate two uses: (1) simply removing the most difficult sentences from the training set, and, (2) reweighting the most difficult sentences.

We again use LSTM-CRF-Pattern as the base model and experimenting on the EBM-NLP corpus (Nye et al., 2018). This is trained on either (1) the training set with difficult sentences removed, or (2) the full training set but with instances reweighted in proportion to their predicted difficulty score. Following (Nye et al., 2018), we use the Adam optimizer with learning rate of 0.001, decay 0.9, batch size 20 and dropout 0.5. We use pretrained 200d GloVe vectors (Pennington et al., 2014)[6] to initialize word embeddings, and use

Re-weight by agreement	78.63	*82.24*	*82.19*	66.47	54.45	55.22	72.04	65.53	66.06
Re-weight by difficulty	79.57	74.69	73.92	*70.31*	*63.71*	*64.96*	**74.65**	**68.76**	**69.15**

Table 4: Medical IE performance by re-weighting sentences according to predicted agreement or difficulty scores.

100d hidden char representations. Each word is thus represented with 300 dimensions in total. The hidden size is 100 for the LSTM in the character representation component, and 200 for the LSTM in the information extraction component. We train for 15 epochs, saving parameters that achieve the best F1 score on a nested development set.

7.1 Removing Difficult Examples

We first evaluate changes in performance induced by training the sequence labeling model using less data by removing difficult sentences prior to training. The hypothesis here is that these difficult instances are likely to introduce more noise than signal. We used a cross-fold approach to predict sentence difficulties, training on 9/10ths of the data and scoring the remaining 1/10th at a time. We then sorted sentences by predicted difficulty scores, and experimented with removing increasing numbers of these (in order of difficulty) prior to training the LSTM-CRF-Pattern model.

Figure 3 shows the results achieved by the LSTM-CRF-Pattern model after discarding increasing amounts of the training data: the x and y axes correspond to the the percentage of data removed and F1 scores, respectively. We contrast removing sentences predicted to be difficult with removing them *(a)* randomly (i.i.d.), and, *(b)* in inverse order of predicted inter-annotator agreement. The agreement prediction model is trained exactly the same like difficult prediction model, with simply changing the difficult score to annotation agreement. F1 scores actually improve (marginally) when we remove the most difficult sentences, up until we drop 4% of the data for Population and Interventions, and 6% for Outcomes. Removing training points at i.i.d. random degrades performance, as expected. Removing sentences in order of disagreement seems to have similar effect as removing them by difficulty score when removing small amount of the data, but the F1 scores drop much faster when removing more data. These findings indicate that sentences predicted to be difficult are indeed noisy, to the extent that they do not seem to provide the model useful signal.

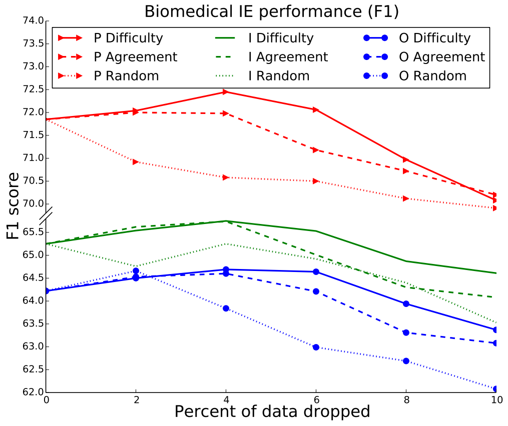

Figure 3: F1 scores achieved when removing increasingly large fractions of the training data.

7.2 Re-weighting by Difficulty

We showed above that removing a small number of the most difficult sentences does not harm, and in fact modestly improves, medical IE model performance. However, using the available data we are unable to test if this will be useful in practice, as we would need additional data to determine how many difficult sentences should be dropped.

We instead explore an alternative, practical means of exploiting difficulty predictions: we re-weight sentences during training inversely to their *predicted* difficulty. Formally, we weight sentence i with difficulty scores above τ according to: $1-a\cdot(d_i-\tau)/(1-\tau)$, where d_i is the difficulty score for sentence i, and a is a parameter codifying the minimum weight value. We set τ to 0.8 so as to only re-weight sentences with difficulty in the top 20th percentile, and we set a to 0.5. The re-weighting is equivalent to down-sampling the difficult sentences. LSTM-CRF-Pattern is our base model.

Table 4 reports the precision, recall and F1 achieved both with and without sentence re-weighting. Re-weighting improves all metrics modestly but consistently. All F1 differences are statistically significant under a sign test ($p < 0.01$). The model with best precision is different for Patient, Intervention and Outcome labels. However re-weighting by difficulty does consistently yield the best recall for all three extraction types, with the most notable improvement for I and O, where recall improved by 10 percentage points. This performance increase translated to improvements in F1 across all types, as compared to the base model and to re-weighting by agreement.

8 Involving Expert Annotators

The preceding experiments demonstrate that re-weighting difficult sentences annotated by the crowd generally improves the extraction models. Presumably the performance is influenced by the annotation quality.

We now examine the possibility that the higher quality and more consistent annotations of domain experts on the difficult instances will benefit the extraction model. This simulates an annotation strategy in which we route difficult instances to domain experts and easier ones to crowd annotators. We also contrast the value of difficult data to that of an i.i.d. random sample of the same size, both annotated by experts.

8.1 Expert annotations of Random and Difficult Instances

We re-annotate by experts a subset of most difficult instances and the same number of random instances. As collecting annotations from experts is slow and expensive, we only re-annotate the difficult instances for the interventions extraction task. We re-annotate the abstracts which cover the sentences with predicted difficulty scores in the top 5 percentile. We rank the abstracts from the training set by the count of difficult sentences, and re-annotate the abstracts that contain the most difficult sentences. Constrained by time and budget, we select only 2000 abstracts for re-annotation; 1000 of these are top-ranked, and 1000 are randomly sampled. This re-annotation cost $3,000. We have released the new annotation data at: `https://github.com/bepnye/EBM-NLP`.

Following (Nye et al., 2018), we recruited five medical experts via Up-work[7] with advanced medical training and strong technical reading/writing skills. The expert annotator were asked to read the entire abstract and highlight, using the BRAT toolkit (Stenetorp et al., 2012), all spans describing medical Interventions. Each abstract is only annotated by one expert. We examined 30 re-annotated abstracts to ensure the annotation quality before hiring the annotator.

Table 5 presents the results of LSTM-CRF-Pattern model trained on the reannotated difficult subset and the random subset. The first two rows show the results for models trained with expert annotations. The model trained on random data has a slightly better F1 than that trained on the same amount of difficult data. The model trained on random data has higher precision but lower recall.

Rows 3 and 4 list the results for models trained on the same data but with crowd annotation. Models trained with expert-annotated data are clearly superior to those trained with crowd labels with respect to F1, indicating that the experts produced higher quality annotations. For crowdsourced annotations, training the model with data sampled at i.i.d. random achieves 2% higher F1 than when difficult instances are used. When expert annotations are used, this difference is less than 1%. This trend in performance may be explained by differences in annotation quality: the randomly sampled set was more consistently annotated by both experts and crowd because the difficult set is harder. However, in both cases expert annotations are better, with a bigger difference between the expert and crowd models on the difficult set.

The last row is the model trained on all 5k abstracts with crowd annotations. Its F1 score is lower than either expert model trained on only 20% of data, suggesting that expert annotations should be collected whenever possible. Again the crowd model on complete data has higher precision than expert models but its recall is much lower.

8.2 Routing To Experts or Crowd

So far a system was trained on one type of data, either labeled by crowd or experts. We now examine the performance of a system trained on data that was routed to either experts or crowd annotators depending on their predicted difficult. Given the results presented so far mixing annotators may be beneficial given their respective trade-offs of precision and recall. We use the annotations from experts for an abstract if it exists otherwise use crowd

	Precision	**Recall**	**F1**
Difficult-Expert	68.46	65.06	66.72
Random-Expert	70.84	63.46	67.04
Difficult-Crowd	83.68	44.63	58.45
Random-Crowd	78.55	49.23	60.52
Base (All-Crowd)	81.99	54.19	65.25

Table 5: Interventions IE model performance trained crowd or expert. The first four models are trained with a subset of 1k abstracts and the base model is trained with all 5k abstracts.

	Precision	**Recall**	**F1**
(D)ifficult-Expert	68.46	65.06	66.72
(R)andom-Expert	70.84	63.46	67.04
D+R	68.57	67.54	69.62
D+Other	83.55	60.73	70.33
R+Other	85.10	57.08	68.34
D+R+Other	82.19	61.88	70.60

Table 6: Interventions IE model performance trained by mixing annotations from experts and crowd workers. [D]: Difficult-Expert; [R]: Random-Expert; [Other]: the rest of the abstracts with crowd annotation only.

annotations. The results are presented in Table 6.

Rows 1 and 2 repeat the performance of the models trained on difficult subset and random subset with expert annotations only respectively. The third row is the model trained by combining difficult and random subsets with expert annotations. There are around 250 abstracts in the overlap of these two sets, so there are total 1.75k abstracts used for training the D+R model. Rows 4 to 6 are the models trained on all 5k abstracts with mixed annotations, where *Other* means the rest of the abstracts with crowd annotation only.

The results show adding more training data with crowd annotation still improves at least 1 point F1 score in all three extraction tasks. The improvement when the difficult subset with expert annotations is mixed with the remaining crowd annotation is 3.5 F1 score, much larger than when a random set of expert annotations are added. The model trained with re-annotating the difficult subset (D+Other) also outperforms the model with re-annotating the random subset (R+Other) by 2 points in F1. The model trained with re-annotating both of difficult and random subsets (D+R+Other), however, achieves only marginally higher F1 than the model trained with the re-annotated difficult subset (D+Other).

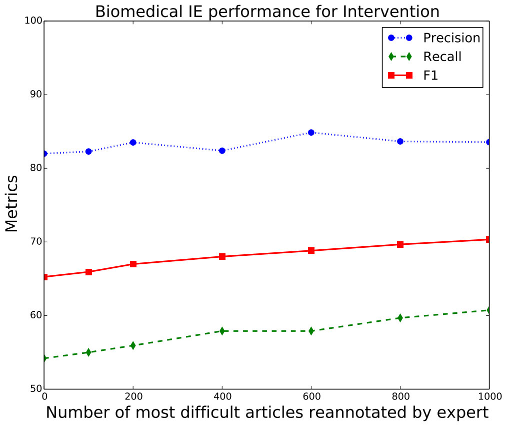

Figure 4: Precision/Recall/F1 as a function of the number of articles re-annotated by expert, in decreasing order of difficulty.

In sum, the results clearly indicate that mixing expert and crowd annotations leads to better models than using solely crowd data, and better than using expert data alone. More importantly, there is greater gain in performance when instances are routed according to difficulty, as compared to randomly selecting the data for expert annotators. These findings align with our motivating hypothesis that annotation quality for difficult instances is important for final model performance. They also indicate that mixing annotations from expert and crowd could be an effective way to achieve acceptable model performance given a limited budget.

8.3 How Many Expert Annotations?

We established that crowd annotation are still useful in supplementing expert annotations for medical IE. Obtaining expert annotations for the one thousand most difficult instances greatly improved the model performance. However the choice of how many difficult instances to annotate was an uninformed choice. Here we check if less expert data would have yielded similar gains. Future work will need to address how best to choose this parameter for a routing system.

We simulate a routing scenario in which we send consecutive batches of the most difficult examples to the experts for annotation. We track changes in performance as we increase the number of most-difficult-articles sent to domain experts. As shown in Figure 4, adding expert annotations for difficult articles consistently increases F1 scores. The performance gain is mostly from increased recall; the precision changes only a bit with higher quality annotation. This observation implies that crowd workers often fail to mark target tokens, but do not tend to produce large numbers of false positives. We suspect such failures to identify relevant spans/tokens are due to insufficient domain knowledge possessed by crowd workers.

The F1 score achieved after re-annotating the 600 most-difficult articles reaches 68.1%, which is close to the performance when re-annotating 1000 random articles. This demonstrates the effectiveness of recognizing difficult instances. The trend when we use up all expert data is still upward, so adding even more expert data is likely to further improve performance. Unfortunately we exhausted our budget and were not able to obtain additional expert annotations. It is likely that as the size of the expert annotations increases, the value of crowd annotations will diminish. This investigation is left for future work.

9 Conclusions

We have introduced the task of predicting annotation difficulty for biomedical information extraction (IE). We trained neural models using different learned representations to score texts in terms of their difficulty. Results from all models were strong with Pearsons correlation coefficients higher than 0.45 in almost all evaluations, indicating the feasibility of this task. An ensemble model combining universal and task specific feature sentence vectors yielded the best results.

Experiments on biomedical IE tasks show that removing up to $\sim$10% of the sentences predicted to be most difficult did not decrease model performance, and that re-weighting sentences inversely to their difficulty score during training improves predictive performance. Simulations in which difficult examples are routed to experts and other instances to crowd annotators yields the best results, outperforming the strategy of randomly selecting data for expert annotation, and substantially improving upon the approach of relying exclusively on crowd annotations. In future work, routing strategies based on instance difficulty could be further investigated for budget-quality trade-off.

Abstract

Nowadays social media platforms are the most popular way for people to share information, from work issues to personal matters. For example, people with health disorders tend to share their concerns for advice, support or simply to relieve suffering. This provides a great opportunity to proactively detect these users and refer them as soon as possible to professional help. We propose a new representation called Bag of Sub-Emotions (BoSE), which represents social media documents by a set of fine-grained emotions automatically generated using a lexical resource of emotions and subword embeddings. The proposed representation is evaluated in the task of depression detection. The results are encouraging; the usage of fine-grained emotions improved the results from a representation based on the core emotions and obtained competitive results in comparison to state of the art approaches.

1 Introduction

Mental Disorders affect millions of people around the world. Out of these disorders, depression has been ranked among the most common, even with a high incidence in mortality rates (Kessler et al., 2017; Mathers and Loncar, 2006). It is imperative then, to come with effective approaches to detect depression before it causes irreparable damage to mere individuals that suffer it and their loved ones. In a connected world where we live, it is very normal to share personal information, matters and concerns in social media platforms. This fact poses an opportunity, since the understanding of depression through the analysis of social media documents increases the chances to detect people that present signs of depression and could lead to provide them professional help (Guntuku et al., 2017; Pestian et al., 2010).

Several works in literature have explored how to use linguistic and sentiment analysis to detect depression (Xue et al., 2013). For example, in (Huang et al., 2014) the authors applied sentiment analysis (SA) to assign polarity to tweets. They count the number of positive, negative, neutral words, and the ratio of the negative and positive words, and found that depressed users post longer emotional tweets. The work of Wang et al. (2013) enriched SA with features derived from psychological research like the use of first person pronouns, user social interaction and user behaviors in micro blogs. An interesting finding is that the time of the posts is useful to detect people with high risk of committing suicide. In a recent work, Chen et al. (2018) proposed to use emotions with the aim to identify depression on Twitter users. That study openly exposed the potential of using discrete emotions as features, instead of only using linguistic features, and broad categories to represent them. To further investigate this latter point, in this study we propose to model emotions in a fine-grained way and use them to build a new representation to tackle the problem of detecting depression in users of social media. We construct these fine-grained emotions using lexical information extracted from emotions combined with subword embeddings. The leading hypothesis of our study is that emotions could be better, and more flexible, represented at a lower level, instead of only using broad categories such as as ”anger”, ”joy”, ”negative” or ”positive”.

2 The Bag of Sub-Emotions (BoSE) Representation

Figure 1 depicts ourproposed approach. In a first step, we compute a set of fine-grained emotions for each broad emotion described in the lexical resource by Mohammad and Turney (2013). Then,

Proceedings of NAACL-HLT 2019, pages 1481–1486
Minneapolis, Minnesota, June 2 - June 7, 2019.

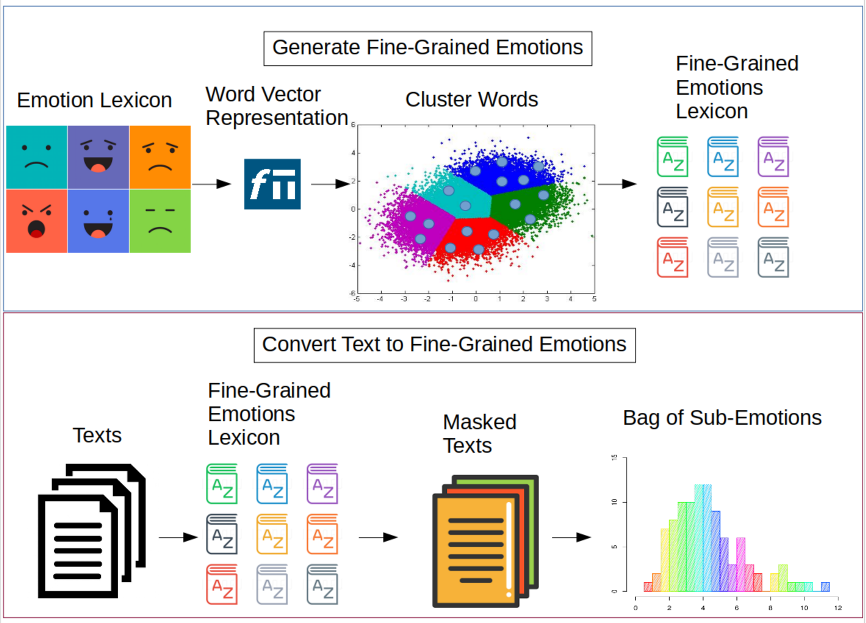

Figure 1: Diagram that represents the creation of the Bag of Sub-Emotions (**BoSE**) representation. First, Fine-Grained Emotions are generated from a given Emotion Lexicon; then, texts are masked using these fine-grained emotions and their histogram is build as final representation.

we use the obtained fine-grained emotions to mask the texts, eventually representing them by a histogram of their frequencies. Accordingly, we named this new representation **BoSE**, for Bag of Sub-Emotions. In the following sections we detail each step of our proposed approach.

2.1 Generating Fine-Grained Emotions

To generate the fine-grained emotions we use a lexical resource based on eight recognized emotions, e.g., Anger, Anticipation, Disgust, Fear, Joy, Sadness, Surprise and Trust (Ekman and Davidson, 1994), and two main sentiments[1], Positive and Negative. We represent this as $E = \{E_1, E_2, ..., E_{10}\}$, where E is the set of emotions in the lexical resources and $E_i = \{w_1, .., w_n\}$ is the set of words associated to the emotion E_i. We compute a word vector for each word using pre-trained Wikipedia sub-word embeddings from FastText (Bojanowski et al., 2016) of size 300, and then we create subgroups of words by emotion using the *Affinity Propagation* (*AP*) clustering algorithm (Thavikulwat, 2008). This AP clustering algorithm has several appealing characteristics, e.g. it does not employ artificial elements (centroids) to create clusters and it does not require to specify the number of groups before running the algorithm. To have an idea of how the vocabulary was distributed among emotions and the number of generated clusters after applying AP to the lexical resource we present Table 1.

After this process, now each (broad) emotion is represented by a set of fine-grained emotions, $E_i = \{F_{i1}, ..., F_{ij}\}$, where each F_{ij} is a subset of the words from E_i and is represented by the average vector of their respective embeddings. These subgroups of words allow separating each broad emotion in different topics that help identify and capture the fine-grained emotions expressed by users in their posts. Figure 2 presents some examples of groups of fine-grained emotions that were automatically computed by our approach. We can appreciate that words with similar context tend to group together, as shown in each column. We can also notice that words corresponding to the same broad emotion consider very different topics, for example, in the Anger emotion, the group *anger3* is related to fighting and battles, whereas the group *anger2* is about growls or loud noises. Another interesting example are the groups from the Surprise emotion, where groups express different kinds of surprises like art and museums (*surprise2*), accidents and disasters (*surprise1*), as well as magic and illusions (*surprise3*).

---

[1] In the rest of the paper we refer to these sentiments as emotions as well.

Anger			Joy		
anger1	***anger2***	***anger3***	***joy1***	***joy2***	***joy3***
abomination	growl	battle	accomplish	bounty	charity
fiend	growling	combat	achieve	cash	foundation
inhuman	thundering	fight	gain	money	trust
abominable	snarl	battler	reach	reward	humanitarian
unholy	snort	fists	goal	wealth	charitable
Surprise			**Disgust**		
surprise1	***surprise2***	***surprise3***	***disgust1***	***disgust2***	***disgust3***
accident	art	magician	accusation	criminal	cholera
crash	museum	wizard	suspicion	homicide	epidemic
disaster	artwork	magician	complaint	delinquency	malaria
incident	gallery	illusionist	accuse	crime	aids
collision	visual	sorcerer	slander	enforcement	polio

Figure 2: Examples of words grouped by Fine-Grained Emotions.

Emotion	Vocabulary	Clusters
anger	6035	444
anticipation	5837	395
disgust	5285	367
fear	7178	488
joy	4357	318
sadness	5837	395
surprise	3711	274
trust	5481	383
positive	11021	740
negative	12508	818

Table 1: Size of the vocabulary for each emotion presented in the lexical resources, and number of generated clusters.

2.2 Converting Text to Fine-Grained Emotions

Text masking: In this step documents are masked by replacing each word with the label of its closest fine-grained emotion. To this end, we compute the vector representation of each word using sub-word embeddings from FastText, then we measure the distance of each word vector against the centroid vectors from all fine-grained emotions by means of the cosine similarity, and, finally, we substitute each word by the label of its closest fine-grained emotion. To illustrate this process consider the text "*Leave no stone unturned*", which will be masked as "*fear2 negative8 anger10 anticipation3*".

Text representation: Based on the masked documents, we build their **BoSE** representations computing a frequency histogram of their fine-grained emotions. To build these representations we follow two different approaches: *i*) similar to the Bag-of-Words representation we create a histogram counting the number of occurrences of each fine-grained emotion in the text, we refer to this representation as **BoSE-unigrams**, and *ii*) we create a histogram counting the number of occurrences of fine-grained emotion sequences in the text, we refer to this representation as **BoSE-ngrams**. For the latter representation, we tested different sizes and combinations of sequences; using unigrams and bigrams we obtained the best performance for this task.

3 Experimental Settings

Preprocessing: For our experiments, we normalized the texts by removing special characters and lowercasing all the words. After preprocessing we masked the texts using the fine-grained emotions.
Classification: Once built the BoSE representation, we selected the more relevant features (i.e., sequences of fine-grained emotions) using the chi^2 distribution X_k^2 (Walck, 2007). Then, we used a Support Vector Machine (SVM) with a linear kernel and $C = 1$ to classify the documents.
Baselines: To properly evaluate the relevance of using fine-grained emotions in the detection of depression, we considered a representation based on the occurrences of broad emotions and the words that do not have an associated emotion. We named this approach Bag-of-Emotions (BoE). We also compared our results against a Bag-of-Words representation based on word unigrams and n-grams, since they are the common baseline approaches for text classification. Additionally, we compared our results against the f_1 results from the participants of the eRisk 2017 and 2018 evaluation tasks (Losada et al., 2017, 2018).

Data set	**Training**		**Testing**	
	Dep	ND	Dep	ND
eRisk'17	83	403	52	349
eRisk'18	135	752	79	741

Table 2: Depression data sets used for experimentation. Each data set have two classes (Depressed = Dep, Non-Depressed = ND).

Data Collections: We evaluated our approach in the task of depression detection, using the data sets from the eRisk 2017 and 2018 evaluation tasks (Losada et al., 2017, 2018). These data sets contain Reddit posts for several users. The users which explicitly mentioned that were diagnosed with depression were automatically labeled as positive. Vague expressions like "I think I have depression" or "I'm depressed" were discarded, the rest of them were labeled as negative. Table 2 shows some numbers from these data sets; (Losada and Crestani, 2016) describes these collections in more detail.

4 Experimental Results

The goal of our first experiment was to evaluate the appropriateness of the BoSE representation to identify depressed users. To accomplish this, we compared its performance against the results from a traditional BOW representation as well as to a representation considering only the broad emotions. Table 3 shows the f_1 performance over the positive class for the BOW, BoE and BoSE approaches. It can be noticed that the BoSE representation outperforms both baseline results, particularly when sequences of fine-grained emotions were considered. To better characterize the BoSE representation, we evaluated it without considering the clusters associated to the positive and negative sentiments. We refer to these experiments as BoSE8. Results from this variant show a drop in performance, confirming that sentiment information is relevant to the identification of depressed users.

To further evaluate the relevance of the BoSE representation, Table 4 compares its results against those from the first three places at the eRisk 2017 and 2018 evaluation tasks (Losada et al., 2017, 2018). To contextualize this comparison, consider that the first place in both years (Trotzek et al., 2017, 2018) defined multiple strategies and considered a wide range of features to build their models, e.g., they extract readability features, LIWC features, user-level linguistic metadata, neural word embeddings, specific terms related to depression, and used models based on LSTM neural networks and convolutional neural networks, using four machine learning models in an ensemble model. Other top performers (Villegas et al., 2017) combined semantic representation considering partial information and temporal variation features. In (Funez et al., 2018) they implemented two models; one based on flexible temporal variation of terms and a second model based on sequential incremental classification.

Method	Dep'17	Dep'18
BoW-unigrams	0.59	0.58
BoE-unigrams	0.57	0.60
BoSE8-unigrams	0.56	0.60
BoSE-unigrams	**0.61**	**0.61**
BOW-ngrams	0.58	0.60
BoE-ngrams	0.61	0.58
BoSE8-ngrams	0.57	0.59
BoSE-ngrams	**0.64**	**0.63**

Table 3: F1 results over the positive class against baseline methods

Method	Dep'17	Dep'18
first place	**0.64**	**0.64**
second place	0.59	0.60
third place	0.53	0.58
BoSE-ngrams	**0.64**	0.63

Table 4: F1 results over the positive class against top performers at eRisk

From the obtained results we highlight the following observations:

1. Our approach outperformed the traditional BOW representation in both data sets, indicating that considering emotional information is quite relevant for the detection of depression in online communications.

2. The use of fine-grained emotions as features helps improving the results from a representation that only considers broad emotions. This result confirms our hypothesis that depressive users tend to express their emotions in a different way than non depressive users.

Examples of relevant sequences	
"anger1" "anger11-anticipation10" "disgust16-anger11" "disgust11-fear17"	
anger1	abandoned, deserted, unattended
anger11	unsociable, crowd, mischievous
anticip10	disappointed, inequality, infidelity
disgust16	unsatisfactory, dilution, influence
disgust11	insecurity, desolation, incursion
fear17	hysterical, immaturity, injury

Table 5: Examples of words that create the fine-grained emotions

3. Our approach obtained comparable results to the best reported approaches in both data sets. It is important to highlight that the participants of these tasks tested different complex models with a wide range of features and sophisticated approaches based on traditional and deep learning representations of texts, whereas ours only relies on the use of fine-grained emotions as features.

4.1 Analysis of the Fine-Grained Emotions

To offer a glimpse of what fine-grained emotions actually capture, we selected the most relevant sequences for the detection of depression according to the chi^2 distribution. Table 5 shows some relevant sequences of fine-grained emotions as well as some examples of the words that correspond to these sequences.

Most of the fine-grained emotions that present high relevance for the detection of depression are related to negative topics, for example, the anger emotion is associated to the feeling of abandonment or unsociable, and the disgust emotion is related to dilution, insecurity and desolation. These fine-grained emotions seems to capture the way a depressed user expresses about himself or his environment.

5 Conclusions and Future Work

In this study we proposed a new representation that creates fine-grained emotions that were automatically generated using a lexical resource of emotions and sub-word embeddings from FastText. Using these fine-grained emotions our approach can automatically capture more specific topics and emotions that are expressed in the documents by users that have depression. BoSE obtained better results than the proposed baselines and also improved the results of only using broad emotions. It is worth mentioning the simplicity and interpretability of our approach, which contrasts with the best previous eRisk competition methods that are much more complex and difficult to interpret (most of the participants used plenty of different features and a vast range of models, including deep). Our results encourage to attempt this approach based on fine-grained emotions in other relevant health and safety tasks such as the detection of anorexia and self-harm. In addition, we also plan to explore the learning of emotional-based representations by means of a deep neural network from which we could exploit local invariance properties to model fine-grained emotions.

A Silver Standard Corpus of Human Phenotype-Gene Relations

Diana Sousa*, Andre Lamurias and Francisco M. Couto

LASIGE, Faculdade de Ciências, Universidade de Lisboa, Portugal

Abstract

Human phenotype-gene relations are fundamental to fully understand the origin of some phenotypic abnormalities and their associated diseases. Biomedical literature is the most comprehensive source of these relations, however, we need Relation Extraction tools to automatically recognize them. Most of these tools require an annotated corpus and to the best of our knowledge, there is no corpus available annotated with human phenotype-gene relations. This paper presents the Phenotype-Gene Relations (PGR) corpus, a silver standard corpus of human phenotype and gene annotations and their relations. The corpus consists of 1712 abstracts, 5676 human phenotype annotations, 13835 gene annotations, and 4283 relations[1]. We generated this corpus using Named-Entity Recognition tools, whose results were partially evaluated by eight curators, obtaining a precision of 87.01%. By using the corpus we were able to obtain promising results with two state-of-the-art deep learning tools, namely 78.05% of precision. The PGR corpus was made publicly available to the research community.[2]

1 Introduction

Automatic extraction of relations between entities mentioned in literature is essential to obtain knowledge that was already available but required considerable manual effort and time to retrieve. Recently, biomedical relation extraction has gained momentum in several text-mining applications, such as event extraction and slot-filling (Lamurias and Couto, 2019b). Some of the commonly extracted biomedical relations are protein-protein interactions (Papanikolaou et al., 2015), drug-drug interactions (Lamurias et al., 2019) and disease-gene relationships (Kim et al., 2017).

There are a few worth mention systems regarding biomedical Relation Extraction (RE) (Verga et al., 2018), and that specifically focus on the extraction of phenotype-gene relations regarding different species types like plants (Xing et al., 2018) and humans (Collier et al., 2015). The main problem that these systems face is a lack of specific high quality annotated corpora (gold standard corpus), mostly because this task requires not only a considerable amount of manual effort but also specific expertise that is not widely available. A solution to these limitations is to generate the corpus in a fully automated manner (silver standard corpus).

Connecting human phenotypes to genes helps us to understand the origin of some phenotypic abnormalities and their associated diseases. To extract human phenotype-gene relations, both entities, human phenotypes and genes have to be recognized. With genes, as a result of lexical features being relatively regular, many systems can successfully identify them in text (Leaman and Gonzalez, 2008). Even though Named-Entity Recognition (NER) research has significantly improved in the last years, human phenotype identification is still a complex task, only tackled by a handful of systems (Lobo et al., 2017).

To generate a silver standard for phenotype-gene relation extraction, we used a pipeline that performs: i) NER to recognize genes and human phenotype entities; ii) RE to classify a relation between human phenotype and gene entities. First, we gathered abstracts using the PubMed API with manually defined keywords, namely each gene name, *homo sapiens*, and *disease*. Then we used the Minimal Named-Entity Recognizer (MER) tool (Couto and Lamurias, 2018) to extract gene mentions in the abstracts and the Identifying Human Phenotypes (IHP) tool (Lobo et al.,

Proceedings of NAACL-HLT 2019, pages 1487–1492
Minneapolis, Minnesota, June 2 - June 7, 2019.

2017) to extract human phenotype mentions. At last, we used a gold standard relations file, provided by the Human Phenotype Ontology (HPO), to classify the relations obtained by co-occurrence in the same sentence as *Known* or *Unknown*.

To the best of our knowledge, there is no corpus available specific to human phenotype-gene relations. This work, overcame this issue by creating a large and versatile silver standard corpus. To assess the quality of the Phenotype-Gene Relations (PGR) corpus, eight curators manually evaluated a subset of PGR. We obtained highly promising results, for example 87.18% in precision. Finally, we evaluated the impact of using the corpus on two deep learning RE systems, obtaining 69.23% (BO-LSTM) and 78.05% (BioBERT) in precision.

2 PGR Corpus

The HPO is responsible for providing a standardized vocabulary of phenotypic abnormalities encountered in human diseases (Köhler et al., 2017). The developers of the HPO also made available a file that links these phenotypic abnormalities to genes. These phenotype-gene relations are regularly extracted from texts in Online Mendelian Inheritance in Man (OMIM) and Orphanet (ORPHA) databases, where all phenotype terms associated with any disease that is related with a gene are assigned to that gene in the relations file. In this work, we used the relations file created by HPO as a gold standard for human phenotype-gene relations.

We started by retrieving abstracts from PubMed, using the genes involved in phenotype-gene relations and *homo sapiens* as keywords, and the Entrez Programming Utilities (E-utilities) web service (`https://www.ncbi.nlm.nih.gov/books/NBK25501/`), retrieving one abstract per gene (Query 1).

Later, we added the keyword *disease* and filter for abstracts in English (Query 2)[3]. Query 2 represents a more focused search of the type of abstracts to retrieve, such as abstracts regarding diseases, their associated phenotypes and genes.

For each gene, we opted for the most recent abstract (Query 1) and the two most recent abstracts (Query 2).

We opted by searching per gene and not human phenotype or the combination of both terms because this approach was the one that retrieved abstracts with the higher number of gene and human phenotype annotations, in the following NER and RE phases. We removed the abstracts that did not check the conditions of being written in English, with a correct XML format and content. The final number of abstracts was 1712 for Query 1 and 2657 for Query 2 as presented in Table 1. Then we proceeded to use the MER tool (Couto and Lamurias, 2018) for the annotation of the genes and the IHP framework (Lobo et al., 2017) for the annotation of human phenotype terms.

2.1 Gene Extraction

MER is a dictionary-based NER tool which given any lexicon or ontology (e.g., an OWL file) and an input text returns a list of recognized entities, their location, and links to their respective classes.

To annotate genes with MER we need to provide a file of gene names and their respective identifiers. To this goal, we used a list created by the HUGO Gene Nomenclature Committee (HGNC) at the European Bioinformatics Institute (`http://www.genenames.org/`). The HGNC is responsible for approving unique symbols and names for human loci, including protein-coding genes, ncRNA genes, and pseudogenes, with the goal of promoting clear scientific communication. Considering that we intended not only to map the genes to their names but also their Entrez Gene (`www.ncbi.nlm.nih.gov/gene/`) identifiers, we used the API from MyGene (`http://mygene.info/`) with the keyword *human* in species. The MyGene API provides several gene characteristics, including the confidence score for several possible genes that match the query. For this work, we chose the Entrez Gene identifier with a higher confidence score.

After corresponding all gene names to their respective identifiers, we were left with three genes that did not have identifiers (*CXorf36*, *OR4Q2*, and *SCYGR9*). For the first two genes (*CXorf36* and *OR4Q2*), a simple search in Entrez Gene allowed us to match them to their identifiers. For the last gene (*SCYGR9*) we were not able to find an Entrez Gene identifier, so we used the HGNC identifier for that gene instead. We opted to use the Entrez Gene identifiers because of their widespread use in the biomedical research field.

To the original gene list, we added gene synonyms using a synonyms list file provided by

[3] Query 2, corresponds to the *11/03/2019* release of PGR

Query	Abstracts	Annotations		Relations		
		Phenotype	Gene	Known	Unknown	Total
1 (10/12/2018)	1712	5676	13835	1510	2773	4283
2 (11/03/2019)	2657	9553	23786	2480	5483	7963

Table 1: The final number of abstracts retrieved, number of phenotype and gene annotations extracted and the number of known, unknown and total of relations extracted between phenotype and genes, for Query 1 and 2.

`https://github.com/macarthur-lab/gene_lists` (expanding the original list almost 3-fold). These synonyms were matched to their identifiers and filtered according to their length to exclude one character length synonyms and avoid a fair amount of false positives. The number of genes in the original gene list was 19194, and by including their synonyms that number increased to 56670, representing a total gain of 37476 genes.

At last, we identified some missed gene annotations that were caught using regular expressions. These missed gene annotations were next to forward/back slash and dashes characters (Example 1).

Example 1. Missed gene annotation because of forward slash.

- **Gene:** *BAX*
- **Gene Identifier:** 581
- **Abstract Identifier:** 30273005
- **Sentence:** According to the morphological observations and DNA fragmentation assay, the MPS compound induced apoptosis in both cell lines, and also cause a significant increase in the expression of **Bax**/Bcl-2.

2.2 Phenotype Extraction

IHP is a Machine Learning-based NER tool, specifically created to recognize HPO entities in unstructured text. It uses Stanford CoreNLP (Manning et al., 2014) for text processing and applies Conditional Random Fields trained with a rich feature set, combined with hand-crafted validation rules and a dictionary to improve the recognition of phenotypes.

To use the IHP system we chose to update the HPO ontology for the most recent version[4]. The annotations that originated from the IHP system were matched to their HPO identifier. There was a total of 7478 annotations for Query 1 and 10973 annotations for Query 2 that did not match any HPO identifier. We put aside these annotations to be confirmed or discarded manually as some of them are incorrectly identified entities but others are parts of adjacent entities that can be combined for an accurate annotation.

We did not use the MER system for phenotype extraction mainly because a more efficient tool for this task was available without the limitations of a dictionary-based NER tool for complex terms as phenotypes are.

2.3 Relation Extraction

After filtering abstracts that did not have annotations of both types, gene and phenotype, we gathered a total of 1712 abstracts for Query 1 and 2656 abstracts for Query 2 as presented in Table 1. The abstracts retrieved by Query 1 were not specific enough for human phenotype-gene relations and therefore about half of them did not contained entities from both types, which we addressed in Query 2, increasing from about 2.5 relations per abstract to about 3.0 relations per abstract.

Using a distant supervision approach, with the HPO file that links phenotypic abnormalities to genes, we were able to classify a relation with *Known* or *Unknown*. For this end, we extract pairs of entities, of gene and human phenotype, by co-occurrence in the same sentence (Example 2). The final number of both *Known* and *Unknown* annotations is also presented in Table 1.

Example 2. Relation extraction.

- **Abstract Identifier:** 23669344
- **Sentence:** A homozygous mutation of **SERPINB6**, a gene encoding an intracellular protease inhibitor, has recently been associated with post-lingual, autosomal-recessive, nonsyndromic **hearing loss** in humans (DFNB91).
- **Gene:** *SERPINB6*
- **Gene Identifier:** 5269
- **Phenotype:** *hearing loss*
- **Phenotype Identifier:** HP_0000365
- **Relation: Known**

[4] *09/10/2018* release

3 Evaluation

To evaluate the quality of the classifier, we randomly selected 260 relations from Query 1 to be reviewed by eight curators (50 relations each, with an overlap of 20 relations). All researchers work in the areas of Biology and Biochemistry. These curators had to evaluate the correctness of the classifier by attributing to each sentence one of the following options: *C* (correct), *I* (incorrect) or *U* (uncertain). The *U* option was given to identify cases of ambiguity and possible errors in the NER phase. We classified as a true positive (TP) a *Known* relation that was marked *C* by the curator, a false positive (FP) as a *Known* relation marked *I*, a false negative (FN) as a *Unknown* relation marked *I* and a true negative (TN) as a *Unknown* relation marked *C*.

3.1 State-of-the-art Applications

The PGR corpus was applied to two state-of-the-art systems that were compared against a co-occurrence (or all-true) baseline method.

3.1.1 BO-LSTM Application

The BO-LSTM system (Lamurias et al., 2019) is a deep learning system that is used to extract and classify relations via long short-term memory networks along biomedical ontologies. This system was initially created to detect and classify drug-drug interactions and later adapted to detect other types of relations between entities like human phenotype-gene relations. It takes advantage of domain-specific ontologies, like the HPO and the Gene Ontology (GO) (Ashburner et al., 2000). The BO-LSTM system represents each entity as the sequence of its ancestors in their respective ontology.

3.1.2 BioBERT Application

The BioBERT system (Lee et al., 2019) is a pre-trained biomedical language representation model for biomedical text mining based on the BERT (Devlin et al., 2018) architecture. Trained on large-scale biomedical corpora, this system is able to perform diverse biomedical text mining tasks, namely NER, RE and Question Answering (QA). The novelty of the architecture is that these systems (BioBERT and BERT) are designed to pre-train deep bidirectional representations by jointly conditioning on both left and right context in all layers. These feature allows easy adaption to several tasks without loss in performance.

4 Results and Discussion

The final results are presented in Table 2. The inter-curator agreement score, calculated from a total of 20 relations classified by eight curators, was 87.58%. Besides the fact that there were a few incorrectly extracted relations due to errors in the NER phase, that were discarded, the inter-curator agreement is not higher due to the complexity of the sentences where the relations between entities were identified. Even with highly knowledgeable curators in the fields of Biology and Biochemistry, most of them expressed difficulties in deciding which mark to choose on complex sentences that did not necessarily imply a relation between the identified entities (Example 3).

Example 3. Relation marked with *U* (Uncertain).

- **Abstract Identifier:** 27666346
- **Sentence: FRMD4A** antibodies were used to probe 78 paraffin-embedded specimens of **tongue squamous cell carcinoma** and 15 normal tongue tissues, which served as controls.
- **Mark:** ***U***

The precision obtained from the test-set (about 6% of the total of relations), was 87.01%. Although we cannot state that this test-set is representative of the overall data-set, this is a solid evidence of the effectiveness of our pipeline to automate RE corpus creation, especially between human phenotype and genes, and other domains if a gold standard relations file is provided. Our lower recall is mostly due to incorrectly retrieved human phenotype annotations by IHP, that can be manually confirmed in a future optimized version of the PGR corpus, as some of them are parts of adjacent entities that can be combined for an accurate annotation.

4.1 Impact on Deep Learning

For BioBERT we used the available pre-trained weights for training and testing of RE model on our corpus. The results of BO-LSTM and BioBERT in the test-set are presented in Table 3. We also measured the performance of the co-occurrence (i.e. assuming all-true) baseline method. This baseline method assumes that all relations in the test-set are *Known* and therefore the recall is 100%. These results are comparable to

Relations		Marked Relations				Metrics		
Known	Unknown	True Positive	False Negative	False Positive	True Negative	Precision	Recall	F-Measure
77	143	67	86	10	57	0.8701	0.4379	0.5826

Table 2: The *Known* and *Unknown* number of relations selected, the number of true positives, false negatives, false positives and true negatives, and the evaluation metrics for the *Known* relations.

Method	Precision	Recall	F-Measure
Co-occurrence	0.3500	1.0000	0.5185
BO-LSTM	0.6923	0.4200	0.5228
BioBERT	0.7895	0.5844	0.6716

Table 3: Precision, recall and F-measure of the co-occurrence baseline, BO-LSTM and BioBERT.

the ones obtained from the evaluation stage by the curators, and show the applicability of our corpus.

BioBERT significantly outperforms BO-LSTM in all metrics proving that is indeed a viable language representation model for biomedical text mining. Even though the recall for both systems is relatively low, the purpose of this work was mainly to extract correct relations between entities to facilitate Machine Learning (ML), which was achieved by obtaining the precision of 69.23% (BO-LSTM) and 78.95% (BioBERT).

The most relevant metric for a silver standard corpus, directed towards ML tools, is precision. ML tools depend on correct examples to create effective models that can detect new cases, afterwards, being able to deal with small amounts of noise in the assigned labels.

5 Conclusions

This paper showed that our pipeline is a feasible way of generating a silver standard human phenotype-gene relation corpus. The pipeline required the application of two NER tools, and the availability of a list of known relations. We manually evaluated the corpus using eight curators obtaining a 87.01% precision with an inter-agreement of 87.58%. We also measured the impact of using the corpus in state-of-the-art deep learning RE systems, namely BO-LSTM and BioBERT. The results were promising with 69.23%, and 78.95% in precision, respectively. We believe that our pipeline and silver standard corpus will be a highly useful contribution to overcome the lack of gold standards.

Future work includes manually correcting the human phenotype annotations that did not match any HPO identifier, with the potential of expanding the number of human phenotype annotations almost 2-fold and increasing the overall recall. Also, we intend to expand the corpus by identifying more missed gene annotations using pattern matching, which is possible due to our approach being fully automated. Another possibility is the expansion of the test-set for a more accurate capture of the variance in the corpus. For example, we can select a subset of annotated documents in which two curators could work to grasp the complexity of manually annotating some of these abstracts. Further, we intend to use semantic similarity to validate the human phenotype-gene relations. Semantic similarity has been used to compare different types of biomedical entities (Lamurias and Couto, 2019a), and is a measure of closeness based on their biological role. For example, if the *BRCA1* gene is semantically similar to the *BRAF* gene and the *BRCA1* has an established relation with the *tumor* phenotype, it could be possible to infer that *BRAF* gene also has a relation with the *tumor* phenotype, even if that is not evident by the training data. Finally, the effect of different NER systems applied to the pipeline should be studied.

Improving Lemmatization of Non-Standard Languages with Joint Learning

Enrique Manjavacas[1], **Ákos Kádár**[2], and **Mike Kestemont**[1]

[1]Computational Linguistics and Psycholinguistics Research Center, University of Antwerp, Belgium
[2]Tilburg Center for Cognition and Communication, Tilburg University, The Netherlands
{firstname,lastname}@uantwerpen.be,a.kadar@uvt.nl

Abstract

Lemmatization of standard languages is concerned with (i) abstracting over morphological differences and (ii) resolving token-lemma ambiguities of inflected words in order to map them to a dictionary headword. In the present paper we aim to improve lemmatization performance on a set of non-standard historical languages in which the difficulty is increased by an additional aspect (iii): spelling variation due to lacking orthographic standards. We approach lemmatization as a string-transduction task with an encoder-decoder architecture which we enrich with sentence context information using a hierarchical sentence encoder. We show significant improvements over the state-of-the-art when training the sentence encoder jointly for lemmatization and language modeling. Crucially, our architecture does not require POS or morphological annotations, which are not always available for historical corpora. Additionally, we also test the proposed model on a set of typologically diverse standard languages showing results on par or better than a model without enhanced sentence representations and previous state-of-the-art systems. Finally, to encourage future work on processing of non-standard varieties, we release the dataset of non-standard languages underlying the present study, based on openly accessible sources.

1 Introduction

Lemmatization is the task of mapping a token to its corresponding dictionary head-form to allow downstream applications to abstract away from orthographic and inflectional variation (Knowles and Mohd Don, 2004). While lemmatization is considered to be solved for analytic and resource-rich languages such as English, it remains an open challenge for morphologically complex (e.g. Estonian, Latvian) and low-resource languages with unstable orthography (e.g. historical languages). Especially for languages with higher surface variation, lemmatization plays a crucial role as a preprocessing step for downstream tasks such as topic modeling, stylometry and information retrieval.

In the case of standard languages, lemmatization complexity arises primarily from two sources: (i) morphological complexity affecting the number of inflectional patterns a lemmatizer has to model and (ii) token-lemma ambiguities (e.g. "living" can refer to lemmas "living" or "live") which require modeling sentence context information. In the case of historical languages, however, the aforementioned spelling variation introduces further complications. For instance, the regularity of the morphological system is drastically reduced since the evidence supporting token-lemma mappings becomes more sparse. As an example, while the modern Dutch lemma "jaar" (en. "year") can be inflected in 2 different ways ("jaar", "jaren"), in a Middle Dutch corpus used in this study it is found in combination with 70 different forms ("iare", "ior", "jaer", etc.). Moreover, spelling variation increases token-lemma ambiguities by conflating surface realizations of otherwise unambiguous tokens—e.g. Middle Low German "bath" can refer to lemmas "bat" (en. "bad") and "bidden" (en. "bet") due to different spellings of the dental occlusive in final position.

Spelling variation is not exclusive of historical languages and it can be found in contemporary forms of on communication, such as microblogs, with loose orthographic conventions (Crystal, 2001). An important difference, however, is that while for modern languages normalization is feasible (Schulz et al., 2016), for many historic languages such is not possible, because one is dealing with an amalgam of regional dialects that lacked any sort of supra-regional variant functioning as target domain (Kestemont et al., 2016).

In the present paper, we apply representation

Proceedings of NAACL-HLT 2019, pages 1493–1503
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

learning to lemmatization of historical languages. Our method shows improvements over a plain encoder-decoder framework, which reportedly achieves state-of-the-art performance on lemmatization and morphological analysis (Bergmanis and Goldwater, 2018; Peters et al., 2018). In particular, we make the following contributions:

1. We introduce a simple joint learning approach based on a bidirectional Language Model (LM) loss and achieve relative improvements in overall accuracy of 7.9% over an encoder-decoder trained without joint loss and 30.72% over edit-tree based approaches.
2. We provide a detailed analysis of the linguistic and corpus characteristics that explain the amount of improvement we can expect from LM joint training.
3. We probe the hidden representations learned with the joint loss and find them significantly better predictors of POS-tags and other morphological categories than the representations of the simple model, confirming the efficiency of the joint loss for feature extraction.

Additionally, we test our approach on a typologically varied set of modern standard languages and find that the joint LM loss significantly improves lemmatization accuracy of ambiguous tokens over the encoder-decoder baseline (with a relative increase of 15.1%), but that, in contrast to previous literature (Chakrabarty et al., 2017; Bergmanis and Goldwater, 2018), the overall performance of encoder-decoder models is not significantly higher than that of edit-tree based approaches. Taking into account the type of inflectional morphology dominating in a particular language, we show that the benefit of encoder-decoder approaches is highly dependent on typological morphology. Finally, to assure reproducibility, all corpus preprocessing pipelines and train-dev-test splits are released. With this release, we hope to encourage future work on processing of lesser studied non-standard varieties.[1]

2 Related Work

Modern data-driven approaches typically treat lemmatization as a classification task where classes are represented by binary edit-trees induced from the training data. Given a token-lemma pair, its binary edit-tree is induced by computing the prefix and suffix around the longest common subsequence, and recursively building a tree until no common character can be found. Such edit-trees manage to capture a large proportion of the morphological regularity, especially for languages that rely on suffixation for morphological inflection (e.g. Western European languages), for which such methods were primarily designed.

Based on edit-tree induction, different lemmatizers have been proposed. For example, Chrupala et al. (2008) use a log-linear model and a set of hand-crafted features to decode a sequence of edit-trees together with the sequence of POS-tags using a beam-search strategy. A related approach is presented by Gesmundo and Samardži (2012), where edit-trees are extracted using a non-recursive version of the binary edit-tree induction approach. More recently, Cotterell et al. (2015) have used an extended set of features and a second-order CRF to jointly predict POS-tags and edit-trees with state-of-the-art performance. Finally, Chakrabarty et al. (2017) employed a softmax classifier to predict edit-trees based on sentence-level features implicitly learned with a neural encoder over the input sentence.

With the advent of current encoder-decoder architectures, lemmatization as a string-transduction task has gained interest partly inspired by the success of such architectures in Neural Machine Translation (NMT). For instance, Bergmanis and Goldwater (2018) apply a state-of-the-art NMT system with the lemma as target and as source the focus token with a fixed window over neighboring tokens. Most similar to our work is the approach by Kondratyuk et al. (2018), which conditions the decoder on sentence-level distributional features extracted from a sentence-level bidirectional RNN and morphological tags.

Recently, work on non-standard historical varieties has focused on spelling normalization using rule-based, statistical and neural string-transduction models (Pettersson et al., 2014; Bollmann and Søgaard, 2016; Tang et al., 2018). Previous studies on lemmatization of historical variants focused on evaluating off-the-shelf systems.

---

[1] Datasets and training splits are available at `https://www.github.com/emanjavacas/pie-data`. Experiments are conducted with our framework `pie` available at: `https://www.github.com/emanjavacas/pie`. All our experiments are implemented using `PyTorch` (Paszke et al., 2017).

For instance, Eger et al. (2016) evaluates different pre-existing models on a dataset of German and Medieval Latin, and Dereza (2018) focuses on Early Irish. The most similar to the present paper in this area is work by Kestemont et al. (2016), which tackled lemmatization of Middle Dutch with a neural encoder that extracts character and word-level features from a fixed-length token window and predicts the target lemma from a closed-set of true lemmas.

Using Language Modeling as a task to extract features in a Transfer Learning setup has gained momentum only in the last year, partly thanks to overall improvements over previous state-of-the-art across multiple tasks (NER, POS, QA, etc.). Different models have been proposed around the same idea varying in implementation, optimization and task definition. For instance, Howard and Ruder (2018) present a method to fine-tune a pretrained LM for text classification. Peters et al. (2018) learn task-specific weighting schemes over different layer features extracted by a pretrained bidirectional LM. Recently, Akbik et al. (2018) used context-sensitive word-embeddings extracted from a bidirectional character-level LM to improve NER, POS-tagging and chunking.

3 Proposed Model

Here we describe our encoder-decoder architecture for lemmatization. In Section 3.1 we start by describing the basic formulation known from the machine translation literature. Section 3.2 shows how sentential context is integrated into the decoding process as an extra source of information. Finally, Section 3.3 describes how we learn richer representations for the encoder through the addition of an extra language modeling task.

3.1 Encoder-Decoder

We employ a character-level Encoder-Decoder architecture that takes an input token x_t character-by-character and has as goal the character-level decoding of the target lemma l_t conditioned on an intermediate representation of x_t. For token x_t, a sequence of token character embeddings $c^x_1, \ldots, c^x_n$ is extracted from embedding matrix $W_{enc} \in \mathbb{R}^{|C| \times d}$ (where $|C|$ and d represent, respectively, the size of the character vocabulary and the embedding dimensionality). These are then passed to a bidirectional RNN encoder, that computes a forward and a backward sequence of hidden states: $\overrightarrow{h^{enc}_1}, \ldots, \overrightarrow{h^{enc}_n}$ and $\overleftarrow{h^{enc}_1}, \ldots, \overleftarrow{h^{enc}_n}$. The final representation of each character i is the concatenation of the forward and the backward states: $h^{enc}_i = [\overrightarrow{h^{enc}_i}; \overleftarrow{h^{enc}_i}]$.

At each decoding step j, a RNN decoder generates the hidden state h^{dec}_j, given the lemma character embedding c^l_j from embedding matrix $W_{dec} \in \mathbb{R}^{|L| \times d}$, the previous hidden state h^{dec}_{j-1} and additional context. This additional context consists of a summary vector r_j obtained via an attentional mechanism (Bahdanau et al., 2014) that takes as input the previous decoder state h^{dec}_{j-1} and the sequence of encoder activations $h^{enc}_1, \ldots, h^{enc}_n$.[2] Finally, the output logits for character j are computed by a linear projection of the current decoder state h^{enc}_j with parameters $O \in \mathbb{R}^{H \times |L|}$, which are normalized to probabilities with the $softmax$ function. The model is trained to maximize the probability of the target character sequence expressed in Equation 1 using teacher-forcing.

$$P(l_t|x_t) = \prod_{j=1}^{m} P(c^l_j | c^l_{<j}, r_j; \theta_{enc}, \theta_{dec}) \qquad (1)$$

3.2 Adding sentential context

Lemmatization of ambiguous tokens can be improved by incorporating sentence-level information. Our architecture is similar to Kondratyuk et al. (2018) in that it incorporates global sentence information by extracting distributional features with a hierarchical bidirectional RNN over the input sequence of tokens $x_1, ..., x_m$. For each token x_t, we first extract word-level features re-using the last hidden state of character-level bidirectional RNN Encoder from Section 3.1 $w_t = [\overrightarrow{h^{enc}_t}; \overleftarrow{h^{enc}_t}]$. Optionally, word-level features can be enriched with extra lookup parameters from an embedding matrix $W_{word} \in \mathbb{R}^{|V| \times e}$ – where V and e denote respectively the vocabulary size in words and the word embedding dimensionality.[3] Given these word-level features w_t, the sentence-level features s_t are computed as the concatenation of

---

[2] We refer to Bahdanau et al. (2014) for the description of the attentional mechanism.

[3] During development word embeddings did not contribute significant improvements on historical languages, and we therefore exclude them from the rest of the experiments. It must be noted, however, that word embeddings might still be helpful for lemmatization of standard languages where the type-token ratio is smaller as well as when pretrained embeddings are available.

forward and backward activations of an additional sentence-level bidirectional RNN $s_t = [\overrightarrow{s_t}; \overleftarrow{s_t}]$.

In order to perform sentence-aware lemmatization for token x_t, we condition the decoder on the sentence-level encoding s_t and optimize the probability given by Equation 2.

$$P(l_t|x_t) = \prod_{j=1}^{m} P(c_j^l|c_{<j}^l, r_j, s_t; \theta_{enc}, \theta_{dec}) \qquad (2)$$

Our architecture ensures that both word-level and character-level features of each input token in a sentence can contribute to the sentence-level features at any given step and therefore to the lemmatization of any other token in the sentence. From this perspective, our architecture is more general than those presented in Kestemont et al. (2016); Bergmanis and Goldwater (2018), where sentence information is included by running the encoder over a predetermined fixed-length window of neighboring characters. Moreover, we let the character-level embedding extractor and the lemmatizer encoder share parameters in order to amplify the training signal coming into the latter. Figure 1 visualizes the proposed architecture.

3.3 Improved sentence-level features

We hypothesize that the training signal from lemmatization alone might not be enough to extract sufficiently high quality sentence-level features. As such we include an additional bidirectional word-level language-model loss over the input sentence. Given the forward and backward subvectors of the sentence encoding $s^t = [\overrightarrow{s^t}; \overleftarrow{s^t}]$, we train two additional softmax classifiers to predict token x^{t+1} given $\overrightarrow{s_t}$ and x^{t-1} given $\overleftarrow{s_t}$ with parameters O_{LMfwd} and $O_{LMbwd} \in \mathbb{R}^{S\times|V|}$.[4]

We train our model to jointly minimize the negative log-likelihood of the probability defined by Equation 2 and the LM probability defined by Equation 3.

$$\begin{aligned} P_{LM}(\mathbf{x}) = 1/2 \prod_{t=2}^{n} P(x_t|x_1, \ldots, x_{t-1}) \\ + 1/2 \prod_{t=1}^{n-1} P(x_t|x_{t+1}, \ldots, x_n) \end{aligned} \qquad (3)$$

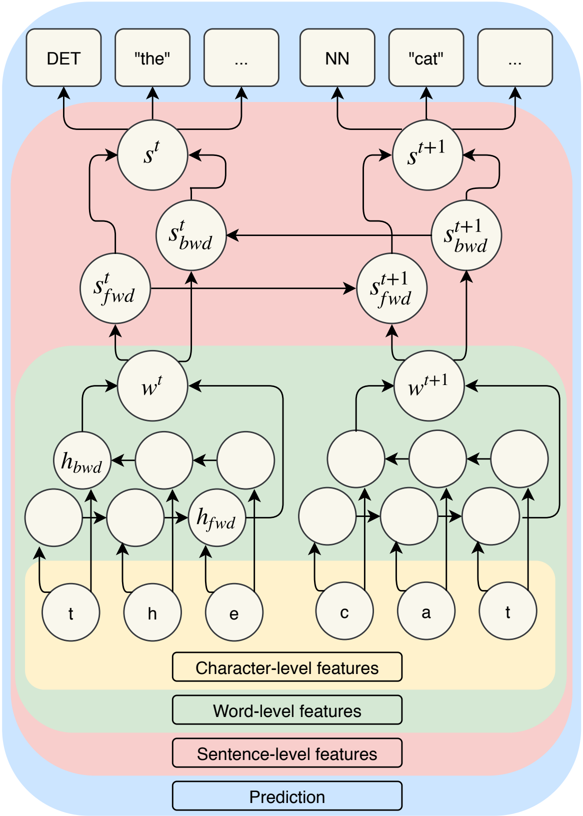

Figure 1: Hierarchical sentence encoding architecture with feature extraction at different levels.

Following a Multi-Task Learning (Caruana, 1997), we set a weight on the LM negative log-likelihood which we decrease over training based on lemmatization accuracy on development data to reduce its influence on training after convergence.

4 Experiments

Section 4.1 first introduces the datasets, both the newly introduced dataset of historical languages, and the dataset of modern standard languages sampled from Universal Dependencies (v2.2) corpus (Nivre et al., 2016). Finally, Section 4.2 describes model training and settings in detail.

4.1 Datasets

Historical Languages In recent years, a number of historical corpora have appeared thanks to an increasing number of digitization initiatives (Piotrowski, 2012). For the present study, we chose a representative collection of medieval and early modern datasets, favoring publicly available data, corpora with previously published results and datasets covering multiple genres and historic periods. We include a total of 8 corpora covering Middle Dutch, Middle Low German, Medieval

---

[4] We have found the joint loss most effective when both forward and backward classifiers shared parameters.

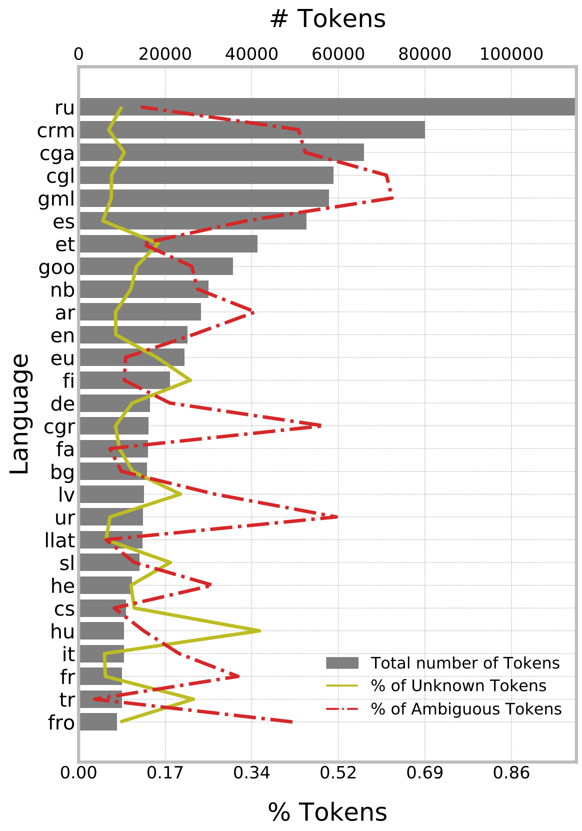

Figure 2: Statistics of total number of tokens, ambiguous and unknown tokens in the test sets. The full list of languages for both historical and standard corpora as well as the corresponding ISO 639-1 codes used in the present study can be found in the Appendix. Statistics for unknown and ambiguous tokens are shown as percentages.

French, Historical Slovene and Medieval Latin, which we take from the following sources.

Both `cga` and `cgl` contain medieval Dutch material from the Gysseling corpus curated by the Institute for Dutch Lexicology[5] `cga` is a charter collection (administrative documents), whereas `cgl` concerns a variety of literary texts that greatly vary in length. `crm` is another Middle Dutch charter collection from the 14th century with wide geographic coverage (Van Reenen and Mulder, 1993; van Halteren and Rem, 2013). `cgr`, finally, is a smaller collection of samples from Middle Dutch religious writings that include later medieval texts (Kestemont et al., 2016). `fro` offers a corpus of Old French heroic epics, known as *chansons de geste* (Camps, 2016). `llat` dataset is taken from the Late Latin Charter Treebank, consisting of early medieval Latin documentary texts (Korkiakangas and Lassila, 2013). `goo` comes from the reference corpus of historical Slovene, sampled from 89 texts from the period 1584-1899 (Erjavec, 2015). `gml` refers to the reference corpus of Middle Low German and Low Rhenish texts, found in manuscripts, prints and inscriptions (Barteld et al., 2017). Finally, `cap` is a corpus of early medieval Latin ordinances decreed by Carolingian rulers (Eger et al., 2016).

Standard Languages For a more thorough comparison between systems across domains and a better examination of the effect of the LM loss, we evaluate our systems on a set of 20 standard languages sampled from the UD corpus, trying to guarantee typological diversity while selecting datasets with at least 20k words. We use the pre-defined splits from the original UD corpus (v2.2).[6]. Figure 2 visualizes the test set sizes in terms of total, ambiguous and unknown tokens for both historical and standard languages.

4.2 Models

We refer to the full model trained with joint LM loss by `Sent-LM`. In order to test the effectiveness of sentence information and the importance of enhancing the quality of the sentence-level feature extraction, we compare against a simple encoder-decoder model without sentence-level information (`Plain`) and a model trained without joint LM loss (`Sent`). Moreover, we compare to previous state-of-the-art lemmatizers based on binary edit-tree induction: `Morfette` (Chrupala et al., 2008) and `Lemming` (Cotterell et al., 2015), which we run with default hyperparameters.

For all our models, we use the same hyperparameter values as follows. All recurrent layers have 150 cells per layer and use GRUs (Cho et al., 2014). Encoder and Decoder have 2 layers but the sentence encoder has only 1. We apply 0.25 dropout (Srivastava et al., 2014) after the embedding layer and before the output layer and 0.25 variational dropout (Gal and Ghahramani, 2016) in between recurrent layers. Models are optimized with Adam (Kingma and Ba, 2015) using an initial learning rate of 1e-3 which is reduced by 25% after each epoch without improvement on development accuracy. Models are trained until fail-

[6] The full list of languages for both historical and standard corpora as well as the corresponding ISO 639-1 codes used in the present study can be found in the Appendix. In the cases where train-dev-test splits were not pre-defined, we randomly split sentences using 10% and 5% for test and dev respectively.

	Full	Ambiguous	Unknown
`Edit-tree`	91.11	91.79	35.48
`Plain`	91.61	87.39	65.69
`Sent`	93.4	91.14	**66.98**
`Sent-LM`	**94.0**	**92.81**	65.39

Table 1: Average accuracy across historical languages. `Lemming` and `Morfette` are shown aggregated by taking the best performing model per dataset.

	Full	Ambiguous	Unknown
`K-2016`	91.88		51.64
`Edit-tree`	89.01	91.18	20.46
`Plain`	90.21	87.4	61.93
`Sent`	92.55	91.6	**64.61**
`Sent-LM`	**93.25**	**93.31**	62.1

Table 2: Accuracy for the Gysseling subcorpora.

ing to achieve any improvement for 3 consecutive epochs. Initial LM loss weight is set to 0.2 and it is halved each epoch after two consecutive epochs without achieving any improvements on development perplexity.

We use sentence boundaries when given and otherwise use POS tags corresponding to full stops as clues. In any case, sentences are split into chunks of maximum 35 words to accommodate to limited memory. Target lemmas during both training and testing are lowercased in agreement with the implementation of `Lemming` and `Morfette`, which also do so. For models with joint loss, we truncate the output vocabulary to the top 50k most frequent words for similar reasons. We run a maximum of 100 optimization epochs in randomized batches containing 25 sentences each. The learning rate is decreased by a factor of 0.75, after every 2 epochs without accuracy increase on held-out data and learning stops after failing to improve for 5 epochs. Decoding is done with beam search with a beam size of 10.[7]

5 Results

As is customary, we report exact-match accuracy on target lemmas. Besides overall accuracy, we also compute accuracy of ambiguous tokens (i.e. tokens that map to more than 1 lemma in the training data) and unknown tokens (i.e. tokens that do not appear in the training data).

5.1 Historical languages

Table 1 shows the aggregated results over all datasets in our historical language corpus.[8] In 4 cases (`cga`, `cgl`, `crm` and `gml`), `Lemming` failed to converge due to memory requirements exceeding 250G RAM due to the large amount of edit-trees. Following Søgaard et al. (2014), we compute p-values with a Wilcoxon's signed rank test. `Sent-LM` is the best performing model with a relative improvement of 7.9% ($p < .01$) over `Sent` and 30.72% ($p < .01$) over the edit-tree approach on full datasets and 10.27% ($p < .1$) and 18.66% ($p < .01$) on ambiguous tokens. Moreover, the edit-tree approach outperforms encoder-decoder models `Plain` and `Sent` on ambiguous tokens, and it is only due to the joint loss that the encoder-decoder paradigm gains an advantage. Finally, for tokens unseen during training, the best performing model is `Sent` with a relative error reduction of 47% ($p < .01$) over the edit-tree approach and 4.77% ($p < .1$) over `Sent-LM`.

Table 2 compares scores for a subset from the corpora coming from the Gysseling corpus, which have been used in previous work on lemmatization of historical languages. The model described by Kestemont et al. (2016) is included as `K-2016` for comparison.[9] It is apparent that both `Sent` and `Sent-LM` outperform `K-2016` on full and unknown tokens. It is worth noting that `K-2016`, a model that uses distributed contextual features but no edit-tree induction, performs better than `Plain` – which highlights the importance of context for the lemmatization of historical languages –, and also better than the edit-tree approaches – which highlights the difficulty of tree induction on this dataset. We find `Sent-LM` to have a significant advantage over `Sent` on full and ambiguous tokens, but a disadvantage vs `Sent` and `Plain` on unknown tokens.

5.2 Standard languages

Table 4 shows overall accuracy scores aggregated across all languages.[10] We observe that on average `Sent-LM` is the best model on full datasets.

---

[7] For all languages, we observed relatively small gains ranging from 0.1% to 0.5% in overall accuracy.

[8] We aggregate both edit-tree based approaches by selecting the best performing model for each corpus. When `Lemming` converge, the results were better than `Morfette`.

[9] Unfortunately, scores on ambiguous tokens were not reported and therefore cannot be compared.

[10] Similarly to results on historical languages, we aggregate `Morfette` and `Lemming` due to the later failing to converge on `et`.

	Full			Ambiguous			Unknown		
	Type 1	Type 2	Type 3	Type 1	Type 2	Type 3	Type 1	Type 2	Type 3
`Edit-tree`	96.34	93.02	**98.37**	92.47	**92.47**	**97.5**	84.99	74.66	**91.39**
`Plain`	96.21	94.6	97.5	88.87	90.51	95.34	85.43	**83.78**	86.37
`Sent`	96.42	94.41	97.84	91.12	92.01	96.65	**85.44**	84.02	86.67
`Sent-LM`	**96.52**	**94.62**	97.86	**93.01**	92.07	97.48	85.15	83.32	85.36

Table 3: Average accuracy across morphologically related standard languages. Type 1 encloses `bg`, `cs`, `lv`, `ru` and `sl`. Type 2 comprises `et`, `fi`, `hu`, `tr`. Finally, Type 3 encompasses `de`, `en`, `es`, `fr`, `it` and `nb`.

	Full	Ambiguous	Unknown
`Edit-tree`	96.1	**94.35**	**83.26**
`Plain`	95.93	91.44	83.02
`Sent`	96.19	93.25	82.61
`Sent-LM`	**96.28**	94.08	82.58

Table 4: Average accuracy across all 20 standard languages. `Lemming` and `Morfette` are shown aggregated by taking the best performing model per dataset.

However, in contrast to previous results, the edit-tree approach has an advantage over all encoder-decoder models for both ambiguous and unknown tokens.

Since the differences in performance are not statistically significant ($p > 0.05$), we seek to shed light on the advantages and disadvantages of the encoder-decoder and edit-tree paradigms by conducting a more fine-grained analysis with respect to the morphological typology of the considered languages. To this end, we group languages into morphological types depending on the dominant morphological processes of each language and aggregate scores over languages in each type:

Type 1. Balto-Slavic languages which are known for their strongly suffixing morphology and complex case system.

Type 2. Uralic and Altaic languages, which are characterized by agglutinative morphology and a tendency towards monoexponential case and vowel harmony.

Type 3. Western European languages with a tendency towards synthetic morphology and partially lacking nominal case.

Table 3 shows accuracy scores per morphological group for each model type. It is apparent that the `Edit-tree` approach is very effective for Type 3 languages both in ambiguous and unknown tokens. In both Type 1 and Type 2 languages, the best overall performing model is `Sent-LM`. In the case of ambiguous tokens, `Sent-LM` achieves highest accuracy for Type 1 languages, but it is surpassed by the `Edit-tree` approach on Type 2 languages. Finally, in the case of unknown tokens, we observe a similar pattern to the historical languages where `Plain` and `Sent` have an advantage over `Sent-LM`.

6 Discussion

For clarity, we group the discussion of the main findings according to four major discussion points.

How does the joint LM loss help? As Section 5 shows, `Sent-LM` is the overall best model, and its advantage is biggest on ambiguous datasets, always outperforming the second-best encoder-decoder model on ambiguous tokens. For a more detailed comparison of the two models we tested the following two hypotheses: (i) the joint LM loss helps by providing sentence representations with stronger disambiguation capacities (ii) The joint LM loss helps in cases when the evidence of a token-lemma relationship is sparse —e.g in languages with highly synthetic morphological systems and in the presence of spelling variation.

As Figure 3 shows, improvement over `Sent` is correlated with percentage of token-lemma ambiguity in the corpus, providing evidence for hypothesis (i). Finally, as Figure 4 shows, improvement over `Sent` is correlated with higher token-lemma ratio, suggesting that the improvement is likely to be due to learned representations that better identify the input token. These two aspects help explain the efficiency of the joint learning approach on non-standard languages where high levels of spelling variation provide increased ambiguity by conflating unrelated forms and also lower evidence for token-lemma mappings.

Another factor certainly related to the efficiency of the proposed joint LM-loss is the size of the training dataset. However, dataset size should be considered a necessary but not a sufficient condition for the feasibility of the joint LM-loss and has therefore weak explanation power for the performance of the proposed approach.

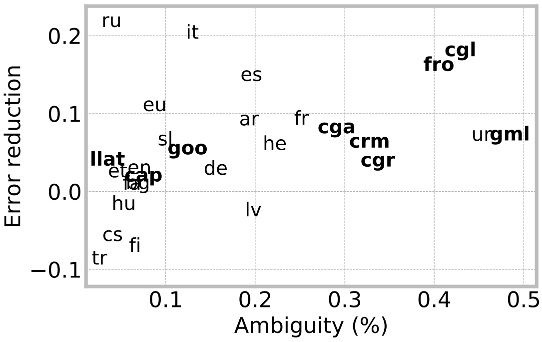

Figure 3: Error reduction of `Sent-LM` vs `Sent` by percentage of ambiguous tokens (Spearman's $R = 0.53; p < .01$). Historical languages are shown in bold.

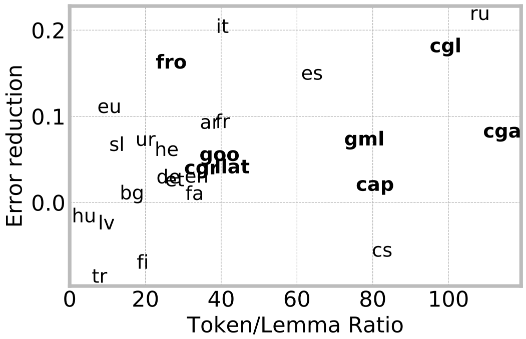

Figure 4: Error reduction of `Sent-LM` vs `Sent` by Token-Lemma ratio on 50k tokens of the training set (Spearman's $R = 0.47; p < .05$). Historical languages are shown in bold.

LM loss leads to better representations In order to analyze the representations learned with the joint loss, we turn to "representation probing" experiments following current approaches on interpretability (Linzen et al., 2016; Adi et al., 2017). Using the same train-dev-test splits from the current study, we exploit additional POS, Number, Gender, Case and syntactic function (Dep) annotations provided in the UD corpora and compare the ability of the representations extracted by `Sent` and `Sent-LM` to predict these labels.[11] Model parameters are frozen and a linear softmax layer $Q \in \mathbb{R}^{H\times V}$ per task is learned using a cross-entropy loss function.[12] The results of this experiment are reported in Table 5. The classifier trained with `Sent-LM` outperforms the one with `Sent` on all considered labeling tasks, confirming the efficiency of the LM loss at extracting better representations.

	Pos	Dep	Gender	Case	Num
`Majority`	82.61	62.93	85.83	80.76	83.92
`Sent`	79.27	64.14	83.39	83.01	81.01
`Sent-LM`	**83.62**	**68.36**	**86.55**	**84.44**	**84.37**
Support	29	20	15	19	20

Table 5: Overall accuracy of `Sent` and `Sent-LM` models and a `Majority` baseline on 5 probing tasks and actual number of languages per morphological category. All differences over `Sent` except for Case are significant at $p < 0.05$. Support is shown in terms of number of languages exhibiting such grammatical distinctions.

Edit-tree vs. Encoder-Decoder Our fine-grained analysis suggests that the performance of the edit-tree and encoder-decoder approaches depends on the underlying morphological typology of the studied languages. Neural approaches seem to be stronger for languages with complex case systems and agglutinative morphology. In contrast, edit-tree approaches excel on more synthetic languages (e.g. Type 3) and languages with lower ambiguity (e.g. Type 2).

Figure 5 illustrates that as the number of edit-trees increase the encoder-decoder models start to excel. This is most likely due to the fact that, from an edit-tree approach perspective, a large number of trees creates a large number of classes, which leads to higher class imbalance and more sparsity. However, edit-tree based approaches do outperform representation learning methods for languages with lower number of trees, which leads to the intuition that the edit-tree formalism does provide a useful inductive bias to the task of lemmatization and it should not be discarded in future work. Our results, in fact, point to a future direction which applies the edit-tree formalism, but alleviates the edit-tree explosion by exploiting the relationships between the edit-tree classes potentially using representation learning methods.

---

[11] Note that not all tasks are available for all languages, due to some corpora not providing all annotations and some categories not being relevant for particular languages.

[12] Models trained for 50 epochs using the Adam optimizer with default learning rate and training stops after 2 epochs without accuracy increase on dev set.

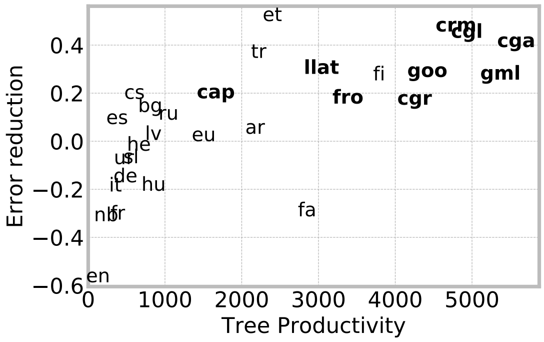

Figure 5: Error reduction of best encoder-decoder model vs best tree-edit model over tree productivity computed as number of unique binary edit-trees in the first 50k tokens of the training corpora (Spearman's $R = 0.79$; $p < .001$). Historical languages are shown in bold.

Accuracy on unknown tokens We observe that while overall the joint loss outperforms the simpler encoder-decoder, it seems, however, detrimental to the accuracy on unknown tokens. This discrepancy is probably due to the fact that (i) unknown tokens are likely unambiguous and therefore less likely to profit from improved context representations and to (ii) our design choice of word-level language modeling, where the model is forced to predict UNK for unknown words. As `Sent-LM` is the overall best model, in future work we will explore character-level language modeling in order to harness the full potential of the joint-training approach even on unknown tokens.

7 Conclusion

We have presented a method to improve lemmatization with encoder-decoder models by improving context representations with a joint bidirectional language modeling loss. Our method sets a new state-of-the-art for lemmatization of historical languages and is competitive on standard languages. Our examination of the learned representations indicates that the LM loss helps enriching sentence representations with features that capture morphological information. In view of a typologically informed comparison of encoder-decoder and edit-tree based approaches, we have shown that the latter can be very effective for highly synthetic languages. Such result might have been overlooked in previous studies due to only considering a reduced number of languages (Chakrabarty et al., 2017) or pooling results across typology (Bergmanis and Goldwater, 2018). With respect to languages with higher ambiguity and token-lemma ratio, the encoder-decoder approach is preferable and the joint loss generally provides a substantial improvement. Finally, while other models use morphological information to improve the representation of context (e.g. edit-tree approaches), our joint language modeling loss does not rely on any additional annotation, which can be crucial in low resource and non-standard situations where annotation is costly and often not trivial.

Acknowledgments

We thank NVIDIA for donating 1 GPU that was used for the experiments in the present paper. We would also like to thank the anonymous reviewers for their valuable comments.

Abstract

Recent work has shown that contextualized word representations derived from neural machine translation are a viable alternative to such from simple word predictions tasks. This is because the internal understanding that needs to be built in order to be able to translate from one language to another is much more comprehensive. Unfortunately, computational and memory limitations as of present prevent NMT models from using large word vocabularies, and thus alternatives such as subword units (BPE and morphological segmentations) and characters have been used. Here we study the impact of using different kinds of units on the quality of the resulting representations when used to model morphology, syntax, and semantics. We found that while representations derived from subwords are slightly better for modeling syntax, character-based representations are superior for modeling morphology and are also more robust to noisy input.

1 Introduction

Recent years have seen the revolution of deep neural networks and the subsequent rise of representation learning based on network-internal activations. Such representations have been shown useful when addressing various problems from fields such as image recognition (He et al., 2016), speech recognition (Bahdanau et al., 2016), and natural language processing (NLP) (Mikolov et al., 2013a). The central idea is that the internal representations trained to solve an NLP task could be useful for other tasks as well. For example, word embeddings learned for a simple word prediction task in context, word2vec-style (Mikolov et al., 2013b), have now become almost obligatory in state-of-the-art NLP models. One issue with such word embeddings is that the resulting representation is context-independent.

Recently, it has been shown that huge performance gains can be achieved by contextualizing the representations, so that the same word could have a different embedding in different contexts. This is best achieved by changing the auxiliary task. For example, ELMo (Peters et al., 2018) learns contextualized word embeddings from language modeling (LM) using long short-term memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997).

It has been further argued that complex auxiliary tasks such as neural machine translation (NMT) are better tailored for representation learning, as the internal understanding of the input language that needs to be built by the network to be able to translate from one language to another needs to be much more comprehensive compared to what would be needed for a simple word prediction task. This idea is implemented in the seq2seq-based CoVe model (McCann et al., 2017).

More recently, the BERT model (Devlin et al., 2019) proposed to use representation from another NMT model, the Transformer, while optimizing for two LM-related auxiliary tasks: (*i*) masked language model and (*ii*) next sentence prediction.

Another important aspect of representation learning is the basic unit the model operates on. In word2vec-style embeddings, it is the word, but this does not hold for NMT-based models, as computational and memory limitations, as of present, prevent NMT from using a large vocabulary, typically limiting it to 30-50k words (Wu et al., 2016). This is a severe limitation, as most NLP applications need to handle vocabularies of millions of words, e.g., word2vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014) and FastText (Mikolov et al., 2018) offer pre-trained embeddings for 3M, 2M, and 2.5M words/phrases. The problem is typically addressed using byte-pair encoding (BPE), where words are segmented into pseudo-word sequences (Sennrich et al., 2016).

Proceedings of NAACL-HLT 2019, pages 1504–1516
Minneapolis, Minnesota, June 2 - June 7, 2019.

A less popular solution is to use characters as the basic unit (Chung et al., 2016; Lee et al., 2017), and in the case of morphologically complex languages, yet another alternative is to reduce the vocabulary size by using unsupervised morpheme segmentation (Bradbury and Socher, 2016).

The impact of using different units of representation in NMT models has been studied in previous work (Ling et al., 2015; Costa-jussà and Fonollosa, 2016; Chung et al., 2016; Lee et al., 2017, among others), but the focus has been exclusively on the quality of the resulting translation output. However, it remains unclear what input and output units should be chosen if we are primarily interested in representation learning. Here, we aim at bridging this gap by evaluating the quality of NMT-derived embeddings originating from units of different granularity when used for modeling morphology, syntax, and semantics (as opposed to end tasks such as sentiment analysis and question answering). Our contributions are as follows:

- We study the impact of using words vs. characters vs. BPE units vs. morphological segments on the quality of representations learned by NMT models when used to model morphology, syntax, and semantics.
- We further study the robustness of these representations with respect to noise.

We found that while representations derived from morphological segments are better for modeling non-local syntactic and semantic dependencies, character-based ones are superior for morphology and are also more robust to noise. There is also value in combining different representations.

2 Related Work

Representation analysis aims at demystifying what is learned inside the neural network blackbox. This includes analyzing word and sentence embeddings (Adi et al., 2017; Qian et al., 2016b; Ganesh et al., 2017; Conneau et al., 2018, among others), RNN states (Qian et al., 2016a; Shi et al., 2016; Wu and King, 2016; Wang et al., 2017), and NMT representations (Shi et al., 2016; Belinkov et al., 2017a), as applied to morphological (Vylomova et al., 2017; Dalvi et al., 2017), semantic (Qian et al., 2016b; Belinkov et al., 2017b) and syntactic (Linzen et al., 2016; Tran et al., 2018; Conneau et al., 2018) tasks. See Belinkov and Glass (2019) for a recent survey. Other studies carried a more fine-grained neuron-level analysis for NMT and LM (Dalvi et al., 2019; Bau et al., 2019; Lakretz et al., 2019). While previous work focused on words, here we compare units of different granularities.

Subword translation units aim at reducing the vocabulary size and the out-of-vocabulary (OOV) rate. Researchers have used BPE units (Sennrich et al., 2016), morphological segmentation (Bradbury and Socher, 2016), characters (Durrani et al., 2014; Lee et al., 2017), and hybrid units (Ling et al., 2015; Costa-jussà and Fonollosa, 2016) to address the OOV word problem in MT. The choice of translation unit impacts what the network learns. Sennrich (2017) carried a systematic error analysis by comparing subword versus character units and found the latter to be better at handling OOV and transliterations, whereas BPE-based subword units were better at capturing syntactic dependencies. In contrast, here we focus on representation learning, not translation quality.

Robustness to noise is an important aspect in machine learning. It has been studied for various models (Szegedy et al., 2014; Goodfellow et al., 2015), including NLP in general (Papernot et al., 2016; Samanta and Mehta, 2017; Liang et al., 2018; Jia and Liang, 2017; Ebrahimi et al., 2018; Gao et al., 2018), and character-based NMT in particular (Heigold et al., 2018; Belinkov and Bisk, 2018). Unlike this work, we compare robustness to noise for units of different granularity. Moreover, we focus on representation learning rather than on the quality of the translation output.

3 Methodology

Our methodology is inspired by research on interpreting neural network (NN) models. A typical framework involves extracting feature representations from different components (e.g., encoder/decoder) of a trained model and then training a classifier to make predictions for an auxiliary task. The performance of the trained classifier is considered to be a proxy for judging the quality of the extracted representations with respect to the particular auxiliary task.

Formally, for each input word $\mathbf{x}_i$ we extract the corresponding LSTM hidden state(s) from each layer of the encoder/decoder. We then concatenate the representations of the layers and use them as a feature vector $\mathbf{z}_i$ for the auxiliary task.

Words	Obama	receives	Netanyahu	in	the	capital	of	USA
POS	NP	VBZ	NP	IN	DT	NN	IN	NP
Sem.	PER	ENS	PER	REL	DEF	REL	REL	GEO
CCG	NP	((S[dcl]\NP)/PP)/NP	NP	PP/NP	PP/N	N	(NP\NP)/NP	NP

Table 1: Example sentence with different annotations.

Words	He admits to shooting girlfriend
BPE	He admits to sho@@ oting gir@@ l@@ friend
Morfessor	He admit@@ s to shoot@@ ing girl@@ friend
Characters	H e _ a d m i t s _ t o _ s h o o t i n g _ g i r l f r i e n d

Table 2: Example with different segmentations.

We then train a logistic regression classifier, minimizing the cross-entropy loss:

$$\mathcal{L}(\theta) = -\sum_i \log P_\theta(\mathbf{l}_i|\mathbf{x}_i)$$

where $P_\theta(\mathbf{l}|\mathbf{x}_i) = \frac{\exp(\theta_l \cdot \mathbf{z}_i)}{\sum_{l'} \exp(\theta_{l'} \cdot \mathbf{z}_i)}$ is the probability that word $\mathbf{x}_i$ is assigned label $\mathbf{l}$.

We learn the weights $\theta \in \mathbb{R}^{D \times L}$ using gradient descent. Here D is the dimensionality of the latent representations $\mathbf{z}_i$ and L is the size of the label set for property $\mathcal{P}$. See Section 4 for details.

3.1 Word Representation Units

We consider four representation units: words, byte-pair encoding (BPE) units, morphological units, and characters. Table 2 shows an example of each representation unit. *BPE* splits words into symbols (a symbol is a sequence of characters) and then iteratively replaces the most frequent sequences of symbols with a new merged symbol. In essence, frequent character n-grams merge to form one symbol. The number of merge operations is controlled by a hyper-parameter `OP`; a high value of `OP` means coarse segmentation and a low value means fine-grained segmentation (Sajjad et al., 2017). For *morphologically segmented units*, we use an unsupervised morphological segmenter, Morfessor (Smit et al., 2014). Note that although BPE and Morfessor segment words at a similar level of granularity, the segmentation generated by Morfessor is linguistically motivated. For example, it splits the gerund verb *shooting* into root *shoot* and the suffix *ing*. Compare this to the BPE segmentation *sho* + *oting*, which has no linguistic connotation. On the extreme, the fully *character-level* units treat each word as a sequence of characters.

3.2 Extracting Activations for Subword and Character Units

Previous work on analyzing NMT representations has been limited to the analysis of word representations only,[1] where there is a one-to-one mapping from input units (words) and their NMT representations (hidden states) to their linguistic annotations (e.g., morphological tags).

In the case of subword-based systems, each word may be split into multiple subword units, and each unit has its own representation. It is less trivial to define which representations should be evaluated when predicting a word-level linguistic property such as part of speech. We consider two simple approximations to estimate a word representation from subword units:

(*i*) **Average**: for each source (or target) word, we average the activation values of all the subwords (or characters) comprising it. In the case of a bi-directional encoder, we concatenate the averages from the forward and the backward activations of the encoder on the subwords (or characters) that represent the current word.[2]

(*ii*) **Last**: we consider the activation of the last subword (or character) as the representation of the word. For the bi-directional encoder, we concatenate the forward encoder's activation on the last subword unit with the backward encoder's activation on the first subword unit.

This formalization allows us to analyze the quality of character- and subword-based representations at the word level via prediction tasks. Such kind of analysis has not been performed before.

---

[1] Belinkov et al. (2017a) analyzed representations trained from character CNN models (Kim et al., 2016), but the extracted features were still based on word representations produced by the character CNN. As a result, they could not analyze and compare results for the BPE and character-based models that do not assume segmentation into words.

[2] One could envision more sophisticated averages, such as weighting via an attention mechanism.

4 Linguistic Properties

We choose three fundamental NLP tasks that serve as a good representative of various properties inherent in a language, ranging from morphology (word structure), syntax (grammar), and semantics (meaning). In particular, we experiment with *morphological tagging* for German, Czech, Russian, and English,[3] *lexical semantic tagging* for English and German, and *syntactic tagging* via CCG supertagging for English. Table 1 shows an example sentence with annotations for each task.

The morphological tags capture word structure, the semantic tags reflect lexical semantics, and the syntactic tags (CCG supertags) capture global syntactic information locally, at the lexical level.

For example, in Table 1, the morphological tag `VBZ` for the word *receives* marks it as a verb in third person, singular, present tense; the semantic tag `ENS` describes a *present simple event* category; and the syntactic tag `PP/NP`) can be thought of as a function that takes a noun phrase on the right (e.g., *the capital of USA*), and returns a prepositional phrase (e.g., *in the capital of USA*).

Artificial Error Induction Recent studies have shown that small perturbations in the input can cause significant deterioration in the performance of the deep neural networks. Here, we evaluate the robustness of various representations under noisy input conditions. We use corpora of real errors harvested by Belinkov and Bisk (2018). The errors contain a good mix of typos, misspellings, and other kinds of errors. In addition, we created data with synthetic noise. We induced two kinds of errors: (*i*) *swap* and (*ii*) *middle*. *Swap* is a common error, which occurs when neighboring characters are mistakenly swapped, e.g., *word* → *wodr*. In *Middle* errors, the order of the first and the last characters of a word are preserved, while the middle characters are randomly shuffled (Rawlinson, 1976), e.g., *example* → *eaxmlpe*. We corrupt $n\%$ words randomly in each test sentence, using *swap* or *middle* heuristics, or replace words using real-error corpora. We then re-extract feature vectors for the erroneous words in a sentence and we re-evaluate the prediction capability of these embeddings on the linguistic tasks.

Table 3: Statistics about NMT and classifier training data for English (en), German (de), Russian (ru), and Czech (cs). Here, CV stands for cross-validation.

5 Experimental Setup

Data and Languages We trained NMT systems for four language pairs: German-English, Czech-English, Russian-English, and English-German, using data made available through two popular machine translation campaigns, namely, WMT (Bojar et al., 2017) and IWSLT (Cettolo et al., 2016). We trained the MT models using a concatenation of the NEWS and the TED training datasets, and we tested on official TED test sets (testsets-11-13) to perform the evaluation using BLEU (Papineni et al., 2002). We trained the morphological classifiers and we tested them on a concatenation of the NEWS and the TED testsets, which were automatically tagged as described in the next paragraph. We trained and evaluated the semantic and the syntactic classifiers on existing annotated corpora. See Table 3 for details about the datasets.

---

[3] As English is morphologically poor, we use part-of-speech tags for it. We refer to English part-of-speech tags as morphological tags later in the paper in order to keep the terminology consistent.

Taggers We used RDRPOST (Nguyen et al., 2014) to annotate data for the classifier. For semantic tagging, we used the gold-annotated semantic tags from the Groningen Parallel Meaning Bank (Abzianidze et al., 2017), which were made available by (Bjerva et al., 2016). The tags are grouped into coarse categories such as events, names, time, and logical expressions. There is enough data for English (≈42K), and we randomly sampled the same amount of data we used to train our morphological classifiers to train the semantic classifiers. Yet, only 1,863 annotated sentences (12,783 tokens) were available for German. Thus, in the experiments, we performed 5-fold cross-validation. For CCG supertagging, we used the English CCGBank (Hockenmaier and Steedman, 2007), which contains 41,586/2,407 train/test sentences.[4] See Table 3 for more detailed statistics about the train/dev/test datasets we used.

MT Systems and Classifiers We used `seq2seq-attn` (Kim, 2016) to train a two-layer encoder-decoder NMT model based on LSTM representation with attention (Hochreiter and Schmidhuber, 1997) with a bidirectional encoder and a unidirectional decoder.[5] We used 500 dimensions for both word embeddings and LSTM states. We trained the systems with SGD for 20 epochs and we used the final model, i.e., the one with the lowest loss on the development dataset, to generate features for the classifier.

We trained our neural machine translation models in both *-to-English and English-to-* translation directions, and we analyzed the representations from both the *encoder* and the *decoder*. In order to analyze the representations derived from the encoder side, we fixed the decoder side with BPE-based embeddings, and we trained the source side with word/BPE/Morfessor/character units. Similarly, when analyzing the representations from the decoder side, we trained the encoder representation with BPE units, and we varied the decoder side using word/BPE/char units. Our motivation for this setup is that we wanted to analyze the encoder/decoder side representations in isolation, keeping the other half of the network (i.e., the decoder/encoder) static across different settings.[6]

In our experiments, we used 50k BPE operations and we limited the vocabulary of all systems to 50k. Moreover, we trained the word, BPE, Morfessor, and character-based systems with maximum sentence lengths of 80, 100, 100, and 400 units, respectively.

For the classification tasks, we used a logistic regression classifier whose input is either the hidden states in the case of the word-based models, or the **Last** or the **Average** representations in the case of character- and subword-based models. Since for the bidirectional encoder we concatenate forward and backward states from all layers, this yields 2,000/1,000 dimensions when classifying using the representations from the encoder/decoder: 500 dimensions×2 layers×2 directions (1 for the decoder, as it is uni-directional). In all cases, we trained the logistic regression classifier for ten epochs.

6 Results

We now present the evaluation results for using representations learned from different input units to predict morphology, semantics, and syntax. For subword and character units, we found the activation of the last subword/character unit of a word to be consistently better than using the average of all activations (See Table 4). Therefore, we report only the results using the **Last** method, for the remainder of the paper.

	de		cs		ru	
	sub	char	sub	char	sub	char
Last	78.5	80.5	78.6	88.3	80.0	88.8
Avg	76.3	79.2	76.4	84.9	78.3	84.4

Table 4: Classifier accuracy for the representations generated by aggregating subword (sub) or character (char) representations using either the average or the last LSTM state for each word.

6.1 Morphological Tagging

Figure 1 summarizes the results for predicting morphological tags with representations learned using different units. The character-based representations consistently outperformed other representations on all language pairs, while the word-based ones performed worst. The differences are more significant in the case of languages with relatively complex morphology such as Czech.

---

[4] There are no available CCG banks for the other languages we experiment with, except for a German CCG bank, which is not publicly available (Hockenmaier, 2006).

[5] The decoder has to be unidirectional as, at decoding time, the future is unknown.

[6] Heigold et al. (2018) used a similar setup.

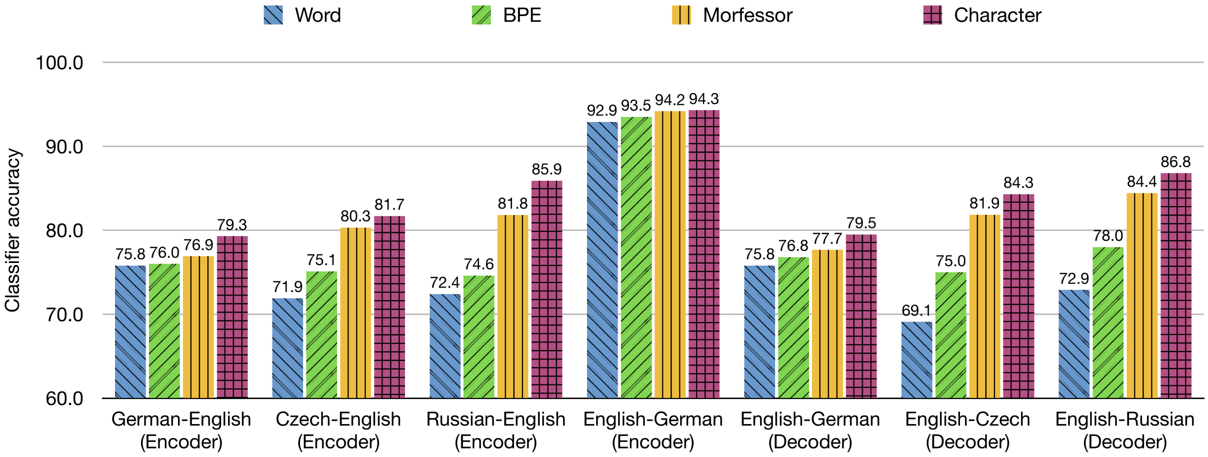

Figure 1: Morphological tagging accuracy across various systems and language pairs. The first four groups of results use BPE on the decoder side, while the last three groups use BPE on the encoder side.

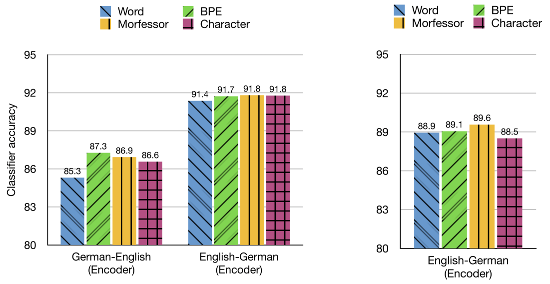
MT	3.42	6.46	6.86	0.82
Classifier	4.42	6.13	6.61	2.09

Table 6: OOV rate for the MT and the classifier testsets.

We see in Figure 1 a difference of up to 14% in favor of character-based representations when compared with word-based ones. The improvement is minimal in the case of English (1.2%), which is a morphologically simpler language. This is also somewhat reflected in the translation quality.

We can see in Table 5 that character-based segmentation yielded higher BLEU scores in the case of a morphologically rich language such as Czech, but performed poorly in the case of German, which requires handling long-distance dependencies. Comparing subword units, we found Morfessor to yield much better morphological tagging performance, especially in the case of morphologically rich languages such as Czech and Russian, supposedly due to the Morfessor's linguistically motivated segmentations, which are helpful for learning morphology.

We further investigated whether the performance difference between the representations is due to the difference in modeling infrequent and out-of-vocabulary (OOV) words. Table 6 shows the OOV rate for each language, which is higher for morphologically rich languages. Figure 2 shows that the gap between different representations is inversely proportional to the frequency of



(a) Semantic tagging. (b) Syntactic tagging.

Figure 3: Semantic and syntactic tagging for English and German (using BPE on the decoder).

the word in the training data, and character-based models handle infrequent and OOV words better.

Decoder Representations Next, we used the decoder representations from the English-to-* models. We saw similar performance trends as for the encoder-side representations: characters performed best, and words performed worst. Again, the morphological units performed better than the BPE-based units. Comparing encoder representations to decoder representations, it is interesting to see that in several cases the decoder side representations performed better than the encoder side ones, even though the former were trained using a uni-directional LSTM. However, since there is no difference in the general trends between the encoder- and the decoder-side representations, below we focus on the encoder-side only.

6.2 Semantic Tagging

Figure 3a summarizes the experimental results for evaluating representtaion units of the semantic tagging task. For English, the subword (BPE and Morfessor) and the character representations yielded comparable results. However, for German, BPE performed better. This is in contrast with the morphology prediction experiments, where the character representations were consistently better. We will discuss this in more detail in Section 7.

6.3 Syntactic Tagging

The final task we experimented with is CCG super-tagging, which reflects modeling syntactic structure. Here we only have English tags, and thus we evaluate the performance of encoder representations for English→German models, trained using words, characters, and subword units.

We can see in Figure 3b that the morphologically segmented representation units performed the best overall. Moreover, there is no much difference when using word-based vs. BPE-based representations.

The character-based representations lag behind, but the difference in accuracy is small compared to the morphological tagging results.[7] It is noteworthy that here character-based representations perform worse than both words and subwords, contrary to their superior performance on morphology. We will return to this in Section 7 below.

6.4 Robustness to Noise

Next, we evaluated the robustness of the representations with respect to noise. We induced errors in the test sets by corrupting 25% of the words in each sentence using different error types (synthetic or real noise), as described in Section 4. We extracted the representations of the noisy test sets and we re-evaluated the classifiers. Figure 4 shows the performance on each task. We can see that characters yielded much better performance on all tasks and for all languages, showing minimal drop in accuracy, in contrast to earlier results where they did not outperform subword units[8] on the task of syntactic tagging. This shows that character representations are more robust to noise.

Surprisingly, in a few cases, BPE performed worse than word units, e.g., in the case of syntactic tagging (80.3 vs. 81.1). We found that BPE can segment a noisy word into two or more known subword units that have no real relationship to the actual word. Thus, using representations of wrong subword units could hurt the performance.

We further investigated the robustness of each classifier by increasing the percentage of noise in the test data. We found that the difference in representation quality stays constant across BPE and character representations, whereas word representations deteriorate significantly as the amount of noise increases (see Figure 5).

7 Discussion

7.1 Performance Across Various Tasks

Our experiments show a complicated picture, where none of the representations is superior in all scenarios. Characters were found to be better for morphological tagging, BPE was ahead in

---

[7] For perspective, these numbers are above a majority class baseline of 72% and below the state-of-the-art, which is around 94-95% (Kadari et al., 2018; Xu, 2016).

[8] Morphological segmentation showed similar results compared to BPE-based segmentation in these experiments.

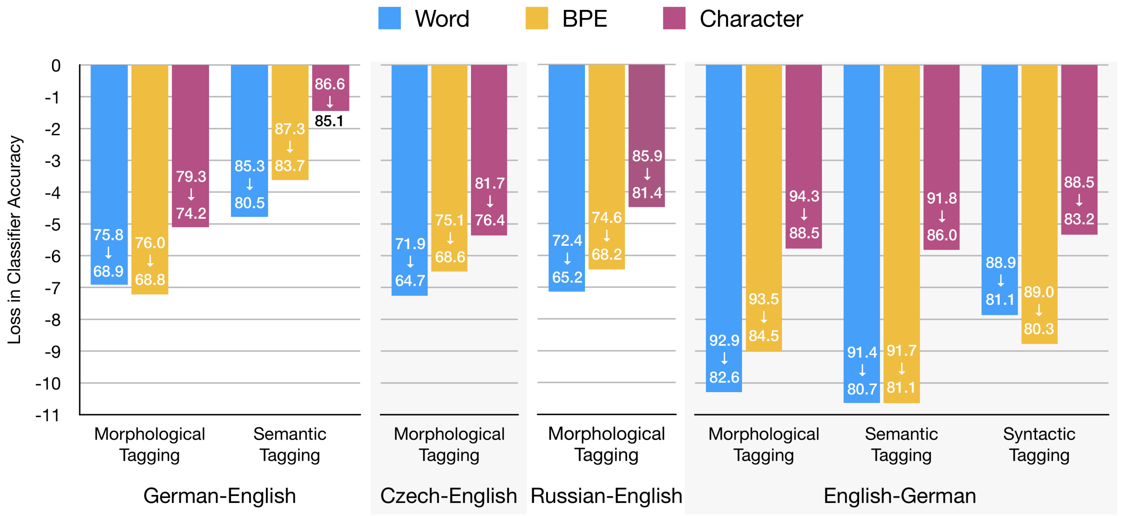


Figure 4: Classification accuracy for morphological, syntactic and semantic tagging with 25% noise in each sentence. Absolute scores (original → noisy) are shown inset.

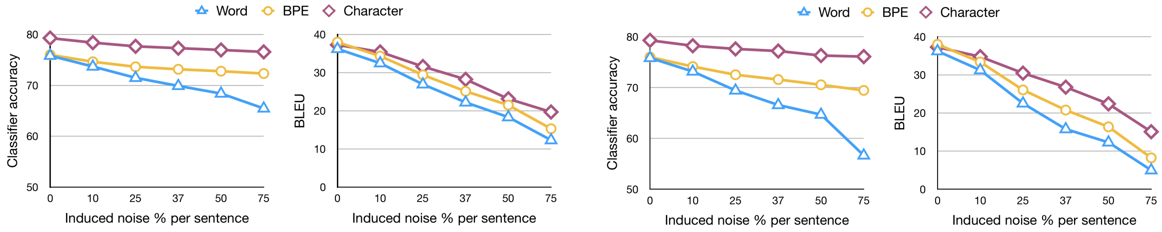

(a) Real noise.

(b) Synthetic noise.

Figure 5: Results for morphological classification when adding induced noise.

the semantic tagging task for German (and about the same in English), and Morfessor units were slightly better for syntax.

Syntactic tagging requires knowledge about the complete sentence. Splitting a sentence into characters substantially increases its length: on average from 50 words to 250 single-character tokens. Thus, character-based models struggle to capture long-distance dependencies. Sennrich (2017) also found this to be true in their evaluation based on contrastive translation pairs in German-English.

Similarly, in the case of morphological tagging, the information about the morphological structure of a word is dependent on the surrounding words plus some internal information (root, morphemes, etc.) present inside the word. A character-based system has access to all of this information, and thus performs well. Morphological segmentation performed better than BPE for the morphological tagging because its segments are linguistically motivated units (segmented into root + morphemes), thus making the information about the word morphology explicit in the representation. In contrast, BPE solely focuses on the frequency of characters occurring together in the corpus, and thus can generate linguistically incorrect units.

		W	B	C	W+B	B+C	W+C	ALL

Table 7: Classification accuracy for combined representations for morphological and semantic tagging. Here, W/B/C stand for word/BPE/character units.

7.2 The Best of Many Worlds

The variations in performance for different representations suggest that they are learning different aspects of language, which might be complementary. Thus, we tried to combine them. Table 7 summarizes the results for morphological and semantic tagging.[9] We can see that combinations involving characters (B+C, W+C in the table) yield

---

[9] We observed similar trends for the other tasks.

larger improvement compared to combining word- and BPE-based representations (W+B). However, combining all three performed best for all languages and for all tasks.

7.3 State-of-the-Art Embeddings

We connect our findings with recent work on training state-of-the-art embeddings: CoVe (McCann et al., 2017), ELMo (Peters et al., 2018), and BERT (Devlin et al., 2019). Each of these architectures uses different units of representations: e.g., CoVe uses words, BERT is based on subword units, while ELMo focuses on characters.[10]

We speculate that, although these models yield state-of-the-art results for several tasks, their performance may be suboptimal because of the choice of their underlying representation units. In our experiments above, we have shown that it is possible to achieve potentially better performance when using units of different granularity jointly.

We have further shown that the best-performing representation unit is target task-dependent. We believe this would be true for more complex NLP tasks as well. For example, question answering generally requires learning long-range dependencies, and thus embeddings from a character-based model might not be the right choice in this case. Our results show that character-based models are not a viable option for handling long-range dependencies, and subword-based representations might be a better option for such tasks.

7.4 Translation vs. Representation Quality

Table 5 summarizes the translation performance of each system. We can see that in most cases, the subword-based systems perform better than the word-based and the character-based ones. However, this is not true in the case of using their representations as features for a core NLP task as in our experiments above. For example, we have found that character-based representations perform best for the morphological tagging task. On a side note, although BPE-based representations perform better for some tasks, they are sensitive to noise. Their capability of segmenting any OOV word into known subwords may result in less reliable systems. Notably, the translation performance of the BPE-based system can fall below that of the character-based system even in the presence of only 10% noise: from 0.7 BLEU in favor of BPE on clean data to 0.8/1.1 BLEU in favor of characters with synthetic/real errors.

8 Conclusion and Future Work

We studied the impact of using different representation units—words, characters, BPE units, and morphological segments—on the representations learned by seq2seq models trained for neural machine translation. In particular, we evaluated the performance of such representations on core natural language processing tasks modeling morphology, syntax, and semantics.

Based on our experiments, we can make the following conclusions:

- Representations derived from subword units are better for modeling syntax.
- Character-based representations are distinctly better for modeling morphology.
- Character-based representations are very robust to noise.
- Using a combination of different representations often works best.

Based on our findings, we further conjecture that although subword-based segmentation based on BPE are a de-facto standard when building state-of-the-art NMT systems, the underlying representations they yield are suboptimal for many external tasks. Character-based representations provide a more viable and robust alternative in this regard, followed by morphological segmentation.

In future work, we plan to study how different units affect representation quality in non-recurrent models such as the Transformer (Vaswani et al., 2017) as well as in convolutional architectures (Gehring et al., 2017). We would also like to explore representations from robustly trained systems, which should improve performance on noisy input (Belinkov and Bisk, 2018; Heigold et al., 2018). Finally, it would be interesting to study representations in other NLP tasks besides neural machine translation.

Acknowledgements

This work was funded by the QCRI, HBKU, as part of the collaboration with the MIT, CSAIL. Yonatan Belinkov was also partly supported by the Harvard Mind, Brain, and Behavior Initiative.

---

[10] However, note that ELMo uses character convolutions, which is different from a fully character-based model.

A Simple Joint Model for Improved Contextual Neural Lemmatization

Chaitanya Malaviya[*,β] and **Shijie Wu**[*,ə] and **Ryan Cotterell**[ə,ﬁ]

Abstract

English verbs have multiple forms. For instance, *talk* may also appear as *talks*, *talked* or *talking*, depending on the context. The NLP task of lemmatization seeks to map these diverse forms back to a canonical one, known as the lemma. We present a simple joint neural model for lemmatization and morphological tagging that achieves state-of-the-art results on 20 languages from the Universal Dependencies corpora. Our paper describes the model in addition to training and decoding procedures. Error analysis indicates that joint morphological tagging and lemmatization is especially helpful in low-resource lemmatization and languages that display a larger degree of morphological complexity. Code and pre-trained models are available at `https://sigmorphon.github.io/sharedtasks/2019/task2/`.

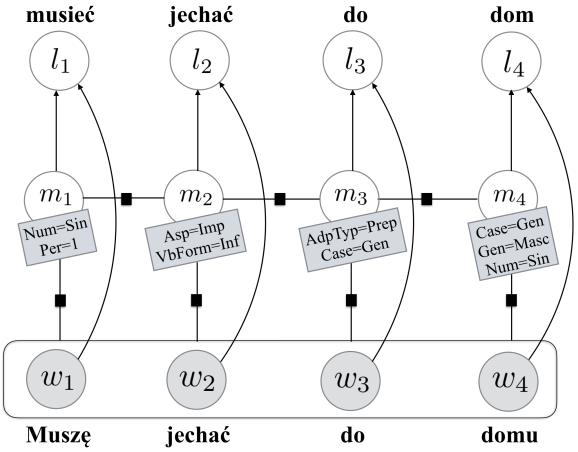

Figure 1: Our structured neural model shown as a hybrid (directed-undirected) graphical model (Koller and Friedman, 2009). Notionally, the w_i denote inflected word forms, the m_i denote morphological tags and the ℓ_i denote lemmata.

1 Introduction

Lemmatization is a core NLP task that involves a string-to-string transduction from an inflected word form to its citation form, known as the lemma. More concretely, consider the English sentence: *The bulls are running in Pamplona*. A lemmatizer will seek to map each word to a form you may find in a dictionary—for instance, mapping *running* to *run*. This linguistic normalization is important in several downstream NLP applications, especially for highly inflected languages. Lemmatization has previously been shown to improve recall for information retrieval (Kanis and Skorkovská, 2010; Monz and De Rijke, 2001), to aid machine translation (Fraser et al., 2012; Chahuneau et al., 2013) and is a core part of modern parsing systems (Björkelund et al., 2010; Zeman et al., 2018).

However, the task is quite nuanced as the proper choice of the lemma is context dependent. For instance, in the sentence *A running of the bulls took place in Pamplona*, the word *running* is its own lemma, since, here, *running* is a noun rather than an inflected verb. Several counter-examples exist to this trend, as discussed in depth in Haspelmath and Sims (2013). Thus, a good lemmatizer must make use of some representation of each word's sentential context. The research question in this work is, then, how do we design a lemmatization model that best extracts the morpho-syntax from the sentential context?

Recent work (Bergmanis and Goldwater, 2018) has presented a system that directly summarizes the sentential context using a recurrent neural network to decide how to lemmatize. As Bergmanis and Goldwater (2018)'s system currently achieves state-of-the-art results, it *must* implicitly learn a contextual representation that encodes the necessary morpho-syntax, as such knowledge is requisite for the task. We contend, however, that rather than expecting the network to *implicitly* learn some no-

Translation:	All	happy	families	are similar		to each other	

Figure 2: Example of a morphologically tagged (in purple) and lemmatized (in red) sentence in Russian using the annotation scheme provided in the UD dataset. The translation is given below (in blue).

tion of morpho-syntax, it is better to *explicitly* train a joint model to morphologically disambiguate and lemmatize. Indeed, to this end, we introduce a joint model for the introduction of morphology into a neural lemmatizer. A key feature of our model is its *simplicity*: Our contribution is to show how to stitch existing models together into a joint model, explaining how to train and decode the model. However, despite the model's simplicity, it still achieves a significant improvement over the state of the art on our target task: lemmatization.

Experimentally, our contributions are threefold. First, we show that our joint model achieves state-of-the-art results, outperforming (on average) all competing approaches on a 20-language subset of the Universal Dependencies (UD) corpora (Nivre et al., 2017). Second, by providing the joint model with gold morphological tags, we demonstrate that we are far from achieving the upper bound on performance—improvements on morphological tagging could lead to substantially better lemmatization. Finally, we provide a detailed error analysis indicating *when* and *why* morphological analysis helps lemmatization. We offer two tangible recommendations: one is better off using a joint model (i) for languages with fewer training data available and (ii) languages that have richer morphology.

Our system and pre-trained models on all languages in the latest version of the UD corpora[1][2] are released at `https://sigmorphon.github.io/sharedtasks/2019/task2/`.

2 Background: Lemmatization

Most languages (Dryer and Haspelmath, 2013) in the world exhibit a linguistic phenomenon known as **inflectional morphology**, which causes word forms to mutate according to the syntactic category of the word. The syntactic context in which the word form occurs determines which form is properly used. One privileged form in the set of inflections is called the **lemma**. We regard the lemma as a lexicographic convention, often used to better organize dictionaries. Thus, the choice of which inflected form is the lemma is motivated by tradition and convenience, e.g., the lemma is the infinitive for verbs in some Indo-European languages, rather than by linguistic or cognitive concerns. Note that the **stem** differs from the lemma in that the stem may not be an actual inflection.[3] In the NLP literature, the syntactic category that each inflected form encodes is called the **morphological tag**. The morphological tag generalizes traditional part-of-speech tags, enriching them with further linguistic knowledge such as tense, mood, and grammatical case. We call the individual key–attribute pairs **morphological attributes**.

An example of a sentence annotated with morphological tags and lemmata in context is given in Figure 2. The task of mapping a sentence to a sequence of morphological tags is known as **morphological tagging**.

Notation. Let $\mathbf{w} = w_1, \ldots, w_n$ be a sequence of n words. Each individual word is denoted as w_i. Likewise, let $\mathbf{m} = m_1, \ldots, m_n$ and $\boldsymbol{\ell} = \ell_1, \ldots, \ell_n$ be sequences of morphological tags and lemmata, respectively. We will denote the set of all tags seen in a treebank as $\mathcal{Y}$. We remark that m_i is w_i's morphological tag (e.g. $[\text{POS}{=}\text{N}, \text{CASE}{=}\text{NOM}, \text{NUM}{=}\text{SG}]$ as a single label) and

---

[1] We compare to previously published numbers on non-recent versions of UD, but the models we release are trained on the current version (2.3).

[2] Instead of UD schema for morphological attributes, we use the UniMorph schema (Sylak-Glassman, 2016) instead. Note the mapping from UD schema to UniMorph schema is not one-to-one mapping (McCarthy et al., 2018).

[3] The stem is also often ill-defined. What is, for instance, the stem of the word *running*, is it *run* or *runn*?

ℓ_i is w_i's lemma. We will denote a language's discrete alphabet of characters as Σ. Thus, we have $w_i, \ell_i \in \Sigma^*$. Furthermore, we $\mathbf{c} = c_1, \ldots, c_n$ be a vector of characters where $c_i \in \Sigma$.

3 A Joint Neural Model

The primary contribution of this paper is a joint model of morphological tagging and lemmatization. The intuition behind the joint model is simple: high-accuracy lemmatization requires a representation of the sentential context, in which the word occurs (this behind has been evinced in §1)—a morphological tag provides the precise summary of the context required to choose the correct lemma. Armed with this, we define our joint model of lemmatization and morphological tagging as:

$$p(\boldsymbol{\ell}, \mathbf{m} \mid \mathbf{w}) = p(\boldsymbol{\ell} \mid \mathbf{m}, \mathbf{w})\, p(\mathbf{m} \mid \mathbf{w}) \quad (1)$$
$$= \left(\prod_{i=1}^{n} \underbrace{p(\ell_i \mid m_i, w_i)}_{\textit{Neural Transducer}} \right) \underbrace{p(\mathbf{m} \mid \mathbf{w})}_{\textit{Neural Tagger}}$$

Figure 1 illustrates the structure of our model in the form of a graphical model. We will discuss the lemmatization factor and the morphological tagging factor following two subsections, separately. We caution the reader that the discussion of these models will be brief: Neither of these particular components is novel with respect to the literature, so the formal details of the two models is best found in the original papers. The point of our paper is to describe a simple manner to combine these existing parts into a state-of-the-art lemmatizer.

3.1 Morphological Tagger: $p(\mathbf{m} \mid \mathbf{w})$

We employ a simple LSTM-based tagger to recover the morphology of a sentence (Heigold et al., 2017; Cotterell and Heigold, 2017). We also experimented with the neural conditional random field of Malaviya et al. (2018), but Heigold et al. (2017) gave slightly better tagging scores on average and is faster to train. Given a sequence of n words $\mathbf{w} = w_1, \ldots, w_n$, we would like to obtain the morphological tags $\mathbf{m} = m_1, \ldots, m_n$ for each word, where $m_i \in \mathcal{Y}$. The model first obtains a word representation for each token using a character-level biLSTM (Graves et al., 2013) embedder, which is then input to a word-level biLSTM tagger that predicts tags for each word. Given a function cLSTM that returns the last hidden state of a character-based LSTM, first we obtain a word representation $\mathbf{u}_i$ for word w_i as,

$$\mathbf{u}_i = [\text{cLSTM}(c_1 \ldots c_n); \text{cLSTM}(c_n \ldots c_1)] \quad (2)$$

where $c_1, \ldots, c_n$ is the character sequence of the word. This representation $\mathbf{u}_i$ is then input to a word-level biLSTM tagger. The word-level biLSTM tagger predicts a tag from $\mathcal{Y}$. A full description of the model is found in Heigold et al. (2017). We use standard cross-entropy loss for training this model and decode greedily while predicting the tags during test-time. Note that greedy decoding is optimal in this tagger as there is no interdependence between the tags m_i.

3.2 A Lemmatizer: $p(\ell_i \mid m_i, w_i)$

Neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) have yielded state-of-the-art performance on the task of generating morphological variants—including the lemma—as evinced in several recent shared tasks on the subject (Cotterell et al., 2016, 2017, 2018). Our lemmatization factor in eq. (1) is based on such models. Specifically, we make use of a hard-attention mechanism (Xu et al., 2015; Rastogi et al., 2016), rather than the original soft-attention mechanism. Our choice of hard attention is motivated by the performance of Makarov and Clematide (2018)'s system at the CoNLL-SIGMORPHON task. We use a nearly identical model, but opt for an exact dynamic-programming-based inference scheme (Wu et al., 2018).[4]

We briefly describe the model here. Given an inflected word w and a tag m, we would like to obtain the lemma $\ell \in \Sigma^*$, dropping the subscript for simplicity. Moreover, for the remainder of *this* section the subscripts will index into the character string ℓ, that is $\ell = \ell_1, \ldots, \ell_{|\ell|}$, where each $\ell_i \in \Sigma$. A character-level biLSTM encoder embeds w to $\mathbf{h}^{(enc)}$. The decoder LSTM produces $\mathbf{h}^{(dec)}_j$, reading the concatenation of the embedding of the previous character $\ell_{j-1} \in \Sigma$ and the tag embedding $\mathbf{h}^{(tag)}$, which is produced by an order-invariant linear function. In contrast to soft attention, hard attention models the alignment distribution explicitly.

We denote $A = \{a_1, \ldots, a_{|w|}\}^{|\ell|}$ as the set of all monotonic alignments from w to ℓ where an alignment aligns each target character ℓ_j to exactly one source character in w and for $\mathbf{a} \in A$, $a_j = i$

---

[4] Our formulation differs from the work of Wu et al. (2018) in that we enforce monotonic hard alignments, rather than allow for non-monotonic alignments.

refers to the event that the j^{th} character of ℓ is aligned to the i^{th} character of w. We factor the probabilistic lemmatizer as,

$$p(\ell \mid m, w) = \sum_{\mathbf{a} \in A} p(\ell, \mathbf{a} \mid m, w) \tag{3}$$

$$= \sum_{\mathbf{a} \in A} \prod_{j=1}^{|\ell|} p(\ell_j \mid a_j, \ell_{<j}, m, w) \tag{4}$$
$$p(a_j \mid a_{j-1}, \ell_{<j}, m, w)$$

$$= \sum_{\mathbf{a} \in A} \prod_{j=1}^{|\ell|} p(\ell_j \mid \mathbf{h}^{(enc)}_{a_j}, \mathbf{h}^{(dec)}_j) \tag{5}$$
$$p(a_j \mid a_{j-1}, \mathbf{h}^{(enc)}, \mathbf{h}^{(dec)}_j)$$

The summation is computed with dynamic programming—specifically, using the forward algorithm for hidden Markov models (Rabiner, 1989). $p(\ell_j \mid \mathbf{h}^{(enc)}_{a_j}, \mathbf{h}^{(dec)}_j)$ is a two-layer feed-forward network followed by a softmax. The transition $p(a_j \mid a_{j-1}, \mathbf{h}^{(enc)}, \mathbf{h}^{(dec)}_j)$ is the multiplicative attention function with $\mathbf{h}^{(enc)}$ and $\mathbf{h}^{(dec)}_j$ as input. To enforce monotonicity, $p(a_j \mid a_{j-1}) = 0$ if $a_j < a_{j-1}$.

3.3 Decoding

We consider two manners, by which we decode our model. The first is a greedy decoding scheme. The second is a **crunching** (May and Knight, 2006) scheme. We describe each in turn.

Greedy Decoding. In the greedy scheme, we select the best morphological tag sequence

$$\mathbf{m}^\star = \text{argmax}_{\mathbf{m}} \log p(\mathbf{m} \mid \mathbf{w}) \tag{6}$$

and then decode each lemmata

$$\ell_i^\star = \text{argmax}_\ell \log p(\ell \mid m_i^\star, w_i) \tag{7}$$

Note that we slightly abuse notation since the argmax here is *approximate*: exact decoding of our neural lemmatizer is hard. This sort of scheme is also referred to as pipeline decoding.

Crunching. In the crunching scheme, we first extract a k-best list of taggings from the morphological tagger. For an input sentence $\mathbf{w}$, call the k-best tags for the i^{th} word $\mathcal{K}(w_i)$. Crunching then says we should decode in the following manner

$$\ell_i^\star = \text{argmax}_\ell \tag{8}$$
$$\log \sum_{m_i \in \mathcal{K}(w_i)} p(\ell \mid m_i, w_i)\, p(m_i \mid \mathbf{w})$$

Crunching is a tractable heuristic that approximates true joint decoding[5] and, as such, we expect it to outperform the more naïve greedy approach.

3.4 Training with Jackknifing

In our model, a simple application of maximum-likelihood estimation (MLE) is unlikely to work well. The reason is that our model is a discriminative directed graphical model (as seen in Figure 1) and, thus, suffers from **exposure bias** (Ranzato et al., 2015). The intuition behind the poor performance of MLE is simple: the output of the lemmatizer depends on the output of the morphological tagger; as the lemmatizer has only ever seen correct morphological tags, it has never learned to adjust for the errors that will be made at the time of decoding. To compensate for this, we employ **jackknifing** (Agić and Schluter, 2017), which is standard practice in many NLP pipelines, such as dependency parsing.

Jackknifing for training NLP pipelines is quite similar to the oft-employed cross-validation. We divide our training data into κ splits. Then, for each split $i \in \{1, \ldots, \kappa\}$, we train the morphological tagger on the i^{th} split, and then decode it, using either greedy decoding or crunching, on the remaining $(\kappa - 1)$ splits. This technique helps avoid exposure bias and improves the lemmatization performance, which we will demonstrate empirically in §4. Indeed, the model is quite ineffective without this training regime. Note that we employ jackknifing for both the greedy decoding scheme and the crunching decoding scheme.

4 Experimental Setup

4.1 Dataset

To enable a fair comparison with Bergmanis and Goldwater (2018), we use the Universal Dependencies Treebanks (Nivre et al., 2017) for all our experiments. Following previous work, we use v2.0 of the treebanks for all languages, except Dutch, for which v2.1 was used due to inconsistencies in v2.0. The standard splits are used for all treebanks.

---

[5] True joint decoding would sum over all possible morphological tags, rather than just the k-best. While this is tractable in our setting in the sense that there are, at, most, 1662 morphological tags (in the case of Basque), it is significantly slower than using a smaller k. Indeed, the probability distribution that morphological taggers learn tend to be peaked to the point that considering improbable tags is not necessary.

4.2 Training Setup and Hyperparameters

For the morphological tagger, we use the baseline implementation from Malaviya et al. (2018). This implementation uses an input layer and linear layer dimension of 128 and a 2-layer LSTM with a hidden layer dimension of 256. The Adam (Kingma and Ba, 2014) optimizer is used for training and a dropout rate (Srivastava et al., 2014) of 0.3 is enforced during training. The tagger was trained for 10 epochs.

For the lemmatizer, we use a 2-layer biLSTM encoder and a 1-layer LSTM decoder with 400 hidden units. The dimensions of character and tag embedding are 200 and 40, respectively. We enforce a dropout rate of 0.4 in the embedding and encoder LSTM layers. The lemmatizer is also trained with Adam and the learning rate is 0.001. We halve the learning rate whenever the development log-likelihood increases and we perform early-stopping when the learning rate reaches 1×10^{-5}. We apply gradient clipping with a maximum gradient norm of 5.

4.3 Baselines (and Related Work)

We compare our approach against recent competing methods that report results on UD datasets.

Lematus. The current state of the art is held by Bergmanis and Goldwater (2018), who, as discussed in §1, provide a direct context-to-lemma approach, avoiding the use of morphological tags. We remark that Bergmanis and Goldwater (2018) assume a setting where lemmata are annotated at the token level, but morphological tags are not available; we contend, however, that such a setting is not entirely realistic as almost all corpora annotated with lemmata at the token level include morpho-syntactic annotation, including the vast majority of the UD corpora. Thus, we do not consider it a stretch to assume the annotation of morphological tags to train our joint model.[6]

UDPipe. Our next baseline is the UDPipe system of Straka and Straková (2017). Their system performs lemmatization using an averaged perceptron tagger that predicts a (lemma rule, UPOS) pair. Here, a lemma rule generates a lemma by removing parts of the word prefix/suffix and prepending and appending a new prefix/suffix. A guesser first produces correct lemma rules and the tagger is used to disambiguate from them.

Lemming. The strongest non-neural baseline we consider is the system of Müller et al. (2015), who, like us, develop a joint model of morphological tagging lemmatization. In contrast to us, however, their model is globally normalized (Lafferty et al., 2001). Due to their global normalization, they directly estimate the parameters of their model with MLE without worrying about exposure bias. However, in order to efficiently normalize the model, they heuristically limit the set of possible lemmata through the use of **edit trees** (Chrupała, 2008), which makes the computation of the partition function tractable.

Morfette. Much like Müller et al. (2015), Morfette relies on the concept of edit trees. However, a simple perceptron is used for classification with hand-crafted features. A full description of the model is given in Chrupała et al. (2008).

5 Results and Discussion

Experimentally, we aim to show three points. i) Our joint model (eq. (1)) of morphological tagging and lemmatization achieves state-of-the-art accuracy; this builds on the findings of Bergmanis and Goldwater (2018), who show that context significantly helps neural lemmatization. Moreover, the upper bound for contextual lemmatizers that make use of morphological tags is much higher, indicating room for improved lemmatization with better morphological taggers. ii) We discuss a number of error patterns that the model seems to make on the languages, where absolute accuracy is lowest: Latvian, Estonian and Arabic. We suggest possible paths forward to improve performance. iii) We offer an explanation for *when* our joint model does better than the context-to-lemma baseline. We show through a correlational study that our joint approach with morphological tagging helps the most in two cases: low-resource languages and morphologically rich languages.

---

[6] After correspondence with Toms Bergmanis, we would like to clarify this point. While Bergmanis and Goldwater (2018) explores the model in a token-annotated setting, as do we, the authors argue that such a model is better for a very low-resource scenario where the entire sentence is not annotated for lemmata. We concede this point—our current model is not applicable in such a setting. However, we note that a semi-supervised morphological tagger could be trained in such a situation as well, which may benefit lemmatization.

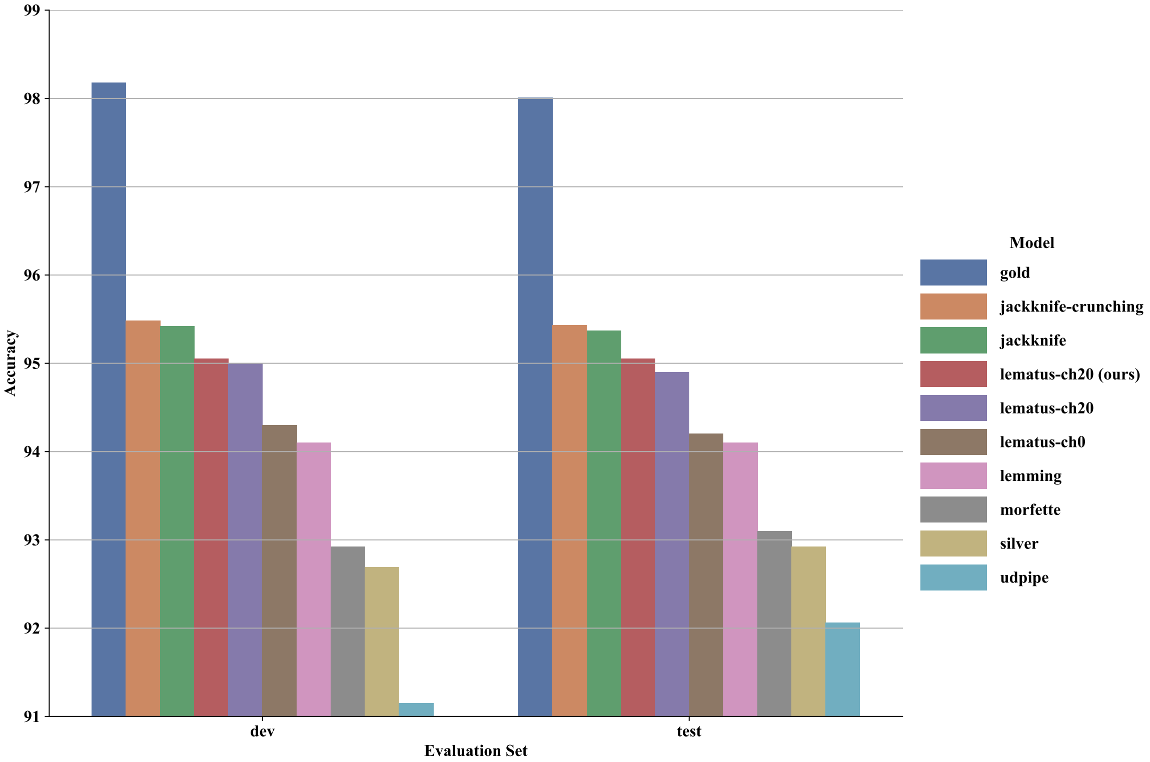

Figure 3: We present performance (in accuracy) averaged over the 20 languages from UD we consider. Our method (second from the left) significantly outperforms the strongest baseline (fourth from the left; Bergmanis and Goldwater (2018)). The blue column is a skyline that gives our model gold tags during decoding, showing improved tagging should lead to better lemmatization. The remaining are baselines described in §4.3.

5.1 Main Results

The first experiment we run focuses on pure performance of the model. Our goal is to determine whether joint morphological tagging and lemmatization improves average performance in a state-of-the-art neural model.

Evaluation Metrics. For measuring lemmatization performance, we measure the accuracy of guessing the lemmata correctly over an entire corpus. To demonstrate the effectiveness of our model in utilizing context and generalizing to unseen word forms, we follow Bergmanis and Goldwater (2018) and also report accuracies on tokens that are i) **ambiguous**, i.e., more than one lemmata exist for the same inflected form, ii) **unseen**, i.e., where the inflected form has not been seen in the training set, and iii) **seen unambiguous**, i.e., where the inflected form has only one lemma and is seen in the training set.

Results. The results showing comparisons with all other methods are summarized in Figure 3. Each bar represents the average accuracy across 20 languages. Our method achieves an average accuracy of 95.42 and the strongest baseline, Bergmanis and Goldwater (2018), achieves an average accuracy of 95.05. The difference in performance (0.37) is statistically significant with $p < 0.01$ under a paired permutation test. We outperform the strongest baseline in 11 out of 20 languages and underperform in only 3 languages with $p < 0.05$. The difference between our method and all other baselines is statistical significant with $p < 0.001$ in all cases. We highlight two additional features of the data. First, decoding using gold morphological tags gives an accuracy of 98.04 for a difference in performance of $+2.62$. We take the large difference between the upper bound and the current performance of our model to indicate that improved morphological tagging is likely to significantly help lemmatization. Second, it is noteworthy that training with gold tags, but decoding with predicted tags, yields performance that is significantly worse than every baseline except for UDPipe. This speaks for the importance of jackknifing in the training of joint morphological tagger-lemmatizers that are directed and, therefore, suffer from exposure bias.

In Figure 4, we observed crunching further im-

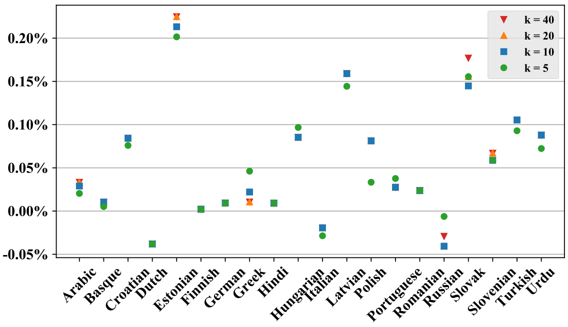

Figure 4: Relative improvement on validation set with crunching over greedy decoding for different values of k.

proves performance of the greedy decoding scheme. In 8 out of 20 languages, the improvement is statistical significant with $p < 0.05$. We select the best k for each language based on the development set.

In Figure 5, we provide a language-wise breakdown of the performance of our model and the model of Bergmanis and Goldwater (2018). Our strongest improvements are seen in Latvian, Greek and Hungarian. When measuring performance solely over unseen inflected forms, we achieve even stronger gains over the baseline method in most languages. This demonstrates the generalization power of our model beyond word forms seen in the training set. In addition, our accuracies on ambiguous tokens are also seen to be higher than the baseline on average, with strong improvements on highly inflected languages such as Latvian and Russian. Finally, on seen unambiguous tokens, we note improvements that are similar across all languages.

5.2 Error Patterns

We attempt to identify systematic error patterns of our model in an effort to motivate future work. For this analysis, we compare predictions of our model and the gold lemmata on three languages with the weakest absolute performance: Estonian, Latvian and Arabic. First, we note the differences in the average lengths of gold lemmata in the tokens we guess incorrectly and all the tokens in the corpus. The lemmata we guess incorrectly are on average 1.04 characters longer than the average length of all the lemmata in the corpus. We found that the length of the incorrect lemmata does not correlate strongly with their frequency. Next, we identify the most common set of edit operations in each language that would transform the incorrect hypothesis to the gold lemma. This set of edit operations was found to follow a power-law distribution.

Table 1: Here we present the number of tokens in each of the UD treebanks we use as well as the number of morphological tags. Note, we take the number of tags as a proxy for the morphological complexity of the language. Finally, we present numbers on validation set from our method with greedy decoding and from the strongest baseline (Lematus) as well as the difference. Correlations between the first two columns and the differences are shown in Table 2.

For the case of Latvian, we find that the operation {*replace*: s → a} is the most common error made by our model. This operation corresponds to a possible issue in the Latvian treebank, where adjectives were marked with gendered lemmas. This issue has now been resolved in the latest version of the treebank. For Estonian, the operation {*insert*: m, *insert*: a} is the most common error. The suffix *-ma* in Estonian is used to indicate the infinitive form of verbs. Gold lemmata for verbs in Estonian are marked in their infinitive forms whereas our system predicts the stems of these verbs instead. These inflected forms are usually ambiguous and we believe that the model doesn't generalize well to different form-lemma pairs, partly due to fewer training data available for Estonian. This is an example of an error pattern that could be corrected using improved morphological information about the tokens. Finally, in Arabic, we find that the most common error pattern corresponds to a single ambiguous word form, *'an* , which can be lemmatized as *'anna* (like "that" in English) or *'an* (like "to" in English) depending on the usage of the word in

Figure 5: Dev accuracy breakdown by type of inflected form on all languages comparing our system with greedy decoding against our run of Lematus-ch20, colored by relative improvement in percentage. In each entry, the bottom score is from Lematus-ch20 and the top one is from our system, and the number in the parenthesis is the number of tokens for the corresponding setting.

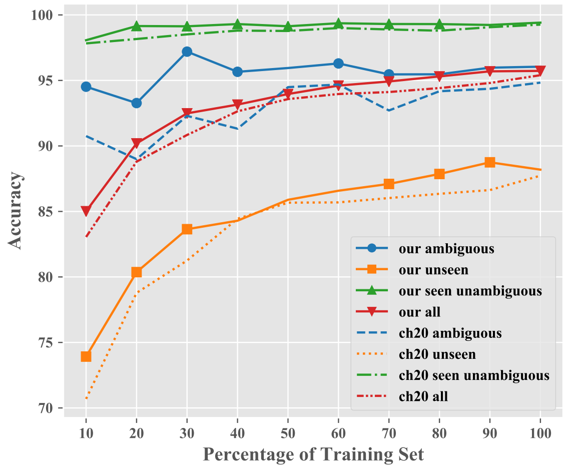

Figure 6: Learning curve showing the accuracy on the validation set of the Polish treebank as the percentage of training set is increased. Markers indicate statistically significant better system with paired permutation test ($p < 0.05$). Our model is decoded greedily.

context. The word *'anna* must be followed by a nominal sentence while *'an* is followed by a verb. Hence, models that can incorporate rich contextual information would be able to avoid such errors.

5.3 Why our model performs better?

Simply presenting improved results does not entirely satiate our curiosity: we would also like to understand *why* our model performs better. Specifically, we have assumed an additional level of supervision—namely, the annotation of morphological tags. We provide the differences between our method and our retraining of the Lematus system presented in Table 1. In addition to the performance of the systems, we also list the number of tokens in each treebank and the number of distinct morphological tags per language. We perform a correlational study, which is shown in Table 2.

	Pearson's Rv	Spearman's ρ
# tags vs. Δ	0.206	0.209
# tokens vs. Δ	-0.808	-0.845

Table 2: The table shows the correlations between the differences in dev performance between our model with greedy decoding and Lematus and two aspects of the data: number of tokens and number of tags.

Morphological Complexity and Performance. We see that there is a moderate positive correlation ($\rho = 0.209$) between the number of morphological tags in a language and the improvement our model obtains. As we take the number of tags as a proxy for the morphological complexity in the language, we view this as an indication that attempting to directly extract the relevant morpho-syntactic information from the corpus is not as effective when there is more to learn. In such languages, we recommend exploiting the additional annotation to achieve better results.

Amount of Data and Performance. The second correlation we find is a stronger negative correlation ($\rho = -0.845$) between the number of tokens available for training in the treebank and the gains in performance of our model over the baseline. This is further demonstrated by the learning curve plot in Figure 6, where we plot the validation accuracy on the Polish treebank for different sizes of the training set. The gap between the performance of our model and Lematus-ch20 is larger when fewer training data are available, especially for ambiguous tokens. This indicates that the incorporation of morphological tags into a model helps more in the low-resource setting. Indeed, this conclusion makes sense—neural networks are good at extracting features from text when there is a sufficiently large amount of data. However, in the low-resource case, we would expect direct supervision on the sort of features we desire to extract to work better. Thus, our second recommendation is to model tags jointly with lemmata when fewer training tokens are available. As we noted earlier, it is almost always the case that token-level annotation of lemmata comes with token-level annotation of morphological tags. In low-resource scenarios, a data augmentation approach such as the one proposed by Bergmanis and Goldwater (2019) can be helpful and serve complementary to our approach.

6 Conclusion

We have presented a simple joint model for morphological tagging and lemmatization and discussed techniques for training and decoding. Empirically, we have shown that our model achieves state-of-the-art results, hinting that explicitly modeling morphological tags is a more effective manner for modeling context. In addition to strong numbers, we tried to explain *when* and *why* our model does better. Specifically, we show a significant correlation between our scores and the number of tokens and tags present in a treebank. We take this to indicate that our method improves performance more for low-resource languages as well as morphologically rich languages.

Acknowledgments

We thank Toms Bergmanis for his detailed feedback on the accepted version of the manuscript. Additionally, we would like to thank the three anonymous reviewers for their valuable suggestions. The last author would like to acknowledge support from a Facebook Fellowship.

Abstract

In the principles-and-parameters framework, the structural features of languages depend on parameters that may be toggled on or off, with a single parameter often dictating the status of multiple features. The implied covariance between features inspires our probabilisation of this line of linguistic inquiry—we develop a generative model of language based on exponential-family matrix factorisation. By modelling all languages and features within the same architecture, we show how structural similarities between languages can be exploited to predict typological features with near-perfect accuracy, outperforming several baselines on the task of predicting held-out features. Furthermore, we show that language embeddings pre-trained on monolingual text allow for generalisation to unobserved languages. This finding has clear practical and also theoretical implications: the results confirm what linguists have hypothesised, i.e. that there are significant correlations between typological features and languages.

1 Introduction

Linguistic typologists dissect and analyse languages in terms of their structural properties (Croft, 2002). For instance, consider the phonological property of word-final obstruent decoding: German devoices word-final obstruents (*Zug* is pronounced /zuk/), whereas English does not (*dog* is pronounced /dɒg/). In the tradition of generative linguistics, one line of typological analysis is the principles-and-parameters framework (Chomsky, 1981), which posits the existence of a set of universal parameters, switches as it were, that languages toggle. One arrives at a kind of factorial typology, to borrow terminology from optimality theory (Prince and Smolensky, 2008), through different settings of the parameters. Within the principle-and-parameters research program, then, the goal is to identify the parameters that serve as axes, along which languages may vary.

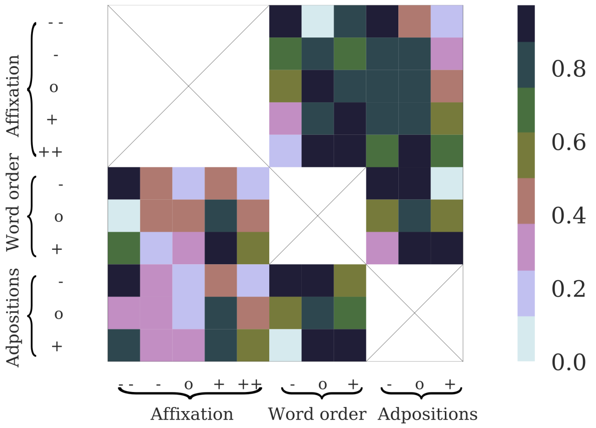

Figure 1: Correlations between selected typological parameters. Feature values are classified according to head-directionality (head-initial **+**, head-final **-**, no dominant order **o**). For instance, **++** under Affixation means strongly suffixing.

It is not enough, however, to simply write down the set of parameters available to language. Indeed, one of the most interesting facets of typology is that different parameters are correlated. To illustrate this point, we show a heatmap in Figure 1 that shows the correlation between the values of selected parameters taken from a typological knowledge base (KB). Notice how head-final word order, for example, highly correlates with strong suffixation. The primary contribution of this work is a probabilisation of typology inspired by the principles-and-parameters framework. We assume a given set of typological parameters and develop a generative model of a language's parameters, casting the problem as a form of exponential-family matrix factorisation. We observe a binary matrix that encodes the settings of each parameter for each language. For example, the Manchu head-final entry of this matrix would be set to 1, because Manchu

Proceedings of NAACL-HLT 2019, pages 1529–1540
Minneapolis, Minnesota, June 2 - June 7, 2019.

is a head-final language. The goal of our model is to *explain* each entry of matrix as arising through the dot product of a language embedding and a parameter embedding passed through a sigmoid.

We test our model on The World Atlas of Language Structures (WALS), the largest available knowledge base of typological parameters at the lexical, phonological, syntactic and semantic level. Our contributions are: (i) We develop a probabilisation of typology inspired by the principles-and-parameters framework. (ii) We introduce the novel task of typological collaborative filtering, where we observe some of a language's parameters, but hold some out. At evaluation time, we predict the held-out parameters using the generative model. (iii) We develop a semi-supervised extension, in which we incorporate language embeddings output by a neural language model, thus improving performance with unlabelled data. Indeed, when we partially observe some of the typological parameters of a language, we achieve near-perfect (97%) accuracy on the prediction of held-out parameters. (iv) We perform an extensive qualitative and quantitative analysis of our method.

2 Typology in Generative Grammar

What we will present in this paper is a generative model that corresponds to a generative tradition of research in linguistic typology. We first outline the technical linguistic background necessary for the model's exposition. Chomsky famously argued that the human brain contains a prior, as it were, over possible linguistic structures, which he termed **universal grammar** (Chomsky, 1965). The connection between Chomsky's Universal Grammar and the Bayesian prior is an intuitive one, but the earliest citation we know for the connection is Eisner (2002, §2). As a theory, universal grammar holds great promise in explaining the typological variation of human language. Cross-linguistic similarities and differences may be explained by the influence universal grammar exerts over language acquisition and change. While universal grammar arose early on in the writtings of Chomsky, early work in generative grammar focused primarily on English (Harris, 1995). Indeed, Chomsky's *Syntactic Structures* contains exclusively examples in English (Chomsky, 1957). As the generative grammarians turned their focus to a wider selection of languages, the **principles and parameters** framework for syntactic analysis rose to prominence. Given the tight relationship between the theory of universal grammar and typology, principles and parameters offers a fruitful manner in which to research typological variation.

The principles and parameters takes a parametric view of linguistic typology. The structure of human language is governed by a series of **principles**, which are hard constraints on human language. A common example of a principle is the requirement that every sentence has a subject, even if one that is not pronounced; see the discussion on the pro-drop parameter in Carnie (2013). Principles are universally true for all languages. On the other hand, languages are also governed by **parameters**. Unlike principles, parameters are the parts of linguistic structure that are allowed to vary. It is useful to think of parameters as attributes that can take on a variety of values. As Chomsky (2000) himself writes "we can think of the initial state of the faculty of language as a fixed network connected to a switch box; the network is constituted of the principles of language, while the switches are the options to be determined by experience. When the switches are set one way, we have Swahili; when they are set another way, we have Japanese. Each possible human language is identified as a particular setting of the switches-a setting of parameters, in technical terminology."

What are possible parameters? Here, in our formalisation of the parameter aspect of the principles-and-parameters framework, we take a catholic view of parameters, encompassing all areas of linguistics, rather than just syntax. For example, as we saw before, consider the switch of devoicing word-final obstruents a parameter. We note that while principle-and-parameters typology has primarily been applied to syntax, there are also interesting applications to non-syntactic domains. For instance, van Oostendorp (2015) applies a parametric approach to metrical stress in phonology; this is in line with our view. In the field of linguistic typology, there is a vibrant line of research, which fits into the tradition of viewing typological parameters through the lens of principles and parameters. Indeed, while earlier work due to Chomsky focused on what have come to be called macro-parameters, many linguists now focus on micro-parameters, which are very close to the features found in the WALS dataset that we will be modelling (Baker, 2008; Nicolis and Biberauer, 2008; Biberauer et al., 2009). This justifies our viewing

WALS through the lens of principles and parameters, even though the authors of WALS adher to the functional-typological school.[1]

Notationally, we will represent the parameters as a vector $\boldsymbol{\pi} = [\pi_1, \ldots, \pi_n]$. Each typological parameter π_i is a binary variable; for instance, does the language admit word-final voiced obstruents?

3 A Generative Model of Typology

We now seek a probabilistic formalisation of the linguistic theory presented in §2; specifically, for every language ℓ, we seek to explain the observed binary vector of parameters $\boldsymbol{\pi}^\ell$: $\pi_i^\ell = 1$ indicates that the i^{th} parameter is "on" in language ℓ. The heart of our model will be quite simple: every language ℓ will have a language embedding $\boldsymbol{\lambda}^\ell \in \mathbb{R}^d$ and every parameter will have a parameter embedding $\mathbf{e}_{\pi_i} \in \mathbb{R}^d$. Now, $\pi_i^\ell \sim \textit{sigmoid}(\mathbf{e}_{\pi_i}^\top \boldsymbol{\lambda}^\ell)$.

This model also takes inspiration from work in relation extraction (Riedel et al., 2013). Writing the joint distribution over the entire binary vector of parameters, we arrive at

$$p(\boldsymbol{\pi}^\ell \mid \boldsymbol{\lambda}^\ell) = \prod_{i=1}^{|\boldsymbol{\pi}|} p(\pi_i^\ell \mid \boldsymbol{\lambda}^\ell) \tag{1}$$

$$= \prod_{i=1}^{|\boldsymbol{\pi}|} \textit{sigmoid}\left(\mathbf{e}_{\pi_i}^\top \boldsymbol{\lambda}^\ell\right) \tag{2}$$

$$= \prod_{i=1}^{|\boldsymbol{\pi}|} \frac{1}{1 + \exp(-\mathbf{e}_{\pi_i}^\top \boldsymbol{\lambda}^\ell)} \tag{3}$$

We define the the prior over language embeddings:

$$p(\boldsymbol{\lambda}^\ell) = \mathcal{N}\left(\mathbf{0}; \sigma^2 I\right) \tag{4}$$

where $\boldsymbol{\mu}$ is the mean of the Gaussian whose covariance is fixed at I. Now, give a collection of languages $\mathcal{L}$, we arrive at the joint distribution

$$\prod_{\ell \in \mathcal{L}} p(\boldsymbol{\pi}^\ell, \boldsymbol{\lambda}^\ell) = \prod_{\ell \in \mathcal{L}} p(\boldsymbol{\pi}^\ell \mid \boldsymbol{\lambda}^\ell) \cdot p(\boldsymbol{\lambda}^\ell) \tag{5}$$

Note that $p(\boldsymbol{\lambda}^\ell)$ is, spiritually at least, a universal grammar: it is the prior over what sort of languages can exist, albeit encoded as a real vector. In the parlance of principles and parameters, the prior represents the principles.

Then our model parameters are $\boldsymbol{\Theta} = \{\mathbf{e}_{\pi_1}, \ldots, \mathbf{e}_{\pi_{|\boldsymbol{\pi}|}}, \boldsymbol{\lambda}^1, \ldots, \boldsymbol{\lambda}^{|\mathcal{L}|}\}$. Note that for the remainder of the paper, we will never shorten 'model parameters' to simply 'parameters' to avoid ambiguity. We will, however, refer to 'typological parameters' as simply 'parameters.'

We can view this model as a form of exponential-family matrix factorisation (Collins et al., 2001). Specifically, our model seeks to explain a binary matrix of parameters. We consider such matrices as the one in Figure 2, which depicts some of the binarised feature values for word order and affixation for English, Dutch, German, Vietnamese, Turkish, and Marind. We will have some parameters seen during training (highlighted in blue), some we use for evaluation (highlighted in red), and some which are unknown due to the nature of WALS (highlighted in green). Crucially, the model in eq. (5) allows us to learn the correlations between typological parameters, as illustrated in Figure 1. We train the model over 10 epochs with a batch size of 64, using the Adam optimiser (Kingma and Ba, 2014) and L_2 regularisation (0.1), which corresponds to the Gaussian prior with variance $\sigma^2 = 10$.

4 A Semi-Supervised Extension

A natural question we might ask is if our model can exploit unlabelled monolingual data to improve its performance. We explain how we can induce language embeddings from unlabelled data below and then incorporate these into our model through the prior eq. (4). This results in a semi-supervised model, as we incorporate an unsupervised pretraining step. This is motivated by the fact that related languages tend to exhibit correlations between each other. Figure 3 shows the distribution

---

[1] For an overview of differences between these schools, we refer the reader to Haspelmath (2008).

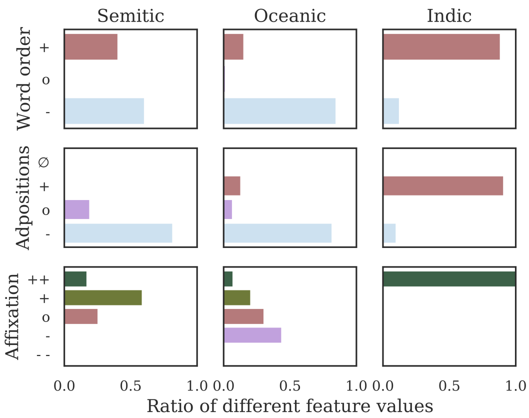

Figure 3: Distribution of feature values across three of the biggest language families in WALS. The representation of feature values is described in Figure 1.

of a few features within the Semitic, Oceanic, and Indic language branches. Notice, for instance, the skewed distribution of feature values within the Indic branch: languages in that branch are almost exclusively head-initial with respect to word order, order of adposition and noun, and affixation.

4.1 Distributional Language Embeddings

Words can be represented by distributed word representations, currently often in the form of word embeddings. Similarly to how words can be embedded, so can languages, by associating each language with a real-valued vector known as a *language embedding*. Training such representations as a part of a multilingual model allows us to infer similarities between languages. This is due to the fact that in order for multilingual parameter sharing to be successful in this setting, the neural network needs to use the language embeddings to encode features of the languages. Previous work has explored this type of representation learning in various tasks, such as NMT (Malaviya et al., 2017), language modelling (Tsvetkov et al., 2016; Östling and Tiedemann, 2017), and tasks representing morphological, phonological, and syntactic linguistic levels (Bjerva and Augenstein, 2018a).

In the context of computational typology, representations obtained through language modelling have been the most successful (Östling and Tiedemann, 2017). This approach is particularly interesting since unlabelled data is available for a large portion of the world's languages, meaning that high quality language embeddings can be obtained for more than 1,000 of the world's languages.

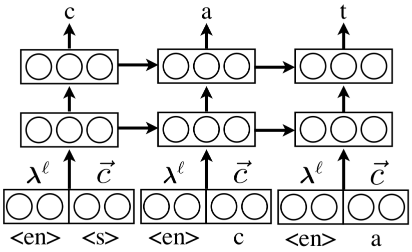

Figure 4: Char LSTM LM with language embeddings concatenated to char embeddings at every time step.

4.2 Language Embeddings through LMs

In this work, we use a language modelling objective to pre-train language embeddings; we train a character-level neural language model with a distributed language embedding of language ℓ. Specifically, we use the model of Östling and Tiedemann (2017), visualised in Figure 4. The model is a stacked character-based LSTM (Hochreiter and Schmidhuber, 1997) with two layers, followed by a softmax output layer. In order to accommodate the language embeddings, this relatively standard model is modified such that language embeddings are concatenated to the character embeddings at each time step. This method returns a language embedding, which we denote $\tilde{\boldsymbol{\lambda}}^\ell$ to distinguish it from the language embeddings $\boldsymbol{\lambda}^\ell$ discussed in the previous section. We use the same hyperparameter settings as Östling and Tiedemann (2017), with 1024-dimensional LSTMs, 128-dimensional character embeddings, and 64-dimensional language embeddings. Training is done with Adam (Kingma and Ba, 2014), and using early stopping.

In the semi-supervised regime, we use the estimated language embedding $\tilde{\boldsymbol{\lambda}}^\ell$ from the language model and define the model as follows

$$p(\boldsymbol{\pi}^\ell \mid \tilde{\boldsymbol{\lambda}}^\ell) = \prod_{i=1}^{|\boldsymbol{\pi}|} sigmoid(\mathbf{e}_{\pi_i}^\top \tilde{\boldsymbol{\lambda}}^\ell) \qquad (6)$$

omitting the learned language embedding $\boldsymbol{\lambda}$ in the matrix factorisation. The likelihood of this model is now convex in the parameter embeddings. In contrast to the full matrix factorisation setting, here, all language-specific knowledge must come from an external source, namely, the unlabelled text.

5 A Novel Task: Typological Collaborative Filtering

In this section, we introduce a novel task for linguistic typology, which we term **typological collaborative filtering**. Typological KBs such as WALS are known to be incomplete. In other words, not all parameters π_i^ℓ are observed for all languages. Thus, a natural question we may ask how well our models can predict unobserved (or held-out) parameters. We view this problem as analogous to collaborative filtering (CF). Our task is similar to knowledge base population or completion in that we start off with a partly populated KB which we aim to complete, but differs in the aspect that we attempt to infer values from correlations between features and similarities between languages, rather than inferring these from a collection of texts.

CF is a common technique for recommender systems (see §9). Consider the task of recommending a new movie to a customer. Given which movies different users have liked (equivalent to a typological parameter being 'on') and which movies the user has disliked (equivalent to the typological parameter being 'off'), a CF model tries to figure out the (latent) preferences of each user and the latent genre of each movie. In our setting, the languages are analogous to users and movies are analogous to parameters. Our model in eq. (5) seeks to learn what latent properties of languages and what latent properties of parameters explain their correlations.

6 Data

WALS. The World Atlas of Language Structures (WALS) is a large knowledge base of typological properties at the lexical, phonological, syntactic and semantic level on which we will run our experiments. The documentation of linguistic structure is spread throughout a wide variety of academic works, ranging from field linguistics to grammars describing the nuances of individual grammatical uses. KB creation is a laborious tasks as it involves distilling knowledge into a single, standardised resource, which, naturally, will be incomplete, prompting the need for methods to complete them (Min et al., 2013). In the case of WALS, few languages have all values annotated for all of the properties. In this section, we offer a formalisation of typological KBs to allow for our development of a probabilistic model over vectors of properties. WALS, for instance, contains $n = 202$ different parameters (Dryer and Haspelmath, 2013).

Binarisation of WALS. Many common typological KBs, including WALS, the one studied here, contain binary as well as non-binary parameters. To deal with this, we binarise the KB as follows: Whenever there is a typological parameter that takes ≥ 3 values, e.g., 'Feature 81A: Order of Subject, Object and Verb' which takes the 7 values 'SOV', 'SVO', 'VSO', 'VOS', 'OVS', 'OSV', 'No dominant order', we introduce that many binary parameters. At test time, we get non-binary predictions by using a simple decoder that returns the arg max over the predicted probabilities for the binary features.

As each typological parameter with $n \geq 3$ feature values is coded as a one-hot binary vector of length n, we need to make sure that we do not mix a single typological parameter for a language into the training and test sets. This is visualised in Figure 2, where we train on the blue squares, i.e., the binarised 81A feature for for English, and the 26A feature for Dutch, as well as all features for all non-Germanic languages. The model is then evaluated on the held-out features for Germanic highlighted in red, i.e., 26A for English, 81A for Dutch, and both of these for German. This is important, as knowing that a language is SVO would make it trivial to infer that it is not, e.g., SOV.

Unlabelled multilingual data. To induce language embeddings, we need a considerable amount of multilingual unlabelled data. We use an in-house version of the massively multilingual Bible corpus, so as to have comparable data for all languages, although parallel data is not a strict necessity for our method.[2] We train the multilingual language model on a collection of 975 languages, each with approximately 200,000 tokens available. We only train on languages for which the symbol size is relatively modest, a criterion which we fulfil by only using translations with Latin, Cyrillic, and Greek alphabets.

Language used in the bible differs substantially from most modern language use, which would be a challenge if one were interested in transferring the language model itself. Here, we are only interested in the distributed language embeddings for each language ℓ. It is safe to assume that the typological features underlying the texts we use will be representative of those coded in WALS, hence the domain should not matter much and the method should work equally well given any domain of input texts for the unsupervised training of language embeddings.

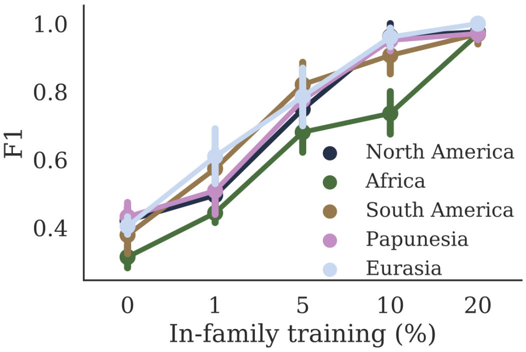

Figure 5: F1 score for feature prediction separated by macroarea with varying in-branch training data.

7 Experiments

7.1 General Experimental Setup

As described in §6, we binarise WALS. In order to compare directly with our semi-supervised extension, we limit our evaluation to the subset of languages which is the intersection of the languages for which we have Bible data, and the languages which are present in WALS. Finally, we observe that some languages have very few features encoded, and some features are encoded for very few languages. For instance, feature 10B (Nasal Vowels in West Africa), is only encoded for a total of 40 languages, and only one feature value appears for more than 10 languages. Because of this, we restrict our evaluation to languages and feature values which occur at least 10 times. Note that we evaluate on the original parameters, and not the binarised ones.

Our general experimental set-up is as follows. We first split the languages in WALS into each language branch (*genus* using WALS terminology). This gives us, e.g., a set of Germanic languages, a set of Romance languages, a set of Berber languages, and so on. (We note that this does not correspond to the notion of a language family, e.g., the Indo-European language family.) We wish to evaluate on this type of held-out set, as it is both relatively challenging: If we know the parameters of Portuguese, predicting the parameters for Spanish is a much easier task. This setup will both give us a critical estimate of how well we can predict features overall, in addition to mimicking a scenario in which we either have a poorly covered language or branch, which we wish to add to WALS.

7.2 Typological Collaborative Filtering

We evaluate our method for typological collaborative filtering on each language branch in WALS in a series of experiments. Given a branch B (a set of languages), we randomly select 80% of the feature-language combinations from the languages $\ell \in B$, which we use for evaluation (e.g. those highlighted in red in Figure 2). The remaining 20% is either not considered, or (partially) used for training, as we run experiments in which we train on $(0, 1, 5, 10, 20)\%$ relative of the held-out data. The idea behind this is that it should be very difficult to predict features if nothing is known for a language at all, whereas knowing a few features of a language, or of related languages, should allow the model to take advantage of the strong correlations between features (Figure 1) and between languages (Figure 3). We train on all data in WALS for languages which are not in the current evaluation branch under consideration.

Each experiment is then an evaluation of how well we can predict features for a completely or relatively unseen language family. Evaluation is done across the branches in WALS with more than four languages represented, after filtering away languages for which we have fewer than 10 features available. This amounts to a total of 36 branches, and 448 languages. We repeat each experiment 5 times per language branch, for each proportion of in-branch training data in $(0, 1, 5, 10, 20)\%$, yielding a total of 900 experiment runs. The results reported are the mean across these runs.

Figure 5 shows the micro F1 score we obtain averaged across macroareas. The bars indicate 95% confidence intervals. We can see that, with access to 20% of the in-branch training data, we can predict features at above 90% F1 score regardless of macroarea. Prediction generally is more challenging for languages in the macroarea Africa. This can be explained by, e.g., contrasting with the Eurasian macroarea. Whereas the latter includes branches which are relatively uncontroversial, such as Germanic and Slavic languages, this is not the case with the former. One such example is Bongo-Bagirmi (one of the evaluation branches, spoken in Central Africa), for which there is poor agreement in terms of classification (Bender, 2000).

7.3 Semi-supervised extension

We next evaluate the semi-supervised extension, which requires unlabelled texts for a large amount

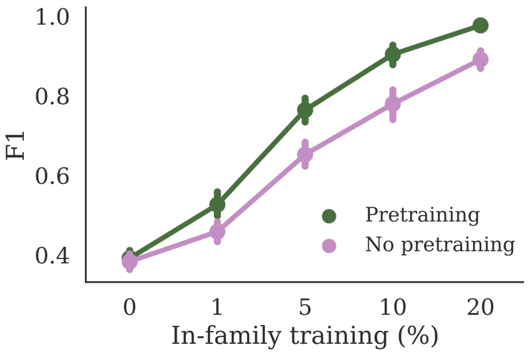

Figure 6: F1 scores across all held-out language families, comparing pretraining with no pretraining.

of languages, although the domain of these texts should not matter much. This allows us to take advantage of correlations between similar languages to point the model in the right direction. Even with 1% training data, it may be very useful for a model to know that, e.g., German and Dutch are grammatically very similar. Hence, if the 1% training data contains features for Dutch, it should be quite easy for the model to learn to transfer these to German.

Figure 6 shows results with pre-training. Without any in-branch training data, using pretrained embeddings does not offer any improvement in prediction power. This can be explained by the fact language embeddings are updated during training, which leads to a drift in the representations present in the training material. This was chosen since not updating the representations yielded poor performance in all settings explored. We hypothesise that this is because, although a language modelling objective offers a good starting point in terms of encoding typological features, it is not sufficient to explain the typological diversity of languages. For instance, a language model should hardly care about the phonological nature of a language. This is in line with previous work which shows that the linguistic nature of the target task is important when predicting typological features with language embeddings (Bjerva and Augenstein, 2018a). However, once we have access to $> 5\%$ of in-branch training data, language embeddings offers a substantial improvement, e.g. an F1 error reduction of more than 50% with access to 10% of the in-branch data (see Table 1 and Table 3 for per-branch results in the appendix). This shows that we can partially aid a typologist's work by utilising unannotated data.

In-branch train %	Freq. F1	Indiv. pred. F1	T-CF F1	SemiSup F1
0.00	0.2950	0.2990	0.3998	0.3916
0.01	0.2949	0.2976	0.4578	0.5263
0.05	0.2947	0.2970	0.6552	0.7641
0.10	0.2945	0.2971	0.7807	0.9040
0.20	0.2938	0.2973	0.8835	**0.9767**

Table 1: Aggregate results w. 0-20% relative use of in-branch training data. Columns show: most frequent class (Freq.), individual prediction per feature with language-embeddings (Individual pred.), typological collaborative filtering (T-CF), semi-supervised extension (SemiSup). For standard deviations across runs and per-branch results, see appendix.

7.4 Quantitative comparison

In addition to evaluating our method of typological CF, we compare to some baselines drawn from earlier work. First, we report a most frequent value baseline. As many typological features are heavily skewed, this is quite high already. For instance, defaulting to the most frequent value for word order (i.e. SVO) would yield an accuracy of 41% (**Freq.** in Table 1). A more involved baseline is Bjerva and Augenstein (2018a), who use pre-trained language embeddings in a k-NN classifier trained on individual WALS features (**Individual pred.** in Table 1). For the baseline reported here, we only use one nearest neighbour for this prediction. The scores we obtain here are quite low compared to Bjerva and Augenstein (2018a), which is explained by the fact that we have access to very little training data in the current setting, and highlights the importance of taking advantage of correlations between languages and features, and not simply looking at these factors in isolation. Finally, we compare our typological collaborative filtering approach, as well as our semi-supervised extension (**T-CF** and **SemiSup** in Table 1).

8 Analysis

Accuracy for several experimental settings is visualised in Figure 7, broken down by the linguistic category of the predicted features. Since results change little between the 5% in-branch setting and higher percentages, we only look at 0%, 1% and 5% here. We also visualise accuracy without (Figure 7, left) and with our semi-supervised extension (Figure 7, right) in each setting.

8.1 Typological collaborative filtering with variable amounts of data

Focussing on Figure 7 (left) alone first we observe an expected pattern: using increasingly more in-branch data boosts performance across all feature groups. This increase in accuracy can be attributed to the model having more knowledge about each query language in itself and about how languages relate to one another, based on similarities in their parameter configurations.

Making a prediction about the order of adposition and noun phrase in a given language, lacking any other information about that language, is basically a shot in the dark. In-branch training data, in our experiments, includes in-language training data, too. Having one piece of information about the word order of that language, its ordering of relative clause and noun, or even its affixational properties, immediately makes the prediction informed rather than random: in many other languages within and outside this particular language family the model would have likely observed a strong correlation between these features and the order of adposition and noun phrase, which are all subject to the more general headedness parameter.

Certain features and feature configurations may not be as abundant cross-linguistically as the set of headedness features. In those cases, access to in-branch data is crucial. Consider e.g. the feature 10B Nasal Vowels in West Africa: a handful of language branches exhibit this feature and at least one of its values, *no nasal vs. oral vowel contrast*, is characteristic predominantly of Niger-Congo languages. Without *any* in-branch training data, the model's knowledge of this feature value is extremely limited, making its correct prediction for a Niger-Congo language virtually impossible. A small amount of in-branch training data thus increases the chance of a correct prediction greatly.

8.2 Semi-supervised extension

Comparing Figure 7 to Figure 6 reveals a crucial finding. While we see very little improvement from pretraining for 0% in-branch training overall, for individual linguistic categories, it mostly benefits prediction: seven out of nine feature groups are predicted more accurately with pretraining. Phonological and morphological predictions experience moderate deterioration, however, counterbalancing much of the improvement in other categories, which leads to the overall result of seemingly little improvement from pretraining. The limited effect of pretraining on prediction of phonological and morphological features can be explained with reference to the richness and complexity of these linguistic domains, which makes for data sparsity and generally makes them harder to learn based on distributional information alone. Moreover, a number of phonological features refer to aspects of language that may not be reflected in writing, such as stress and devoicing. All other categories concern syntactic and semantic information, which is known to be learnable from word distribution, and therefore benefit from the knowledge carried by language embeddings.

Language	**Genus**	**Fixed Stress Location**	**Weight-Sensitive Stress**
English	Germanic	?	Right-oriented
Icelandic	Germanic	Initial	Fixed stress

Table 2: In-branch training data in example scenario

Figure 7 (right) shows an unsteady interaction between pretraining and the addition of increasing amounts of in-branch data. While pretraining alone helps for predicting most features, as pointed out above, an extra 1% of in-branch data in the pretrained setting has a rather variable impact across feature groups. For a few groups it helps, as is expected, for a few it has no effect and for two groups, 'Word Order' and 'Simple Clauses', it makes for quite a drop in accuracy. We speculate that this effect, while negative, is indicative of the general power of language embeddings in associating related languages. Consider the test query 'Fixed Stress Location' in English, where the 1% of in-branch training data contains the information in Table 2. Based on feature correlation alone, the model should predict 'No fixed stress' for English, since this value always co-occurs with 'Right-oriented stress'. Yet, due to the proximity in the English and Icelandic embeddings, the model may copy the value of Icelandic and falsely predict 'Initial stress' for English, too. The risk of this happening decreases with more in-branch training data, since the model can generalise over more in-branch features.

Lastly, notice that accuracy for phonological features remains low even with 5% of in-branch data, and it is lower in the pretrained setting compared to the no-pretraining one. This brings us to the conclusion that using pretrained embeddings which are fine-tuned for specific tasks which encode different linguistic levels, as in Bjerva and Augen-

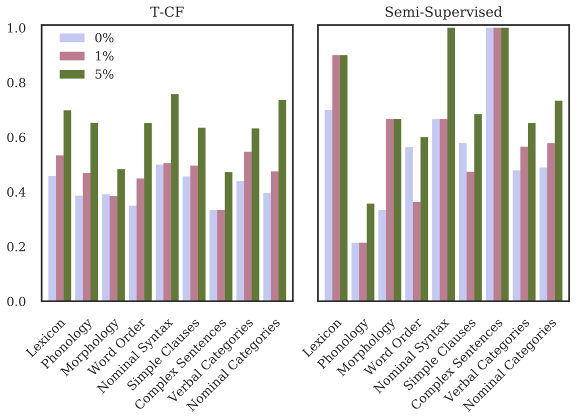

Figure 7: Accuracy per feature group (Germanic).

stein (2018a), might also be useful in our semi-supervised extension of typological collaborative filtering.

9 Related Work

Computational Typology The availability of unlabelled datasets for hundreds of languages permits inferring linguistic properties and categories (Östling, 2015; Asgari and Schütze, 2017). Individual prediction of typological features has been attempted in conjunction with several NLP tasks (Malaviya et al., 2017; Bjerva and Augenstein, 2018a,b). Our work is most similar to Murawaki (2017), who presents a Bayesian approach to utilising relations between features and languages for feature prediction. However, our work differs on several important counts, as we (i) include language information obtained through unsupervised learning, which allows us to take advantage of raw data and predict features for completely unannotated languages, (ii) analyse the effects of varying amounts of known features, especially in situations with and without in-branch training data, and (iii) view the problem of typological features through the lens of parameters from principles and parameters (Chomsky, 2000). Deep generative models have also been explored previously for modelling phonology (Cotterell and Eisner, 2017). Our work builds on these research directions, by (i) developing a deep generative model which (ii) takes advantage of correlations, rather than predicting features individually, and (iii) exploits unlabelled data. This work is also related to linguistic representations encoded in neural models (Kádár et al., 2017) and language embeddings (Bjerva et al., 2019), multilingual relations between languages in various representational levels (Beinborn and Choenni, 2019), as well as the related problem of phylogenetic inference (Farach et al., 1995; Nichols and Warnow, 2008). For a survey of typology in NLP, see Ponti et al. (2018).

Matrix Factorisation Collaborative Filtering was popularised in the early 1990s as a technique for recommender systems with applications such as mail filtering (Goldberg et al., 1992), and article (Resnick et al., 1994) and movie recommendation (Dahlen et al., 1998). Model-based algorithms soon became popular (Breese et al., 1998) to overcome the cold start problem arising for unseen users or items at test time. The most successful one of these, in turn, is matrix factorisation, as applied in this paper, which represents users and items as (dense) vectors in the same latent feature space and measures their compatibility by taking the dot product between the two representations (Koren et al., 2009; Bokde et al., 2015). Beyond recommender systems, matrix factorisation has shown successes in a wide variety of subareas of NLP (Riedel et al., 2013; Rocktäschel et al., 2015; Levy and Goldberg, 2014; Lei et al., 2014; Augenstein et al., 2018).

10 Conclusion

We introduce a generative model inspired by the principles-and-parameters framework, drawing on the correlations between typological features of languages to solve the novel task of typological collaborative filtering. We further show that raw text can be utilised to infer similarities between languages, thus allowing for extending the method with semi-supervised language embeddings.

Abstract

Brown and Exchange word clusters have long been successfully used as word representations in Natural Language Processing (NLP) systems. Their success has been attributed to their seeming ability to represent both semantic and syntactic information. Using corpora representing several language families, we test the hypothesis that Brown and Exchange word clusters are highly effective at encoding morphosyntactic information. Our experiments show that word clusters are highly capable of distinguishing Parts of Speech. We show that increases in Average Mutual Information, the clustering algorithms' optimization goal, are highly correlated with improvements in encoding of morphosyntactic information. Our results provide empirical evidence that downstream NLP systems addressing tasks dependent on morphosyntactic information can benefit from word cluster features.

1 Introduction

Distributionally generated word classes (often referred to as *word clusters*) are hard clusters, containing all word types observed in a corpus, allocated to clusters based on contextual information observed in the corpus. They have found wide use in Natural Language Processing (NLP) systems as an alternative to word embeddings such as word2vec (Mikolov et al., 2013). Word clusters differentiate themselves from word embeddings by requiring estimation of many fewer parameters, and by their ability to derive qualitative representations from smaller corpora (Qu et al., 2015; Bansal et al., 2014).

Brown Clusters (Brown et al., 1992) are a well-known approach based on hard, hierarchical, distributionally derived groups of word types observed in a corpus of unstructured text, with Average Mutual Information (AMI) as the optimization goal. Exchange Clusters are an alternative approach obtained by applying the Exchange Algorithm (Kneser and Ney, 1993) to the same optimization goal. Unlike Brown, Exchange outputs a flat clustering, with no hierarchy (Martin et al., 1998). When only the bottom of the hierarchy is used, like in this paper, Exchange and Brown clusters are interchangeable.

Both Brown and Exchange clusters have been used as word representations for various Natural Language Processing tasks such as Part of Speech tagging in clean and noisy text (Swain and Cole, 2016; Owoputi et al., 2013; Derczynski et al., 2015), dependency parsing (Koo et al., 2008; Bansal et al., 2014), Chinese Word Segmentation (Liang, 2005), and Named Entity Recognition (Swain and Cole, 2016; Derczynski et al., 2015; Liang, 2005). Word clusters distinguish themselves from word embedding models by their ability to learn from little data (Bansal et al., 2014; Qu et al., 2015); for example, in cases like (Bansal et al., 2014), word clusters outperform other kinds of representations, including word embeddings. In the literature, it is often observed that word clusters seem to encode a considerable amount of morphosyntactic and semantic knowledge (Brown et al., 1992; Derczynski et al., 2015). However, it has not yet been studied to which extent such knowledge is encoded, as previous work on Brown and Exchange clusters focuses mostly on algorithmic improvements and on applications to different NLP tasks.

In this work, we present a principled study of the morphosyntactic information encoded in flat word clusters induced exclusively from class-based language models via Brown Clustering and Exchange algorithm. In particular, we focus on how well these approaches derive clusters that represent Parts of Speech as a measure of the morphosyntactic information encoded.

Proceedings of NAACL-HLT 2019, pages 1541–1550
Minneapolis, Minnesota, June 2 - June 7, 2019.

We find that Brown and Exchange clusters are highly effective at representing morphosyntactic information, even when hyper-parameters are set such that they match only the number of Parts of Speech, thereby grouping into relatively few word clusters only. Our results provide empirical evidence for the observed performance gains when including Brown and Exchange word clusters as features in NLP systems that rely on morphosyntactic information.

Furthermore, we find that there is a strong correlation between the optimization goal of Brown clustering and the Exchange Algorithm (i.e., Average Mutual Information), and performance at Parts of Speech separation, which again confirms the appropriateness of choosing AMI in word clustering for morphosyntactic information.

2 Background

Class-based language models address the problem of brittleness in classic n-gram language models by trading precision for performance stability over different text styles (Brown et al., 1992).

Brown Clustering (Brown et al., 1992) and Exchange (Kneser and Ney, 1993) are greedy algorithms that construct word classes by optimizing for higher Average Mutual Information (AMI). Maximizing Average Mutual Information is a proxy for maximizing the log-likelihood of the underlying class-based language model on the given corpus (Martin et al., 1998). Despite their age, most research on Brown or Exchange clusters has so far followed two major directions: algorithm improvements and applications in Natural Language Processing. In contrast little focus has been placed on understanding and evaluating the information content of the clusters.

In the direction of algorithm improvements, work has been done on the effect of greedy merge choices in Brown Clustering (Derczynski and Chester, 2016; Ciosici, 2015) and extension of AMI to n-grams (Martin et al., 1998). Model relaxations, particularly to Exchange, aim to improve computational performance by reducing the effect of words swapping clusters (Dehdari et al., 2016; Uszkoreit and Brants, 2008).

As mentioned earlier, both Brown and Exchange clusters have seen many applications in Natural Language Processing (NLP) systems: PoS tagging (Swain and Cole, 2016; Owoputi et al., 2013; Derczynski et al., 2015), dependency parsing (Koo et al., 2008; Bansal et al., 2014), Chinese Word Segmentation (Liang, 2005), and Named Entity Recognition (Swain and Cole, 2016; Derczynski et al., 2015; Liang, 2005). Most of this work, like (Swain and Cole, 2016) uses the word clusters as sources of features which are combined with hand-designed ones. While word clusters derived using Exchange and Brown clustering have found wide use in NLP systems, their use has been based on the assumption that they encode morphosyntactic and semantic information rather that a principled use.

In relation to Parts of Speech, early on Martin et al. (1998) concluded that initializing Exchange with PoS-homogeneous clusters has no effect on final clustering AMI, but that it does help accelerate convergence. More recently, Christodoulopoulos et al. (2010) found that Brown clusters match the performance of more sophisticated clustering methods, despite their simple algorithmic construction. The study focused on using word clustering algorithms as sources of prototypal information to prototype-driven learning models for classification. In this paper, we study the amount of morphosyntactic information encoded in Brown and Exchange word clusters with the goal of providing empirical results for a principled use of such clusters in downstream tasks.

3 Metric selection

In order to determine the amount of morphosyntactic information encoded in Brown and Exchange word clusters, we measure their ability to separate word types by their Parts of Speech. For this, we require cluster quality measures. Brown and Exchange clusters do not exist in a metric space; therefore unsupervised cluster quality measures relying on distances between points or clusters, such as the Silhouette coefficient (Rousseeuw, 1987), cannot be used. Instead, we focus on two quality measures that compare clusters with a ground truth partitioning. We work under the hypothesis that Brown and Exchange clusters represent parts of speech and thus, we consider parts of speech as the ground-truth partitioning of the data. This makes it possible to use cluster quality measures that require as input an existing ground-truth partitioning. We use PoS tags resulting from manual or automatic annotation. We evaluate using a widespread and easy to interpret measure based on overlap (*purity*), and an information theoretical measure (*Adjusted Mutual Information*).

3.1 Clustering Purity

Cluster purity measures how many points in a clustering (in our case words) have been assigned to a cluster whose predominant label they share (e.g. adjectives clustered with other adjectives, nouns with other nouns etc). Intuitively, it measures the percentage of points properly classified (via their cluster membership). Formally, cluster purity is defined as:

$$purity(C_i) = \frac{1}{|C_i|} \max_{l=1}^{|L|} |label(C_i, l)| \tag{1}$$

$$purity(C) = \sum_{i=1}^{k} \frac{|C_i|}{|V|} purity(C_i) \tag{2}$$

$$= \frac{1}{|V|} \sum_{i=1}^{k} \max_{l=1}^{|L|} |label(C_i, l)| \tag{3}$$

Where the function $label(C_i, l)$ provides the number of elements from C_i with label l and L is the set of labels. *Purity* reaches a value of 1 when the clustering is identical to the ground-truth partitioning, or each point is allocated to its own cluster (i.e. $k = |V|$). When $k = 1$, *purity* is equal to the fraction of points labeled with the most popular label, and thus provides a baseline. In our case, that is equal to the percentage of vocabulary allocated to the most popular PoS class, usually nouns. For values of $k \in (1, |V|)$, it varies depending on cluster quality. If $k > |L|$, *purity* can take a value of 1 if each cluster is a subset of a ground partition. Thus, *purity* is expected to increase as k grows higher than $|L|$.

In our experiments, *purity* measures the percentage of vocabulary that is labeled correctly. In other words, *purity* does not depend on word frequency. Thus, it is not an approximation of PoS tagging accuracy, like the M-1 measure used by Bansal et al. (2014). Since we focus on morphosyntactic information encoded in word clusters, we do not want a measure that takes into account word frequency in the given corpus (i.e, one that is a good approximation of PoS tagging performance), but one that focuses exclusively on the clusters and their content.

3.2 Adjusted Mutual Information

Since the vocabulary size is fixed, as the number of clusters k increases, *purity* can increase even if cluster membership is randomly assigned, as it is easier for smaller clusters to randomly achieve label agreement. *Adjusted Mutual Information (AdjMI)* (Vinh et al., 2009), not to be confused with *AMI* (Brown and Exchange's optimization goal), measures the amount of information shared by the ground truth partitioning U and a clustering C. In our evaluation that corresponds to the amount of information shared by the PoS ground-truth partitioning and the clustering resulting from Brown or Exchange. AdjMI corrects for the mutual information expected to exist between the ground truth partitioning U and a random clustering. Formally, it is defined as:

Data Set	Vocabulary	Length
EN UD	33 904	488 579
EN EuroParl	159 716	73 577 783
FR UD	51 670	575 887
FR EuroParl	204 166	65 878 206
CZ UD	164 483	2 226 848
CZ EuroParl	177 631	15 193 309

Table 1: Overview of data sets

$$AdjMI(U, C) = \frac{MI(U, C) - E\{MI(U, C)\}}{avg\{H(U), H(C)\} - E\{MI(U, C)\}} \tag{4}$$

Where MI and H stand for Mutual Information and Entropy, respectively. Intuitively, *AdjMI* measures how much information we gain about a point's membership in to a cluster in the ground-truth partitioning U, when we know its membership to a cluster in an induced clustering C, and the other way around. As k increases over the number of ground partitions L, *AdjMI* has the opposite effect to *purity*, i.e., it scores lower due to the higher effect attributed to randomness. Just like *purity*, *AdjMI* takes values in the interval $[0, 1]$. An *AdjMI* value of 1 corresponds to a clustering identical to the ground-truth partitioning, while a value of 0 corresponds to a clustering that is not better than a random allocation of points to clusters. Unlike *purity*, values of *AdjMI* cannot be interpreted to say anything about the percentage of points that have been properly allocated. In other words, a value of, say 0.3, does not indicate that 30% of the points have been properly separated.

4 Experiments

4.1 Data and preprocessing

We use manually annotated data from Universal Dependencies (UD) (Leung et al., 2017) for English, French and Czech[1]. We chose the group of languages so that it represents different language families. Our choice of languages is based on the amount of manually labeled data, and the presence of each language in the larger, not annotated, EuroParl corpus. We append the manual or automatic PoS tags and convert text to lowercase. Therefore, a sentence such as "Words have meaning." is transformed into "words_NOUN have_VERB meaning_NOUN ._PUNCT". Both word clustering algorithms studied in this paper are insensitive to the appended PoS tags as they operate at word and not character level. The appended tags allow us to evaluate the quality of word clusters using the measures described in the previous section. We replace all numbers, dates, times, URLs and emails with placeholders in order to reduce vocabulary size. Universal Dependencies is the largest manually annotated corpus we have access to. For experiments on larger corpora, we use the unlabeled EuroParl corpus (Koehn, 2005). More specifically, the English-French and English-Czech pairs. Since manually annotated PoS tags are not available for Europarl, we append automatically assigned PoS tags, obtained by using UDPipe (Straka and Straková, 2017) pretrained on manually annotated corpora from Universal Dependencies.

We use flat clusters from the Exchange clustering algorithm for all experiments reported in this section as they outperform the flat clustering resulting from Brown in terms of *Average Mutual Information* (their optimization goal), *Adjusted Mutual Information (AdjMI)* and cluster *purity*. All observations in the following section also apply to the flat clusters resulting from Brown. For interested readers, we include all experiments with Brown Clustering as supplementary material. The fact that Exchange outperforms Brown Clustering in terms of AMI is well-understood (Brown et al., 1992), but its effect on cluster content is not.

4.2 Morphosyntactic content in Exchange and Brown clusters

Using Exchange, we induce flat clusterings with k in the range 18 to 800. We start with $k = 18$ as it matches the observed number of distinct PoS tags in the Universal Dependencies corpora (17 distinct tags and one catch-all tag). When setting the hyper-parameter k to be higher than 18, if Exchange separates clusters by Parts of Speech, then the expectation is that clusters are subsets of words sharing the same PoS tags, and that *purity* for such clusterings will be high. In Figure 1a, we show *purity* measured on the aforementioned clusters. We can see that, even when the number of clusters is equal to that of PoS tags ($k = 18$), between 55% and 62% of the vocabulary is properly separated. *Purity* increases as k increases towards 100. At $k = 500$ and $k = 800$, between 64% and 70% of the vocabulary is grouped based on PoS, not that much more than at $k = 100$.

Increasing the number of clusters k to high values is not guaranteed to improve *purity*, for any of the languages studied. This is contrary to the expectation that *purity* increases when $k > 18$. This indicates that Exchange and Brown do not exclusively optimize for Part of Speech separation. We believe the clustering algorithms might be striking a balance between encoding semantic and morphosyntactic information, since at higher values of k we usually see more clusters with a coherent semantic theme such as names of geographic locations, names of men, names of women, nouns determining times, similar to the clusters observed in previous literature (Brown et al., 1992). For example, when using $k = 18$ in English, the token "cat_NOUN" appears in the same cluster as the plural version "cats_NOUN". At $k = 800$, the clusters distinguish between the two tokens and "cat_NOUN" is placed together with a number of nouns in the singular such as "budget_NOUN, computer_NOUN, pet_NOUN, wheel_NOUN", while "cats_NOUN" is placed in a cluster of mostly pluralized nouns like "children_NOUN, rooms_NOUN, dogs_NOUN, families_NOUN".

Adjusted Mutual Information (AdjMI) for the same clusterings, Figure 1b, shows a considerable decrease as the hyper-parameter k increases, especially at high values of 500 and 800. This is in line with the expected punishment due to the effect attributed to randomness (see the term for expected

---

[1] We use data from release 2.2 of Universal Dependencies.

value of Mutual Information in Equation (4)). At values of k closer to the number of PoS tags in the data, *AdjMI* varies little from one clustering to the other. More interestingly, the relative order of separation performance between the languages studied is maintained going from *purity* to *AdjMI*, suggesting that no measure-specific effects are at play.

By studying the frequency of incorrectly classified words types (i.e., of those whose PoS tag does not match the most popular one in their cluster), we find that most (about 85%) occur less than 5 times in the corpora. Such few observations likely do not provide enough information for Brown or Exchange to properly place those words. Therefore, from the already computed clusterings, we remove words with a frequency less than 5 and recalculate the two quality measures.

In Figures 1c and 1d, we can see that both *purity* and *AdjMI* improve considerably. Even in the most difficult case ($k = 18$), where the number of clusters matches that of distinct PoS tags, between 68% and 78% of words are properly placed, an increase of $21\% - 28\%$ compared to the values in Figure 1a. For *AdjMI*, the scores more than double. These results show that even for small corpora, a large amount of morphosyntactic information can be encoded, completely unsupervised, using the Exchange clustering algorithm. (The same behavior can be observed for clusters derived using the Brown Clustering algorithm, see supplementary material.) It also shows that, for low frequency terms, there is not enough contextual information for a proper clustering.

One disadvantage of thresholding by frequency is that, due to the zipfian distribution of word frequencies in natural language, only a fraction of the original vocabulary remains after filtering out words with a frequency less than 5: English ($8\,143\ words - 24.01\%$), French ($9\,020\ words - 17.45\%$), Czech ($37\,026\ words - 22.51\%$). In order to benefit from more reliable word usage estimates, it is necessary to perform the same experiment on larger corpora. Unfortunately bigger manually annotated data sets do not exist. We therefore turn to automatic PoS tagging.

We use UDPipe (Straka and Straková, 2017) with models pretrained on the Universal Dependencies corpora to automatically tag text from the EuroParl multi-language corpus containing transcriptions of European Parliament proceedings (Koehn, 2005). Automated annotations introduce labeling noise that should lead to a decrease in separation performance. Despite this, we expect to still be able to observe good PoS separation.

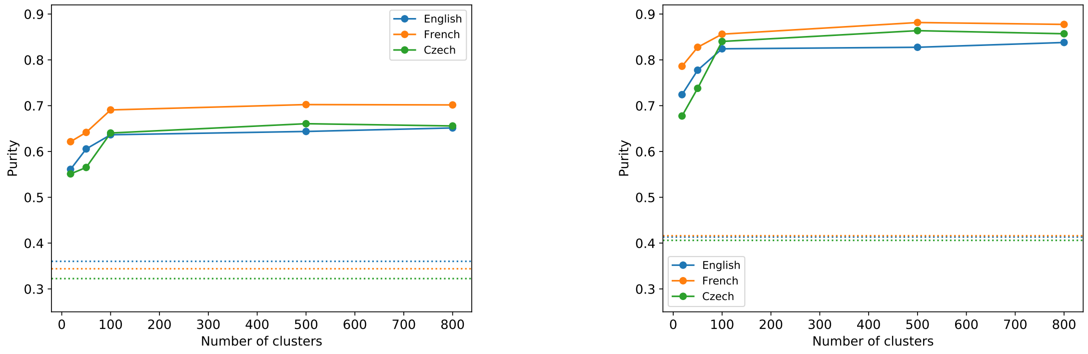
After filtering the EuroParl corpora, the size of remaining vocabulary is considerably larger: English ($60\,373\ words - 37.80\%$), French ($78\,822\ words - 38.60\%$), Czech ($62\,512\ words - 35.19\%$). In Figure 2a we can see that there is a drop in performance that varies with language, but when looking at purity, even in the worst performing clustering (French at $k = 50$), 60% of the vocabulary is still properly separated according to Parts of Speech. A drop in performance can also be observed for *AdjMI* in Figure 2b, with the value dropping for all languages, in some cases reducing by half.

More interestingly, the relative performance order of the languages is changed. PoS separation for Czech outperforms that of the other languages. Actually, PoS separation for Czech on EuroParl data (Figure 2) is scored higher than that of Czech on Universal Dependencies (Figures 1c and 1d). The source of this improvement requires more study for a proper attribution, but could be due to “beneficial” noise introduced by the automatic tagging, or due to the introduction of more sentence structure by human translators.

The fact that even at low values of k, for all languages studied, on both corpora, Exchange Word clusters (and also Brown word clusters, see supplementary material) can successfully separate by Parts of Speech, helps understand why word clusters have had such success at PoS tagging whether coupled with Markov Models (Derczynski et al., 2015), Markov Models and morphological features (Owoputi et al., 2013), or just by themselves via M-1 (Bansal et al., 2014).

4.3 The relation between AMI and PoS

Neither Exchange, nor Brown are guaranteed to converge to a global optimum. Both are greedy algorithms that optimize for high Average Mutual Information (AMI). As we have mentioned earlier, word clusters resulting from Exchange outperform those induced using the Brown clustering algorithm in terms of both *AMI* (the algorithm’s optimization goal), *PoS purity* and *Adjusted Mutual Information (AdjMI)*. A natural question to ask is: can one improve the morphosyntactic content of word clusters by obtaining higher AMI, maybe by



(a) Cluster purity with baselines for $k = 1$. No frequency thresholding.

(c) Cluster purity with baselines for $k = 1$. Only words with frequency minimum 5.

developing new and better AMI-based clustering algorithms?

We answer this question by studying the correlation between *Average Mutual Information* and the two cluster quality measures used earlier: *purity* and *AdjMI*. Brown clustering is a predictable, bottom-up, agglomerative, hard clustering algorithm that for the same hyper-parameter k, generates the same clusters and therefore only one data sample.[2] However, the Exchange algorithm is an iterative clustering algorithm that has a complete and valid cluster partitioning at the end of each iteration. Thus, we can also measure morphosyntactic content in each of these clusterings. In our experiments, we only obtain 10 different data samples from each run of the algorithm, not enough for a correlation analysis.

In order to collect more data samples (i.e. more clusterings), we suggest using a stochastic version of Exchange where a percentage of all swaps are performed at random, rather than with the goal of improving AMI. This version of Exchange terminates based on the number of iterations, and generates valid word partitionings of varying quality (from an *AMI* perspective) at the end of each iteration. In this manner, it provides us with more data points (i.e. more different clusterings) for analysis. Due to the small amount of random swaps, at varying *AMI*, we obtain a sufficient number of distinct clusterings to perform a correlation study with sufficient data.

With the stochastic implementation of Exchange, we run 50 iterations for all languages and k combinations studied earlier. In Tables 2 and 3, we show the Pearson and Spearman correlation coefficients between AMI of all clusterings generated by StochasticExchange for a given run, and the two scores used earlier: *purity* and *AdjMI*. Due to space considerations, we only show results for $k = 18$ (i.e., same number of clusters as the number of PoS tags). Correlation coefficients for other combinations are included in the supplementary material. $p < 0.01$ for all correlation experiments here and in the supplementary material and for both correlation coefficients. The analysis presented below also holds for all the correlation re-

sults included in the supplementary material.

For both *purity* and *AdjMI*, there is a strong Pearson correlation between higher AMI and better values of the evaluation score. This is independent of the language studied or the number of clusters derived. For Spearman, except for one case, in all combinations studied, there is a high correlation, although to a slightly less extreme degree as with Pearson.

Our experiments show that there is strong correlation between *AMI* and performance in separation of Parts of Speech as measured by *purity* and *AdjMI*. The strong correlation provides grounding for research into new AMI-maximizing word clustering algorithms that can achieve higher AMI than Exchange, or Brown, as such algorithms might be able to separate Parts of Speech even better.

4.4 Effect of polysemy on cluster purity

In previous sections, we studied the ability of word clusters to encode morphosyntactic information. We clustered word types from unstructured text, where each token had its Part of Speech tag appended. The post-pended PoS tags are not used by either Brown, or Exchange. They are essentially invisible to the algorithms, since the both Brown and Exchange recognize words exclusively by internally assigned integer IDs and do not operate at character level.

However, post-pending PoS tags does introduce some information into the text by providing PoS-role disambiguation for each word occurrence.

For example, without post-pended PoS tags, both Exchange, and Brown algorithms, would conflate the two distinct grammatical roles of *show* in the sentence: “Everyone must show their show tickets at the entrance”. In this section, we study PoS separation effects caused by such polysemy on Brown and Exchange word clusters.

Both Exchange and Brown construct hard clusters, i.e. each word can be assigned to exactly one word class. Thus, words with multiple roles, such as denominal verbs or deverbal nouns, cannot be differentiated by the algorithms when operating on corpora from languages where the such morphological derivations are performed without employing suffixes or prefixes. In other words, if the lexical form does not change, neither Brown nor Exchange can identify which tokens represent what grammatical role.

The extent of this effect is dependent on language. In English, for example, nouns are often turned into verbs without changing the lexical form through morphological derivation, e.g. *show* as a verb vs *show* as a noun. On the other hand, Czech is highly inflected accounting for gender, case, number and person. This property of each language was not problematic in the experiments we have performed so far due to the fact that post-pending the PoS tag from ground-truth (or automatic tags) effectively provides disambiguation of grammatical role. Measuring on the Universal Dependencies corpora, we find that the percentage of polyclass words (i.e. word types that are assigned more than one PoS class tag throughout the corpus) varies by language and increases (as percentage of remaining vocabulary) as we raise the minimum frequency threshold, see Table 4. For English and French, up to 43% of the vocabulary words have more than one tag, while only $5,5\%$ of the Czech vocabulary shares the same property. Part of the reason why so many words have multiple PoS tags has to do with how the various language families derive new words, and part of the reason stems from errors in PoS tagging of large text corpora (Silberztein, 2018).

From a practical point of view, polysemous words create an upper bound on the effectiveness of hard clustering for Part of Speech separation (PoS). In Figure 3, we show PoS purity for clusters induced over Universal Dependencies (UD) corpora, where we consider all polyclass words as clustered incorrectly. We also show the minimum purity (when $k = 1$) as well as the upper bound given by the polysemy of each language as observed from the manual labels. The evaluation strictly penalizes multiclass polysemy and ignores errors in labeling, such as those identified by Silberztein (2018). For example, in the UD English corpus, even though only 3 occurrences of the word “them” are incorrectly tagged as adverb, while the remaining 750 are correctly labeled as pronoun. We defer to the data and consider the word to be impossible to correctly allocate to a cluster. We use such a strict evaluation as it provides a lower bound on what can be expected from Exchange and Brown clusters given the current data. Correcting PoS tags in the data would probably improve PoS separation, however, such corrections are outside the scope of the work in this paper.

We should point out that this evaluation is not representative of the expected PoS tagging performance of word clusters on any given corpus, as for such taggers one would employ a different strategy, such as, for instance, always outputting the most popular PoS tag for any given word type. On top of that, our evaluation here does not take into account the frequency of tokens, which would be highly relevant for PoS taggining performance, but not for our evaluation.

As expected, the most affected language is English, due to the high level of polysemy in the data. Here *purity* drops from 72.4 to 42.32 for $k = 18$, when compared with results in Figure 1c. It is followed by a 20 point drop for French, and only a few points for Czech, the most morphologically rich of the three and with the least amount of ambiguity in grammatical role. The results suggest that even in the presence of language ambiguity, and considering the strictest evaluation, Exchange and Brown clusters successfully encode a considerable amount of morphosyntactic information, which varies by language. These, together with results presented earlier in this paper provide empirical evidence for using word clusters as word representations in downstream NLP systems addressing tasks that rely on morphosyntactic knowledge of the language targeted (e.g. dependency parsing), or for use in new paradigms such as data programming (Ratner et al., 2016), where cluster membership can be a strong signal for probabilistic data labeling, even when considering language ambiguity.

Data Set	Min 1	Min 5
EN UD	15.39	43.02
FR UD	9.09	41.04
CZ UD	1.81	5.51

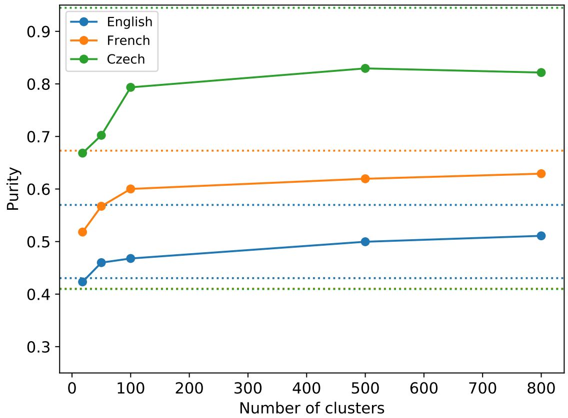

Figure 3: Cluster purity for manually annotated corpora from UD. Only words with frequency minimum 5. Dotted lines are baselines for $k = 1$ and highest achievable purity given polysemy in corpus.

5 Conclusion

In this paper, we quantified the amount of morphosyntactic information encoded in Brown and Exchange word clusters, in a number of languages, from different language families. Our empirical quantification helps explain the success of word clusters as word representations in NLP tasks that rely on morphosyntactic information, such as PoS tagging and Named Entity Recognition. It further provides empirical evidence for using word clusters as word representations in other NLP tasks that require morphosyntactic knowledge of the language targeted (e.g. dependency parsing), or for use in new paradigms such as data programming (Ratner et al., 2016), where cluster membership can be a strong signal for probabilistic data labeling. We have also shown that there is a strong correlation between *AMI* (Brown and Exchange's optimization goal) and performance in PoS separation. The strong correlation demonstrated provides grounding for research into new AMI-maximizing word representation algorithms that can achieve even better AMI optimization than Exchange or Brown.

Analyzing Bayesian Crosslingual Transfer in Topic Models

Abstract

We introduce a theoretical analysis of crosslingual transfer in probabilistic topic models. By formulating posterior inference through Gibbs sampling as a process of language transfer, we propose a new measure that quantifies the loss of knowledge across languages during this process. This measure enables us to derive a PAC-Bayesian bound that elucidates the factors affecting model quality, both during training and in downstream applications. We provide experimental validation of the analysis on a diverse set of five languages, and discuss best practices for data collection and model design based on our analysis.

1 Introduction

Crosslingual learning is an important area of natural language processing that has driven applications including text mining in multiple languages (Ni et al., 2009; Smet and Moens, 2009), cultural difference detection (Gutiérrez et al., 2016), and various linguistic studies (Shutova et al., 2017; Barrett et al., 2016). Crosslingual learning methods generally extend monolingual algorithms by using various multilingual resources. In contrast to traditional high-dimensional vector space models, modern crosslingual models tend to rely on learning low-dimensional word representations that are more efficient and generalizable.

A popular approach to representation learning comes from the word embedding community, in which words are represented as vectors in an embedding space shared by multiple languages (Ruder et al., 2018; Faruqui and Dyer, 2014; Klementiev et al., 2012). Another direction is from the topic modeling community, where words are projected into a probabilistic topic space (Ma and Nasukawa, 2017; Jagarlamudi and III, 2010). While formulated differently, both types of models apply the same principles—low-dimensional vectors exist in a shared crosslingual space, wherein vector representations of similar concepts across languages (*e.g.,* "dog" and "hund") should be nearby in the shared space.

To enable crosslingual representation learning, knowledge is transferred from a source language to a target language, so that representations have similar values across languages. In this study, we will focus on probabilistic topic models, and "knowledge" refers to a word's probability distribution over topics. Little is known about the characteristics of crosslingual knowledge transfer in topic models, and thus this paper provides an analysis, both theoretical and empirical, of crosslingual transfer in multilingual topic models.

1.1 Background and Contributions

Multilingual Topic Models Given a multilingual corpus $D^{(1,\dots,L)}$ in languages $\ell = 1,\dots,L$ as inputs, a multilingual topic model learns K topics. Each multilingual topic $k^{(1,\dots,L)}$ ($k = 1,\dots,K$), is defined as an L-dimensional tuple $\left(\phi_k^{(1)},\dots,\phi_k^{(L)}\right)$, where $\phi_k^{(\ell)}$ is a multinomial distribution over the vocabulary $V^{(\ell)}$ in language ℓ. From a human's perspective, a multilingual topic $k^{(1,\dots,L)}$ can be interpreted by looking at the word types that have C highest probabilities in $\phi_k^{(\ell)}$ for each language ℓ. C here is called *cardinality* of the topic. Thus, a multilingual topic can loosely be thought of as a group of word lists where each language ℓ has its own version of the topic.

Multilingual topic models are generally extended from Latent Dirichlet Allocation (Blei et al., 2003, LDA). Though many variations have been proposed, the underlying structures of multilingual topic models are similar. These models require either a parallel/comparable corpus in multiple languages, or word translations from a

Proceedings of NAACL-HLT 2019, pages 1551–1565
Minneapolis, Minnesota, June 2 - June 7, 2019.

dictionary. One of the most popular models is the polylingual topic model (Mimno et al., 2009, PLTM), where comparable document pairs share distributions over topics θ, while each language ℓ has its own distributions $\{\phi_k^{(\ell)}\}_{k=1}^K$ over the vocabulary $V^{(\ell)}$. By re-marginalizing the estimations $\{\widehat{\phi}_k^{(\ell)}\}_{k=1}^K$, we obtain word representations $\widehat{\varphi}^{(w)} \in \mathbb{R}^K$ for each word w, where $\widehat{\varphi}_k^{(w)} = \Pr(z_w = k|w)$, *i.e.,* the probability of topic k given a word type w.

Crosslingual Transfer Knowledge transfer through crosslingual representations has been studied in prior work. Smet and Moens (2009) and Heyman et al. (2016) show empirically how document classification using topic models implements the ideas of crosslingual transfer, but to date there has been no theoretical framework to analyze this transfer process in detail.

In this paper, we describe two types of transfer—on-site and off-site—based on the nature of where and how the transfer takes place. We refer to transfer that happens while training topic models (*i.e.,* during representation learning) as *on-site*. Once we obtain the low-dimensional representations, they can be used for downstream tasks. We refer to transfer in this phase as *off-site*, since the crosslingual tasks are usually detached from the process of representation learning.

Contributions Our study provides a theoretical analysis of crosslingual transfer learning in topic models. Specifically, we first formulate on-site transfer as circular validation, and derive an upper bound based on PAC-Bayesian theories (Section 2). The upper bound explicitly shows the factors that can affect knowledge transfer. We then move on to off-site transfer, and focus on crosslingual document classification as a downstream task (Section 3). Finally, we show experimentally that the on-site transfer error can have impact on the performance of downstream tasks (Section 4).

2 On-Site Transfer

On-site transfer refers to the training procedure of multilingual topic models, which usually involves Bayesian inference techniques such as variational inference and Gibbs sampling. Our work focuses on the analysis of collapsed Gibbs sampling (Griffiths and Steyvers, 2004), showing how knowledge is transferred across languages and how a topic space is formed through the sampling process. To this end, we first describe a specific formulation of knowledge transfer in multilingual topic models as a starting point of our analysis (Section 2.1). We then formulate Gibbs sampling as circular validation and quantify a loss during this phase (Section 2.2). This formulation leads us to a PAC-Bayesian bound that explicitly shows the factors that affect the crosslingual training (Section 2.3). Lastly, we look further into different transfer mechanisms in more depth (Section 2.4).

2.1 Transfer through Priors

Priors are an important component in Bayesian models like PLTM. In the original generative process of PLTM, each comparable document pair (d_S, d_T) in the source and target languages (S, T) is generated by the same multinomial $\theta \sim \text{Dir}(\alpha)$.

Hao and Paul (2018) showed that knowledge transfer across languages happens through priors. Specifically, assume the source document is generated from $\theta^{(d_S)} \sim \text{Dir}(\alpha)$, and has a sufficient statistics $\mathbf{n}_{d_S} \in \mathbb{N}^K$ where each cell $n_{k|d_S}$ is the count of topic k in document d_S. When generating the corresponding comparable document d_T, the Dirichlet prior of the distribution over topics $\theta^{(d_T)}$, instead of a symmetric α, is parameterized by $\alpha + \mathbf{n}_{d_S}$. This formulation yields the same posterior estimation as the original joint model and is the foundation of our analysis in this section.

To see this transfer process more clearly, we look closer to the conditional distributions during sampling, and take PLTM as an example. When sampling a token in target language x_T, the Gibbs sampler calculates a conditional distribution $\mathcal{P}_{x_T}$ over K topics, where a topic k is randomly drawn and assigned to x_T (denoted as z_{x_T}). Assume the token x_T is in document d_T whose comparable document in the source language is d_S. The conditional distribution for x_T is

$$\begin{aligned}\mathcal{P}_{x,k} &= \Pr(z_x = k; \mathbf{w}_-, \mathbf{z}_-) \qquad (1)\\ &\propto \left(n_{k|d_T} + n_{k|d_S} + \alpha\right) \cdot \frac{n_{w_T|k} + \beta}{n_{\cdot|k} + V^{(T)}\beta},\end{aligned}$$

where the quantity $n_{k|d_S}$ is added and thus transferred from the source document. Thus, the calculation of $\mathcal{P}_x$ incorporates the knowledge transferred from the other language.

Now that we have identified the transfer process, we provide an alternative view of Gibbs sampling, *i.e.,* circular validation, in the next section.

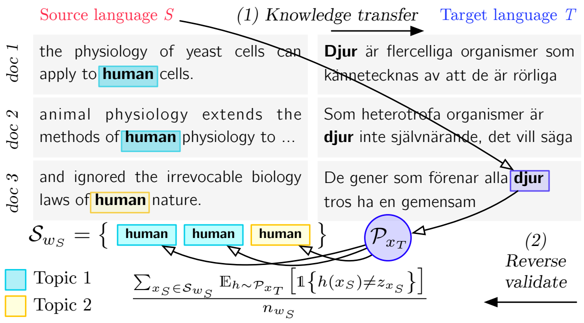

Figure 1: The Gibbs sampler is sampling the token "djur" (animal). Using the classifier h_k sampled from its conditional distribution $\mathcal{P}_{x_T}$, circular validation evaluates h_k on all the tokens of type "human".

2.2 Circular Validation

Circular validation (or reverse validation) was proposed by Zhong et al. (2010) and Bruzzone and Marconcini (2010) in transfer learning. Briefly, a learning algorithm $\mathcal{A}$ is trained on both source and target datasets (D_S and D_T), where the source is labeled and target is unlabeled. After predicting the labels for the target dataset using $\mathcal{A}$ (predictions denoted as $\mathcal{A}(D_T)$), circular validation trains another algorithm $\mathcal{A}'$ in the reverse direction, *i.e.,* uses $\mathcal{A}(D_T)$ and D_T as the labeled dataset and D_S as the unlabeled dataset. The error is then evaluated on $\mathcal{A}'(D_S)$. This "train-predict-reverse-repeat" cycle has a similar flavor to the iterative manner of Gibbs sampling, which inspires us to look at the sampling process as circular validation.

Figure 1 illustrates this process. Suppose the Gibbs sampler is currently sampling x_T of word type w_T in target language T. As discussed for Equation (1), the calculation of the conditional distribution $\mathcal{P}_{x_T}$ incorporates the knowledge transferred from the source language. We then treat the process of drawing a topic from $\mathcal{P}_{x_T}$ as a *classification* of the token x_T. Let $\mathcal{P}_{x_T}$ be a distribution over K unary *classifiers*, $\{h_k\}_{k=1}^{K}$, and the k-th classifier labels the token as topic k with a probability of one:

$$h_k \sim \mathcal{P}_{x_T}, \text{ and } \Pr\left(z_{x_T} = k; h_k\right) = 1. \quad (2)$$

This process is repeated between the two languages until the Markov chain converges.

The training of topic models is unsupervised, *i.e.,* there is no ground truth for labeling a topic, which makes it difficult to analyze the effect of transfer learning. Thus, after calculating $\mathcal{P}_{x_T}$, we take an additional step called *reverse validation*, where we design and calculate a measure—circular validation loss—to quantify the transfer.

Definition 1 (Circular validation loss, CVL)**.** *Let $\mathcal{S}_w$ be the set containing all the tokens of type w throughout the whole training corpus, and call it the sample of w. Given a bilingual word pair (w_T, w_S) where w_T is in target language T while w_S in source S, let $\mathcal{S}_{w_T}$ and $\mathcal{S}_{w_S}$ be the samples for the two types respectively, and n_{w_T} and n_{w_S} the sizes of them. The empirical circular validation score ($\widehat{\text{CVL}}$) is defined as*

$$\begin{aligned}
\widehat{\text{CVL}}(w_T, w_S) &= \frac{1}{2} \mathop{\mathbb{E}}_{x_S, x_T} \left[\widehat{\mathcal{L}}(x_T, w_S) + \widehat{\mathcal{L}}(x_S, w_T) \right], \\
\widehat{\mathcal{L}}(x_T, w_S) &= \frac{1}{n_{w_S}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathbb{E}_{h \sim \mathcal{P}_{x_T}} \left[\mathbb{1}\left\{ h(x_S) \neq z_{x_S} \right\} \right] \\
&= \frac{1}{n_{w_S}} \sum_{x_S \in \mathcal{S}_{w_S}} \left(1 - \mathcal{P}_{x_T, z_{x_S}} \right),
\end{aligned}$$

where $\mathcal{P}_{x_T,k}$ is the conditional probability of token x_T assigned with topic k. Taking expectations over all tokens x_S and x_T, we have general CVL*:*

$$\begin{aligned}
\text{CVL}(w_T, w_S) &= \frac{1}{2} \mathop{\mathbb{E}}_{x_S, x_T} \left[\mathcal{L}(x_T, w_S) + \mathcal{L}(x_S, w_T) \right], \\
\mathcal{L}(x_T, w_S) &= \mathbb{E}_{x_S} \mathbb{E}_{h \sim \mathcal{P}_{x_T}} \left[\mathbb{1}\left\{ h(x_S) \neq z_{x_S} \right\} \right].
\end{aligned}$$

When sampling a token x_T, we still follow the two-step process as in Equation (2), but instead of labeling x_T itself, we use its conditional $\mathcal{P}_{x_T}$ to label the entire sample of a word type w_S in the source language. Since all the topic labels for the source language are fixed, we take them as the assumed "correct" labelings, and compare x_S's labels and the predictions from $\mathcal{P}_{x_T}$. This is the intuition behind CVL.

Note that the choice of word types w_T and w_S to calculate $\widehat{\text{CVL}}$ is arbitrary. However, $\widehat{\text{CVL}}$ is only meaningful when the two word types are semantically related, such as word translations, because those word pairs are where the knowledge transfer takes place. On the other hand, the Gibbs sampler does not calculate this $\widehat{\text{CVL}}$ explicitly, and thus adding reverse validation step does not affect the training of the model. It does, however, help us to expose and analyze the knowledge transfer mechanism. In fact, as we show in the next theorem, sampling is also a procedure of optimizing $\widehat{\text{CVL}}$.

Theorem 1. *Let $\widehat{\text{CVL}}^{(t)}(w_T, w_S)$ be the empirical circular validation loss of any bilingual word pair at iteration t of Gibbs sampling. Then $\widehat{\text{CVL}}^{(t)}(w_T, w_S)$ converges as $t \to \infty$.*

Proof. See Appendix. □

2.3 PAC-Bayes View

A question following the formulation of $\widehat{\text{CVL}}$ is, what factors could lead to better transfer during this process, particularly for semantically related words? To answer this, we turn to theory that bounds the performance of classifiers and apply this theory to this formulation of topic sampling as classification.

The PAC-Bayes theorem was introduced by McAllester (1999) to bound the performance of Bayes classifiers. Given a hypothesis set $\mathcal{H}$, the majority vote classifier (or Bayes classifier) uses every hypothesis $h \in \mathcal{H}$ to perform binary classification on an example $\mathbf{x}$, and uses the majority output as the final prediction. Since minimizing the error by Bayes classifier is NP-hard, an alternative way is to use a *Gibbs classifier* as approximation. The Gibbs classifier first draws a hypothesis $h \in \mathcal{H}$ according to a posterior distribution over $\mathcal{H}$, and then uses this hypothesis to predict the label of an example $\mathbf{x}$ (Germain et al., 2012). The generalization loss of this Gibbs classifier can be bounded as follows.

Theorem 2 (PAC-Bayes theorem, McAllester (1999))**.** *Let $\mathcal{P}$ be a posterior distribution over all classifiers $h \in \mathcal{H}$, and Q a prior distribution. With a probability at least $1-\delta$, we have*

$$\mathcal{L} \le \widehat{\mathcal{L}} + \sqrt{\frac{1}{2n}\left(\mathrm{KL}\left(\mathcal{P}||Q\right) + \ln\frac{2\sqrt{n}}{\delta}\right)},$$

where $\mathcal{L}$ and $\widehat{\mathcal{L}}$ are the general loss and the empirical loss on a sample of size n.

In our framework, a token x_T provides a posterior $\mathcal{P}_{x_T}$ over K classifiers. The loss $\widehat{\mathcal{L}}(x_T, w_S)$ is then calculated on a sample of $\mathcal{S}_{w_S}$ in language S. The following theorem shows that for a bilingual word pair (w_T, w_S), the general CVL can be bounded with several quantities.

Theorem 3. *Given a bilingual word pair (w_T, w_S), with probability at least $1-\delta$, the following bound holds:*

$$\begin{gathered}\text{CVL}(w_T, w_S) \le \widehat{\text{CVL}}(w_T, w_S) + \qquad (3)\\ \frac{1}{2}\sqrt{\frac{1}{n}\left(\mathrm{KL}_{w_T} + \mathrm{KL}_{w_S} + 2\ln\frac{2}{\delta}\right)} + \frac{\ln n^\star}{n},\\ n = \min\left\{n_{w_T}, n_{w_S}\right\}, \quad n^\star = \max\left\{n_{w_T}, n_{w_S}\right\}.\end{gathered}$$

For brevity we use KL_w to denote $\mathrm{KL}(\mathcal{P}_x||Q_x)$, where $\mathcal{P}_x$ is the conditional distribution from Gibbs sampling of token x with word type w that gives highest loss $\widehat{\mathcal{L}}(x,w)$, and Q_x a prior.

Proof. See Appendix. □

2.4 Multilevel Transfer

Recall that knowledge transfer happens through priors in topic models (Section 2.1). Because the KL-divergence terms in Theorem 3 include this prior Q, we can use this theorem to analyze the transfer mechanisms more concretely.

The conditional distribution for sampling a topic z_x for a token x during sampling can be factorized into document-topic and topic-word levels:

$$\begin{aligned}\mathcal{P}_{x,k} &= \Pr\left(z_x = k | w_x = w, \mathbf{w}_-, \mathbf{z}_-\right)\\ &= \Pr\left(z_x = k | \mathbf{z}_-\right) \cdot \Pr\left(w_x = w | z_x = k, \mathbf{w}_-, \mathbf{z}_-\right)\\ &\propto \underbrace{\Pr\left(z_x = k | \mathbf{z}_-\right)}_{\text{document level}} \cdot \underbrace{\Pr\left(z_x = k | w_x = w, \mathbf{w}_-\right)}_{\text{word level}}\\ &\triangleq \mathcal{P}_{\theta,x,k} \cdot \mathcal{P}_{\varphi,x,k},\\ \mathcal{P}_x &\triangleq \mathcal{P}_{\theta,x} \otimes \mathcal{P}_{\varphi,x},\end{aligned}$$

where $\otimes$ is element-wise multiplication. Thus, we have the following inequality:

$$\begin{aligned}\mathrm{KL}\left(\mathcal{P}_x||Q_x\right) &= \mathrm{KL}\left(\mathcal{P}_{\theta,x} \otimes \mathcal{P}_{\varphi,x}||Q_{\theta,x} \otimes Q_{\varphi,x}\right)\\ &\le \mathrm{KL}\left(\mathcal{P}_{\theta,x}||Q_{\theta,x}\right) + \mathrm{KL}\left(\mathcal{P}_{\varphi,x}||Q_{\varphi,x}\right),\end{aligned}$$

and the KL-divergence term in Theorem 3 is simply the sum of the KL-divergences between the conditional and prior distributions on all levels.

Recall that PLTM transfers knowledge at the document level, through $Q_{\theta,x}$, by linking document translations together (Equation (1)). Assume the current token x is from a target document linked to a document d_S in the source language. Then the prior for $\mathcal{P}_{\theta,x}$ is $\widehat{\theta}^{(d_S)}$, *i.e.,* the normalized empirical distribution over topics of d_S.

Since the words are generated *within* each language under PLTM, *i.e.,* $\phi_k^{(S)}$ is irrelevant to $\phi_k^{(T)}$, no transfer happens at the word level. In this case, $Q_{\varphi,x}$, the prior for $\mathcal{P}_{\varphi,x}$, is simply a K-dimensional uniform distribution $\mathcal{U}$. Then:

$$\begin{aligned}\mathrm{KL}_w &\le \mathrm{KL}\left(\mathcal{P}_{\theta,x}||\widehat{\theta}^{(d_S)}\right) + \mathrm{KL}\left(\mathcal{P}_{\varphi,x}||\mathcal{U}\right)\\ &= \underbrace{\mathrm{KL}\left(\mathcal{P}_{\theta,x}||\widehat{\theta}^{(d_S)}\right)}_{\text{crosslingual entropy}} + \log K - \underbrace{H(\mathcal{P}_{\varphi,x})}_{\text{monolingual entropy}}.\end{aligned}$$

Thus, at levels where transfer happens (document- or word-level), a low crosslingual entropy is preferred, to offset the impact of monolingual entropy where no transfer happens.

Most multilingual topic models are generative admixture models in which the conditional probabilities can be factorized into different levels, thus KL-divergence term in Theorem 3 can be decomposed and analyzed in the same way as in this section for models that have transfer at other levels, such as Hao and Paul (2018), Heyman et al. (2016), and Hu et al. (2014). For example, if a model has word-level transfer, *i.e.,* the model assumes that word translations share the same distributions, we have a KL-divergence term as,

$$\begin{aligned}\mathrm{KL}_w &\le \mathrm{KL}\left(\mathcal{P}_{\varphi,x}||\widehat{\varphi}^{(w_S)}\right) + \mathrm{KL}(\mathcal{P}_{\theta,x}||\mathcal{U}) \\ &= \mathrm{KL}\left(\mathcal{P}_{\varphi,x}||\widehat{\varphi}^{(w_S)}\right) + \log K - H(\mathcal{P}_{\theta,x}),\end{aligned}$$

where w_S is the word translation to word w.

3 Off-Site Transfer

Off-site transfer refers to language transfer that happens while applying trained topic models to downstream crosslingual tasks such as document classification. Because transfer happens using the trained representations, the performance of off-site transfer heavily depends on that of on-site transfer. To analyze this problem, we focus on the task of crosslingual document classification.

In crosslingual document classification, a *document classifier*, h, is trained on documents from one language, and h is then applied to documents from another language. Specifically, after training bilingual topic models, we have K bilingual word distributions $\{\widehat{\phi}_k^{(S)}\}_{k=1}^K$ and $\{\widehat{\phi}_k^{(T)}\}_{k=1}^K$. These two distributions are used to infer document-topic distributions $\widehat{\theta}$ on unseen documents in the test corpus, and each document is represented by the inferred distributions. A document classifier is then trained on the $\widehat{\theta}$ vectors as features in source language S and tested on the target T.

We aim to show how the generalization risk on target languages T, denoted as $R_T(h)$, is related to the training risk on source languages S, $\widehat{R_S}(h)$. To differentiate the loss and classifiers in this section from those in Section 2, we use the term "risk" here, and h refers to the document classifiers, not the topic labeling process by the sampler.

3.1 Languages as Domains

Classic learning theory requires training and test sets to come from the same distribution $\mathcal{D}$, *i.e.,* $(\theta, y) \sim \mathcal{D}$, where θ is the document representation (features) and y the document label (Valiant, 1984). In practice, however, corpora in S and T may be sampled from different distributions, *i.e.,* $D^{(S)} = \{(\widehat{\theta}^{(d_S)}, y)\} \sim \widehat{\mathcal{D}}^{(S)}$ and $D^{(T)} = \{(\widehat{\theta}^{(d_T)}, y)\} \sim \widehat{\mathcal{D}}^{(T)}$. We refer to these distributions as *document spaces.* To relate $R_T(h)$ and $\widehat{R_S}(h)$, therefore, we have to take their distribution bias into consideration. This is often formulated as a problem of domain adaptation, and here we can formulate this such that each language is treated as a "domain".

We follow the seminal work by Ben-David et al. (2006), and define $\mathcal{H}$-distance as follows.

Definition 2 ($\mathcal{H}$-distance, Ben-David et al. (2006))**.** *Let $\mathcal{H}$ be a symmetric hypothesis space,* i.e., *for every hypothesis $h \in \mathcal{H}$ there exists its counterpart $1-h \in \mathcal{H}$. We let $m = \left|D^{(S)}\right| + \left|D^{(T)}\right|$, the total size of test corpus. The $\mathcal{H}$-distance between $\widehat{\mathcal{D}}^{(S)}$ and $\widehat{\mathcal{D}}^{(T)}$ is defined as*

$$\begin{aligned}&\frac{1}{2}\widehat{d}_{\mathcal{H}}\left(\widehat{\mathcal{D}}^{(S)}, \widehat{\mathcal{D}}^{(T)}\right) \\ &= \max_{h\in\mathcal{H}} \frac{1}{m} \sum_{\ell\in\{S,T\}} \sum_{\mathbf{x}_d : h(\mathbf{x}_d)=\ell} \mathbb{1}\left\{\mathbf{x}_d \in D^{(\ell)}\right\},\end{aligned}$$

where $\mathbf{x}_d$ is the representation for document d, and $h(\mathbf{x}_d)$ outputs the language of this document.

This distance measures how identifiable the languages are based on their representations. If source and target languages are from entirely different distributions, a classifier can easily identify language-specific features, which could affect performance of the document classifiers.

With $\mathcal{H}$-distances, we have a measure of the "distance" between the two distributions $\widehat{\mathcal{D}}^{(S)}$ and $\widehat{\mathcal{D}}^{(T)}$. We state the following theorem from domain adaptation theory.

Theorem 4 (Ben-David et al. (2006))**.** *Let m be the corpus size of the source language,* i.e., $m = \left|D^{(S)}\right|$, *c the VC-dimension of document classifiers $h \in \mathcal{H}$, and $\widehat{d}_{\mathcal{H}}\left(\widehat{\mathcal{D}}^{(S)}, \widehat{\mathcal{D}}^{(T)}\right)$ the $\mathcal{H}$-distance between two languages in the document space. With probability at least $1-\delta$, we have the following bound,*

$$\begin{aligned}R_T(h) &\le \widehat{R}_S(h) + \widehat{d}_{\mathcal{H}}\left(\widehat{\mathcal{D}}^{(S)}, \widehat{\mathcal{D}}^{(T)}\right) + \widehat{\lambda} + \\ &\qquad \sqrt{\frac{4}{m}\left(c\log\frac{2em}{c} + \log\frac{4}{\delta}\right)}, \qquad (4)\\ \widehat{\lambda} &= \min_{h\in\mathcal{H}} \widehat{R}_S(h) + \widehat{R}_T(h). \qquad (5)\end{aligned}$$

The term $\widehat{\lambda}$ in Theorem 4 defines a *joint risk*, *i.e.,* the training error on both source and target documents. This term usually cannot be estimated in practice since the labels for target documents are unavailable. However, we can still calculate this term for the purpose of analysis.

The theorem shows that the crosslingual classification risk is bounded by two critical components: the $\mathcal{H}$-distance, and the joint risk $\widehat{\lambda}$. Interestingly, these two quantities are based on the same set of features with different labeling rules: for $\mathcal{H}$-distance, the label for each instance is its language, while $\widehat{\lambda}$ uses the actual document label. Therefore, a better bound requires the consistency of features across languages, both in language and document labelings.

3.2 From Words to Documents

Since consistency of features depends on the document representations $\widehat{\theta}$, we need to trace back to the upstream training of topic models and show how the errors propagate to the formation of document representations. Thus, we first show the relations between $\widehat{\text{CVL}}$ and word representations $\widehat{\varphi}$ in the following lemma.

Lemma 1. *Given any bilingual word pair* (w_T, w_S), *let* $\widehat{\varphi}^{(w)}$ *denote the distribution over topics of word type* w. *Then we have,*

$$1 - \widehat{\varphi}^{(w_T)\top} \cdot \widehat{\varphi}^{(w_S)} \quad \leq \quad \widehat{\text{CVL}}(w_T, w_S).$$

Proof. See Appendix. □

We need to connect the word representations $\widehat{\varphi}$, which are central to on-site transfer, to the document representations $\widehat{\theta}$, which are central to off-site transfer. To do this, we make an assumption that the inferred distribution over topics $\widehat{\theta}^{(d)}$ for each test document d is a weighted average over all word vectors, *i.e.,* $\widehat{\theta}^{(d)} \propto \sum_w f_w^d \cdot \widehat{\varphi}^{(w)}$, where f_w^d is the normalized frequency of word w in document d (Arora et al., 2013). When this assumption holds, we can bound the similarity of document representations $\widehat{\theta}^{(d_S)}$ and $\widehat{\theta}^{(d_T)}$ in terms of word representations and hence their $\widehat{\text{CVL}}$.

Theorem 5. *Let* $\widehat{\theta}^{(d_S)}$ *be the distribution over topics for document* d_S *(similarly for* d_T*),* $F(d_S, d_T) = \left(\sum_{w_S} {f_{w_S}^{d_S}}^2 \cdot \sum_{w_T} {f_{w_T}^{d_T}}^2\right)^{\frac{1}{2}}$ *where* f_w^d *is the* normalized *frequency of word* w *in document* d, *and* K *the number of topics. Then*

$$\widehat{\theta}^{(d_S)\top} \cdot \widehat{\theta}^{(d_T)} \leq F(d_S, d_T) \cdot \sqrt{K \cdot \sum_{w_S, w_T} \left(\widehat{\text{CVL}}(w_T, w_S) - 1\right)^2}.$$

Proof. See Appendix. □

This provides a spatial connection between document pairs and word pairs they have. Many kernalized classifiers such as support vector machines (SVM) explicitly use this inner product in the dual optimization objective (Platt, 1998). Since the inner product is directly related to the cosine similarity, Theorem 5 indicates that if two documents are spatially close, their inner product should be large, and thus the $\widehat{\text{CVL}}$ of all word pairs they share should be small. In an extreme case, if $\widehat{\text{CVL}}(w_T, w_S) = 1$ for all the bilingual word pairs appearing in document pair (d_S, d_T), then $\widehat{\theta}^{(d_S)\top} \cdot \widehat{\theta}^{(d_T)} = 0$, meaning the two documents are orthogonal and tend to be irrelevant topically.

With upstream training discussed in Section 2, we see that $\widehat{\text{CVL}}$ has an impact on the consistency of features across languages. A low $\widehat{\text{CVL}}$ indicates that the transfer from source to target is sufficient in two ways. First, languages share similar distributions, and therefore, it is harder to distinguish languages based on their distributions. Second, if there exists a latent mapping from a distribution to a label, it should produce similar labeling on both source and target data since they are similar. These two aspects correspond to the language $\mathcal{H}$-distance and joint risk $\widehat{\lambda}$ in Theorem 4.

4 Experiments

We experiment with five languages: Arabic (AR, Semitic), German (DE, Germanic), Spanish (ES, Romance), Russian (RU, Slavic), and Chinese (ZH, Sinitic). In the first two experiments, we pair each with English (EN, Germanic) and train PLTM on each language pair individually.

Training Data For each language pair, we use a subsample of 3,000 Wikipedia comparable documents, *i.e.,* 6,000 documents in total. We set $K = 50$, and train PLTM with default hyperparameters (McCallum, 2002). We run each experiment five times and average the results.

Test Data For experiments with document classification, we use Global Voices (GV) in all five language pairs as test sets. Each document in this dataset has a "categories" attribute that can be used as the document label. In our classification experiments, we use *culture*, *technology*, and *education* as the labels to perform multiclass classification.

Evaluation To evaluate topic qualities, we use Crosslingual Normalized Pointwise Mutual Information (Hao et al., 2018, CNPMI), an intrinsic metric of crosslingual topic coherence. For any bilingual word pair (w_T, w_S),

$$\text{CNPMI}(w_T, w_S) = -\frac{\log \frac{\Pr(w_T, w_S)}{\Pr(w_T)\Pr(w_S)}}{\log \Pr(w_T, w_S)}, \quad (6)$$

where $\Pr(w_T, w_S)$ is the occurrence of w_T and w_S appearing in the same pair of comparable documents. We use 10,000 Wikipedia comparable document pairs outside PLTM training data for each language pair to calculate CNPMI scores. All datasets are publicly available at `http://opus.nlpl.eu/` (Tiedemann, 2012). Additional details of our datasets and experiment setup can be found in the appendix.

4.1 Sampling as Circular Validation

Our first experiment shows how $\widehat{\text{CVL}}$ changes over time during Gibbs sampling. According to the definition, the arguments of $\widehat{\text{CVL}}$ can include any bilingual word pairs; however, we suggest that it should be calculated specifically among word pairs that are expected to be related (and thus enable transfer). In our experiments, we select word pairs in the following way.

Recall that the output of a bilingual topic model is K topics, where each language has its own distribution. For each topic k, we can calculate $\widehat{\text{CVL}}(w_S, w_T)$ such that w_S and w_T belong to the same topic (*i.e.,* are in the top C most probable words in that topic), from the two languages, respectively. Using a cardinality C for each of the K topics, we have in total $C^2 \times K$ bilingual word pairs in the calculation of $\widehat{\text{CVL}}$.

At certain iterations, we collect the topic words as described above with cardinality $C = 5$, and calculate $\widehat{\text{CVL}}(w_T, w_S)$, $\text{CNPMI}(w_T, w_S)$, and the error term (the $\frac{1}{2}\sqrt{\cdots}$ term in Theorem 3) of all the bilingual word pairs. In the middle panel of Figure 2, $\widehat{\text{CVL}}$ over all word pairs from topic words is decreasing as sampling proceeds and becomes stable by the end of sampling. On the other hand, the correlations between CNPMI and $\widehat{\text{CVL}}$ are constantly decreasing. The negative correlations between $\widehat{\text{CVL}}$ and CNPMI implies that lower $\widehat{\text{CVL}}$ is associated with higher topic quality, since higher-quality topic has higher CNPMI but lower $\widehat{\text{CVL}}$.

4.2 What the PAC-Bayes Bound Shows

Theorem 3 provides insights into how knowledge is transferred during sampling and the factors that could affect this process. We analyze this bound from two aspects, the size of the training data (corresponding to $\frac{\ln n^\star}{n}$ term) and model assumptions (as in the crosslingual entropy terms).

4.2.1 Training Data: Downsampling

One factor that could affect $\widehat{\text{CVL}}$, according to Theorem 3, is the balance of tokens of a word pair. In an extreme case, if a word type w_S has only one token, while another word type w_T has a large number of tokens, the transfer from w_S to w_T is negligible. In this experiment, we will test if increasing the ratio term $\frac{\ln n^\star}{n}$ in the corpus lowers the performance of crosslingual transfer learning.

To this end, we specify a *sample rate* $\rho = 0.2, 0.4, 0.6, 0.8$, and 1.0. For each word pair (w_T, w_S), we calculate n as in the ratio term $\frac{\ln n^\star}{n}$, and remove $(1-\rho)\cdot n$ tokens from the corpus (rounded to the nearest integer). Smaller ρ removes more tokens from the corpus and thus yields a larger ratio term on average.

We use a dictionary from Wiktionary to collect word pairs, where each word pair (w_S, w_T) is a translation pair. Figure 3 shows the results of downsampling using these two methods. Decreasing the sample rate ρ lowers the topic qualities. This implies that although PLTM can process comparable corpora, which need not be exact translations, one still needs to be careful about the token balance between linked document pairs.

For many low-resource languages, the target language corpus is much smaller than the source corpus, so the effect of this imbalance is important to be aware of. This is an important issue when choosing comparable documents, and Wikipedia is an illustrative example. Although one can collect comparable documents via Wikipedia's interlanguage links, articles under the same title but in different languages can have very large variations on document length, causing the imbalance of samples $\frac{\ln n^\star}{n}$, and thus potentially suboptimal performance of crosslingual training.

4.2.2 Model Assumptions

Recall that the crosslingual entropy term can be decomposed into different levels, *e.g.,* document

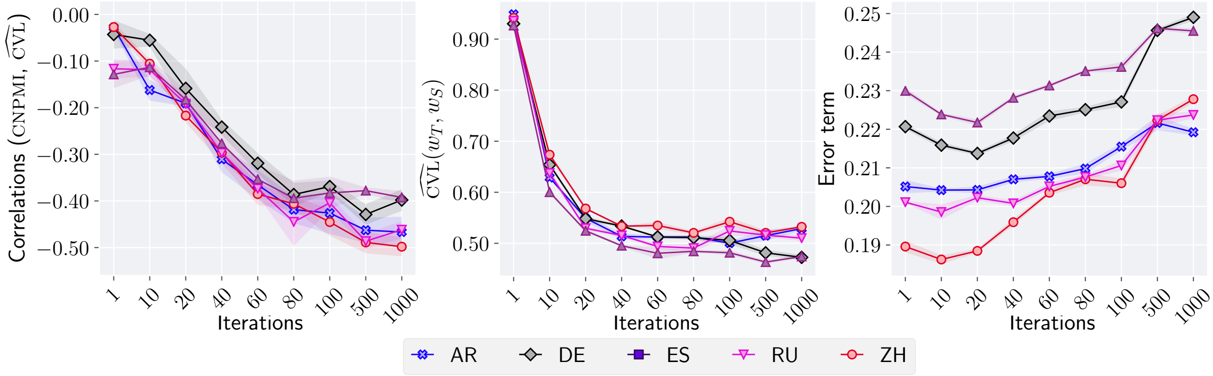

Figure 2: As Gibbs sampling progresses, $\widehat{\mathrm{CVL}}$ of topic words drops, which leads to higher quality topics, and thus increases CNPMI. The left panel shows this negative correlation, and we use shades to indicate standard deviations across five chains.

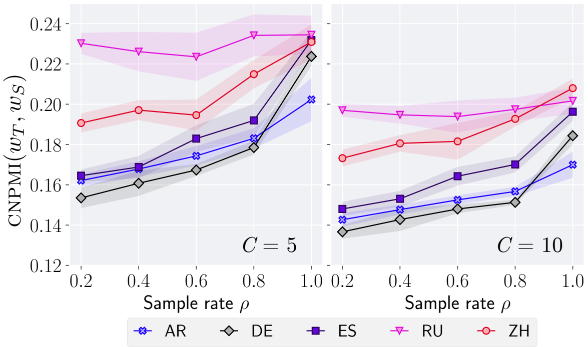

Figure 3: Increasing ρ results in smaller values of $\frac{\ln n^\star}{n}$ for translation pairs. Topic quality, evaluated by CNPMI, increases as well.

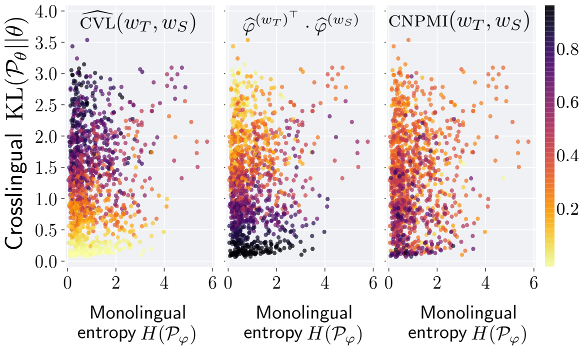

Figure 4: Each dot is a (EN,DE) word pair, and its color shows corresponding values of the indicated quantity. Best viewed in color.

level and word level, and we prefer a model with low crosslingual entropy but high monolingual entropy. In this experiment, we show how these two quantities affect the topic qualities, using English-German (EN-DE) documents as an example.

Given PLTM output in (EN,DE) and a cardinality $C = 5$, we collect $C^2 \times K$ bilingual word pairs as described in Section 4.1. For each word pair, we calculate three quantities: $\widehat{\mathrm{CVL}}$, CNPMI, and the inner product of the word representations. In Figure 4, each dot is a word pair (w_S, w_T) colored by the values of these quantities. The word pair dots are positioned by their crosslingual and monolingual entropies.

We observe that $\widehat{\mathrm{CVL}}$ decreases with crosslingual entropy on document level. The larger the crosslingual entropy, the harder it is to get a low $\widehat{\mathrm{CVL}}$ because it needs larger monolingual entropy to decrease the bound, as shown in Section 2.4. On the other hand, the inner product of word pairs shows an opposite pattern of $\widehat{\mathrm{CVL}}$, indicating a negative correlation (Lemma 1). In Figure 2 we see the correlation between CNPMI and $\widehat{\mathrm{CVL}}$ is around -0.4 at the end of sampling, so there are fewer clear patterns for CNPMI in Figure 4. However, we also notice that the word pairs with higher CNPMI scores often appear at the bottom where crosslingual entropy is low while the monolingual entropy is high.

4.3 Downstream Task

We move on to crosslingual document classification as a downstream task. At various iterations of Gibbs sampling, we infer topics on the test sets for another 500 iterations and calculate the quantities shown in the Figure 5 (averaged over all languages), including the $\mathcal{H}$-distances for both training and test sets, and the joint risk $\widehat{\lambda}$.

We treat English as the source language and train support vector machines to obtain the best classifier $h^\star$ that fits the English documents. This classifier is then used to calculate the source and target risks $\widehat{R}_S(h^\star)$ and $\widehat{R}_T(h^\star)$. We also include $\frac{1}{2}\widehat{d}_{\mathcal{H}}(S, T)$, the $\mathcal{H}$-distance based on word rep-

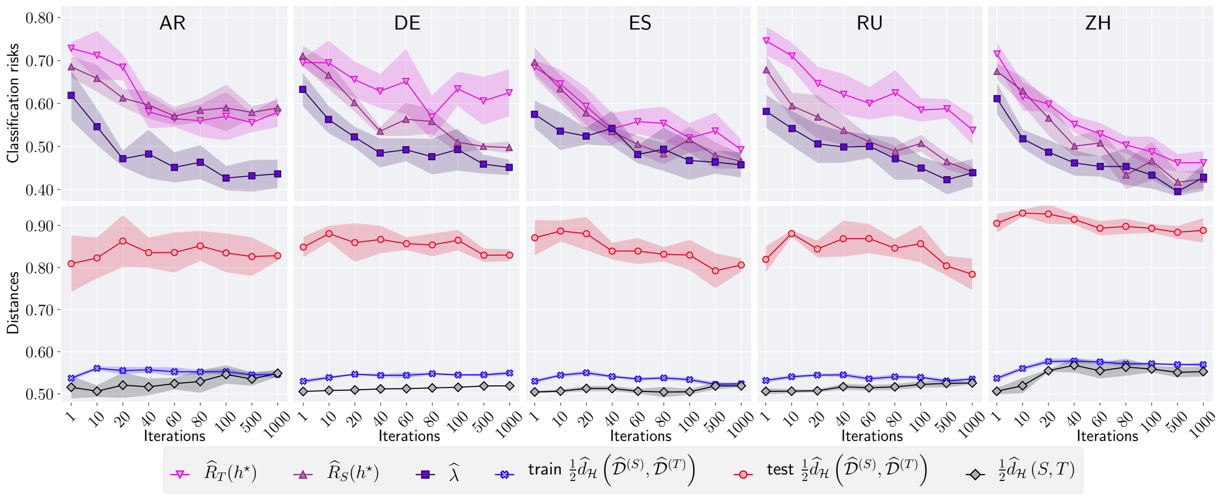

Figure 5: Gibbs sampling optimizes $\widehat{\text{CVL}}$, which decreases the joint risk $\widehat{\lambda}$ and $\mathcal{H}$-distances for test data.

resentations $\widehat{\varphi}$. As mentioned in Section 3.1, we train support vector machines to use languages as labels, and the accuracy score as the $\mathcal{H}$-distance.

The classification risks, such as $\widehat{R}_S(h^\star)$, $\widehat{R}_T(h^\star)$, and $\widehat{\lambda}$, are decreasing as expected (upper row in Figure 5), which shows very similar trends as $\widehat{\text{CVL}}$ in Figure 2. On the other hand, we notice that the $\mathcal{H}$-distances of training documents and vocabularies, $\frac{1}{2}\widehat{d}_{\mathcal{H}}\left(\widehat{\mathcal{D}}^{(S)}, \widehat{\mathcal{D}}^{(T)}\right)$ and $\frac{1}{2}\widehat{d}_{\mathcal{H}}(S, T)$, stabilize around 0.5 to 0.6, meaning it is difficult to differentiate the languages based on their representations. Interestingly, the $\mathcal{H}$-distances of test documents are at a less ideal value, although they are slightly decreasing in most of the languages except AR. However, recall that the target risk also depends on other factors than $\mathcal{H}$-distance (Theorem 4), and we use Figure 6 to illustrate this point.

We further explore the relationship between the predictability of languages vs document classes in Figure 6. We collect documents correctly classified for both document class and language labels, from which we randomly choose 200 documents for each language, and use $\widehat{\theta}$ to plot t-SNE scatterplots. Note that the two plots are from the same set of documents, and so the spatial relations between any two points are fixed, but we color them with different labelings. Although the classifier can identify the languages (right panel), the features are still consistent, because on the left panel, the decision boundary changes its direction and also successfully classifies the documents based on actual label class. This illustrates why a single $\mathcal{H}$-distance does not necessarily mean inconsistent features across languages and high target risks.

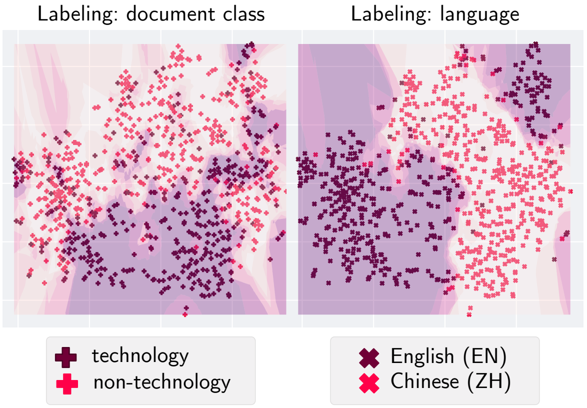

Figure 6: Although the classifier identifies the languages (right), the features are still consistent based on actual document class (left).

5 Conclusions and Future Directions

This study gives new insights into crosslingual transfer learning in multilingual topic models. By formulating the inference process as a circular validation, we derive a PAC-Bayesian theorem to show the factors that affect the success of crosslingual learning. We also connect topic model learning with downstream crosslingual tasks to show how errors propagate.

As the first step toward more theoretically justified crosslingual transfer learning, our study suggests considerations for constructing crosslingual transfer models in general. For example, an effective model should strengthen crosslingual transfer while minimizing non-transferred components, use a balanced dataset or specific optimization algorithms for low-resource languages, and support evaluation metrics that relate to CVL.

Appendix A Notation

See Table 1.

Notation	Description
S, T	Source and target languages. They are interchangeable during Gibbs sampling. For example, when training English and German, English can be either source or target.
w_ℓ	A **word type** of language ℓ.
x_ℓ	An individual **token** of language ℓ.
z_{x_ℓ}	The topic assignment of token x_ℓ.
$\mathcal{S}_{w_\ell}$	The sample of word type w_ℓ, the set containing all the tokens x_ℓ that are of this word type.
$\mathcal{P}_{x_\ell}$, $\mathcal{P}_{x_\ell,k}$	$\mathcal{P}_{x_\ell}$ denotes the conditional distribution over all topics for token x_ℓ. The conditional probability of sampling a topic k from $\mathcal{P}_{x_\ell}$ is denoted as $\mathcal{P}_{x_\ell,k}$.
$D^{(\ell)}$	The set of documents in language ℓ. This usually refers to the test corpus.
$\widehat{\mathcal{D}}^{(\ell)}$	The array of document representations from the corpus $D^{(\ell)}$ and their document labels.
$\widehat{\phi}_k^{(\ell)}$	The empirical distribution over vocabulary of language ℓ for topic $k = 1, \ldots, K$.
$\widehat{\varphi}^{(w)}$	The word representation, *i.e.,* the empirical distribution over K topics for a word type w. This can be obtained by re-normalizing $\widehat{\phi}_k^{(\ell)}$.
$\widehat{\theta}^{(d)}$	The document representation, *i.e.,* the empirical distribution over K topics for a document d.

Table 1: Notation table.

Appendix B Proofs

Theorem 1. *Let $\widehat{\mathrm{CVL}}^{(t)}(w_T, w_S)$ be the empirical circular validation loss of any bilingual word pair at iteration t of Gibbs sampling. Then $\widehat{\mathrm{CVL}}^{(t)}(w_T, w_S)$ converges as $t \to \infty$.*

Proof. We first notice the triangle inequality:

$$
\begin{aligned}
&\left|\widehat{\mathrm{CVL}}^{(t)}(w_T, w_S) - \widehat{\mathrm{CVL}}^{(t-1)}(w_T, w_S)\right| \\
=& \left| \mathop{\mathbb{E}}_{x_S, x_T}\left[\widehat{\mathcal{L}}^{(t)}(x_T, w_S) + \widehat{\mathcal{L}}^{(t)}(x_S, w_T)\right] \right. \\
&\left. - \mathop{\mathbb{E}}_{x_S, x_T}\left[\widehat{\mathcal{L}}^{(t-1)}(x_T, w_S) + \widehat{\mathcal{L}}^{(t-1)}(x_S, w_T)\right] \right| \\
=& \left| \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}^{(t)}(x_T, w_S)\right] + \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}^{(t)}(x_S, w_T)\right] \right. \\
& - \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}^{(t-1)}(x_T, w_S)\right] \\
&\left. - \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}^{(t-1)}(x_S, w_T)\right] \right| \\
\leq& \left| \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}^{(t)}(x_T, w_S)\right] - \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}^{(t-1)}(x_T, w_S)\right] \right. \\
&\left. + \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}^{(t)}(x_S, w_T)\right] - \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}^{(t-1)}(x_S, w_T)\right] \right| \\
\equiv& \left| \Delta \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}(x_T, w_S)\right] + \Delta \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}(x_S, w_T)\right] \right| \\
\leq& \left| \Delta \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}}\left[\widehat{\mathcal{L}}(x_T, w_S)\right] \right| + \left| \Delta \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}}\left[\widehat{\mathcal{L}}(x_S, w_T)\right] \right|.
\end{aligned}
$$

We look at the first term of the last equation, and the other term can be derived in the same way. We use $\mathcal{P}_{x_T}$ to denote the invariant distribution of the conditional $\mathcal{P}_{x_T}^{(t)}$ as $t \to \infty$. Additionally, let $\mathcal{P}_{x_T, z_{x_S}}$ be the conditional probability for the token x_T being assigned to topic z_{x_S}:

$$\mathcal{P}_{x_T, z_{x_S}} = \Pr\left(k = z_{x_S}; w = w_{x_T}, \mathbf{z}_-, \mathbf{w}_-\right).$$

Another assumption we made is once the source language is converged, we keep the states of it fixed. That is, $z_{x_S}^{(t)} = z_{x_S}^{(t-1)}$, and only sample the target language. Taking the difference between the expectation at iterations t and $t-1$, we have

$$\begin{aligned}
& \lim_{t\to\infty} \left| \Delta \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}} \left[\widehat{\mathcal{L}}(x_T, w_S) \right] \right| \\
= & \lim_{t\to\infty} \left| \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}} \left[\widehat{\mathcal{L}}^{(t)}(x_T, w_S) \right] \right. \\
& \left. - \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}} \left[\widehat{\mathcal{L}}^{(t-1)}(x_T, w_S) \right] \right| \\
= & \lim_{t\to\infty} \left| \mathop{\mathbb{E}}_{x_T} \left[\frac{1}{n_{w_S}} \sum_{x_S} \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S}^{(t)} \right\} \right] \right. \\
& \left. - \mathop{\mathbb{E}}_{x_T} \left[\frac{1}{n_{w_S}} \sum_{x_S} \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t-1)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S}^{(t-1)} \right\} \right] \right| \\
= & \lim_{t\to\infty} \frac{1}{n_{w_S}} \sum_{x_S} \mathop{\mathbb{E}}_{x_T} \left[\left| \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S}^{(t)} \right\} \right. \right. \\
& \left. \left. - \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t-1)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S}^{(t-1)} \right\} \right| \right] \\
= & \lim_{t\to\infty} \frac{1}{n_{w_S}} \sum_{x_S} \mathop{\mathbb{E}}_{x_T} \left[\left| \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S} \right\} \right. \right. \\
& \left. \left. - \mathbb{E}_{h \sim \mathcal{P}_{x_T}^{(t-1)}} \mathbb{1}\left\{ h(x_S) \neq z_{x_S} \right\} \right| \right] \\
= & \lim_{t\to\infty} \frac{1}{n_{w_S}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \left[\left| \left(1 - \mathcal{P}_{x_T, z_{x_S}}^{(t)} \right) \right. \right. \\
& \left. \left. - \left(1 - \mathcal{P}_{x_T, z_{x_S}}^{(t-1)} \right) \right| \right] \\
= & \lim_{t\to\infty} \frac{1}{n_{w_S}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \left[\left| \mathcal{P}_{x_T, z_{x_S}}^{(t-1)} - \mathcal{P}_{x_T, z_{x_S}}^{(t)} \right| \right] \\
= & \lim_{t\to\infty} \frac{1}{n_{w_S}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \left[\left| \mathcal{P}_{x_T, z_{x_S}} - \mathcal{P}_{x_T, z_{x_S}} \right| \right] \\
= & \ 0.
\end{aligned}$$

Therefore, we have

$$\begin{aligned}
& \lim_{t\to\infty} \left| \widehat{\mathrm{CVL}}^{(t)}(w_T, w_S) - \widehat{\mathrm{CVL}}^{(t-1)}(w_T, w_S) \right| \\
\leq & \lim_{t\to\infty} \left| \Delta \mathop{\mathbb{E}}_{x_T \in \mathcal{S}_{w_T}} \left[\widehat{\mathcal{L}}(x_T, w_S) \right] \right| \\
& + \left| \Delta \mathop{\mathbb{E}}_{x_S \in \mathcal{S}_{w_S}} \left[\widehat{\mathcal{L}}(x_S, w_T) \right] \right| \\
= & \ 0.
\end{aligned}$$

$\square$

Theorem 3. *Given a bilingual word pair (w_T, w_S), with probability at least $1-\delta$, the following bound holds:*

$$\begin{aligned}
& \mathrm{CVL}(w_T, w_S) \leq \widehat{\mathrm{CVL}}(w_T, w_S) + \\
& \frac{1}{2}\sqrt{\frac{1}{n}\left(\mathrm{KL}_{w_T} + \mathrm{KL}_{w_S} + 2\ln\frac{2}{\delta}\right) + \frac{\ln n^\star}{n}}, \\
& n = \min\left\{n_{w_T}, n_{w_S}\right\}, \quad n^\star = \max\left\{n_{w_T}, n_{w_S}\right\}.
\end{aligned}$$

For brevity we use KL_w to denote $\mathrm{KL}(\mathcal{P}_x || Q_x)$, where $\mathcal{P}_x$ is the conditional distribution from Gibbs sampling of token x with word type w that gives highest loss $\widehat{\mathcal{L}}(x, w)$, and Q_x a prior.

Proof. From Theorem 2, for target language, with probability at least $1-\delta$,

$$\begin{aligned}
& \mathcal{L}(x_T, w_S) \\
\leq & \ \widehat{\mathcal{L}}(x_T, w_S) + \sqrt{\frac{\mathrm{KL}\left(\mathcal{P}_{x_T} || Q_{x_T}\right) + \ln\frac{2\sqrt{n_{w_S}}}{\delta}}{2n_{w_S}}} \\
= & \ \widehat{\mathcal{L}}(x_T, w_S) + \sqrt{\frac{\mathrm{KL}\left(\mathcal{P}_{x_T} || Q_{x_T}\right) + \ln\frac{2}{\delta} + \frac{\ln n_{w_S}}{2n_{w_S}}}{2}} \\
\equiv & \ \widehat{\mathcal{L}}(x_T, w_S) + \epsilon(x_T, w_S).
\end{aligned}$$

For the source language, similarly, with probability at least $1-\delta$,

$$\begin{aligned}
& \mathcal{L}(x_S, w_T) \\
\leq & \ \widehat{\mathcal{L}}(x_S, w_T) + \sqrt{\frac{\mathrm{KL}\left(\mathcal{P}_{x_S} || Q_{x_S}\right) + \ln\frac{2}{\delta} + \frac{\ln n_{w_T}}{2}}{2n_{w_T}}} \\
\equiv & \ \widehat{\mathcal{L}}(x_S, w_T) + \epsilon(x_S, w_T).
\end{aligned}$$

Given a word type w_T, we notice that only the KL-divergence term in $\epsilon(x_T, w_S)$ varies among different tokens x_T. Thus, we use KL_{w_S} and KL_{w_T} to denote the maximal values of KL-divergence over all the tokens,

$$\begin{aligned}
\mathrm{KL}_{w_S} &= \mathrm{KL}\left(\mathcal{P}_{x_T^\star} || Q_{x_T^\star}\right), \\
x_T^\star &= \mathop{\arg\max}_{x_T \in \mathcal{S}_{w_T}} \epsilon(x_T, w_S); \\
\mathrm{KL}_{w_T} &= \mathrm{KL}\left(\mathcal{P}_{x_S^\star} || Q_{x_S^\star}\right), \\
x_S^\star &= \mathop{\arg\max}_{x_S \in \mathcal{S}_{w_S}} \epsilon(x_S, w_T).
\end{aligned}$$

Let $n = \min\{n_{w_T}, n_{w_S}\}$, and $n^\star = \max\{n_{w_T}, n_{w_S}\}$. Due to the fact that $\sqrt{x} + \sqrt{y} \leq \frac{2}{\sqrt{2}}\sqrt{x+y}$ for $x, y > 0$, we have

$$
\begin{aligned}
&\text{CVL}(w_T, w_S)\\
&= \frac{1}{2} \mathop{\mathbb{E}}_{x_S, x_T} \left[\mathcal{L}(x_T, w_S) + \mathcal{L}(x_S, w_T)\right]\\
&= \frac{1}{2} \left(\mathbb{E}_{x_T} \mathcal{L}(x_T, w_S) + \mathbb{E}_{x_S} \mathcal{L}(x_S, w_T)\right)\\
&\leq \frac{1}{2} \left(\mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \widehat{\mathcal{L}}(x_T, w_S) + \mathbb{E}_{x_S \in \mathcal{S}_{w_S}} \widehat{\mathcal{L}}(x_S, w_T)\right)\\
&\quad + \frac{1}{2} \left(\mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \epsilon(x_T, w_S) + \mathbb{E}_{x_S \in \mathcal{S}_{w_S}} \epsilon(x_S, w_T)\right)\\
&= \widehat{\text{CVL}}(w_T, w_S)\\
&\quad + \frac{1}{2} \left(\mathbb{E}_{x_T \in \mathcal{S}_{w_T}} \epsilon(x_T, w_S) + \mathbb{E}_{x_S \in \mathcal{S}_{w_S}} \epsilon(x_S, w_T)\right)\\
&\leq \widehat{\text{CVL}}(w_T, w_S) + \frac{1}{2} \left(\epsilon(x_T^\star, w_S) + \epsilon(x_S^\star, w_T)\right)\\
&\leq \widehat{\text{CVL}}(w_T, w_S)\\
&\quad + \frac{1}{2} \left(\sqrt{\frac{1}{2n_{w_T}} \left(\text{KL}_{w_T} + \ln \frac{2}{\delta} + \frac{1}{2} \ln n_{w_T}\right)} \right.\\
&\quad \left. + \sqrt{\frac{1}{2n_{w_S}} \left(\text{KL}_{w_S} + \ln \frac{2}{\delta} + \frac{1}{2} \ln n_{w_S}\right)} \right)\\
&\leq \widehat{\text{CVL}}(w_T, w_S)\\
&\quad + \frac{1}{2} \sqrt{\frac{\text{KL}_{w_T} + \text{KL}_{w_S} + 2 \ln \frac{2}{\delta}}{n} + \left(\frac{\ln\left(n_{w_T} \cdot n_{w_S}\right)}{2n}\right)}\\
&\leq \widehat{\text{CVL}}(w_T, w_S)\\
&\quad + \frac{1}{2} \sqrt{\frac{\text{KL}_{w_T} + \text{KL}_{w_S} + 2 \ln \frac{2}{\delta}}{n} + \left(\frac{\ln n^\star}{n}\right)},
\end{aligned}
$$

which gives us the result. □

Lemma 1. *Given any bilingual word pair* (w_T, w_S)*, let* $\widehat{\varphi}^{(w)}$ *denote the distribution over topics of word type* w*. Then we have,*

$$
1 - \widehat{\varphi}^{(w_T)\top} \cdot \widehat{\varphi}^{(w_S)} \;\leq\; \widehat{\text{CVL}}(w_T, w_S).
$$

Proof. We expand the equation of $\widehat{\text{CVL}}$ as follows,

$$
\begin{aligned}
&\widehat{\text{CVL}}(w_T, w_S)\\
&= \frac{1}{2} \mathop{\mathbb{E}}_{x_S, x_T} \left[\widehat{\mathcal{L}}(x_T, w_S) + \widehat{\mathcal{L}}(x_S, w_T)\right]\\
&= \frac{1}{2} \left(\mathbb{E}_{x_T} \left[\widehat{\mathcal{L}}(x_T, w_S)\right] + \mathbb{E}_{x_S} \left[\widehat{\mathcal{L}}(x_S, w_T)\right]\right)\\
&= \frac{1}{2} \left(\frac{\sum_{x_T \in \mathcal{S}_{w_T}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathbb{E}_{h \sim \mathcal{P}_{x_T}} \left[\mathbb{1}\left\{h(x_S) \neq z_{x_S}\right\}\right]}{n_{w_T} \cdot n_{w_S}} \right.\\
&\quad \left. + \frac{\sum_{x_S \in \mathcal{S}_{w_S}} \sum_{x_T \in \mathcal{S}_{w_T}} \mathbb{E}_{h \sim \mathcal{P}_{x_S}} \left[\mathbb{1}\left\{h(x_T) \neq z_{x_T}\right\}\right]}{n_{w_S} \cdot n_{w_T}} \right)\\
&= \frac{1}{2} \left(\frac{\sum_{x_T \in \mathcal{S}_{w_T}} \sum_{x_S \in \mathcal{S}_{w_S}} \left(1 - \mathcal{P}_{x_T, z_{x_S}}\right)}{n_{w_T} \cdot n_{w_S}} \right.\\
&\quad \left. + \frac{\sum_{x_S \in \mathcal{S}_{w_S}} \sum_{x_T \in \mathcal{S}_{w_T}} \left(1 - \mathcal{P}_{x_S, z_{x_T}}\right)}{n_{w_S} \cdot n_{w_T}} \right)\\
&= 1 - \frac{1}{2} \left(\frac{\sum_{x_T \in \mathcal{S}_{w_T}} \sum_{x_S \in \mathcal{S}_{w_S}} \mathcal{P}_{x_T, z_{x_S}}}{n_{w_T} \cdot n_{w_S}} \right.\\
&\quad \left. + \frac{\sum_{x_S \in \mathcal{S}_{w_S}} \sum_{x_T \in \mathcal{S}_{w_T}} \mathcal{P}_{x_S, z_{x_T}}}{n_{w_S} \cdot n_{w_T}} \right)\\
&= 1 - \frac{1}{2} \sum_{k=1}^{K} \left(\frac{n_{k|w_S} \cdot \sum_{x_T \in \mathcal{S}_{w_T}} \mathcal{P}_{x_T, k}}{n_{w_T} \cdot n_{w_S}} \right.\\
&\quad \left. + \frac{n_{k|w_T} \cdot \sum_{x_S \in \mathcal{S}_{w_S}} \mathcal{P}_{x_S, z_{x_T}}}{n_{w_S} \cdot n_{w_T}} \right)\\
&= 1 - \frac{1}{2} \sum_{k=1}^{K} \left(\widehat{\varphi}_k^{(w_S)} \cdot \frac{\sum_{x_T \in \mathcal{S}_{w_T}} \mathcal{P}_{x_T, k}}{n_{w_T}} \right.\\
&\quad \left. + \widehat{\varphi}_k^{(w_T)} \cdot \frac{\sum_{x_S \in \mathcal{S}_{w_S}} \mathcal{P}_{x_S, z_{x_T}}}{n_{w_S}} \right)\\
&\geq 1 - \frac{1}{2} \sum_{k=1}^{K} \left(\widehat{\varphi}_k^{(w_S)} \cdot \frac{n_{k|w_T}}{n_{w_T}} + \widehat{\varphi}_k^{(w_T)} \cdot \frac{n_{k|w_S}}{n_{w_S}} \right)\\
&= 1 - \frac{1}{2} \sum_{k=1}^{K} \left(\widehat{\varphi}_k^{(w_S)} \cdot \widehat{\varphi}_k^{(w_T)} + \widehat{\varphi}_k^{(w_T)} \cdot \widehat{\varphi}_k^{(w_S)} \right)\\
&= 1 - \widehat{\varphi}^{(w_S)\top} \cdot \widehat{\varphi}^{(w_T)}
\end{aligned}
$$

which concludes the proof. □

Theorem 5. *Let* $\widehat{\theta}^{(d_S)}$ *be the distribution over topics for document* d_S *(similarly for* d_T*),* $F(d_S, d_T) = \left(\sum_{w_S} {f_{w_S}^{d_S}}^2 \cdot \sum_{w_T} {f_{w_T}^{d_T}}^2\right)^{\frac{1}{2}}$ *where* f_w^d *is the* normalized *frequency of word* w *in document* d*, and* K *the number of topics. Then*

$$
\begin{aligned}
\widehat{\theta}^{(d_S)\top} \cdot \widehat{\theta}^{(d_T)} &\leq F(d_S, d_T)\\
&\quad \cdot \sqrt{K \cdot \sum_{w_S, w_T} \left(\widehat{\text{CVL}}(w_T, w_S) - 1\right)^2}.
\end{aligned}
$$

Proof. We first expand the inner product of $\widehat{\theta}^{(d_S)\top} \cdot \widehat{\theta}^{(d_T)}$ as follows,

$$
\begin{aligned}
&\widehat{\theta}^{(d_S)\top} \cdot \widehat{\theta}^{(d_T)}\\
&= \sum_{k=1}^{K} \widehat{\theta}_k^{(d_S)} \cdot \widehat{\theta}_k^{(d_T)}\\
&= \sum_{k=1}^{K} \left(\left(\sum_{w_S \in V^{(S)}} f_{w_S}^{d_S} \cdot \widehat{\varphi}_k^{(w_S)} \right) \right.\\
&\quad \left. \cdot \left(\sum_{w_T \in V^{(T)}} f_{w_T}^{d_T} \cdot \widehat{\varphi}_k^{(w_T)} \right) \right)\\
&\leq F(d_S, d_T) \cdot \sum_{k=1}^{K} \left(\left(\sum_{w_S \in V^{(S)}} {\widehat{\varphi}_k^{(w_S)}}^2 \right)^{\frac{1}{2}} \cdot \right.\\
&\quad \left. \left(\sum_{w_T \in V^{(T)}} {\widehat{\varphi}_k^{(w_T)}}^2 \right)^{\frac{1}{2}} \right),\\
&F(d_S, d_T)\\
&= \left(\sum_{w_S \in V^{(S)}} {f_{w_S}^{d_S}}^2 \right)^{\frac{1}{2}} \cdot \left(\sum_{w_T \in V^{(T)}} {f_{w_T}^{d_T}}^2 \right)^{\frac{1}{2}},
\end{aligned}
$$

where $F(d_S, d_T)$ is a constant independent of topic k, and the last inequality due to Hölder's. We then focus on the topic-dependent part of the last inequality.

$$\begin{aligned}
&\sum_{k=1}^{K}\left(\left(\sum_{w_S\in V^{(S)}}\widehat{\varphi}_k^{(w_S)^2}\right)^{\frac{1}{2}}\cdot\left(\sum_{w_T\in V^{(T)}}\widehat{\varphi}_k^{(w_T)^2}\right)^{\frac{1}{2}}\right)\\
&=\sum_{k=1}^{K}\left(\sum_{w_S,w_T}\left(\widehat{\varphi}_k^{(w_S)}\cdot\widehat{\varphi}_k^{(w_T)}\right)^2\right)^{\frac{1}{2}}\\
&\leq\sqrt{K}\cdot\left(\sum_{k=1}^{K}\sum_{w_S,w_T}\left(\widehat{\varphi}_k^{(w_S)}\cdot\widehat{\varphi}_k^{(w_T)}\right)^2\right)^{\frac{1}{2}}\\
&=\sqrt{K}\cdot\left(\sum_{w_S,w_T}\sum_{k=1}^{K}\left(\widehat{\varphi}_k^{(w_S)}\cdot\widehat{\varphi}_k^{(w_T)}\right)^2\right)^{\frac{1}{2}}\\
&\leq\sqrt{K}\cdot\left(\sum_{w_S,w_T}\left(\sum_{k=1}^{K}\widehat{\varphi}_k^{(w_S)}\cdot\widehat{\varphi}_k^{(w_T)}\right)^2\right)^{\frac{1}{2}}\\
&=\sqrt{K}\cdot\left(\sum_{w_S,w_T}\left(\widehat{\varphi}^{(w_T)\top}\cdot\widehat{\varphi}^{(w_S)}\right)^2\right)^{\frac{1}{2}}.
\end{aligned}$$

Thus, we have the following inequality:

$$\begin{aligned}
\widehat{\theta}^{(d_S)\top}\cdot\widehat{\theta}^{(d_T)} \;\leq\;& F(d_S,d_T)\cdot\sqrt{K}\\
&\cdot\left(\sum_{w_S,w_T}\left(\widehat{\varphi}^{(w_T)\top}\cdot\widehat{\varphi}^{(w_S)}\right)^2\right)^{\frac{1}{2}}.
\end{aligned}$$

Plug in Lemma 1, we see that

$$\begin{aligned}
\widehat{\theta}^{(d_S)\top}\cdot\widehat{\theta}^{(d_T)} \;\leq\;& F(d_S,d_T)\cdot\sqrt{K}\\
&\cdot\left(\sum_{w_S,w_T}\left(\widehat{\mathrm{CVL}}(w_T,w_S)-1\right)^2\right)^{\frac{1}{2}}.
\end{aligned}$$

$\square$

Appendix C Dataset Details

C.1 Pre-processing

For all the languages, we use existing stemmers to stem words in the corpora and the entries in Wiktionary. Since Chinese does not have stemmers, we loosely use "stem" to refer to "segment" Chinese sentences into words. We also use fixed stopword lists to filter out stop words. Table 2 lists the source of the stemmers and stopwords.

C.2 Training Sets

Our training set is a comparable corpus from Wikipedia. For each Wikipedia article page, there exists an interlingual link to view the article in another language. This interlingual link provides the same article in different languages and is commonly used to create comparable corpora in multilingual studies. We show the statistics of this training corpus in Table 3. The numbers are calculated after stemming and lemmatization.

C.3 Test Sets

C.3.1 Topic Coherence Evaluation Sets

Topic coherence evaluation for multilingual topic models was proposed by Hao et al. (2018), where a comparable corpus is used to calculate bilingual word pair co-occurrence and CNPMI scores. We use a Wikipedia corpus to calculate this score, and the statistics are shown in Table 4. This Wikipedia corpus does not overlap with the training set.

C.3.2 Unseen Document Inference

We use the Global Voices (GV) corpus to create test sets, which can be retrieved from the website `https://globalvoices.org` directly, or from the OPUS collection at `http://opus.nlpl.eu/GlobalVoices.php`. We show the statistics in Table 5. After the column showing number of documents, we also include the statistics of specific labels. The multiclass labels are mutual exclusive, and each document has only one label.

Note that although all the language pairs share the same set of English test documents, the document representations are inferred from different topic models trained specifically for that language pair. Thus, the document representations for the same English document are different across different language pairs.

Lastly, the number of word types is based on the training set and after stemming and lemmatization. When a word type in the test set does not appear in the training set, we ignore this type.

C.3.3 Wiktionary

In downsampling experiments (Section 4.2), we use English Wiktionary to create bilingual dictionaries, which can be downloaded at `https://dumps.wikimedia.org/enwiktionary/`.

Appendix D Topic Model Configurations

For each experiment, we run five chains of Gibbs sampling using the Polylingual Topic Model implemented in MALLET, [5] and take the average over all chains. Each chain has $1{,}000$ iterations, and we do not set a burn-in period. We set the topic number $K = 50$. Other hyperparameters are $\alpha = \frac{50}{K} = 1$ and $\beta = 0.01$ which are the default settings. We do not enable hyperparameter optimization procedures.

Recursive Subtree Composition in LSTM-Based Dependency Parsing

Abstract

The need for tree structure modelling on top of sequence modelling is an open issue in neural dependency parsing. We investigate the impact of adding a tree layer on top of a sequential model by recursively composing subtree representations (composition) in a transition-based parser that uses features extracted by a BiLSTM. Composition seems superfluous with such a model, suggesting that BiLSTMs capture information about subtrees. We perform model ablations to tease out the conditions under which composition helps. When ablating the backward LSTM, performance drops and composition does not recover much of the gap. When ablating the forward LSTM, performance drops less dramatically and composition recovers a substantial part of the gap, indicating that a forward LSTM and composition capture similar information. We take the backward LSTM to be related to lookahead features and the forward LSTM to the rich history-based features both crucial for transition-based parsers. To capture history-based information, composition is better than a forward LSTM on its own, but it is even better to have a forward LSTM as part of a BiLSTM. We correlate results with language properties, showing that the improved lookahead of a backward LSTM is especially important for head-final languages.

1 Introduction

Recursive neural networks allow us to construct vector representations of trees or subtrees. They have been used for constituency parsing by Socher et al. (2013) and Dyer et al. (2016) and for dependency parsing by Stenetorp (2013) and Dyer et al. (2015), among others. In particular, Dyer et al. (2015) showed that composing representations of subtrees using recursive neural networks can be beneficial for transition-based dependency parsing. These results were further strengthened in Kuncoro et al. (2017) who showed, using ablation experiments, that composition is key in the Recurrent Neural Network Grammar (RNNG) generative parser by Dyer et al. (2016).

In a parallel development, Kiperwasser and Goldberg (2016b) showed that using BiLSTMs for feature extraction can lead to high parsing accuracy even with fairly simple parsing architectures, and using BiLSTMs for feature extraction has therefore become very popular in dependency parsing. It is used in the state-of-the-art parser of Dozat and Manning (2017), was used in 8 of the 10 highest performing systems of the 2017 CoNLL shared task (Zeman et al., 2017) and 10 out of the 10 highest performing systems of the 2018 CoNLL shared task (Zeman et al., 2018).

This raises the question of whether features extracted with BiLSTMs in themselves capture information about subtrees, thus making recursive composition superfluous. Some support for this hypothesis comes from the results of Linzen et al. (2016) which indicate that LSTMs can capture hierarchical information: they can be trained to predict long-distance number agreement in English. Those results were extended to more constructions and three additional languages by Gulordava et al. (2018). However, Kuncoro et al. (2018) have also shown that although sequential LSTMs can learn syntactic information, a recursive neural network which explicitly models hierarchy (the RNNG model from Dyer et al. (2015)) is better at this: it performs better on the number agreement task from Linzen et al. (2016).

To further explore this question in the context of dependency parsing, we investigate the use of recursive composition (henceforth referred to as *composition*) in a parser with an architecture like the one in Kiperwasser and Goldberg (2016b). This allows us to explore variations of features and isolate the conditions under which composi-

Proceedings of NAACL-HLT 2019, pages 1566–1576
Minneapolis, Minnesota, June 2 - June 7, 2019.

tion is helpful. We hypothesise that the use of a BiLSTM for feature extraction makes it possible to capture information about subtrees and therefore makes the use of subtree composition superfluous. We hypothesise that composition becomes useful when part of the BiLSTM is ablated, the forward or the backward LSTM. We further hypothesise that composition is most useful when the parser has no access to information about the function of words in the context of the sentence given by POS tags. When using POS tags, the tagger has indeed had access to the full sentence. We additionally look at what happens when we ablate character vectors which have been shown to capture information which is partially overlapping with information from POS tags. We experiment with a wider variety of languages than Dyer et al. (2015) in order to explore whether the usefulness of different model variants vary depending on language type.

2 K&G Transition-Based Parsing

We define the parsing architecture introduced by Kiperwasser and Goldberg (2016b) at a high level of abstraction and henceforth refer to it as K&G. A K&G parser is a greedy transition-based parser.[1] For an input sentence of length n with words $w_1, \ldots, w_n$, a sequence of vectors $x_{1:n}$ is created, where the vector x_i is a vector representation of the word w_i. We refer to these as *type* vectors, as they are the same for all occurrences of a word type. Type vectors are then passed through a feature function which learns representations of words in the context of the sentence.

$$x_i = e(w_i)$$
$$v_i = f(x_{1:n}, i)$$

We refer to the vector v_i as a *token* vector, as it is different for different tokens of the same word type. In Kiperwasser and Goldberg (2016b), the feature function used is a BiLSTM.

As is usual in transition-based parsing, parsing involves taking transitions from an initial configuration to a terminal one. Parser configurations are represented by a stack, a buffer and set of dependency arcs (Nivre, 2008). For each configuration c, the feature extractor concatenates the token representations of core elements from the stack and buffer. These token vectors are passed to a classifier, typically a Multilayer Perceptron (MLP). The MLP scores transitions together with the arc labels for transitions that involve adding an arc. Both the word type vectors and the BiLSTMs are trained together with the model.

3 Composing Subtree Representations

Dyer et al. (2015) looked at the impact of using a recursive composition function in their parser, which is also a transition-based parser but with an architecture different from K&G. They make use of a variant of the LSTM called a stack LSTM. A stack LSTM has push and pop operations which allow passing through states in a tree structure rather than sequentially. Stack LSTMs are used to represent the stack, the buffer, and the sequence of past parsing actions performed for a configuration.

The words of the sentence are represented by vectors of the word types, together with a vector representing the word's POS tag. In the initial configuration, the vectors of all words are in the buffer and the stack is empty. The representation of the buffer is the end state of a backward LSTM over the word vectors. As parsing evolves, the word vectors are popped from the buffer, pushed to and popped from the stack and the representations of stack and buffer get updated.

Dyer et al. (2015) define a recursive composition function and compose tree representations incrementally, as dependents get attached to their head. The composed representation c is built by concatenating the vector h of the head with the vector of the dependent d, as well as a vector r representing the label paired with the direction of the arc. That concatenated vector is passed through an affine transformation and then through a $tanh$ non-linear activation.

$$c = tanh(W[h; d; r] + b)$$

They create two versions of the parser. In the first version, when a dependent is attached to a head, the word vector of the head is replaced by a composed vector of the head and dependent. In the second version, they simply keep the vector of the head when attaching a dependent to a head. They observe that the version with composition is substantially better than the version without, by 1.3 LAS points for English (on the Penn Treebank (PTB) test set) and 2.1 for Chinese (on the Chinese Treebank (CTB) test set).

---

[1] Kiperwasser and Goldberg (2016b) also define a graph-based parser with similar feature extraction, but we focus on transition-based parsing.

Their parser uses POS tag information. POS tags help to disambiguate between different functional uses of a word and in this way give information about the use of the word in context. We hypothesise that the effect of using a recursive composition function is stronger when not making use of POS tags.

4 Composition in a K&G Parser

The parsing architectures of the stack LSTM parser (S-LSTM) and K&G are different but have some similarities.[2] In both cases, the configuration is represented by vectors obtained by LSTMs. In K&G, it is represented by the token vectors of top items of the stack and the first item of the buffer. In the S-LSTM, it is represented by the vector representations of the entire stack, buffer and sequence of past transitions.

Both types of parsers learn vector representations of word types which are passed to an LSTM. In K&G, they are passed to an LSTM in a feature extraction step that happens before parsing. The LSTM in this case is used to learn vectors that have information about the context of each word, a token vector. In the S-LSTM, word type vectors are passed to Stack LSTMs as parsing evolves. In this case, LSTMs are used to learn vector representations of the stack and buffer (as well as one which learns a representation of the parsing action history).

When composition is not used in the S-LSTM, word vectors represent word types. When composition is used, as parsing evolves, the stack and buffer vectors get updated with information about the subtrees they contain, so that they gradually become contextualised. In this sense, those vectors become more like token vectors in K&G. More specifically, as explained in the previous section, when a dependent is attached to its head, the composition function is applied to the vectors of head and dependent and the vector of the head is replaced by this composed vector.

We cannot apply composition on type vectors in the K&G architecture, since they are not used after the feature extraction step and hence cannot influence the representation of the configuration. Instead, we apply composition on the token vectors. We embed those composed representations in the same space as the token vectors.

In K&G, like in the S-LSTM, we can create a composition function and compose the representation of subtrees as parsing evolves. We create two versions of the parser, one where word tokens are represented by their token vector. The other where they are represented by their token vector and the vector of their subtree c_i, which is initially just a copy of the token vector ($v_i = f(x_{1:n}, i) \circ c_i$). When a dependent word d is attached to a word h with a relation and direction r, c_i is computed with the same composition function as in the S-LSTM defined in the previous section, repeated below.[3]

This composition function is a simple recurrent cell. Simple RNNs have known shortcomings which have been addressed by using LSTMs, as proposed by Hochreiter and Schmidhuber (1997). A natural extension to this composition function is therefore to replace it with an LSTM cell. We also try this variant. We construct LSTMs for subtrees. We initialise a new LSTM for each new subtree that is formed, that is, when a dependent d is attached to a head h which does not have any dependent yet. Each time we attach a dependent to a head, we construct a vector which is a concatenation of h, d and r. We pass this vector to the LSTM of h. c is the output state of the LSTM after passing through that vector. We denote those models with $+rc$ for the one using an ungated recurrent cell and with $+lc$ for the one using an LSTM cell.

$$c = tanh(W[h; d; r] + b)$$
$$c = \textsc{Lstm}([h; d; r])$$

As results show (see § 5), neither type of composition seems useful when used with the K&G parsing model, which indicates that BiLSTMs capture information about subtrees. To further investigate this and in order to isolate the conditions under which composition is helpful, we perform different model ablations and test the impact of recursive composition on these ablated models.

First, we ablate parts of the BiLSTMs: we ablate either the forward or the backward LSTM. We therefore build parsers with 3 different feature functions $f(x, i)$ over the word type vectors x_i in the sentence x: a BiLSTM (bi) (our baseline), a backward LSTM (bw) (i.e., ablating the forward LSTM) and a forward LSTM (fw) (i.e., ablating

---

[2] Note that we use S-LSTM to denote the stack LSTM parser, not the stack LSTM as an LSTM type.

[3] Note that, in preliminary experiments, we tried replacing the vector of the head by the vector of its subtree instead of concatenating the two but concatenating gave much better results.

the backward LSTM):

$$\begin{aligned} bi(x,i) &= \text{BiLSTM}(x_{1:n}, i) \\ bw(x,i) &= \text{LSTM}(x_{n:1}, i) \\ fw(x,i) &= \text{LSTM}(x_{1:n}, i) \end{aligned}$$

K&G parsers with unidirectional LSTMs are, in some sense, more similar to the S-LSTM than those with a BiLSTM, since the S-LSTM only uses unidirectional LSTMs. We hypothesise that composition will help the parser using unidirectional LSTMs in the same way it helps an S-LSTM.

We additionally experiment with the vector representing the word at the input of the LSTM. The most complex representation consists of a concatenation of an embedding of the word type $e(w_i)$, an embedding of the (predicted) POS tag of w_i, $p(w_i)$ and a character representation of the word obtained by running a BiLSTM over the characters $ch_{1:m}$ of w_i (BiLSTM($ch_{1:m}$)).

$$x_i = e(w_i) \circ p(w_i) \circ \text{BiLSTM}(ch_{1:m})$$

Without a POS tag embedding, the word vector is a representation of the word type. With POS information, we have some information about the word in the context of the sentence and the tagger has had access to the full sentence. The representation of the word at the input of the BiLSTM is therefore more contextualised and it can be expected that a recursive composition function will be less helpful than when POS information is not used. Character information has been shown to be useful for dependency parsing first by Ballesteros et al. (2015). Ballesteros et al. (2015) and Smith et al. (2018b) among others have shown that POS and character information are somewhat complementary. Ballesteros et al. (2015) used similar character vectors in the S-LSTM parser but did not look at the impact of composition when using these vectors. Here, we experiment with ablating either or both of the character and POS vectors. We look at the impact of using composition on the full model as well as these ablated models. We hypothesise that composition is most helpful when those vectors are not used, since they give information about the functional use of the word in context.

Parser We use UUParser, a variant of the K&G transition-based parser that employs the arc-hybrid transition system from Kuhlmann et al. (2011) extended with a SWAP transition and a Static-Dynamic oracle, as described in de Lhoneux et al. (2017b)[4]. The SWAP transition is used to allow the construction of non-projective dependency trees (Nivre, 2009). We use default hyperparameters. When using POS tags, we use the universal POS tags from the UD treebanks which are coarse-grained and consistent across languages. Those POS tags are predicted by UDPipe (Straka et al., 2016) both for training and parsing. This parser obtained the 7th best LAS score on average in the 2018 CoNLL shared task (Zeman et al., 2018), about 2.5 LAS points below the best system, which uses an ensemble system as well as ELMo embeddings, as introduced by Peters et al. (2018). Note, however, that we use a slightly impoverished version of the model used for the shared task which is described in Smith et al. (2018a): we use a less accurate POS tagger (UDPipe) and we do not make use of multi-treebank models. In addition, Smith et al. (2018a) use the three top items of the stack as well as the first item of the buffer to represent the configuration, while we only use the two top items of the stack and the first item of the buffer. Smith et al. (2018a) also use an *extended feature set* as introduced by Kiperwasser and Goldberg (2016b) where they also use the rightmost and leftmost children of the items of the stack and buffer that they consider. We do not use that extended feature set. This is to keep the parser settings as simple as possible and avoid adding confounding factors. It is still a near-SOTA model. We evaluate parsing models on the development sets and report the average of the 5 best results in 30 epochs and 5 runs with different random seeds.

Data We test our models on a sample of treebanks from Universal Dependencies v2.1 (Nivre et al., 2017). We follow the criteria from de Lhoneux et al. (2017c) to select our sample: we ensure typological variety, we ensure variety of domains, we verify the quality of the treebanks, and we use one treebank with a large amount of non-projective arcs. However, unlike them, we do not use extremely small treebanks. Our selection is the same as theirs but we remove the tiny treebanks and replace them with 3 others. Our final set is: Ancient Greek (PROIEL), Basque, Chinese, Czech, English, Finnish, French, Hebrew and Japanese.

---

[4] The code can be found at `https://github.com/mdelhoneux/uuparser-composition`

5 Results

First, we look at the effect of our different recursive composition functions on the full model (i.e., the model using a BiLSTM for feature extraction as well as both character and POS tag information). As can be seen from Figure 1, recursive composition using an LSTM cell ($+lc$) is generally better than recursive composition with a recurrent cell ($+rc$), but neither technique reliably improves the accuracy of a BiLSTM parser.

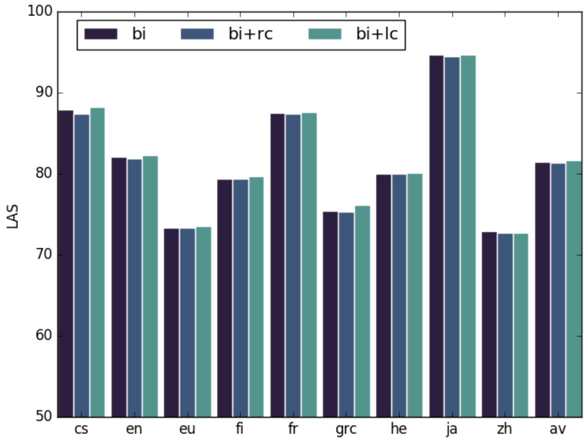

Figure 1: LAS of models using a BiLSTM (bi) without composition, with a recurrent cell ($+rc$) and with an LSTM cell ($+lc$). Bar charts truncated at 50 for visualization purposes.

5.1 Ablating the forward and backward LSTMs

Second, we only consider the models using character and POS information and look at the effect of ablating parts of the BiLSTM on the different languages. The results can be seen in Figure 2. As expected, the BiLSTM parser performs considerably better than both unidirectional LSTM parsers, and the backward LSTM is considerably better than the forward LSTM, on average. It is, however, interesting to note that using a forward LSTM is much more hurtful for some languages than others: it is especially hurtful for Chinese and Japanese. This can be explained by language properties: the right-headed languages suffer more from ablating the backward LSTM than other languages. We observe a correlation between how hurtful a forward model is compared to the baseline and the percentage of right-headed content dependency relations ($R = -0.838$, $p < .01$), see Figure 3.[5]

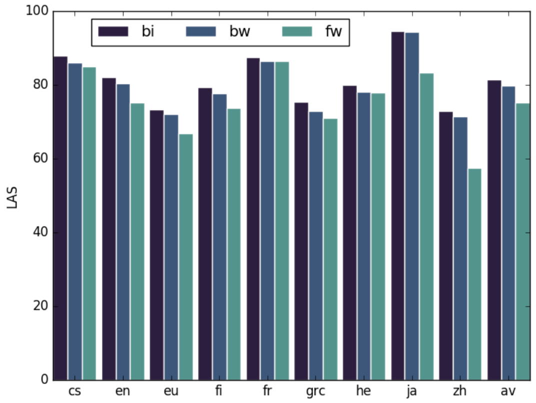

Figure 2: LAS of models using a BiLSTM (bi), backward LSTM (bw) and forward LSTM (fw).

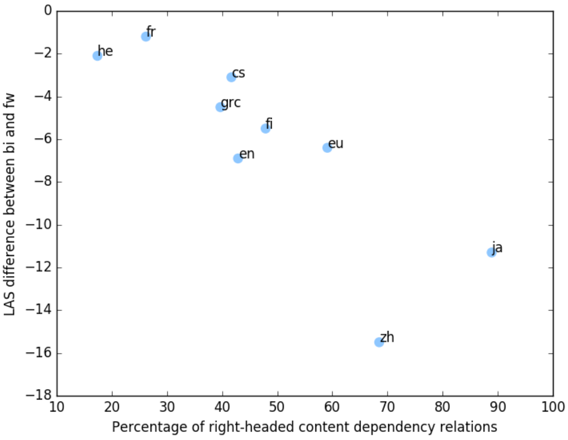

Figure 3: Correlation between how hurtful it is to ablate the backward LSTM and right-headedness of languages.

There is no significant correlation between how hurtful ablating the forward LSTM is and the percentage of left-headed content dependency relations ($p > .05$) indicating that its usefulness is not dependent on language properties. We hypothesise that dependency length or sentence length can play a role but we also find no correlation between how hurtful it is to ablate the forward LSTM and average dependency or sentence length in treebanks. It is finally also interesting to note that the backward LSTM performance is close to the BiLSTMs performance for some languages (Japanese and French).

---

[5] The reason we only consider content dependency relations is that the UD scheme focuses on dependency relations between content words and treats function words as features of content words to maximise parallelism across languages (de Marneffe et al., 2014).

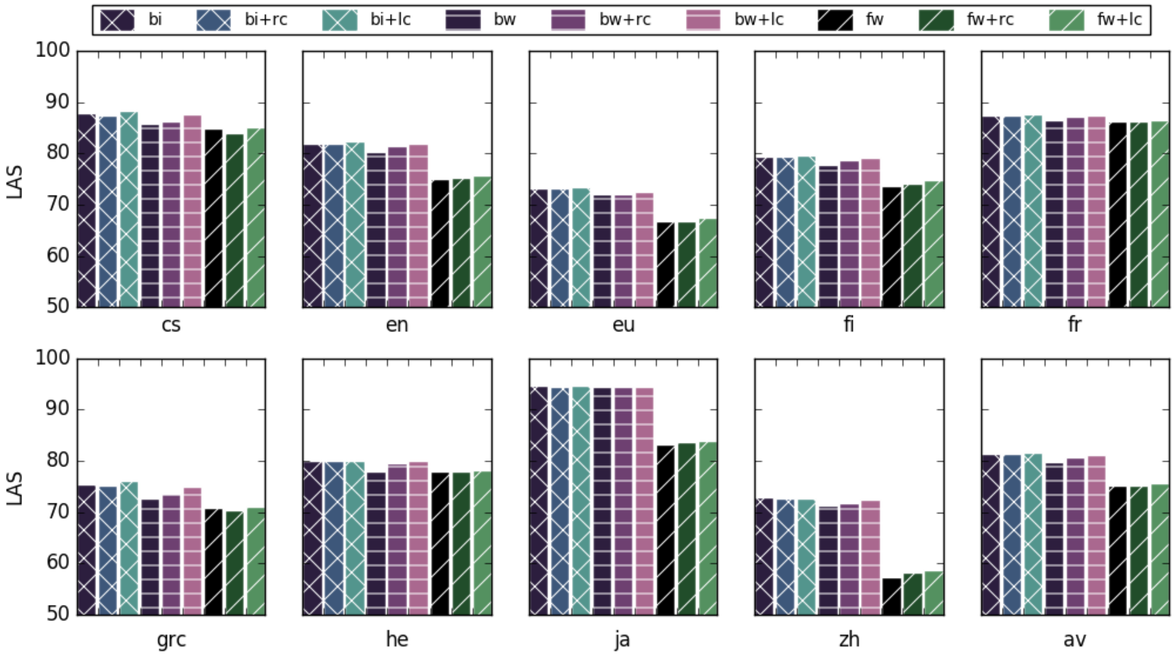

Figure 4: LAS of models using a BiLSTM (bi), backward LSTM (bw) and forward LSTM (fw), without recursive composition, with a recurrent cell ($+rc$) and with a LSTM cell ($+lc$). Bar charts truncated at 50 for visualization purposes.

We now look at the effect of using recursive composition on these ablated models. Results are given in Figure 4. First of all, we observe unsurprisingly that composition using an LSTM cell is much better than using a simple recurrent cell. Second, both types of composition help the backward LSTM case, but neither reliably helps the bi models. Finally, the recurrent cell does not help the forward LSTM case but the LSTM cell does to some extent. It is interesting to note that using composition, especially using an LSTM cell, bridges a substantial part of the gap between the bw and the bi models.

These results can be related to the literature on transition-based dependency parsing. Transition-based parsers generally rely on two types of features: *history-based features* over the emerging dependency tree and *lookahead features* over the buffer of remaining input. The former are based on a hierarchical structure, the latter are purely sequential. McDonald and Nivre (2007) and McDonald and Nivre (2011) have shown that history-based features enhance transition-based parsers as long as they do not suffer from error propagation. However, Nivre (2006) has also shown that lookahead features are absolutely crucial given the greedy left-to-right parsing strategy.

In the model architectures considered here, the backward LSTM provides an improved lookahead. Similarly to the lookahead in statistical parsing, it is sequential. The difference is that it gives information about upcoming words with unbounded length. The forward LSTM in this model architecture provides history-based information but unlike in statistical parsing, that information is built sequentially rather than hierarchically: the forward LSTM passes through the sentence in the linear order of the sentence. In our results, we see that lookahead features are more important than the history-based ones. It hurts parsing accuracy more to ablate the backward LSTM than to ablate the forward one. This is expected given that some history-based information is still available through the top tokens on the stack, while the lookahead information is almost lost completely without the backward LSTM.

A composition function gives hierarchical information about the history of parsing actions. It makes sense that it helps the backward LSTM model most since that model has no access to any information about parsing history. It helps the forward LSTM slightly which indicates that there can be gains from using structured information about parsing history rather than sequential information. We could then expect that composition should help the BiLSTM model which, how-

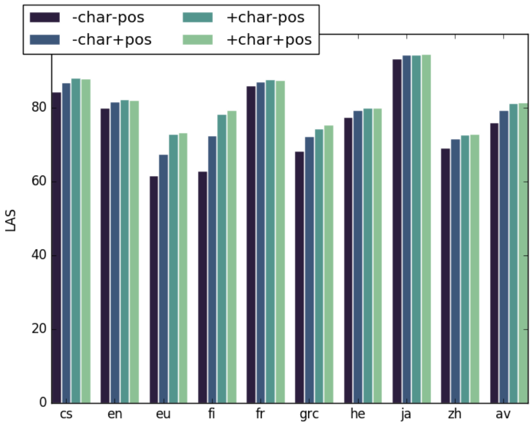

Figure 5: LAS of baseline, using char and/or POS tags to construct word representations

ever, is not the case. This might be because the BiLSTM constructs information about parsing history and lookahead into a unique representation. In any case, this indicates that BiLSTMs are powerful feature extractors which seem to capture useful information about subtrees.

5.2 Ablating POS and character information

Next, we look at the effect of the different word representation methods on the different languages, as represented in Figure 5. As is consistent with the literature (Ballesteros et al., 2015; de Lhoneux et al., 2017a; Smith et al., 2018b), using character-based word representations and/or POS tags consistently improves parsing accuracy but has a different impact in different languages and the benefits of both methods are not cumulative: using the two combined is not much better than using either on its own. In particular, character models are an efficient way to obtain large improvements in morphologically rich languages.

We look at the impact of recursive compositions on all combinations of ablated models, see Table 1. We only look at the impact of using an LSTM cell rather than a recurrent cell since it was a better technique across the board (see previous section).

Looking first at BiLSTMs, it seems that composition does not reliably help parsing accuracy, regardless of access to POS and character information. This indicates that the vectors obtained from the BiLSTM already contain information that would otherwise be obtained by using composition.

Turning to results with either the forward or the backward LSTM ablated, we see the expected pattern. Composition helps more when the model lacks POS tags, indicating that there is some redundancy between these two methods of building contextual information. Composition helps recover a substantial part of the gap of the model with a backward LSTM with or without POS tag. It recovers a much less substantial part of the gap in other cases which means that, although there is some redundancy between these different methods of building contextual information, they are still complementary and a recursive composition function cannot fully compensate for the lack of a backward LSTM or POS and/or character information. There are some language idiosyncracies in the results. While composition helps recover most of the gap for the backward LSTM models without POS and/or character information for Czech and English, it does it to a much smaller extent for Basque and Finnish. We hypothesise that arc depth might impact the usefulness of composition, since more depth means more matrix multiplications with the composition function. However, we find no correlation between average arc depth of the treebanks and usefulness of composition. It is an open question why composition helps some languages more than others.

Note that we are not the first to use composition over vectors obtained from a BiLSTM in the context of dependency parsing, as this was done by Qi and Manning (2017). The difference is that they compose vectors before scoring transitions. It was also done by Kiperwasser and Goldberg (2016a) who showed that using BiLSTM vectors for words in their Tree LSTM parser is helpful but they did not compare this to using BiLSTM vectors without the Tree LSTM.

Recurrent and recursive LSTMs in the way they have been considered in this paper are two ways of constructing contextual information and making it available for local decisions in a greedy parser. The strength of recursive LSTMs is that they can build this contextual information using hierarchical context rather than linear context. A possible weakness is that this makes the model sensitive to error propagation: a wrong attachment leads to using the wrong contextual information. It is therefore possible that the benefits and drawbacks of using this method cancel each other out in the context of BiLSTMs.

5.3 Ensemble

To investigate further the information captured by BiLSTMs, we ensemble the 6 versions of the models with POS and character information with the different feature extractors (bi, bw, fw) with ($+lc$) and without composition. We use the (unweighted) reparsing technique of Sagae and Lavie (2006)[6] and ignoring labels. As can be seen from the UAS scores in Table 2, the ensemble (*full*) largely outperforms the parser using only a BiLSTM, indicating that the information obtained from the different models is complementary. To investigate the contribution of each of the 6 models, we ablate each one by one. As can be seen from Table 2, ablating either of the BiLSTM models or the backward LSTM using composition, results in the least effective of the ablated models, further strengthening the conclusion that BiLSTMs are powerful feature extractors.

6 Conclusion

We investigated the impact of composing the representation of subtrees in a transition-based parser. We observed that composition does not reliably help a parser that uses a BiLSTM for feature extraction, indicating that vectors obtained from the BiLSTM might capture subtree information, which is consistent with the results of Linzen et al. (2016). However, we observe that, when ablating the backward LSTM, performance drops and recursive composition does not help to recover much of this gap. We hypothesise that this is because the backward LSTM primarily improves the lookahead for the greedy parser. When ablating the forward LSTM, performance drops to a smaller extent and recursive composition recovers a substantial part of the gap. This indicates that a forward LSTM and a recursive composition function capture similar information, which we take to be related to the rich history-based features crucial for a transition-based parser. To capture this infor-

---

[6] This method scores all arcs by the number of parsers predicting them and extracts a maximum spanning tree using the Chu-Liu-Edmonds algorithm (Edmonds, 1967).

mation, a recursive composition function is better than a forward LSTM on its own, but it is even better to have a forward LSTM as part of a BiLSTM. We further find that recursive composition helps more when POS tags are ablated from the model, indicating that POS tags and a recursive composition function are partly redundant ways of constructing contextual information. Finally, we correlate results with language properties, showing that the improved lookahead of a backward LSTM is especially important for head-final languages.

Cross-lingual CCG Induction

Kilian Evang
University of Düsseldorf
Germany
`evang@hhu.de`

Abstract

Combinatory categorial grammars are linguistically motivated and useful for semantic parsing, but costly to acquire in a supervised way and difficult to acquire in an unsupervised way. We propose an alternative making use of cross-lingual learning: an existing source-language parser is used together with a parallel corpus to induce a grammar and parsing model for a target language. On the PASCAL benchmark, cross-lingual CCG induction outperforms CCG induction from gold-standard POS tags on 3 out of 8 languages, and unsupervised CCG induction on 6 out of 8 languages. We also show that cross-lingually induced CCGs reflect known syntactic properties of the target languages.

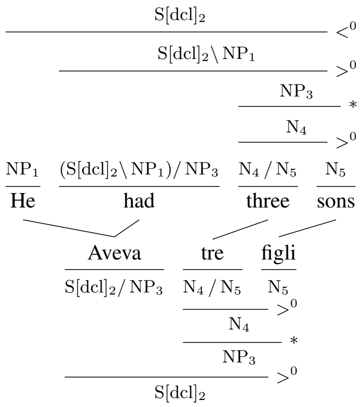

Figure 1: Projection of an English CCG derivation to an Italian translation. The indices distinguish different instances of categories.

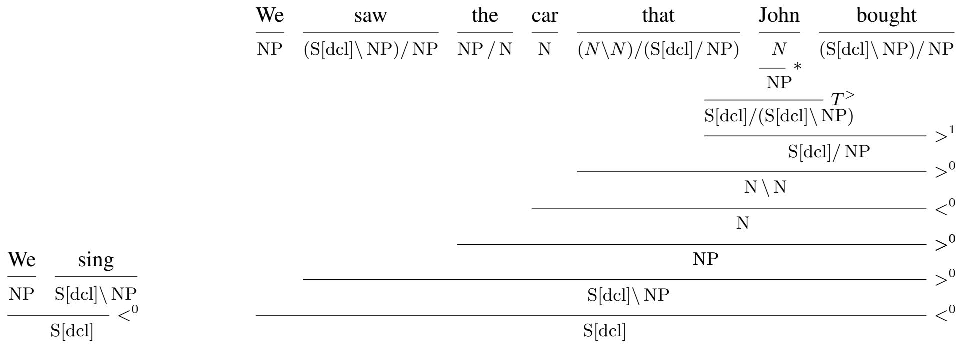
1 Introduction

Combinatory Categorial Grammar (CCG) (Steedman, 2001) is a grammar formalism known for its linguistic elegance and computational efficiency. It has been successfully used for statistical syntactic parsing (Clark and Curran, 2004; Lewis et al., 2016) and has emerged as a leading grammar formalism in semantic parsing (Curran et al., 2007; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011, 2013; Reddy et al., 2014; Artzi et al., 2015; Beschke and Menzel, 2018). Semantic parsing is important because it translates natural language utterances to something that a computer can understand, e.g., database queries, computer commands, or logical formulas, enabling next-generation information systems and knowledge extraction from text, among other applications.

CCGs used in most work to date are either hand-crafted (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2013; Artzi et al., 2015) or extracted from large syntactically annotated corpora (Curran et al., 2007; Reddy et al., 2014). In either case language-specific human effort is required. Acquiring CCGs in an unsupervised way is difficult and does not reach the performance of supervised methods (Bisk and Hockenmaier, 2013). As a result, most research focuses on English and other languages are neglected, meaning that speakers of other languages have delayed or no access to CCG-based semantic parsing technology.

We propose to overcome this bottleneck by inducing CCGs cross-lingually, i.e., transferring an existing grammar from English to other languages via unannotated parallel data. The process is illustrated for one English-Italian sentence pair in Figure 1: the English sentence is parsed by an existing CCG parser and word-aligned to the Italian sentence. Italian words receive categories equivalent to those of the aligned English words, and a semantically equivalent derivation is built for the Italian sentence. With enough derivations projected in this way, they can be used to extract a CCG lexicon and to estimate parameter weights for parsing the target language.

Proceedings of NAACL-HLT 2019, pages 1577–1587
Minneapolis, Minnesota, June 2 - June 7, 2019.



(a) (b)

Figure 2: Two examples of CCG derivations.

Unlike previous competitive methods for CCG induction such as Bisk and Hockenmaier (2013), our method does not require the training data to be POS-tagged. It also induces more fine-grained labels. In this paper, we compare the performance of parsers trained using our method to previous induced CCG parsers. We also investigate whether the cross-lingually induced CCG lexicons correspond with linguistic insights about the target languages.

2 Combinatory Categorial Grammar

In categorial grammars (Bar-Hillel, 1953), words and larger constituents share a single space of labels, called *categories*. For example, the intransitive verb *sing* in Figure 2(a) and the verb phrase *saw the car that John bought* in Figure 2(b) have the same category: $\mathrm{S[dcl]\backslash NP}$. Parse trees are conventionally called *derivations* and their nodes depicted as horizontal lines, placed underneath their children.

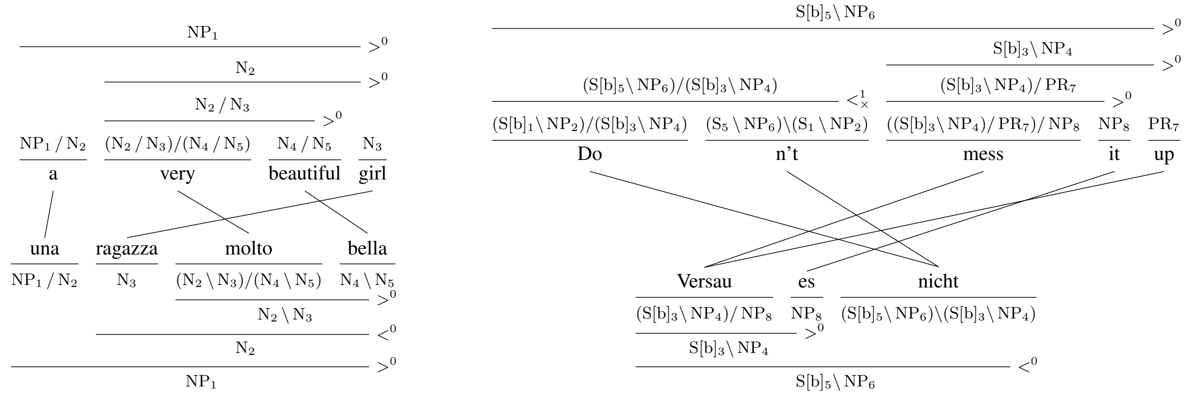
Categorial grammars have only few *basic categories*, typically: N for nouns, NP for noun phrases, PP for argument prepositional phrases, PR for verb particles, and $\mathrm{S}[X]$ for sentences, where X is a feature that indicates the type of sentence or clause, e.g., dcl for declarative sentences or b for infinitives. All other categories are *functional categories*, which contain information about what kinds of arguments constituents with these categories combine with, and what kinds of constituents result. For example, in English, a declarative verb phrase is a constituent that combines with a noun phrase (the subject) to its left to form a declarative sentence. This is expressed by its category: $\mathrm{S[dcl]\backslash NP}$. Similarly, a transitive verb is a constituent that combines with a noun phrase (the object) to its right to form a verb phrase. This results in the functional category $\mathrm{(S[dcl]\backslash NP)/NP}$ for a transitive verb, where the brackets determine the order in which it combines with its arguments.

With such expressive categories, categorial grammars are mainly defined via the lexicon, i.e., which words are associated with which categories. Only few and very general rules are needed to specify how constituents may combine. The basic rules are forward application and backward application ($>^0$, $<^0$). They allow a constituent with a functional category to combine with its argument. Combinatory categorial grammar adds type raising ($T^>$, $T^<$) and generalizes application to (harmonic and crossing) composition ($>^1$, $<^1$, $>^2$, $<^2$...). This allows for dealing with “incomplete” constituents such as the object relative clause *John bought* in Figure 2(b). The object is extracted, thus the transitive verb *bought* cannot combine with the NP it expects to its right. Thanks to type raising and composition, it can nevertheless combine with its subject, resulting in a sentence with an open object argument slot ($\mathrm{S[dcl]/NP}$), which is taken as an argument by the relative pronoun *that*.

Additionally, some unary *type changing* ($*$) rules are used to convert categories, e.g., $\mathrm{N} \Rightarrow \mathrm{NP}$ to convert N to NP when there is no determiner.

3 Derivation Projection

Examples of derivations projected from English to other languages are shown in Figures 1 and 3. Note that we give basic categories indices here to distinguish different instantiations of the same category. For the purposes of derivation projection, different instantiations are treated as different cat-



(a) (b)

Figure 3: Projections of English CCG derivations to Italian and German translations.

egories to ensure that projected derivations are semantically equivalent to the input derivations (e.g., $N_2 / N_3 \neq N_4 / N_5$).

We now describe our derivation projection algorithm. Given a source derivation, a target sentence, and a word alignment, it attempts to produce a target derivation. Note that target derivations are entirely derived from the data by the algorithm; we do not make use of any hand-crafted language-specific rules.

Input The input to derivation projection consists of a source sentence E with a derivation D_E, a target sentence F which is a translation of E, and a (potentially ambiguous) alignment $\mathcal{A}$ which is a set of 1:N translation units $\langle\langle f\rangle, \mathbf{e}\rangle$ where f is a token in F and $\mathbf{e}$ is a subsequence (not necessarily contiguous) of tokens in E, as well as translation units $\langle\langle\rangle, \langle e\rangle\rangle$, indicating that the English word e is not aligned.

Output Derivation projection may succeed or fail; if it succeeds, the output is a derivation D_F for F.

Auxiliary Definitions $\mathcal{C}$ is the set of all categories. A *category assignment* c for a sequence of tokens $\mathbf{t}$ is a relation such that $c \subseteq \mathbf{t} \times \mathcal{C}$.[1] We write c_E for the category assignment relating tokens in E to the categories they have in D_E; this relation is a function. We write R^*_E for the set of type-changing rules used in D_E. We write RootCat(D) for the category of the root of a derivation D. Parse is a function that takes a sequence of tokens $\mathbf{t}$, a category assignment c for $\mathbf{t}$, and a set of type-changing rules R^*. It returns the set of all normal-form CCG derivations (Hockenmaier and Bisk, 2010) that can be built over $\mathbf{t}$ using R^*, forward/backward type raising and harmonic/crossing composition up to degree 2, with possible lexical categories determined by c. To deal with parsing ambiguity during derivation projection, we assume a function Choose that takes a non-empty set of derivations and returns one element. We will say more about it below.

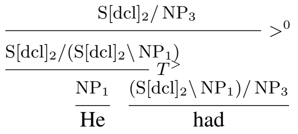


Figure 4: Two source-language categories are merged into one.

Step 1: Transfer Categories This step assigns categories to the words in F based on the categories of aligned words in E. This is straightforward for 1:1 translation units such as ⟨tre, three⟩, but 1:N translation units such as ⟨Aveva, He had⟩ need a bit more care. We define Merge as a partial function from subsequences of E to $\mathcal{C}$. For a single-token subsequence $e \in E$, Merge$(e) = c_E(e)$. For a longer subsequence $\mathbf{e}$, Merge$(\mathbf{e})$ = RootCat(Choose(Parse$(\mathbf{e}, c_E, R^*_E)$)) (if defined). For example, even though *He had* is not a constituent in Figure 1, it has a parse (shown in Figure 4), and so Merge(He had) = $\mathrm{S[dcl]}_2/\,\mathrm{NP}_3$. We then define a preliminary category assignment

---

[1] In a slight abuse of notation, we treat sequences of tokens as sets of tokens when convenient.

for F: $c_F = \{\langle f, \textsc{Merge}(\mathbf{e})\rangle | \langle\langle f\rangle, \mathbf{e}\rangle \in \mathcal{A}, \textsc{Merge}(\mathbf{e}) \text{ is defined}\}$.

Step 2: Transfer Type-changing Rules This step creates a set R^*_F of type-changing rules to be used in D_F. In addition to the type-changing rules used in D_E, we add $\mathrm{N} \Rightarrow \mathrm{NP}$ rules for English determiners that have no corresponding token in the target language. This is a common occurrence, especially with languages which have no articles, such as Czech, or where (some) articles are affixes rather than separate words, such as Swedish. Thus, $R^*_F = R^*_E \cup \{\mathrm{N}_i \Rightarrow \mathrm{NP}_j \,|\langle\langle\rangle, \langle e\rangle\rangle \in \mathcal{A}, c_E(e) = \mathrm{NP}_i \,/\, \mathrm{N}_j \text{ for some } i, j\}$.

Step 3: Flip Slashes This step adapts the directionality of slashes in the assigned categories, because the word order may be different in F than in E. We say that a category C' is a *flip variant* of category C ($\textsc{Flip}(C, C')$) if it is the same as C, except that slashes may lean a different way, as long as subcategories that are modifier categories in C (i.e., are of form X/X or $X\backslash X$, ignoring indices) remain so in C'. For example, in Figure 3(a), the category $(\mathrm{N}_2 \,/\, \mathrm{N}_3)/(\mathrm{N}_4 \,/\, \mathrm{N}_5)$ has a flip variant $(\mathrm{N}_2 \,\backslash\, \mathrm{N}_3)/(\mathrm{N}_4 \,\backslash\, \mathrm{N}_5)$ whereas $(\mathrm{N}_2 \,\backslash\, \mathrm{N}_3)/(\mathrm{N}_4 \,/\, \mathrm{N}_5)$ is not a flip variant because that would destroy the modifier status. In order to be able to construct a derivation for F even with word order different from E, we define a new category assignment: $c'_F = \{\langle f, C'\rangle | \langle f, C\rangle \in c_F, \textsc{Flip}(C, C')\}$. Similarly, we construct a set of type-changing rules with flip variants: $R^{*\prime}_F = \{X' \Rightarrow Y' | X \Rightarrow Y \in R^*_F, \textsc{Flip}(X, X'), \textsc{Flip}(Y, Y')\}$. This constructs more categories and type-changing rules than needed; for example, $(\mathrm{N}_2 \,/\, \mathrm{N}_3)\backslash(\mathrm{N}_4 \,/\, \mathrm{N}_5)$ is a flip variant for *molto* that cannot be used, as the argument category $\mathrm{N}_4 \,/\, \mathrm{N}_5$ does not appear on the left. Such spurious categories are discarded automatically in our implementation.

Step 4: Construct Derivation With c'_F and $R^{*\prime}_F$ constructed, we try to find a parse for F that has the same root category as D_E: $D_F = \textsc{Choose}(\{D | D \in \textsc{Parse}(F, c'_F, R^{*\prime}_F), \textsc{RootCat}(D) = \textsc{RootCat}(D_E)\})$ if defined; otherwise derivation projection fails and no derivation is returned.

Resolving Ambiguity Since parsing in steps 1 and 4 of derivation projection is guided by indexed categories and normal-form constraints, ambiguity primarily arises through ambiguous word alignments, which we use to achieve better projection coverage (see Section 5). For example, in Figure 1, *tre* might also be aligned to *sons*, and *three* to *figli*, giving rise to an additional (incorrect) parse. Our strategy for resolving such ambiguities is to prefer parses whose lexical categories result from word alignments with higher alignment scores. Our current implementations of PARSE and CHOOSE naively order parses by the score of the alignment that produced each lexical target category, greedily from left to right. Future work might improve upon this by ranking parses according to a global score.

4 The Learning Procedure

Given a parallel training corpus of source-target sentence pairs, we parse the source-language part using a source-language parser and run unsupervised word alignment on the entire corpus. Then, for each sentence pair, we run derivation projection using the generated source parses and alignments. If successful, we add the target derivation picked by CHOOSE to a target-language training set. Finally, we use this training set to train a target-language parser in the usual way.

5 Experiments[2]

Target Languages Following prior work, we evaluate the induced CCG parsers in terms of unlabeled attachment score (UAS) on the data of the PASCAL unsupervised grammar induction challenge (Gelling et al., 2012), which includes eight different languages other than English: Arabic, Czech, Danish, Basque, Dutch, Portuguese, Slovenian, and Swedish. For qualitative evaluation, we use German, Italian, and Dutch. We acknowledge the importance of testing our approach on a more typologically diverse range of languages, but leave this for future work.

Training Data To start learning to parse a new language, one needs short and simple example sentences. This is true for human learners, and presumably also for computers. We therefore used the Tatoeba corpus[3] for training, a multilingual parallel corpus gathered by volunteers and aimed at language learners. We extracted English-X sentence pairs for various languages X and tokenized

---

them using UDPipe (Straka and Straková, 2017), not making use of the optional multiword token subdivision feature. The resulting parallel corpora are summarized in Table 1.

Source-language Parser To create derivations to project, we needed a suitable parser for our source language, English. Commonly, English CCG parsers are trained on CCGbank (Hockenmaier and Steedman, 2007) or its derivative CCGrebank (Honnibal et al., 2010). However, these treebanks use special categories for punctuation and conjunctions, which would complicate derivation projection. We thus took CCGrebank, automatically transformed it to use normal categories for these cases (an example is shown in Figure 5), and trained the EasyCCG parser (Lewis and Steedman, 2014) on that. The resulting model was used to produce parses for the English portions of our parallel training corpora.

Word Alignments and Derivation Projection For word-aligning the parallel training data, we used GIZA++ with default settings (Och and Ney, 2003). We generated alignments $\mathcal{A}$ for each sentence pair by taking the union of the n-best GIZA++ alignments, trying out different values for n between 1 and 5.

Target-language Parser Again, we used EasyCCG. Its supertagger component is trained on sentences where the words are annotated with categories. We used the projected derivations for that. We used the Polyglot word embeddings (Al-Rfou et al., 2013). Since we do not have supertagged validation sets for the target languages, the number of training epochs was fixed at 3 following initial experimentation. The parser component requires no training, but for decoding, we made some modifications to it to generalize beyond English: instead of a hard-coded set for English, the modified parser uses the set of unary rules used in the projected derivations for the respective language. It also implements all composition rules up to degree 2 rather than an English-specific subset, and it implements Hockenmaier and Bisk's normal-form constraints.

Dependency Conversion For evaluating the induced target-language parsers on the PASCAL benchmark, we have to be able to convert their output derivations to dependency trees, as exemplified in Figure 6. The simplest way to do this is to make arguments dependents of their functors, similar to Koller and Kuhlmann (2009). That is, a word v with the (indexed) category $X|Y\alpha$

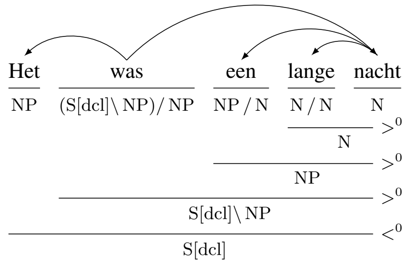

Figure 6: An example derivation and its conversion into a dependency tree.

becomes the head of a word w with category $Y\beta$, where $| \in \{/, \backslash\}$ and α, β stand for any number of additional argument categories with slashes. However, for some categories the head-dependent relation should be inverted. For example, if $X|Y$ is a modifier category, then w becomes the head of v, and any dependents v would get because of additional arguments in X become dependents of w instead. Because dependency treebanks differ in their conventions for attaching certain function words, certain non-modifier categories also need to be treated in this inverted way. They are shown in Table 2. Note that this fine-grained control is only possible because we induce relatively rich CCG categories; by contrast, Bisk and Hockenmaier (2013) use only two basic categories (S and N) and therefore cannot distinguish, e.g., determiners from attributive adjectives (N/N) or *to*-complementizers from auxiliary verbs ($((\mathrm{S}\backslash\mathrm{N})/(\mathrm{S}\backslash\mathrm{N}))$). They do apply treebank-specific conversion rules for coordination, which we also implement.

Hyperparameter Tuning We use the PASCAL development data to tune the hyperparameter n which controls how many GIZA++ alignments are used for derivation projection. Table 3 shows how many sentence pairs our parallel training corpus contains for each of the eight languages, how many of the derivations are successfully projected

language sentence pairs		ara 19 502	ces 11 147	dan 21 409	eus 1 882	nld 44 026	por 161 126	slv 835	swe 24 206

Table 4: UAS of different systems on the PASCAL test data (max sentence length 15, not counting punctuation).

for each value of n, and how accurately the development data is parsed. The numbers show the importance of having enough training examples: Portuguese, Swedish, Dutch, and Danish are leading in terms of corpus size and parsing accuracy, whereas Basque and Slovene are far behind in both. Arabic is a bit of an outlier, performing worse than Czech despite a considerably larger corpus. The ratio of successfully projected derivations increases as n is increased. This makes for more training data but also more noise; different languages peak at different values for n. Languages with little training data (Slovene, Basque, Czech) most clearly profit from more projected derivations. For the final tests, we set $n \leq 5$ to maximize UAS on the development data for each language.

Baselines We compare with two unsupervised CCG induction system and one other cross-lingual CCG induction system. To our knowledge, Bisk and Hockenmaier (2013) represents the state of the art in unsupervised CCG induction. It does, however, use gold-standard POS tags in the training and testing data. These seem to be essential, as a variant of this system which does not rely on POS tags performed much worse (Bisk et al., 2015). Our system does not rely on POS tags but on parallel data and word embeddings instead, which is an advantage as parallel data and word embeddings may be more readily available than POS tags for new languages. We also compare with the system of Evang and Bos (2016), a cross-lingual system similar to ours which was previously only evaluated on a semantic parsing task, not on syntactic dependencies. For the unsupervised systems, we report published results when trained on the complete PASCAL data. For BH13, we also include our best replication attempt using the original software and training data, falling short of the published results as the exact configurations appear to be lost. For the cross-lingual systems which require parallel training data, we train on the Tatoeba dataset. All test scores are on the PASCAL test set, limited to sentences with at most 15 tokens, not counting punctuation.

Results Test results are shown in Table 4. Despite not using POS tags, our system outperforms the cross-lingually supervised system of Evang and Bos (2016) by a large margin on all languages. It also outperforms the unsupervised system of Bisk et al. (2015) on 6 out of 8 languages, and that of Bisk and Hockenmaier (2013) (which uses POS tags) on 3 out of 8 languages. This is also in spite of these two unsupervised systems being trained on more (albeit not parallel) data, which even included the test data.

6 The Induced Lexicons

Have our cross-lingually trained parsers acquired language-specific knowledge? Based on what we know about the syntactic differences between English, German, Italian, and Dutch, we would expect certain categories to be more prominent in the lexicon for some languages than for others:

1. English word order in transitive clauses is almost always SVO, whereas for German and Dutch, SVO is the typical order for main clauses, and SOV the typical order for subordinate clauses (Dryer, 2013c). Thus, we expect the English parser to almost always assign category $(\mathrm{S[X]} \backslash \mathrm{NP}) / \mathrm{NP}$ to transitive verbs, whereas we expect German and Dutch transitive verbs to be split between $(\mathrm{S[X]} \backslash \mathrm{NP}) / \mathrm{NP}$ and $(\mathrm{S[X]} \backslash \mathrm{NP}) \backslash \mathrm{NP}$.

	Category	English	German	Italian	Dutch
1	$(S[dcl]\backslash NP)/NP$	.0366	.0445	.0256	.0389
	$(S[dcl]\backslash NP)\backslash NP$	.0000	.0056	.0046	.0061
	$(S[b]\backslash NP)/NP$	.0284	.0032	.0147	.0044
	$(S[b]\backslash NP)\backslash NP$	.0000	.0169	.0043	.0151
2	$(S[dcl]\backslash NP)/(S[b]\backslash NP)$	.0237	.0184	.0150	.0180
3	$(S[b]\backslash NP)\backslash PR$	.0000	.0000	.0000	.0000
	$(S[b]\backslash NP)/PR$	.0004	.0000	.0000	.0000
4	N/N	.0309	.0299	.0213	.0316
	$N\backslash N$	.0013	.0018	.0099	.0018
	$(N/N)/(N/N)$	.0016	.0018	.0003	.0012
	$(N\backslash N)/(N\backslash N)$	.0001	.0000	.0008	.0000
5	$S[dcl]$	.0000	.0000	.0012	.0001
	$S[dcl]/NP$	.0004	.0013	.0115	.0007

Table 5: Frequency (per sentence) of lexical categories in the output of different parsers when applied to the Tatoeba data, illustrating learned language-specifics. The averages for English are calculated over all three parallel training corpora.

2. German, Italian and Dutch do not have *do*-support for negation (Miestamo, 2013), so we expect the category $(S[dcl]\backslash NP)/(S[b]\backslash NP)$ to be less common in them than in English.

3. In the infinitive mood, German and Dutch spell particle verbs as one token (e.g., *ausgehen*, *uitgaan*), unlike English which spells them apart (*go out*) (Dehé, 2015). Thus, we expect categories such as $(S[b]\backslash NP)\backslash PR$ or $(S[b]\backslash NP)/PR$ to be nonexistent in German and Dutch but common in English.

4. In Italian, attributive adjectives commonly appear after the noun they modify, whereas in English they almost always appear before (Dryer, 2013b). We thus expect the category $N\backslash N$ to be much more common in Italian than in English. Likewise, for adverbs modifying these adjectives, we expect $(N\backslash N)/(N\backslash N)$ in Italian but not in English (cf. Figure 3(a)).

5. In Italian, subject pronouns are frequently dropped (Dryer, 2013a), so we expect to frequently see verb categories like $S[X]$ and $S[X]/NP$, which are uncommon in English (cf. Figure 1).

To quantify these effects on comparable data for all four languages, we applied our parsers to the Tatoeba data to see how often they predict each category for a word. The relative numbers are shown in Table 5. We find all five expectations confirmed, suggesting that training parsers on projected derivations can indeed teach them specifics of each language's syntax.

7 Related Work

Recent years have seen much interest in cross-lingual learning, that is, learning tagging and parsing models for languages without training data for that language, instead relying on training data or existing systems for another language, and on parallel data to transfer knowledge from one language to the other. This is either done by automatically projecting source-language annotations from the source text to the target text (Yarowsky et al., 2001; Hwa et al., 2005; Tiedemann, 2014; Rasooli and Collins, 2015; Johannsen et al., 2016; Agić et al., 2016; Damonte and Cohen, 2018), sharing parameters between models for different languages (Zeman and Resnik, 2008; Ganchev et al., 2009; McDonald et al., 2011; Naseem et al., 2012; Täckström et al., 2013; de Lhoneux et al., 2018), or automatically translating the text from the source language to the target language and synchronously projecting the annotations (Tiedemann et al., 2014). Our work is an application of the first approach to CCG, which as a grammar formalism provides a more systematic framework for the study of syntax and for compositional interpretation than dependency parsers.

Apart from unsupervised syntactic CCG induction, CCG induction has also been done as part of learning semantic parsers, where supervision typically comes from logical forms, and syntax is treated as latent. Much of this work starts with a manually specified inventory of syntactic categories and only learns the semantic parts (Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2013; Reddy et al., 2014; Artzi et al., 2015), whereas we start with no knowledge of the syntactic categories of the target language. Kwiatkowksi et al. (2010); Kwiatkowski et al. (2011); Bisk et al. (2016); Evang and Bos (2016) also learn the syntactic categories but evaluate their parsers only on semantic tasks, so it is unclear how linguistically plausible the induced CCGs are.

Earlier versions of the projection algorithm presented here were used in Evang and Bos (2016) for cross-lingual semantic parsing, and in Abzianidze et al. (2017) for bootstrapping a multilingual CCG treebank.

8 Conclusions and Future Work

Cross-lingual learning is a promising strategy whenever annotated training data for the target language is not available, but annotated training data for a source language as well as a parallel corpus is. This paper has introduced a method to apply this idea to syntactic CCG parsing, based on an algorithm for projecting CCG derivations along word alignments.

Compared to existing work on CCG induction, our method relies on parallel data and word embeddings but obviates the need for POS tags while in many cases outperforming methods that do use POS tags, and with less training data. This should make our method suitable for bringing multilingualism to CCG-based semantic parsers that so far rely on hand-written grammars.

In addition, we have shown that the induced lexicons reflect linguistic knowledge about the target languages. Our method also induces more fine-grained categories than previous approaches. It can thus also be a valuable asset for bootstrapping linguistically informed parsers and CCG treebanks for new languages.

There are various avenues to improving and extending derivation projection: alignment ambiguity could be handled with a global score, and multiple possible parses could be included in the target-language set, potentially improving the tradeoff between the number of projected derivations and the amount of noise. To increase the range of structural differences between languages that can be handled, derivation projection could be extended to consider sub-token units and to handle 1:n translation units in addition to n:1 ones.

Acknowledgments

The author would like to thank Lasha Abzianidze and Johan Bos for invaluable help in planting the seeds for this research, Yonatan Bisk for help with replication, and Laura Kallmeyer, Jakub Waszczuk, and all anonymous reviewers for valuable feedback. This research was supported by the NVIDIA Corporation with a Titan Xp GPU. It was partly carried out within the TreeGraSP project, funded by a Consolidator Grant of the European Research Council (ERC).

Density Matching for Bilingual Word Embedding

Abstract

Recent approaches to cross-lingual word embedding have generally been based on linear transformations between the sets of embedding vectors in the two languages. In this paper, we propose an approach that instead expresses the two monolingual embedding spaces as probability densities defined by a Gaussian mixture model, and matches the two densities using a method called normalizing flow. The method requires no explicit supervision, and can be learned with only a seed dictionary of words that have identical strings. We argue that this formulation has several intuitively attractive properties, particularly with the respect to improving robustness and generalization to mappings between difficult language pairs or word pairs. On a benchmark data set of bilingual lexicon induction and cross-lingual word similarity, our approach can achieve competitive or superior performance compared to state-of-the-art published results, with particularly strong results being found on etymologically distant and/or morphologically rich languages.[1]

1 Introduction

Cross-lingual word embeddings represent words in different languages in a single vector space, capturing the syntactic and semantic similarity of words across languages in a way conducive to use in computational models (Upadhyay et al., 2016; Ruder et al., 2017). These embeddings have been shown to be an effective tool for cross-lingual NLP, e.g. the transfer of models trained on high-resource languages to low-resource ones (Klementiev et al., 2012; Guo et al., 2015; Zoph et al., 2016; Zhang et al., 2018; Gu et al., 2018) or unsupervised learning (Artetxe et al., 2018c).

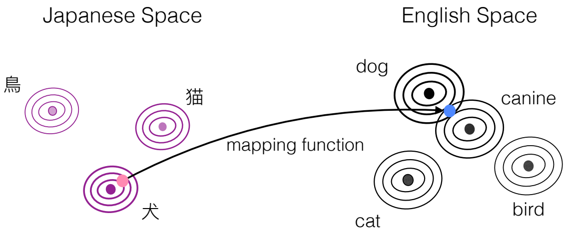

Figure 1: An illustration of our method. Thicker lines represent higher mixture weights, linked to word frequency. The pink point is a continuous training sample in the Japanese embedding space while the blue point is a mapped point in the English space.

There are two major paradigms in the learning of cross-lingual word embeddings: "online" and "offline". "Online" methods learn the cross-lingual embeddings directly from parallel corpora (Hermann and Blunsom, 2014), optionally augmented with monolingual corpora (Gouws et al., 2015). In contrast, "offline" approaches learn a bilingual mapping function or multilingual projections from pre-trained monolingual word embeddings or feature vectors (Haghighi et al., 2008; Mikolov et al., 2013; Faruqui and Dyer, 2014). In this work, we focus on this latter offline approach.

The goal of bilingual embedding is to learn a shared embedding space where words possessing similar meanings are projected to nearby points. Early work focused on supervised methods maximizes the similarity of the embeddings of words that exist in a manually-created dictionary, according to some similarity metric (Mikolov et al., 2013; Faruqui and Dyer, 2014; Jawanpuria et al., 2018; Joulin et al., 2018). In contrast, recently proposed unsupervised methods frame this problem as minimization of some form of distance between the whole set of discrete word vectors in the chosen vocabulary, e.g. Wasserstein distance or Jensen–Shannon divergence (Xu et al., 2018; Conneau et al., 2017; Zhang et al., 2017; Grave

Minneapolis, Minnesota, June 2 - June 7, 2019.

et al., 2018). While these methods have shown impressive results for some language pairs despite the lack of supervision, regarding the embedding space as a set of discrete points has some limitations. First, expressing embeddings as a single point in the space doesn't take into account the inherent uncertainty involved in learning embeddings, which can cause embedding spaces to differ significantly between training runs (Wendlandt et al., 2018). Second, even in a fixed embedding space the points surrounding those of words that actually exist in the pre-trained vocabulary also often are coherent points in the embedding space.

In this work, we propose a method for **density matching for bilingual word embedding (DeMa-BWE)**. Instead of treating the embedding space as a collection of discrete points, we express it as a probability density function over the entire continuous space over word vectors. We assume each vector in the monolingual embedding space is generated from a Gaussian mixture model with components centered at the pretrained word embeddings (Fig. 1), and our approach then learns a bilingual mapping that most effectively matches the two probability densities of the two monolingual embedding spaces.

To learn in this paradigm, instead of using the pre-trained word embeddings as fixed training samples, at every training step we obtain samples from the Gaussian mixture space. Thus, our method is exploring the entire embedding space instead of only the specific points assigned for observed words. To calculate the density of the transformed samples, we use volume-preserving invertible transformations over the target word embeddings, which make it possible to perform density matching in a principled and efficient way (Rezende and Mohamed, 2015; Papamakarios et al., 2017; He et al., 2018). We also have three additional ingredients in the model that proved useful in stabilizing training: (1) a back-translation loss to allow the model to learn the mapping jointly in both directions, (2) an identical-word-matching loss that provides weak supervision by encouraging the model to have words with identical spellings be mapped to a similar place in the space, and (3) frequency-matching based Gaussian mixture weights that accounts for the approximate frequencies of aligned words.

Empirical results are strong; our method is able to effectively learn bilingual embeddings that achieve competitive or superior results on the MUSE dataset (Conneau et al., 2017) over state-of-the-art published results on bilingual word translation and cross-lingual word similarity tasks. The results are particularly encouraging on etymologically distant or morphologically rich languages, as our model is able to explore the integration over the embedding space by treating the space as a continuous one. Moreover, unlike previous unsupervised methods that are usually sensitive to initialization or require sophisticated optimization procedures, our method is robust and requires no special initialization.

2 Background: Normalizing Flows

In this section, we will briefly describe normalizing flows - the backbone of DeMa-BWE.

As mentioned in the introduction and detailed later, our model is based on matching two probability density functions, one representing the source embedding space and one representing the target embedding space. To learn in this framework, we will use the concept of *normalizing flows* (Rezende and Mohamed, 2015). We will explain them briefly here, but refer readers to Rezende and Mohamed (2015) for details due to space constraints.

Concretely, let $\mathbf{u}$ denote a high dimensional random vector (e.g. representing a point in the source embedding space) and $\mathbf{z}$ be a latent variable that corresponds to $\mathbf{u}$ (e.g. a point in the target embedding space). Flow-based generative models (Kingma et al., 2016; Kingma and Dhariwal, 2018) learn invertible transformations $f_\theta(\mathbf{z})$ from the distribution over $\mathbf{z}$ to the distribution over $\mathbf{u}$. The generative story of the model is defined as:

$$\mathbf{z} \sim p_\theta(\mathbf{z}), \quad \mathbf{u} = f_\theta(\mathbf{z}) \tag{1}$$

where $p_\theta(\mathbf{z})$ is the prior distribution. This prior can be any distribution for which we can tractably compute the density of sample points $\mathbf{z}$. A common choice of such distribution is a spherical multivariate Gaussian distribution: $p_\theta(\mathbf{z}) = \mathcal{N}(\mathbf{z}; 0, \mathbf{I})$ (Dinh et al., 2016). Assuming the transformation function $f_\theta(\cdot)$ is invertible, using the rule for change of variables, the probability density of $\mathbf{u}$ can be calculated as:

$$p_\theta(\mathbf{u}) = p_\theta(\mathbf{z}) |\det(J(f^{-1}(\mathbf{u})))| \tag{2}$$

where $\det(J(f^{-1}(\mathbf{u})))$ is determinant of the Jacobian matrix of the function inverse. This term accounts for the way in which f locally expands or contracts regions of $\mathbf{z}$, and enforces the invertibility of the function. A "normalizing flow" is a cascaded sequence of such invertible transformations, which is learned by maximizing the density in Equation (2) over observed data points $\mathbf{u}$. One computational issue with these models lies in calculating the Jacobian matrix, which is expensive in the general case. A common method is to choose transformations whose Jacobians' are a triangular matrix, which renders this computation tractable (Dinh et al., 2016; Papamakarios et al., 2017).

3 Proposed Method

In this section, we present notation used in our method, describe the prior we define for the monolingual embedding space, then detail our density matching method.

3.1 Notation

Given two sets of independently trained monolingual embeddings, the problem of bilingual embedding mapping is to learn a mapping function that aligns the two sets in a shared space. Let $\mathbf{x} \in \mathbb{R}^d, \mathbf{y} \in \mathbb{R}^d$ denote vectors in the source and target language embedding space respectively. Let x_i and y_j denote an actual word in the pretrained source and target vocabularies respectively. Words are sorted by their occurrence counts in the monolingual corpus and the index of the word represents its rank. We use $\mathbf{x}_i$ and $\mathbf{y}_j$ to denote the pretrained word embeddings for word x_i in the source language and word y_j in the target language respectively. Given a pair of languages s and t, our approach learns two mapping functions: f_{xy} that maps the source embedding to the target space and f_{yx} that gives the mapping in the reverse direction.

3.2 Density Estimation in Monolingual Space

To learn the mapping, we project a vector $\mathbf{x}$ in the source embedding space into the target space $\mathbf{y}$. We learn this mapping by maximizing the density of data points in the source space. The density can be computed using the idea of normalizing flow described above. Thus, for the the monolingual embedding spaces, we need to define tractable density functions $p(\mathbf{x})$ and $p(\mathbf{y})$.

While any number of functions could be conceived to calculate these densities, in the current method we opt to use a Gaussian Mixture Model (GMM) with Gaussian components centered at each pretrained word embedding. This is motivated by the assumption that embeddings are likely to appear in the neighborhood of other embeddings, where we define the "neighborhood" to be characterized as closeness in Euclidean space, and the uncertainty of each neighborhood as being Gaussian. Concretely, let N_x and N_y denote the number of pretrained word embeddings that serve as Gaussian component centers during training for the source and target languages, respectively. Then we can express the density of any point in the source embedding space as:

$$p(\mathbf{x}) = \sum_{i \in \{1,\ldots,N_x\}} \pi(x_i)\tilde{p}(\mathbf{x}|x_i) \tag{3}$$

where $\pi(x_i)$ is the frequency of word x_i normalized within the N_x component words, and $\tilde{p}(\mathbf{x}|x_i)$ is a Gaussian distribution centered at the embedding of word x_i. We simply use a fixed variance σ_x^2 for all Gaussian components:

$$\tilde{p}(\mathbf{x}|x_i) = \mathcal{N}(\mathbf{x}|\mathbf{x}_i, \sigma_x^2\mathbf{I}) \tag{4}$$

Similarly, the density of any point in the target embedding space can be written as:

$$p(\mathbf{y}) = \sum_{j \in \{1,\ldots,N_y\}} \pi(y_j)\tilde{p}(\mathbf{y}|y_j) \tag{5}$$

where $\tilde{p}(\mathbf{y}|y_j) = \mathcal{N}(\mathbf{y}|\mathbf{y}_j, \sigma_y^2\mathbf{I})$.

3.3 Density Matching

With the Gaussian mixture model as the prior distribution in the monolingual space, our goal is to learn a mapping function from one embedding space to the other such that the log probabilistic density is maximized in the source space.

While we are jointly learning the two mapping functions f_{xy} and f_{yx} simultaneously, for conciseness we will illustrate our approach using the source to target mapping f_{xy}. First, a continuous vector $\mathbf{x}$ is sampled from the Gaussian mixture model (Eq. (3)) by sampling $x_i \sim \pi(x_i)$ then $\mathbf{x} \sim \tilde{p}(\mathbf{x}|x_i)$ (4). Next, we apply the mapping function f_{xy} to obtain the transformed vector $\mathbf{y}$ in the target space. Concretely, the mapping functions we employ in this work are two linear transformations: $f_{xy}(\cdot) = \mathbf{W}_{xy}\cdot$ and $f_{yx} = \mathbf{W}_{yx}\cdot$. Connecting to the transformation function in Sec. 2, we see that $\mathbf{x} = f(\mathbf{y}) = \mathbf{W}_{xy}^{-1}\mathbf{y}$, $\mathbf{y} = f^{-1}(\mathbf{x}) = \mathbf{W}_{xy}\mathbf{x}$, and $J(f^{-1}(\mathbf{x})) = \mathbf{W}_{xy}$. We can then express the log density of a sample $\mathbf{x}$ as:

$$\log p(\mathbf{x}; \mathbf{W}_{xy}) = \log p(\mathbf{y}) + \log \left|\det(\mathbf{W}_{xy})\right| \tag{6}$$

where the Jacobian regularization term accounts for the volume expansion or contraction resulting from the projection matrix $\mathbf{W}_{xy}$.

We maximize the likelihood function which is equivalent to minimizing expectation of the KL-divergence between the prior distribution and the model distribution of $\mathbf{x}$. This provides a natural objective for optimization:

$$\text{minimize: } \mathrm{KL}(p(\mathbf{x})||p(\mathbf{x};\mathbf{W}_{xy})) \tag{7}$$

By replacing $\mathbf{W}_{xy}\mathbf{x}$ with $\mathbf{y}$, this is equivalent to maximizing the log density of transformed source samples in the target space (see Eq. (6)):

$$\mathcal{L}_{xy} = \mathrm{E}_{\mathbf{x}\sim p(\mathbf{x})}[\log p(\mathbf{y}) + \log\left|\det(\mathbf{W}_{xy})\right|] \tag{8}$$

The objective $\mathcal{L}_{xy}$ contains two parts: the log density function $\log p(\mathbf{y})$ and a regularization term $\log\det(\mathbf{W}_{xy})$. Likewise, for the target to source mapping $\mathbf{W}_{yx}$, we have the density matching objective $\mathcal{L}_{yx}$.

Conditional Density Matching The above marginal density matching method does not take into account the dependency between the embeddings in the two monolingual spaces. To address this issue, we extend the density matching method to the conditional density function:

$$\log p(\mathbf{x}|x_i;\mathbf{W}_{xy}) = \log p(\mathbf{y}|x_i) + \log\left|\det(\mathbf{W}_{xy})\right|$$

The conditional density $p(\mathbf{y}|x_i)$ is the prior distribution in this simple normalizing flow, and for this we use a Gaussian mixture model in the target monolingual space:

$$\begin{aligned} p(\mathbf{y}|x_i) &= \sum_{j\in\{1,\dots,N_y\}} p(\mathbf{y}, y_j|x_i) \\ &= \sum_{j\in\{1,\dots,N_y\}} \tilde{p}(\mathbf{y}|y_j)\pi(y_j|x_i) \end{aligned} \tag{9}$$

Similarly, where $\tilde{p}(\mathbf{y}|y_j)$ is the Gaussian density function in the mixture model defined in Equation (5). $\pi(y_j|x_i)$ allows us to incorporate a-priori assumptions about whether two words are likely to match. In fact, the density matching method in Eq. (6) can be regarded as a special case of the conditional density matching method by adopting a naive prior $\pi(y_j|x_i) := \pi(y_j)$. However previous work (Zhang et al., 2017) has noted that word frequency information is a strong signal – words with similar frequency are likely to be matched – and thus we use $\pi(y_j|x_i)$ to incorporate this prior knowledge.

In this work, we assume that the frequencies of aligned bilingual words in the individual monolingual corpus should be correlated, and to match words that are ranked similarly, we model the Gaussian mixture weights as the negative absolute difference between log-scale word ranks and normalize over all the target Gaussian component words by a $\mathrm{softmax}$ function with temperature τ:

$$\pi(y_j|x_i) = \frac{\exp(-|\log(j) - \log(i)|)/\tau}{\sum_{k=1}^{N_y}\exp(-|\log(k) - \log(i)|/\tau)}$$

Thus, if a word x_i has similarly frequency rank as word y_j, the sample $\mathbf{x}$ from the Gaussian distribution centered at $\mathbf{x}_i$ will be assigned higher weight for the component $\tilde{p}(\mathbf{y}|y_j) = \tilde{p}(\mathbf{W}_{xy}\mathbf{x}|y_j)$. Although this assumption will not hold always (e.g. for languages that have different levels of morphological complexity), intuitively we expect that using this signal will help more overall than it will hurt, and empirically we find that this weighting is not sensitive to language variation and works well in practice.

The updated objective is

$$\begin{aligned} \mathcal{L}_{xy} &= \mathrm{E}_{x_i\sim\pi(x_i)}[\mathrm{KL}(\tilde{p}(\mathbf{x}|x_i)||p(\mathbf{x}|x_i;\mathbf{W}_{xy}))] \\ &= \mathrm{E}_{x_i\sim\pi(x_i),\mathbf{x}\sim\tilde{p}(\mathbf{x}|x_i)}\big[\log p(\mathbf{y}|x_i) \\ &\quad + \log\left|\det(\mathbf{W}_{xy})\right|\big] \end{aligned} \tag{10}$$

In the conditional density above, both the frequency-matching weight and the Gaussian density function play an important role in matching the density of a source-space sample with the target embedding space. The former matches bilingual words with their frequency ranks while the latter matches words with their vector distances.

3.4 Weak Orthogonality Constraint

A common choice of bilingual mapping function is a linear transformation with an orthogonality constraint. Various motivations have been proposed for the orthogonality constraint such as length normalization of embeddings (Xing et al., 2015), and reversible mapping (Smith et al., 2017). In this work, we add a weak orthogonality constraint to the bilingual mappings via a back-translation loss as follows:

$$\begin{aligned} \mathcal{L}_{bt} &= \mathrm{E}_{x_i\sim\pi(x_i),\mathbf{x}\sim\tilde{p}(\mathbf{x}|x_i)}\left[g(\mathbf{W}_{yx}\mathbf{W}_{xy}\mathbf{x},\mathbf{x})\right] \\ &\quad + \mathrm{E}_{y_j\sim\pi(y_j),\mathbf{y}\sim\tilde{p}(\mathbf{y}|x_j)}\left[g(\mathbf{W}_{xy}\mathbf{W}_{yx}\mathbf{y},\mathbf{y})\right] \end{aligned}$$

where $g(\cdot, \cdot) = 1 - \text{cosine}(\cdot, \cdot)$ is the cosine loss. Jointly learning the two mapping matrices by minimizing this cyclic loss encourages $\mathbf{W}_{xy}$ and $\mathbf{W}_{yx}$ to be orthogonal to each other.

3.5 Weak Supervision with Identical Words

To reduce the search space of the mapped bilingual embeddings, we add an additional weakly supervised loss over words that have identical strings in both the source and target languages denoted $\mathcal{W}_{id}$.

$$\mathcal{L}_{sup} = \sum_{v \in \mathcal{W}_{id}} g(\mathbf{v}_x \mathbf{W}_{xy}^T, \mathbf{v}_y) + g(\mathbf{v}_y \mathbf{W}_{yx}^T, \mathbf{v}_x)$$

where $\mathbf{v}_x$ and $\mathbf{v}_y$ are the pretrained word embedding of word v in the source and target side respectively, and $g(\cdot, \cdot)$ is the cosine loss described above. Although using identical strings for supervision is very noisy, especially for languages with little overlap in vocabularies, we find that they provide a enough guidance to training to prevent the model from being trapped in poor local optima.

Putting everything together, the overall objective function of DeMa-BWE includes three parts: the density matching loss, the weak orthogonality loss and the weak supervised loss:

$$\mathcal{L} = \mathcal{L}_{xy} + \mathcal{L}_{yx} + \lambda \cdot \mathcal{L}_{bt} + \alpha \cdot \mathcal{L}_{sup} \qquad (11)$$

where λ and α are coefficients that tradeoff between different losses.

4 Retrieval and Refinement

4.1 Retrieval Method

One standard use case for bilingual embeddings is in bilingual lexicon induction, where the embeddings are used to select the most likely translation in the other language given these embeddings. In this case, it is necessary to have a retrieval metric that selects word or words likely to be translations given these embeddings. When performing this retrieval, it has been noted that high-dimensional embedding spaces tend to suffer from the "hubness" problem (Radovanović et al., 2010) where some vectors (known as *hubs*) are nearest neighbors of many other points, which is detrimental to reliably retrieving translations in the bilingual space. To mitigate the hubness problem, we adopt the *Cross-Domain Similarity Local Scaling* (CSLS) metric proposed in (Conneau et al., 2017) that penalizes the similarity score of the hubs. Specifically, given two mapped embeddings $\mathbf{W}_{xy}\mathbf{x}$ denoted $\mathbf{x}'$ and $\mathbf{y}$, CSLS first computes the average cosine similarity of $\mathbf{x}'$ and $\mathbf{y}$ for their k nearest neighbors denoted $r_T(\mathbf{x}')$ and $r_S(\mathbf{y})$ in the other language respectively, then the corrected similarity measure $\text{CSLS}(\cdot, \cdot)$ is defined as:

$$\text{CSLS}(\mathbf{x}', \mathbf{y}) = 2\text{cos}(\mathbf{x}', \mathbf{y}) - r_T(\mathbf{x}') - r_S(\mathbf{y})$$

where $\cos(\cdot, \cdot)$ is the cosine similarity. Following (Conneau et al., 2017), k is set to be 10.

CSLS consistently outperform cosine similarity on nearest neighbor retrieval, however it does not consider the relative frequency of bilingual words which we hypothesize can be useful in disambiguation. As we discussed in Sec. 3.2, our density matching objective considers both the relative frequencies and vector similarities. The conditional density $p(\mathbf{y}|x_i)$ (Eq. (9)) in our density matching objective (Eq. (8)) is a marginalized distribution over all target component words y_j where the density of each component $p(\mathbf{y}, y_j|x_i)$ can be directly used as a similarity score for a pair of words (y_j, x_i) to replace the cosine similarity $\cos(\mathbf{x}', \mathbf{y})$ in CSLS. Let CSLS-D denote this modified CSLS metric, which we compare to standard CSLS in experiments. We find that using CSLS-D for nearest neighbor retrieval outperforms the CSLS metric in most cases on the bilingual dictionary induction task.

4.2 Iterative Procrustes Refinement

Iterative refinement, which learns the new mapping matrix by constructing a bilingual lexicon iteratively, has been shown as an effective method for improving the performance of unsupervised lexicon induction models (Conneau et al., 2017). Given a learned bilingual embedding mapping $\mathbf{W}$, the refinement starts by inferring an initial bilingual dictionary using the retrieval method above on the most frequent words. Let $\mathbf{X}$ and $\mathbf{Y}$ denote the ordered embedding matrices for the inferred dictionary words for source and target languages respectively. Then a new mapping matrix $\mathbf{W}^*$ is induced by solving the Procrustes problem:

$$\mathbf{W}^* = \underset{\mathbf{W} \in O_d(\mathbb{R})}{\text{argmin}} ||\mathbf{W}\mathbf{X} - \mathbf{Y}||_F = \mathbf{U}\mathbf{V}^T$$
$$s.t.\ \mathbf{U}\Sigma\mathbf{V}^T = \text{SVD}(\mathbf{Y}\mathbf{X}^T)$$

The step above can be applied iteratively by inducing a new dictionary with the new mapping $\mathbf{W}$.

DeMa-BWE is able to achieve very competitive performance without further refinement, but for comparison we also report results with the refinement procedure, which brings small improvements in accuracy for most language pairs. Note that for bilingual dictionary induction during refinement, we use CSLS as the retrieval metric across all experiments for fair comparison to the refinement step in previous work.

5 Experiments

5.1 Dataset and Task

We evaluate our approach extensively on the bilingual lexicon induction (BLI) task, which measures the word translation accuracy in comparison to a gold standard. We report results on the widely used MUSE dataset (Conneau et al., 2017), which consists of FastText monolingual embeddings pre-trained on Wikipedia (Bojanowski et al., 2017), and dictionaries for many language pairs divided into train and test sets. We follow the evaluation setups of (Conneau et al., 2017). We evaluate DeMa-BWE by inducing lexicons between English and different languages including related languages, e.g. Spanish; etymologically distant languages, e.g. Japanese; and morphologically rich languages, e.g. Finnish.

5.2 Implementation Details

Embedding Normalization Following (Artetxe et al., 2018b), we pre-process the monolingual embeddings by first applying length normalization, then mean center each dimension, and then length normalize again to ensure that the final embeddings have a unit length. We observe that this normalization method helps stabilize training and accelerate convergence.

Other Experimental Details We held out 1000 translation pairs randomly sampled from the training set in the MUSE dataset as our validation data. We also tried the unsupervised validation criterion proposed in (Conneau et al., 2017) as the model selection method that computes the average cosine similarity over the model induced dictionary pairs and found that this unsupervised criterion can select models that achieve similar performance as the supervised validation criterion. All hyperparameters are tuned on the validation set and include the following: For the number of base words used as Gaussian components in the GMM, we typically choose the most frequent 20,000 words for all language pairs but en-ja for which we use 10,000 which achieves better performance. We use a batch size of 2048 for all languages but en-ja for which we use 1024. We use Adam (Kingma and Ba, 2014) for optimization with default hyper-parameters.

We empirically set the Gaussian variance to be 0.01 for both the source and target languages in en-es, en-de, en-fr, en-ru; in the experiments for morphologically rich languages (Sec. 5.4), we set the variance to be 0.015 for all these languages except for et whose variance is set to be 0.02 while keeping the variance of English to be 0.01. In the experiments for etymologically distant language pairs en-ja and en-zh, we set different variances for the source and target languages in different mapping directions. For details of the variance setting please check the scripts in our code base. We empirically find that for a language pair the variance of the language with relatively more complex morphological properties needed to be set larger than the other language, indicating that the model needs to explore more in the embedding space for the morphologically richer language.

We initialize mapping matrices $\mathbf{W}_{xy}$ and $\mathbf{W}_{yx}$ with a random orthogonal matrix. For the weak orthogonality constraint loss $\mathcal{L}_{bt}$, we set the weight λ to be 0.5 throughout all language pairs. For the weak supervision loss $\mathcal{L}_{sup}$, we set the weight α to be 10 for all languages except for en-zh where we find 5 performs better. We set the temperature τ used in the $\mathrm{softmax}$ function for Gaussian mixture weights to be 2 across all languages.

5.3 Main Results on BLI

In Tab. 1, we compare the performance of DeMa-BME extensively with the best performing unsupervised and supervised methods on the commonly benchmarked language pairs.

Our unsupervised baselines are: (1) **MUSE (U+R)** (Conneau et al., 2017), a GAN-based unsupervised method with refinement. (2) A strong and robust unsupervised self-learning method **SL-unsup** from (Artetxe et al., 2018b). We also run their published code with identical words as the initial dictionary for fair comparison with our approach, denoted **SL-unsup-ID**. (3) **Sinkhorn** (Xu et al., 2018) that minimizes the Sinkhorn distance between the source and target word vectors. (4) An iterative matching method from (Hoshen and

Table 1: Precision@1 for the MUSE BLI task compared with previous work. All the baseline results employ CSLS as the retrieval metric except for Sinkhorn* which uses cosine similarity. **R** represents refinement. Bold and italic indicate the best unsupervised and overall numbers respectively. ('en' is English, 'es' is Spanish, 'de' is German, 'fr' is French, 'ru' is Russian, 'zh' is traditional Chinese, 'ja' is Japanese.)

Wolf, 2018)): **Non-Adv** and **Non-Adv (R)** with refinement. (5) **WS-Procrustes (R)** using refinement by (Grave et al., 2018). Our supervised methods include: (1) The iterative Procrustes method **Procrustes (R)** (Smith et al., 2017). (2) A multi-step framework **MSF-ISF** (Artetxe et al., 2018a) and its variant **MSF** which uses CSLS for retrieval, whose results are from (Jawanpuria et al., 2018). (3) **CSLS-Sp** by (Joulin et al., 2018) that optimizes the CSLS score, and (4) a geometric approach **GeoMM** by (Jawanpuria et al., 2018). For fair comparisons, all supervised results are trained with the training dictionaries in the MUSE dataset. All baseline methods employ CSLS for retrieval except for the Sinkhorn method.

For DeMa-BME, we present results with and without refinement, and with CSLS and CSLS-D as retrieval methods. From Tab. 1, we can see the overall performance of DeMa-BME is remarkable comparing with other unsupervised methods and is also competitive with strong supervised methods. The results without the iterative refinement **CSLS (w/o R)** are strong on almost all language pairs with particularly strong performance being observed on es-en, en-de and en-fr on which DeMa-BME outperforms or is on par with the best performing methods. Applying refinement to DeMa-BME brings slightly better performance on most language pairs but degrades the performance on some language pairs such as es-en, zh-en for which the DeMa-BME already obtains very good results.

Also, DeMa-BME demonstrates notably better performance on distant language pairs (en-ru, en-ja and en-zh) over other unsupervised methods, which often achieve good performance on etymologically close languages but fail to converge on the distant language pairs. However, when the dictionary is initialized with identical strings for SL-unsup, we obtain decent results on these languages. The strong performance of supervised methods on Russian and Chinese demonstrates that on some language pairs supervised seed lexicons are still necessary.

Finally, when our density-based metric CSLS-D is employed for retrieval, it could achieve further gains in accuracy for most language pairs compared to its counterpart.

5.4 Morphologically Rich Language Results

Søgaard et al. (2018) found that the commonly

Table 2: BLI Precision (@1) for morphologically complex languages. **id+Procrustes (R)*** is the result reported in (Søgaard et al., 2018). **5k+Procrustes (R)** uses the training dictionary with 5k unique query words. ('et' is Estonian, 'fi' is Finnish, 'el' is Greek, 'hu' is Hungarian, 'pl' is Persian, 'tr' is Turkish.)

benchmarked languages are morphologically poor isolating or exclusively concatenating languages. They select several languages with different morphological traits and complexity then studied the impacts of language similarities on the bilingual lexicon induction.

They show that a simple trick, harvesting the identical word strings in both languages as an initial dictionary and running the iterative Procrustes analysis described in Sec. 4.2, enables more robust and competitive bilingual induction results over the GAN-based unsupervised method with refinement. We denote this method 'id+Procrustes (R)'.

Tab. 2 shows results on the morphologically complex languages used by Søgaard et al. (2018). For each language pair we run experiments in both directions. The baseline methods in Søgaard et al. (2018) include id+Procrustes (R) and the MUSE (U+R). We run id+Procrustes (R) ourselves and obtain different results from them: except for en-et and en-el, we obtain significantly better results on other language pairs. In addition, we add another strong supervised baseline (5k+Procrustes (R)) with the training dictionary in the MUSE dataset and iterative Procrustes refinement. From Tab. 2, we observe that even without refinement, DeMa-BME (CSLS (w/o R)) outperforms both the unsupervised and supervised baselines on even these difficult morphologically rich languages.

5.5 Cross-lingual Word Similarity

We evaluate DeMa-BWE on the cross-lingual word similarity task from SemEval 2017 (Camacho-Collados et al., 2016) and compare with some strong baselines in Xu et al. (2018). In Tab. 5, following the convention in benchmark evaluation for this task, we report the Pearson correlation scores (×100). DeMa-BME achieves the best performance among all the listed unsupervised methods. Compared with the supervised methods, DeMa-BME is also very competitive.

Full Model	82.6	82.4	46.7	32.9

Table 4: Ablation study on different components of DeMa-BME.

5.6 Ablation Study

Finally, we perform ablation studies in Tab. 4 to examine the effects of different components of DeMa-BWE. In comparison to the full model, we remove the density matching loss L_{xy} & L_{yx}, the weakly supervised loss L_{sup}, the back-translation loss L_{bt} respectively. First, we observe that without the identical strings as the supervised loss, DeMa-BWE fails to converge as the density matching is difficult given a high-dimensional embedding space to search. Second, when we remove the proposed density matching loss, the model is able to produce reasonable accuracy for fr-en and ja-en, but has undesirable results on en-fr and en-ja, which verifies the necessity of the unsupervised density matching. Third, the back-translation loss is not a crucial component in DeMa-BME; removing it only degrades the model's performance by a small margin. This indicates that orthogonality is not must-have constraint given the model has enough capacity to learn a good transformation.

In addition, we also compare the frequency-matching based Gaussian mixture weights in (9) with the naive target frequency based weights. As shown in the fourth row of Tab. 4, the performance of DeMa-BWE with the naive weights is nominally worse than the model using the frequency-matching based mixture weights.

6 Conclusion

In this work, we propose a density matching based unsupervised method for learning bilingual word embedding mappings. DeMa-BWE performs well in the task of bilingual lexicon induction. In the future work, we will integrate Gaussian embeddings (Vilnis and McCallum, 2015) with our approach.

Abstract

We introduce a novel method for multilingual transfer that utilizes deep contextual embeddings, pretrained in an unsupervised fashion. While contextual embeddings have been shown to yield richer representations of meaning compared to their static counterparts, aligning them poses a challenge due to their dynamic nature. To this end, we construct context-independent variants of the original monolingual spaces and utilize their mapping to derive an alignment for the context-dependent spaces. This mapping readily supports processing of a target language, improving transfer by context-aware embeddings. Our experimental results demonstrate the effectiveness of this approach for zero-shot and few-shot learning of dependency parsing. Specifically, our method consistently outperforms the previous state-of-the-art on 6 tested languages, yielding an improvement of 6.8 LAS points on average.[1]

1 Introduction

Multilingual embedding spaces have been demonstrated to be a promising means for enabling cross-lingual transfer in many natural language processing tasks (e.g. Ammar et al. (2016); Lample et al. (2018)). Similar to how universal part-of-speech tags enabled parsing transfer across languages (Petrov et al., 2012), multilingual word embeddings further improve transfer capacity by enriching models with lexical information. Since this lexical representation is learned in an unsupervised fashion and thus can leverage large amounts of raw data, it can capture a more nuanced representation of meaning than unlexicalized transfer. Naturally, this enrichment is translated into improved transfer accuracy, especially in low-resource scenarios (Guo et al., 2015).

In this paper, we are moving further along this line and exploring the use of contextual word embeddings for multilingual transfer. By dynamically linking words to their various contexts, these embeddings provide a richer semantic and syntactic representation than traditional context-independent word embeddings (Peters et al., 2018). A straightforward way to utilize this richer representation is to directly apply existing transfer algorithms on the contextual embeddings instead of their static counterparts. In this case, however, each token pair is represented by many different vectors corresponding to its specific context. Even when supervision is available in the form of a dictionary, it is still unclear how to utilize this information for multiple contextual embeddings that correspond to a word translation pair.

In this paper, we propose a simple but effective mechanism for constructing a multilingual space of contextual embeddings. Instead of learning the alignment in the original, complex contextual space, we drive the mapping process using context-independent embedding anchors. We obtain these anchors by factorizing the contextual embedding space into context-independent and context-dependent parts. Operating at the anchor level not only compresses the space, but also enables us to utilize a word-level bilingual dictionary as a source of supervision, if available. Once the anchor-level alignment is learned, it can be readily applied to map the original spaces with contextual embeddings.

Clearly, the value of word embeddings depends on their quality, which is determined by the amount of raw data available for their training (Jiang et al., 2018). We are interested in expanding the above approach to the truly low-resource

scenario, where a language not only lacks annotations, but also has limited amounts of raw data. In this case, we can also rely on a data rich language to stabilize monolingual embeddings of the resource-limited language. As above, context-independent anchors are informing this process. Specifically, we introduce an alignment component to the loss function of the language model, pushing the anchors to be closer in the joint space. While this augmentation is performed on the static anchors, the benefit extends to the contextual embeddings space in which we operate.

We evaluate our aligned contextual embeddings on the task of zero-shot cross-lingual dependency parsing. Our model consistently outperforms previous transfer methods, yielding absolute improvement of 6.8 LAS points over the prior state-of-the-art (Ammar et al., 2016). We also perform comprehensive studies of simplified variants of our model. Even without POS tag labeling or a dictionary, our model performs on par with context-independent models that do use such information. Our results also demonstrate the benefits of this approach for few-shot learning, i.e. processing languages with limited data. Specifically, on the Kazakh tree-bank from the recent CoNLL 2018 shared task with only 38 trees for training, the model yields 5 LAS points gain over the top result (Smith et al., 2018a).

2 Related work

Multilingual Embeddings The topic of cross-lingual embedding alignment is an active area of research (Mikolov et al., 2013; Xing et al., 2015; Dinu and Baroni, 2014; Lazaridou et al., 2015; Zhang et al., 2017). Our work most closely relates to MUSE (Conneau et al., 2018a), which constructs a multilingual space by aligning monolingual embedding spaces. When a bilingual dictionary is provided, their approach is similar to those of (Smith et al., 2017; Artetxe et al., 2017). MUSE extends these methods to the unsupervised case by constructing a synthetic dictionary. The resulting alignment achieves strong performance in a range of NLP tasks, from sequence labeling (Lin et al., 2018) to natural language inference (Conneau et al., 2018b) and machine translation (Lample et al., 2018; Qi et al., 2018). Recent work further improves the performance on both the supervised (Joulin et al., 2018) and unsupervised (Grave et al., 2018b; Alvarez-Melis and Jaakkola, 2018; Hoshen and Wolf, 2018) settings for context-independent embeddings.

While MUSE operates over token based embeddings, we are interested in aligning contextual embeddings, which have shown their benefits in several monolingual applications (Peters et al., 2018; McCann et al., 2017; Howard and Ruder, 2018; Radford et al., 2018; Devlin et al., 2018). However, this expansion introduces new challenges which we address in this paper.

In a concurrent study, Aldarmaki and Diab (2019) introduced an alignment that is based only on word pairs in the same context, using parallel sentences. Our method achieves better word translations without relying on such supervision.

Our work also relates to prior approaches that utilize bilingual dictionaries to improve embeddings that were trained on small datasets. For instance, Xiao and Guo (2014) represent word pairs as a mutual vector, while Adams et al. (2017) jointly train cross-lingual word embeddings by replacing the predicted word with its translation. To utilize a dictionary in the contextualized case, we include a soft constraint that pushes those translations to be similar in their context-independent representation. A similar style of regularization was shown to be effective for cross-domain transfer of word embeddings (Yang et al., 2017).

Multilingual Parsing In early work on multilingual parsing, transfer was commonly implemented using delexicalized representation such as part-of-speech tags (McDonald et al., 2011; Petrov et al., 2012; Naseem et al., 2012; Tiedemann, 2015).

Another approach for cross-lingual parsing includes annotation projection and treebank translation (Xiao and Guo, 2015; Wang and Eisner, 2016; Tiedemann, 2017), which mostly require some source of supervision.

Advancements in multilingual word representations opened a possibility of lexicalized transfer. Some of these approaches start by aligning monolingual embedding spaces (Zhang and Barzilay, 2015; Guo et al., 2015, 2016; Ammar et al., 2016), and using resulting word embeddings as word representations instead of universal tags. Other approaches are learning customized multilingual syntactic embeddings bootstrapping from universal POS tags (Duong et al., 2015). While some models also learn a language embedding (Ammar et al., 2016; de Lhoneux et al., 2018), it is unfeasible in a zero-shot scenario.

	ALL WORDS	HOMONYMS
0.85 (±0.09)	0.18 (±0.04)	0.21 (±0.04)

Table 1: Average cosine distances between pairs of embedding anchors (left column) and between contextualized embeddings of words to their corresponding anchor. The right column includes these distances only for homonyms, whereas the center column is averaged across all words. Only alphabetic words with at least 100 occurrences were included.

In all of the above cases, token-level embeddings are used. Inspired by strong results of using contextualized embeddings in monolingual parsing (Che et al., 2018; Wang et al., 2018; Clark et al., 2018), we aim to utilize them in the multilingual transfer case. Our results demonstrate that richer representation of lexical space does lead to significant performance gains.

3 Aligning Contextual Word Embeddings

In this section we describe several approaches for aligning context-dependent embeddings from a source language s to a target language t. We address multiple scenarios, where different amounts of supervision and data are present. Our approach is motivated by interesting properties of context-dependent embeddings, which we discuss later.

We begin with some notations:

- **Context Dependent Embeddings:** Given a context c and a token i, we denote the embedding of i in the context c by $\boldsymbol{e}_{i,c}$. We use $\boldsymbol{e}_{i,\cdot}$ to denote the point cloud of all contextual embeddings for token i.

- **Embedding Anchor:** Given a token i we denote the anchor of its context dependent embeddings by $\bar{\boldsymbol{e}}_i$, where:

$$\bar{\boldsymbol{e}}_i = \mathbb{E}_c\left[\boldsymbol{e}_{i,c}\right] \ . \tag{1}$$

  In practice, we calculate the average over a subset of the available unlabeled data.

- **Shift From Mean:** For any embedding $\boldsymbol{e}_{i,c}$ we can therefore define the shift $\hat{\boldsymbol{e}}_{i,c}$ from the average via:

$$\boldsymbol{e}_{i,c} = \bar{\boldsymbol{e}}_i + \hat{\boldsymbol{e}}_{i,c} \ . \tag{2}$$

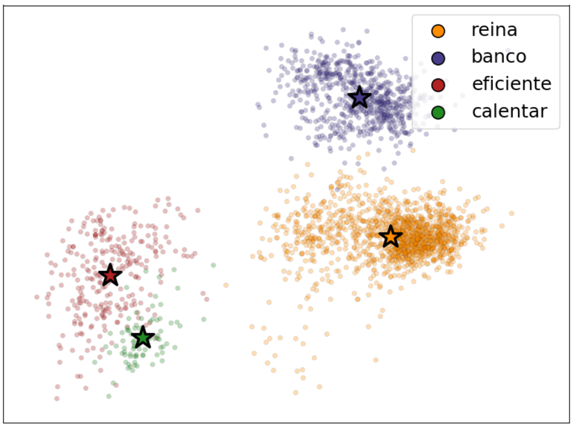

Figure 1: A two dimensional PCA showing examples of contextual representations for four Spanish words. Their corresponding anchors are presented as a star in the same color. (best viewed in color)

- **Embedding Alignment:** Given an embedding $\boldsymbol{e}^{s}_{i,c}$ in s, we want to generate an embedding $\boldsymbol{e}^{s\rightarrow t}_{i,c}$ in the target language space, using a linear mapping $W^{s\rightarrow t}$. Formally, our alignment is always of the following form:

$$\boldsymbol{e}^{s\rightarrow t}_{i,c} = W^{s\rightarrow t}\boldsymbol{e}^{s}_{i,c} \ . \tag{3}$$

3.1 The Geometry of Context-Dependent Embeddings

A given token i can generate multiple vectors $\boldsymbol{e}_{i,c}$, each corresponding to a different context c. A key question is how the point cloud $\boldsymbol{e}_{i,\cdot}$ is distributed. In what follows we explore this structure, and reach several conclusions that will motivate our alignment approach. The following experiments are performed on ELMo (Peters et al., 2018).

Point Clouds are Well Separated A cloud $\boldsymbol{e}_{i,\cdot}$ corresponds to occurrences of the word i in different contexts. Intuitively, we would expect its points to be closer to each other than to points from $\boldsymbol{e}_{j,\cdot}$ for a different word j. Indeed, when measuring similarity between points $\boldsymbol{e}_{i,c}$ and their anchor $\bar{\boldsymbol{e}}_i$, we find that these are much more similar than anchors of different words $\bar{\boldsymbol{e}}_i$ and $\bar{\boldsymbol{e}}_j$ (see Table 1). This observation supports our hypothesis that anchor-driven alignment can guide the construction of the alignment for the contextual space. A visualized example of the contextualized representations of four words is given in Figure 1, demonstrating the appropriateness of their anchors. Still, as previous studies have shown, and

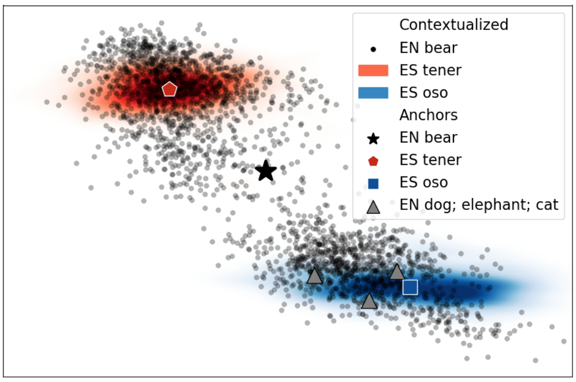

Figure 2: Contextual embeddings for the English word "bear" and its two possible translations in Spanish — "oso" (animal) in blue and "tener" (to have) in red. The figure shows a two dimensional PCA for the aligned space of the two languages. The symbols are the anchors, the clouds represent the distribution of the contextualized Spanish words, and the black dots are for contextualized embeddings of "bear". The gray colored triangles show the anchors of the English words "dog", "elephant", "cat", from left to right respectively.

as our results point, the context component is very useful for downstream tasks.

Homonym Point Clouds are Multi-Modal When a word i has multiple distinct senses, we might expect the embeddings for i to reflect this by separating into multiple distinct clouds, one for each meaning. Figure 2 demonstrates that this indeed happens for the English word "bear". Furthermore, it can be seen that after alignment (Section 3.3) with Spanish, the distinct point clouds are aligned with their corresponding distinct words in Spanish. See App. D for another example.

We examined the shift from mean for a list of 250 English homonyms from Wikipedia.[2] As Table 1 shows, the shift of these words is indeed slightly higher than it is for other words. However, they still remain relatively close to their per-token anchor. Therefore, these anchors can still serve as a good approximation for learning alignments.

3.2 Context-Independent Alignment

We begin by briefly reviewing previous approaches for aligning context-independent embeddings, as they are generalized in this work to the contextual case. We denote the embedding of a word i by $\boldsymbol{e}_i$. At first, assume we are given word pairs $\{(\boldsymbol{e}_i^s, \boldsymbol{e}_i^t)\}$ from a source language s and a target language t, and we look for a mapping between those. Mikolov et al. (2013) proposed to learn a linear transformation whereby $\boldsymbol{e}_i^t$ is approximated via $W\boldsymbol{e}_i^s$, for a learned matrix W. We focus on methods that follow this linear alignment. The alignment matrix is found by solving:

$$W^{s\to t} = \underset{W \in O_d(\mathbb{R})}{\operatorname{argmin}} \sum_{i=1}^{n} \left\| W\boldsymbol{e}_i^s - \boldsymbol{e}_i^t \right\|^2 , \qquad (4)$$

where $O_d(\mathbb{R})$ is the space of orthogonal matrices. This constraint was proposed by Xing et al. (2015) in order to preserve inter-lingual relations. Under this constraint, Eq. 4 is an instance of the orthogonal Procrustes problem, which has a closed-form solution $W^{s\to t} = UV^T$. The columns of U and V are the left and right singular vectors of the multiplication of the source and (transposed) target embedding matrices.

For the *unsupervised* case (i.e. when a dictionary is absent), Conneau et al. (2018a) (MUSE) suggested to learn the alignment via adversarial training, such that a discriminator is trained to distinguish between target and aligned source embeddings. Thereafter, a *refinement* procedure is applied iteratively as follows. First, a dictionary is built dynamically using the current alignment such that only words with high confidence are considered. Using the dictionary, the alignment matrix is re-calculated as in the supervised case.

3.3 Context-Dependent Alignment

We next turn our attention to the main task of this paper, which is aligning context-dependent embeddings. We now describe our generalization of the methods described in Section 3.2 for this case. The first two methods are based only on anchors while the third one uses the contextual vectors themselves. Altogether, we suggest three alignment procedures, one aimed for the supervised and two for the unsupervised cases.

Supervised Anchored Alignment As a first step, we are assuming access to a dictionary for the source and target domains. For each source word i denote by $D(i)$ the corresponding word in the target language.[3]

In the context-dependent case, Eq. 4 is no longer well-defined, as there are many corresponding vectors to both the source and the target

---

[2] `https://en.wikipedia.org/wiki/List_of_true_homonyms`

[3] In practice, we may have multiple target words for a single source word, and the extension is straight-forward.

words. However, this challenge can be addressed by aligning the vectors $\bar{e}_i$ for which we do have one per word. This is motivated by our observations in Section 3.1 that context-dependent embeddings are well clustered around their centers.

Thus, in the case where a dictionary is available, we solve Eq. 4 with token anchors as inputs.

We emphasize that by constraining $W^{s\rightarrow t}$ to be orthogonal, we also preserve relations between $\hat{e}_{i,c}$ and $\hat{e}_{i,c'}$ that represent the contextual information.

Unsupervised Anchored Alignment In this setting, no dictionary is present. As in the supervised case, we can naturally extend a context-independent alignment procedure to the contextual space by leveraging the anchor space $\bar{e}_i$. This can be done using the adversarial MUSE framework proposed by Conneau et al. (2018a) and described at the end of Section 3.2.

Unsupervised Context-based Alignment Alternatively, the alignment could be learned directly on the contextual space. To this end, we follow again the adversarial algorithm of MUSE, but for each word we use multiple embeddings induced by different contexts, rather than the word anchor.

This context-based alignment presents opportunities but also introduces certain challenges. On the one hand, it allows to directly handle homonyms during the training process. However, empirically we found that training in this setting is less stable than unsupervised anchored alignments.

Refinement As a final step, for both of the unsupervised methods, we perform the refinement procedure that is incorporated in MUSE (end of Section 3.2). In order to synthesize a dictionary, we use distance in the anchor space.

3.4 Learning Anchored Language Models

Thus far we assumed that embeddings for both source and target languages are pretrained separately. Afterwards, the source is mapped to the target in a second step via a learned mapping. However, this approach may not work well when raw data for the source languages is scarce, resulting in deficient embeddings. In what follows, we show how to address this problem when a dictionary is available. We focus on embeddings that are learned using a language model objective but this can be easily generalized to other objectives as well.

Our key idea is to constrain the embeddings across languages such that word translations will be close to each other in the embedding space. This can serve as a regularizer for the resource-limited language model. In this case, the anchors are the model representations prior to its context-aware components (e.g., the inputs to ELMo's LSTM).

Denote the anchor for word i in language s by $\boldsymbol{v}_i^s$. Now, assume we have trained a model for the target language and similarly have embeddings $\boldsymbol{v}_i^t$. We propose to train the source model with an added regularization term as follows:

$$\lambda_{\text{anchor}} \cdot \sum_i \|\boldsymbol{v}_i^s - \boldsymbol{v}_{D(i)}^t\|_2^2 \,, \qquad (5)$$

where λ_{anchor} is a hyperparamter. This regularization has two positive effects. First, it reduces overfitting by reducing the effective number of parameters the model fits (e.g., if the regularizer has large coefficient, these parameters are essentially fixed). Second, it provides a certain level of alignment between the source and target language since they are encouraged to use similar anchors.

4 Multilingual Dependency Parsing

Now that we presented our method for aligning contextual embeddings, we turn to evaluate it on the task of cross-lingual dependency parsing. We first describe our baseline model, and then show how our alignment can easily be incorporated into this architecture to obtain a multilingual parser.

Baseline Parser Most previous cross-lingual dependency parsing models used transition-based models (Ammar et al., 2016; Guo et al., 2016). We follow Che et al. (2018); Wang et al. (2018); Clark et al. (2018) and use a first-order graph-based model. Specifically, we adopt the neural edge-scoring architecture from Dozat and Manning (2017); Dozat et al. (2017), which is based on Kiperwasser and Goldberg (2016). We now briefly review this architecture. Given a sentence s, let $\boldsymbol{e}_i$ and $\mathbf{p}_i$ be its word and POS-tag embeddings. These are concatenated and fed into a Bi-LSTM to produce token-level contextual representations $\mathbf{r}_i$. Four Multi-Layer Perceptrons are applied on these vectors, resulting in new representations $\boldsymbol{h}_i^{arc-dep}$, $\boldsymbol{h}_i^{arc-head}$, $\boldsymbol{h}_i^{rel-dep}$ and $\boldsymbol{h}_i^{rel-head}$

for each word i. Arc scores are then obtained by:

$$s_{ij}^{arc} = \left(\boldsymbol{h}_i^{arc-head}\right)^T \left(U^{arc}\boldsymbol{h}_j^{arc-dep} + \boldsymbol{b}^{arc}\right) . \tag{6}$$

Additionally, the score for predicting the dependency label r for an edge (i, j) is defined as

$$\begin{aligned} s_{(i,j),r}^{rel} = &\left(\boldsymbol{h}_i^{rel-head}\right)^T U_r^{rel}\boldsymbol{h}_j^{rel-dep} + \\ &\left(\boldsymbol{u}_r^{rel-head}\right)^T \boldsymbol{h}_i^{rel-head} + \\ &\left(\boldsymbol{u}_r^{rel-dep}\right)^T \boldsymbol{h}_j^{rel-dep} + b_r . \end{aligned} \tag{7}$$

At test time, MST is calculated to ensure valid outputs.

Multilingual Parsing with Alignment We now extend this model, in order to effectively use it for transfer learning. First, we include contextualized word embeddings by replacing the static embeddings with a pre-trained ELMo (Peters et al., 2018) model (instead of $\boldsymbol{e}_i$). Second, we share all model parameters across languages and use the contextual word embeddings after they are aligned to a joint space J. Formally, if s is a sentence of language ℓ, contextual word embeddings are obtained via:

$$\boldsymbol{e}_{i,s}^{\ell \to J} = W^{\ell \to J}\boldsymbol{e}_{i,s} \ , \tag{8}$$

where $W^{\ell \to J}$ is the alignment matrix from language ℓ to the joint space.[4] This alignment is learned apriori and kept fixed during parser training. This setup is applicable for both single and multiple training languages. For the tested language, training data could be available, sometimes limited (few-shot), or absent (zero-shot). The alignment methods are described in detail in Section 3.

In their paper, Peters et al. (2018) suggest to output a linear combination over the representations of each layer of ELMo, learning these weights jointly with a downstream task. Our alignment is learned separately for each layer. Therefore, we keep the weights of the combination fixed during the training to ensure that the parser's inputs are from the joint cross-lingual space. Alternatively, one can share the weights of the combination between the languages and learn them.

All the above modifications are at the word embedding level, making them applicable to any other NLP model that uses word embeddings.

5 Experimental Setup

Contextual Embeddings We use the ELMo model (Peters et al., 2018) with its default parameters to generate embeddings of dimension 1024 for all languages. For each language, training data comprises Wikipedia dumps[5] that were tokenized using UDpipe (Straka and Straková, 2017). We randomly shuffle the sentences and, following the setting of ELMO, use 95% of them for training and 5% for evaluation.

Alignment We utilize the MUSE framework[6] (Conneau et al., 2018a) and the dictionary tables provided by them. The $\bar{e}_i$ (anchor) vectors for the alignment are generated by computing the average of representations on the evaluation set (except for the limited unlabeled data case). To evaluate our alignment, we use the anchors to produce word translations. For all experiments we use the 50k most common words in each language.

Dependency Parsing We used the biaffine parser implemented in AllenNLP (Gardner et al., 2018), refactored to handle our modifications as described in Section 4.[7] The parser is trained on trees from a single or multiple languages, as described in each setting (Section 6). For the multiple case, we randomly alternate between the available languages, i.e. at each iteration we randomly choose one language and sample a corresponding batch. Dropout (Srivastava et al., 2014) is applied on ELMo representations, Bi-LSTM representations and outputs of MLP layers. We also apply early stopping, where validation accuracy is measured as average LAS score on the development set across all training languages. The parser hyperparameters are the same as Dozat et al. (2017) except we reduce the POS tag embedding size from 100 to 50 and increase the head/dependent MLP dimension from 400 to 500. All hyperparameter values used are listed in App. C.

From experiments on the English tree-bank, we found that using the outputs of the first LSTM layer is as good as learning a combination.[8] This

---

[4] We use the space of the training language as our joint space and align the tested language to it. In the multi-source scenario, we align all embeddings to English.

The bottom three rows are models that don't use POS tags at all and/or use an unsupervised anchored alignment. Corresponding UAS results are provided in App. B.

agrees with Belinkov et al. (2017), showing that lower layers capture more syntactic information. Therefore, we fix the weights over ELMo layers to $[0, 1, 0]$, i.e. using only representations from the first LSTM layer.

Evaluation Scenarios for Dependency Parsing For a fair comparison, we use the same setting as used by previous models for each scenario. Our main model (which we refer to as OURS) is using a SUPERVISED ANCHORED ALIGNMENT (Section 3.3) to align the multilingual pretrained ELMo embeddings which are used by the parser. We compare against several variants of our model:

- ALIGNED FASTTEXT: instead of ELMo, we use FASTTEXT pretrained embeddings (Grave et al., 2018a), aligned to English using MUSE.
- ALIGNED $\bar{e}$: instead of contextualized embeddings, we use the anchors themselves as fixed embeddings, aligned to English.
- NO DICTIONARY: we assume the absence of a dictionary and use UNSUPERVISED ANCHORED ALIGNMENT.
- NO POS: no use of part of speech tags.

6 Results

Alignment As mentioned above, we use outputs of the first LSTM layer of ELMo in our parsing experiments. Therefore, we present the alignment accuracy for those in Table 2, summarizing the precision@5 word-translation from 6 languages to English. Results for the other layers are presented in App. A. As expected, supervised alignments outperform unsupervised ones by a large margin. Between the two unsupervised methods, the context-based alignment achieved significantly better results for Spanish and Portuguese but failed to converge for Swedish. In both cases, the value of anchors in the REFINE step is clear, substantially improving the precision for all languages.

# SENTENCES	LANGUAGE MODEL	UAS / LAS		PERPLEXITY		ALIGN
		DEV	TEST	TRAIN	DEV	
28M	ELMO	72.3 / 62.8	72.5 / 61.3	22	44	85
10K	ELMO	52.9 / 38.3	50.1 / 33.1	4	4060	4
	ANCHORED ELMO	**59.2 / 47.3**	**57.2 / 42.2**	92	600	12

Table 4: Zero-shot, single-source results for the Spanish limited unlabeled data experiments. The parsing results are UAS/LAS scores, the perplexity is of the ELMo model, and the alignment scores are precision@5 on the held-out set, based on CSLS. All embeddings were aligned to English using supervised anchored alignment.

MODEL	LAS-F1

Smith et al. (2018a)	31.93
ALIGNED FASTTEXT	26.77
OURS	**36.98**

Table 5: Results for the Kazakh dataset from CoNLL 2018 Shared Task on Multilingual Parsing, compared to the two leading models w.r.t. this treebank.

Zero-Shot Parsing, Multiple Source Languages Table 3 summarizes the results for our zero-shot, multi-source experiments on six languages from Google universal dependency treebank version 2.0.[9] For each tested language, the parser was trained on all treebanks in the five other languages and English. We align each of the six languages to English. We compare our model to the performance of previous methods in the same setting (referred to as $L^t \cap L^s = \emptyset$ in Ammar et al. (2016)). The results show that our multilingual parser outperforms all previous parsers with a large margin of 6.8 LAS points. Even with an unsupervised alignment, our model consistently improves over previous models.

To make a fair comparison to previous models, we also use gold POS tags as inputs to our parser. However, for low-resource languages, we might not have access to such labels. Even without the use of POS tags at all, in five out of six languages the score is still higher than previous methods that do consider such annotations. An exception is the Portuguese language where it leads to a drop of 8.8 LAS points. While in the single language setting this good performance can be explained by the knowledge captured in the character level, contextual embeddings (Smith et al., 2018b; Belinkov et al., 2017), the results suggest that this knowledge transfers across languages.

In order to assess the value of contextual embeddings, we also evaluate our model using non-contextual embeddings produced by FASTTEXT (Bojanowski et al., 2017). While these improve over previous works, our context-aware model outperforms them for all six languages in UAS score and for 5 out of 6 languages in LAS score, obtaining an average higher by 3 points. To further examine the impact of introducing context, we run our model with precomputed anchors ($\bar{e}$). Unlike FASTTEXT embeddings of size 300, these anchors share the same dimension with contextual embeddings but lack the contextual information. Indeed, the context-aware model is consistently better.

Few-Shot Parsing, Small Treebanks In this scenario, we assume a very small tree-bank for the tested language and no POS tags. We use the Kazakh tree-bank from CoNLL 2018 shared task (Zeman et al., 2018). The training set consists of only 38 trees and no development set is provided. Segmentation and tokenization are applied using UDPipe. Similar to Rosa and Mareček (2018); Smith et al. (2018a), we utilize the available training data in Turkish as it is a related language. To align contextual embeddings, we use a dictionary generated and provided by Rosa and Mareček (2018) and compute an alignment from Kazakh to Turkish. The dictionary was obtained using FastAlign (Dyer et al., 2013) on the OpenSubtitles2018 (Lison and Tiedemann, 2016) parallel sentences dataset from OPUS (Tiedemann, 2012).[10]

Table 5 summarizes the results, showing that our algorithm outperforms the best model from the shared task by 5.05 LAS points and improves by

[10] `https://github.com/CoNLL-UD-2018/CUNI-x-ling`

over 10 points over a FASTTEXT baseline.

Zero-Shot Parsing, Limited Unlabeled Data To evaluate our anchored language model (Section 3.4), we simulate a low resource scenario by extracting only 10k random sentences out of the Spanish unlabeled data. We also extract 50k sentences for LM evaluation but perform all computations, such as anchor extraction, on the 10k training data. For a dictionary, we used the 5k training table from Conneau et al. (2018a).[11] Another table of size 1,500 was used to evaluate the alignment. In this scenario, we assume a single training language (English) and no usage of POS tags nor any labeled data for the tested language.

Table 4 shows the results. Reducing the amount of unlabeled data drastically decreases the precision by around 20 points. The regularization introduced in our anchored LM significantly improves the validation perplexity, leading to a gain of 7 UAS points and 9 LAS points.

7 Conclusion

We introduce a novel method for multilingual transfer that utilizes deep contextual embeddings of different languages, pretrained in an unsupervised fashion. At the core of our methods, we suggest to use anchors for tokens, reducing this problem to context-independent alignment. Our methods are compatible both for cases where a dictionary is present and absent, as well as for low-resource languages. The acquired alignment can be used to improve cross-lingual transfer learning, gaining from the contextual nature of the embeddings. We show that these methods lead to good word translation results, and improve significantly upon state-of-the-art zero-shot and few-shot cross-lingual dependency parsing models.

In addition, our analysis reveals interesting properties of the context-aware embeddings generated by the ELMo model. Those findings are another step towards understanding the nature of contextual word embeddings.

As our method is in its core task-independent, we conjecture that it can generalize to other tasks as well.

A Alignment Results for All Layers

Table 6 manifests word-to-word translation results when supervised alignment is performed over different layer outputs from ELMo's LSTM. Even though layer zero produces context independent representations, the anchors computed over the contextual representations achieved higher precision. We conjecture that this is due to the language model objective being applied to the output of the second layer. Hence, unlike token-based embeddings such as FASTTEXT that optimize them directly, the context-independent representations of ELMo are optimized to produce a good base for the contextual embeddings that are computed on top of them.

B Additional Parsing Results

In Table 7 we provide complementary results to those in zero-shot closs-lingual parsing.

LAYER	DE	ES	FR	IT	PT	SV	AVERAGE
0	54 / 71	65 / 80	66 / 80	61 / 78	55 / 71	41 / 61	57 / 74
1	**62 / 78**	**73 / 85**	**74 / 86**	**69 / 82**	**61 / 74**	**49 / 68**	**65 / 79**
2	59 / 75	68 / 82	70 / 83	66 / 79	56 / 72	48 / 67	61 / 76

Table 6: Per ELMo layer word translation to English precision @1 / @5 using CSLS (Conneau et al., 2018a) with a dictionary (supervised) for German (DE), Spanish (ES), French (FR), Italian (IT), Portuguese (PT) and Swedish (SV). Layer 0 representations are the result of the character-level word embeddings (which are context independent). Layer 1 and 2 alignments are based on anchors from the first and second LSTM layer output respectively.

MODEL	DE	ES	FR	IT	PT	SV	AVERAGE
Zhang and Barzilay (2015)	62.5	78.0	78.9	79.3	78.6	75.0	75.4
Guo et al. (2016)	65.0	79.0	77.7	78.5	81.9	78.3	76.7
ALIGNED FASTTEXT	69.2	83.4	84.6	84.3	86.0	80.6	81.4
ALIGNED $\bar{e}$	65.1	82.8	83.9	83.6	83.4	82.0	80.1

OURS, NO DICTIONARY	73.2	84.3	87.0	86.8	84.5	80.4	82.7
OURS, NO POS	69.7	84.8	85.3	85.3	79.7	81.7	81.1
OURS, NO DICTIONARY, NO POS	72.2	84.7	84.9	85.0	78.1	67.9	78.8

Table 7: Zero-shot cross lingual results compared to previous methods, measured in UAS. Aligned fastText and $\bar{e}$ context-independent models are also presented as baselines. The bottom three rows are models that don't use POS tags at all and/or use an unsupervised anchored alignment.
Note that Ammar et al. (2016) did not publish UAS results.

C Hyperparameters

We now detail the hyperparameters used throughout our experiments. All alignment experiments were performed using the default hyperparameters of the MUSE framework (see their github repository). Table 8 depicts the values used in multilingual parsing experiments.

HYPERPARAMETER	VALUE
BATCH SIZE (# SENTENCES)	32
INSTANCES PER EPOCH	32,000
EPOCHS (MAX.)	40
PATIENCE (EARLY STOPPING)	10
ENCODER TYPE	BI-LSTM
POS TAG EMBEDDING DIM.	50
LSTM, HIDDEN SIZE	200
LSTM, # LAYERS	3
DROPOUT RATE	0.33
ARC REPRESENTATION DIM.	500
TAG REPRESENTATION DIM.	100
ADAM	(DEFAULT)

Table 8: Hyper-parameters used in parsing experiments, shared across different settings.

D Additional Alignment Example

We provide an additional example of a homonym. Figure 3 shows the contextual embeddings of the word "bank" in English and the words "banco" (a financial establishment) and "orilla" (shore) in Spanish. In this case, unlike the "bear" example (Figure 2), the embeddings do not form two obvious clusters in the reduced two dimensional space. A possible explanation is that here the two meanings have the same POS tag (Noun). Even so, as shown in Table 9, the alignment succeeds to place the embeddings of words from each context close to the matching translation.

The nearest-neighbors for the "bear" example are presented in Table 10.

k	“BANCO” ANCHOR
1	Unlike in primary succession , the species that dominate secondary succession , are usually present from the start of the process , often in the soil seed **bank** .
2	Canto XLV is a litany against Usura or usury , which Pound later defined as a charge on credit regardless of potential or actual production and the creation of wealth ex nihilo by a **bank** to the benefit of its shareholders .
3	This prompted some investigation , led by Sir Benjamin Hall , which quickly turned up the fact that O’ Connor was registered as the owner of all the estates , and of the associated **bank** .
4	The commercial NaS battery **bank** offers : (Japanese) .
5	Both team leaders are given a mystery word , which along with their team - mates use gigantic foam blocks and place them on the clue **bank** (similar to Boggle) with only giving a clue to the word ...

k	“ORILLA” ANCHOR
1	The combined Protestant forces , now numbering 25,000 strong , positioned themselves on the western **bank** of the Rhine River .
2	The Romans had a small advance guard of auxiliaries and cavalry on the opposite **bank** of the river .
3	Between Vaugirard and the river Seine he had a considerable force of cavalry , the front of which was flanked by a battery advantageously posted near Auteuil on the right **bank** of the river .
4	Mallus therefore stood on the eastern **bank** of the river .
5	The Argentine squadron spent the night of February 7 anchored between Juncal Island and the west **bank** of the river .
6	After marching north from Tewkesbury , Sir William Waller tried to contain the cavalry forces of Maurice on the western **bank** of the Severn , cutting this substantial force off from the rest of the Royalist army .

Table 9: Nearest-neighbors (after alignment) of the Spanish anchors “banco” (a financial establishment) and “orilla” (shore) from the contextual embeddings of the word “bank” in English. The full sentence is presented for context.

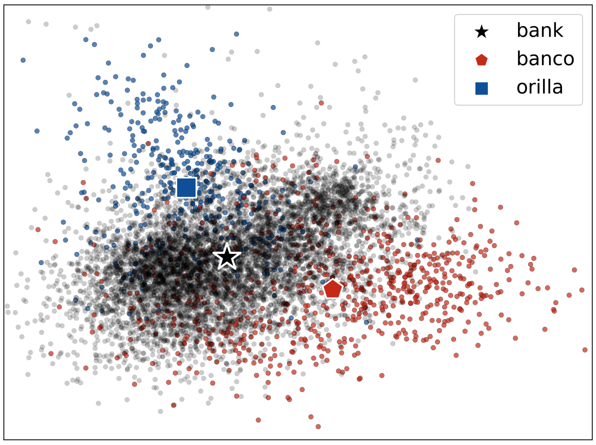

Figure 3: Contextual embeddings for the English word “bank” and its two possible translations in Spanish — “banco” (a financial establishment) in red and “orilla” (shore) in blue. The figure shows a two dimensional PCA for the aligned space of the two languages. The symbols are the anchors and the dots are the contextualized embeddings. (best viewed in color)

k	"TENER" ANCHOR
1	It may be difficult for the patient to **bear** the odour of the smoke at first , but once he gets used to such a smell , it does not really matter .
2	No matter what the better class of slave owners might do , they had to **bear** the stigma of cruelty with the worst of tyrants ...
3	Every new car will **bear** the lan name instead of Van Diemen , so the highly successful marque will gradually disappear .
4	had a sufficient economic stake to **bear** the litigation burden necessary to maintain a private suit for recovery under section 4 .
5	In this example , consumers **bear** the entire burden of the tax ; the tax incidence falls on consumers .

k	"OSO" ANCHOR
1	In 2010 , the government of the NWT decided to update its version of the polar **bear** - shaped plate .
2	Salad Fingers appears to be masochistic , as he can be seen taking pleasure from impaling his finger on a nail , rubbing stinging nettles on himself or stepping onto a **bear** trap .
3	The old **bear** - hunter , on being toasted , made a speech to the Texians , replete with his usual dry humor .
4	Balto arrives , distracts the **bear** , saves Aleu , they both escape and the **bear** disappears .
5	Defeated , the polar **bear** shrinks and transforms into a plush toy .

Abstract

Rumours can spread quickly through social media, and malicious ones can bring about significant economical and social impact. Motivated by this, our paper focuses on the task of rumour detection; particularly, we are interested in understanding how *early* we can detect them. Although there are numerous studies on rumour detection, few are concerned with the timing of the detection. A successfully-detected malicious rumour can still cause significant damage if it isn't detected in a timely manner, and so timing is crucial. To address this, we present a novel methodology for early rumour detection. Our model treats social media posts (e.g. tweets) as a data stream and integrates reinforcement learning to learn the number minimum number of posts required before we classify an event as a rumour. Experiments on Twitter and Weibo demonstrate that our model identifies rumours earlier than state-of-the-art systems while maintaining a comparable accuracy.

1 Introduction

The concept of rumour has a long history, and there are various definitions from different research communities (Allport and Postman, 1947). In this paper, we follow a commonly accepted definition of rumour, that it is an unverified statement, circulating from person to person and pertaining to an object, event, or issue of public concern and it is circulating without known authority for its truthfulness at the current time, but it may turn out to be true, or partly or entirely false; alternatively, it may also remain unresolved (Peterson and Gist, 1951; Zubiaga et al., 2018).

Rumours have the potential to spread quickly through social media, and bring about significant economical and social impact. Figure 1 illustrates an example of a rumour propagating on TWITTER. The source message started a claim about the cause of Michael Brown's shooting, and it was published shortly after the shooting happened. It claimed that he was shot ten times by the police for stealing candy. The message was retweeted by multiple users on TWITTER, and within 24 hours there were about 900K users involved, either by reposting, commenting, or questioning the original source message. From Figure 1, we see some users (e.g. User 7) question the veracity of the original message. Had the rumour been identified timely and rebutted, its propagation could have been contained.

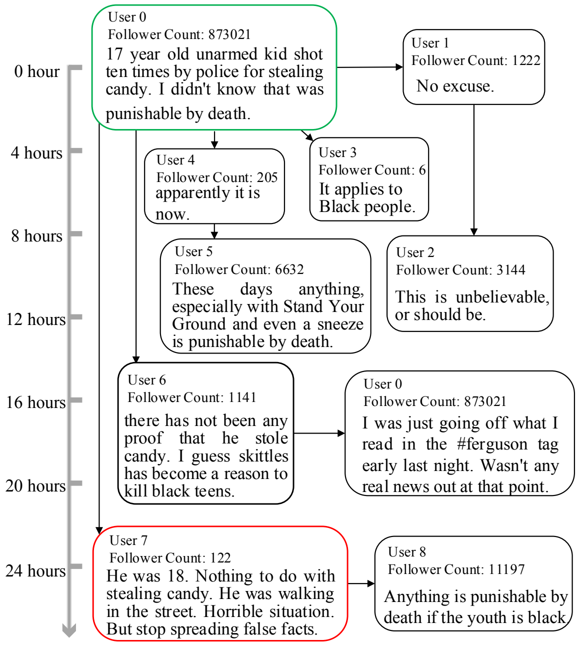

Figure 1: An illustration of a rumour propagating on TWITTER. The green box indicates the source message, and the red box highlights a post that rebuts the rumour.

Most studies (Qazvinian et al., 2011; Zhang et al., 2015) consider rumour detection as a binary classification problem, where they extract various

Proceedings of NAACL-HLT 2019, pages 1614–1623
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

features to capture rumour indicative signals for detecting a rumour, and a few recent works explore deep learning approaches to enhance detection accuracy (Long et al., 2017; Ruchansky et al., 2017). In all these studies, however, the timeliness of the rumour detection is not evaluated.

There are a few exceptions. In Ma et al. (2015) and Kwon et al. (2017), the authors define a checkpoint (e.g. number of posts or time elapsed after the source message) in the timeline and use all the posts prior to this checkpoint to classify a rumour. The checkpoint is often a pre-determined value for all rumours, and so does not capture the variation of propagation patterns for different rumours.

The focus of our paper is on *early* rumour detection. That is, our aim is to identify rumours as early as possible, while keeping a reasonable detection accuracy. Our early rumour detection system (ERD) features two modules: a rumour detection module that classifies whether an event (which consists of a number of posts) constitutes a rumour, and a checkpoint module that determines when to trigger the rumour detection module.

ERD treats incoming posts as a data stream and monitors the posts in real time. When ERD receives a new post, this post — along with all prior posts of the same event — will be used to decide if it constitutes an appropriate checkpoint to trigger the rumour detection module. ERD integrates reinforcement learning for the checkpoint module to guide the rumour detection module, using its classification accuracy as a reward. Through reinforcement learning ERD is able to learn the minimum number of posts required to identify a rumour. In other words, ERD can dynamically determine the appropriate checkpoint for different rumours, and this feature is the core novelty of our methodology.

To evaluate our approach, we use standard microblog data sets from WEIBO and TWITTER. We compare our method with benchmark rumour detection systems (Ma et al., 2016; Ruchansky et al., 2017; Dungs et al., 2018) and found that ERD could on average identify rumours within 7.5 and 3.4 hours with an accuracy of 93.3% and 85.8% on WEIBO and TWITTER respectively. Our detection accuracy performance is better than a state-of-the-art system that that detects rumours within 12 hours.

To summarise, we present a novel methodology for rumour detection. Unlike most rumour detection systems, our approach determines the checkpoint for each event dynamically, by learning when it should classify it as a rumour. Our experimental results showed that ERD outperforms state-of-the-art methods over two benchmark data sets in detection accuracy and timeliness. Our proposed framework is flexible and the individual modules (i.e. the rumour detection and checkpoint module) can be extended to incorporate more complex networks for further improvements. An open source implementation of our model is available at: `https://github.com/DeepBrainAI/ERD`.

2 Related Work

Traditionally, research on rumour detection has mainly focused on developing handcrafted features for machine learning algorithms (Qazvinian et al., 2011). Takahashi and Igata (2012) propose a method for rumour detection on Twitter using cue words and tweets statistics. Yang et al. (2012) apply two new types of features — client-based and location-based features — to rumour detection on Sina Weibo. Beyond this, user-based (Liang et al., 2015) and topic-based (Yang et al., 2015) features have also been explored. Friggeri et al. (2014) demonstrate that there are structural differences in the propagation of rumours and non-rumours, and Wu et al. (2015) and Ma et al. (2017) experiment with using these propagation patterns extensively to improve detection.

More recently, deep learning models are explored for the task. Compared to traditional machine learning approaches, these deep learning models tend to rely less on sophisticated handcrafted features. Ma et al. (2016) introduce a rumour detection model for microblogs based on recurrent networks. The input to their model is simple tf-idf features but it outperforms models leveraging handcrafted features. Sampson et al. (2016) show that implicit linkages between conversation fragments improve detection accuracy. Long et al. (2017) present a deep attention model that learns a hidden temporal representation for each sequential posts to represent the hypothesis. Ruchansky et al. (2017) integrate textual, user response, and source information into their neural models and achieve better performance.

Most of these works focus on detection accuracy, and so largely ignore the timing of the detection. Ma et al. (2015) develop a dynamic time series structure to incorporate temporal information to the features to understand the whole life cycle of rumours. Zhao et al. (2015) propose a detection model using a set of regular expressions to find posts that question or rebut the rumour to detect it earlier. Dungs et al. (2018) present an approach that checks for a rumour after 5 or 10 retweets. These models are interested in *early* rumour detection, although the checkpoint for triggering a detection is pre-determined, and succeeding posts after the checkpoint are usually ignored. On a similar note but a different task, Farajtabar et al. (2017) experiment with reinforcement learning by combining it with a point process network activity model to detect fake news and found some success.

3 Model Architecture

Let E denote an event, and it consists of a series of relevant posts x_i, where x_0 denotes the source message and x_T the last relevant message.[1] The objective of early rumor detection is to make a classification decision whether E is a rumour as early as possible while keeping an acceptable detection accuracy.[2]

As shown in Figure 2, ERD has two modules: a rumour detection module (RDM) that classifies whether an event is a rumour, and a checkpoint module (CM) that decides when the rumour detection module should be triggered. The checkpoint module plays an important role here, as it is responsible for the timeliness of a detection.

3.1 Rumor Detection Module (RDM)

RDM contains three layers: a word embedding layer that maps input words into vectors, a max-pooling layer that extracts important features of a post, and a GRU (Cho et al., 2014) that processes the sequential posts of an event.

In the word embedding layer, we map words in post x_i into vectors, yielding vectors e_i^j for each word. To capture the most salient features of a post, we apply a max pooling operation (Collobert et al., 2011; Kim, 2014; Lau et al., 2017), producing a fixed size vector m_i:

$$m_i = \text{maxpool}([\mathbf{W}_m e_i^0; \mathbf{W}_m e_i^1; ...; \mathbf{W}_m e_i^K])$$

where K is the number of words in the post. Henceforth $\mathbf{W}$ in all equations are model parameters.

To capture the temporal relationship between multiple posts, we use a GRU (Cho et al., 2014):

$$h_i = \text{GRU}(m_i, h_{i-1}) \tag{1}$$

We take the final state h_N (N = number of posts received to date) and use it to perform rumour classification:

$$p = \text{softmax}(\mathbf{W}_p h_N + b_p) \tag{2}$$

where $p \in \mathbb{R}^2$, i.e. p^0 (p^1) gives the probability of the positive (negative) class.[3]

3.2 Checkpoint Module (CM)

Rather than setting a static checkpoint when to classify an event as a rumour, CM learns the number of posts needed to trigger RDM. To this end, we leverage deep reinforcement learning to identify the optimal checkpoint. We reward CM based on RDM's accuracy and also penalise CM slightly every time it decides to not trigger RDM (and continue to monitor the event). This way CM learns the trade-off between detection accuracy and timeliness. The reward function is detailed in Section 3.3.

We use the deep Q-learning model (Mnih et al., 2013) for CM. The optimal action-value function $Q^*(s, a)$ is defined as the maximum expected return achievable under state s, which can be formulated as follows:

$$Q^*(s,a) = E_{s'\ \varepsilon}[r + \gamma \max_{a'} Q_i(s', a')|s, a]$$

where r is the reward value, γ the discount rate, and the optimal action in all action sequence a' is selected to maximise the expected value of $r + \gamma Q^*(s', a')$.

The optimal action-value function obeys the Bellman equation and is used for iterative value update:

$$Q_{i+1}(s,a) = E[r + \gamma \max_{a'} Q_i(s', a')|s, a]$$

The above iterative algorithm will converge and reach the optimal action value function, i.e. $Q_i \rightarrow Q^*$ when $q \rightarrow \infty$ (Sutton et al., 1998).

---

[1] Relevant posts are defined as retweets or responses to a source message.

[2] The earliest possible time to classify E is when we receive the first post x_0.

[3] Although sigmoid activation is more appropriate here as it is a binary classification task, we used the softmax function because in preliminary experiments we considered a third neural class.

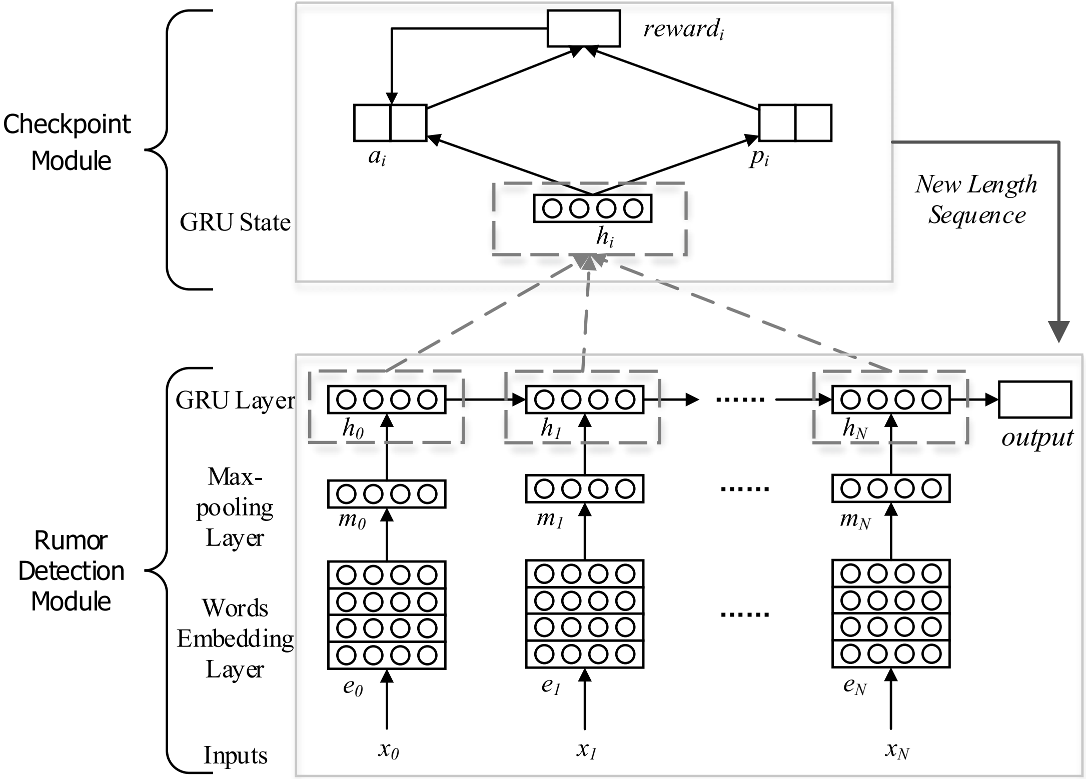

Figure 2: Architecture of ERD.

CM takes as input the hidden states produced by the GRU in RDM to compute the action-value function using a two-layer feedforward network:

$$a_i = \mathbf{W}_a(\text{ReLu}(\mathbf{W}_h h_i + b_h)) + b_a \qquad (3)$$

where $a_i \in \mathbb{R}^2$ is the action value for *terminate* (a_i^0) or *continue* (a_i^1) at post x_i. Note that a random action will be taken with the probability of θ irrespective to the action value a_i.

3.3 Joint Training

We train both RDM and CM jointly, and the training process is similar to that of generative adversarial networks (Goodfellow et al., 2014). The checkpoint module serves as the generator for action sequences, while the detection module is the discriminator. A key contrast, however, is that the two modules are working cooperatively rather than adversarially.

CM is trained using RDM's accuracy as reward. To compute the reward, we first pre-train RDM based on cross entropy:

$$-\sum_j [L_j \log(p_j^0) + (1 - L_j)(\log(p_j^1))] + \alpha l_2$$

where L_j is a binary label indicating the true class for event E_j, p is computed based on Equation (2), l_2 is the L2 loss for RDM parameters, and α is a hyper-parameter for scaling l_2.

We then train CM while keeping RDM's parameters fixed. In each step of the training, new posts that have arrived and previous GRU states are first fed to the RDM to produce the new states (Equation (1)), which will in turn be used by CM to calculate the action values (Equation (3)). This decides whether the system takes the *continue* or *terminate* action. If *terminate* is chosen, the reward is given in accordance to RDM's prediction; otherwise, a small penalty is incurred:

$$r_i = \begin{cases} \log M, & \textit{terminate} \text{ with correct prediction} \\ -P, & \textit{terminate} \text{ with incorrect prediction} \\ -\varepsilon, & \textit{continue} \end{cases}$$

where M is the number of correct predictions accumulated thus far, P is a large value to penalise an incorrect prediction, and ε is a small penalty value for delaying the detection.

To optimise our action value function, we apply the deep Q-learning approach with the experience replay algorithm (Mnih et al., 2013). Based on the optimal action-value function $Q^*(s, a)$, the objective of the action value function y_i is given as

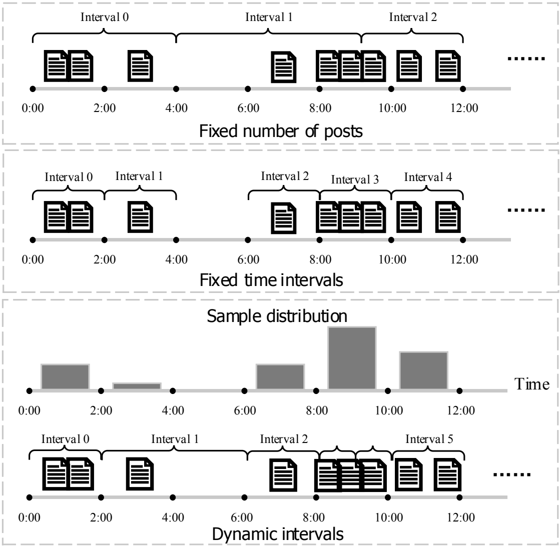

Figure 3: Three bucketing strategies to process streaming posts in batches.

follows:

$$y_i = \begin{cases} r_i, & \textit{terminate} \\ r_i + \gamma \max\limits_{a'} Q(h_{i+1}, a'; \theta), & \textit{continue} \end{cases}$$

where γ is the discount rate that decides how much experience is taken into consideration. And lastly, CM is optimised by minimising the cost:

$$(y_i - a_i)^2$$

We train CM and RDM in an alternating fashion, i.e. we train CM for several iterations while keeping RDM's parameters fixed, and then we move to train RDM for several iterations while keeping CM's parameters fixed. Training converges when CM's reward value stabilises between consecutive epochs.

3.4 Bucketing Strategy

For processing efficiency purposes, instead of processing each incoming post individually, we experiment with several bucketing strategies that group posts together and process them in batches. As Figure 3 illustrates, we group posts based on: (1) a fixed number of posts (FN), e.g. every 3 posts (i.e. 3 posts are combined together forming 1 single post); (2) a fixed time interval (FT), e.g. every 2 hours; and (3) a dynamic interval (DI) that ensures the number of posts collected in an interval is close to the mean number of posts collected in an hour in the full data set.

Max # of posts per event	59,318	346
Min # of posts per event	10	1

Table 1: Statistics of WEIBO and TWITTER.

4 Experiment

4.1 Data Set

We experiment with two data sets: WEIBO and TWITTER, developed by Ma et al. (2016) and Zubiaga et al. (2016) respectively.[4]

Statistics of the data sets is presented in Table 1. Even though both data sets have a comparable number of events, WEIBO is an order of magnitude larger than TWITTER as there are more posts per event. We reserve 10% of the events as the validation set for hyper-parameter tuning and early stopping, and split the rest in a ratio of 3:1 for training and test partitions.

4.2 Model Comparison

As a baseline, we use an SVM with tf-idf features. We also include several state-of-the-art rumour detection systems for comparisons: CSI (Ruchansky et al., 2017) on WEIBO; CRF (Zubiaga et al., 2016) and HMM (Dungs et al., 2018) on TWITTER; and GRU-2 (Ma et al., 2016) on both data sets. For GRU-2 (Ma et al., 2016) we also report performance on several variants that use a different recurrent network: simple RNN with tanh activation (RNN); single-layer LSTM (LSTM); and single-layer GRU (GRU-1).

CSI is a neural model that integrates text and users representations to classify rumours. CRF and HMM are classical models that use crowd opinions (a.k.a. stance) of the event for classification. GRU-2 is based on a two-layer GRU that captures contextual information of posts with tf-idf features as inputs.

---

[4] There is a small difference in the definition of a "rumour" in these two data sets. For WEIBO, all labelled rumours are false rumours (i.e. the source message contains verified untruthful statements), where else for TWITTER, rumours maybe truthful, untruthful, or unverified.

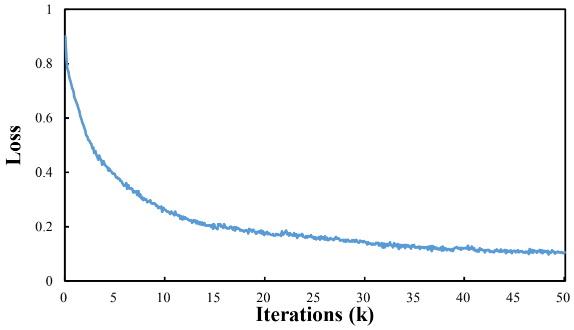

Figure 4: Loss over time during joint training.

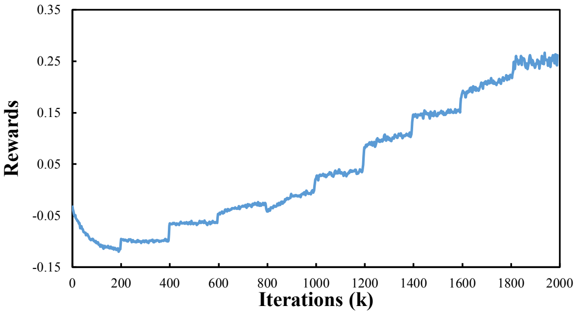

Figure 5: Reward over time during joint training.

4.3 Preprocessing and Hyper-parameters

We preprocess each post by segmenting them into words, and remove all stop words.[5] We pre-train word embeddings and kept them fixed during training.[6] θ is set to 0.01 and γ to 0.95; both values are determined empirically based on validation data. We use the Adam optimiser (Kingma and Ba, 2014) with a learning rate of 0.001 during joint training, which we found to produce stable training.

4.4 Training Loss and Reward

We present the training loss and reward values over time during joint training in Figure 4 and Figure 5. We pre-train RDM for 2 epochs before joint training, and then we train RDM and CM in an alternating fashion for 1 epoch and 200K iterations respectively. We can see that loss declines steadily after 20K iterations and converges at around 50K iterations. The reward curve, on the other hand, fluctuates more as the reward was calculated based on the accuracy of RDM. When switching between training RDM and CM, the reward value tends to change abruptly, although over time we see a consistent improvement.

Method	Accuracy	Precision	Recall	F1

DI	0.814	0.771	0.767	0.769

Table 2: Classification performance for 3 bucketing strategies on TWITTER.

4.5 Results

4.5.1 Bucketing Strategy

Recall that we explore 3 different methods to group posts in order to process them in batches (Section 3.4). Here we evaluate them on rumour classification accuracy over the validation set of TWITTER. Note that we do not use CM here (and hence no reinforcement learning is involved) — we simply use all posts of an event to perform rumour classification with RDM. In terms of metrics we use standard accuracy, precision, recall and F1 scores. Results are presented in Table 2.

We see FN produces the best performance, and so FN is used for all following experiments as the default bucketing strategy.[7] As certain events have a long delay between posts, we also incorporate a maximum delay of one hour before processing the posts in a batch.

4.5.2 Detection Accuracy

In this section, we assess how accurately the models classify rumours. All baselines and benchmark systems uses all posts of an event to perform classification, with the exception of HMM which uses only the first 5 posts. For our models, we present: (1) the full model ERD, which uses a subset of posts for classification (checkpoint decided by CM); and (2) RDM, which uses the full set of posts. Results are detailed in Table 3 and 4.

We can see that RDM outperforms all models across most metrics, including state-of-the-art rumour detection systems CSI (marginally) and CRF (substantially). ERD, on the other hand, performs very competitively, outperforming most

---

[5] For TWITTER, words are tokenised using white spaces, and stopword list is based on NLTK (Bird et al., 2009). For WEIBO, Jieba is used for tokenisation: `https://pypi.org/project/jieba/`; and stopword list is a customised list based on: `http://blog.sina.com.cn/s/blog_a19ab3770102wjav.html`.

[6] For WEIBO, the embeddings are pre-trained using word2vec (Mikolov et al., 2013) on a separate Weibo data set we collected. For TWITTER, the embeddings are pre-trained GloVe embeddings (Pennington et al., 2014). Unknown words are initialised as zero vectors.

[7] FN value: 5 posts for WEIBO and 2 posts for TWITTER.

benchmark systems and baselines, with the exception of CSI on WEIBO. Note, however, that unlike most other systems, ERD leverages only a subset of posts for rumour classification. HMM is the only benchmark system on TWITTER that uses a subset (first 5), and its performance is markedly worse than that of ERD (which uses 4.03 posts on average).

4.5.3 Detection Timeliness

Next we evaluate the timeliness of the detection, and we focus on comparing our system with GRU-2 (Ma et al., 2016), as it performed competitively in Section 4.5.2. Note that GRU-2 uses a manually set checkpoint (12 hours) that were found to be optimal, while ERD determines the checkpoint dynamically.

We first present the proportion of events that are classified by ERD over time (6-hour interval) in Figure 6.[8] We see that for both WEIBO and TWITTER, the majority of the events (approximately 80%) are classified within the first 6 hours. GRU-2's optimal checkpoint is 12 hours (dashed line), and so ERD is detecting rumours much earlier than GRU-2.

We next present the classification accuracy of these events over time (again, in 6-hour interval) in Figure 7. ERD generally outperforms GRU-2 (dashed lines) over all checkpoints. To be fair, checkpoints that are longer than 12 hours are not exactly comparable, as ERD uses more posts than GRU-2 in these instances. But even if we consider only the first 2 intervals (0-6 and 6-12 hours), ERD still outperforms GRU-2 across both data sets, demonstrating that ERD detects rumours earlier and more accurately.

For the two checkpoints on WEIBO where GRU-2 outperforms ERD, in the first checkpoint (24-30) we find that there are only 5 events and so the difference is unlikely to be statistically robust. For the second checkpoint (42-48), we hypothesise that these events are possibly the diffi-

Table 5: Case study of a rumour on WEIBO.

cult cases, and as such the classification decision is deferred until much later (and classification performance is ultimately still low due to its difficulty).

To understand the advantage of incorporating reinforcement learning (CM) for rumour detection, we compute the detection accuracy over time for ERD and RDM in Figure 8. The dashed lines indicate the average accuracy performance of ERD, which detects rumours on average in 7.5 and 3.4 hours on WEIBO and TWITTER respectively. The solid lines show the accuracy performance of RDM, which increases over time as it has more evidence. For RDM to achieve the performance of ERD, we see that it requires approximately at least 20 hours of posts on both data sets. This highlights the importance of the checkpoint module, which allows ERD to detect rumours much earlier. In certain events, they are detected within 3 minutes.

4.5.4 Case Study

To provide a qualitative analysis for our approach, we showcase an example of a rumour event from WEIBO in Table 5. We present a set of salient words (second column) and their translations (third column) extracted from posts published during a particular period (first column) using simple tf-idf features.

The rumour was started by a message claiming that hairy crabs contain harmful hormones and toxins on August 18th, 2012. After the message was posted, within 12 hours 2.3M users participated in its propagation, either by re-posting, commenting, or questioning the original source message. The rumour spread quickly and led to significant economic damage to the aquaculture industry in China. Officially the rumour was rebutted after 24 hours, but in Table 5 we see that ERD detects the rumour in 34 minutes.

5 Conclusions

We present ERD, an early rumour detection system. Rather than setting a static checkpoint that determines when an event should be classified as rumour, ERD learns dynamically the minimum number of posts required to identify a rumour. To this end, we integrate reinforcement learning with recurrent neural networks to monitor social media posts in real time to decide when to classify rumours. We evaluate our model on two standard data sets, and demonstrate that ERD identifies rumours within 7.5 hours and 3.4 hours on WEIBO and TWITTER on average, compared to 12 hours of a competitive system. In terms of detection accuracy, ERD achieves a performance of 93.3% and 85.8%, which is comparable to state-of-the-art rumour detection systems.

Abstract

Automatic hashtag annotation plays an important role in content understanding for microblog posts. To date, progress made in this field has been restricted to phrase selection from limited candidates, or word-level hashtag discovery using topic models. Different from previous work considering hashtags to be inseparable, our work is the first effort to annotate hashtags with a novel *sequence generation* framework via viewing the hashtag as a short sequence of words. Moreover, to address the data sparsity issue in processing short microblog posts, we propose to jointly model the target posts and the *conversation contexts* initiated by them with bidirectional attention. Extensive experimental results on two large-scale datasets, newly collected from English Twitter and Chinese Weibo, show that our model significantly outperforms state-of-the-art models based on classification.[1] Further studies demonstrate our ability to effectively generate rare and even unseen hashtags, which is however not possible for most existing methods.

1 Introduction

Microblogs have become an essential outlet for individuals to voice opinions and exchange information. Millions of user-generated messages are produced every day, far outpacing the human being's reading and understanding capacity. As a result, the current decade has witnessed the increasing demand for effectively discovering gist information from large microblog texts. To identify the key content of a microblog post, hashtags, user-generated labels prefixed with a "#" (such as "*#NAACL*" and "*#DeepLearning*"), have been widely used to reflect keyphrases (Zhang et al., 2016, 2018) or topics (Yan et al., 2013; Hong et al., 2012; Li et al., 2016). Hashtags can further benefit downstream applications, such as microblog search (Efron, 2010; Bansal et al., 2015), summarization (Zhang et al., 2013; Chang et al., 2013), sentiment analysis (Davidov et al., 2010; Wang et al., 2011), and so forth. Despite the widespread use of hashtags, there are a large number of microblog messages without any user-provided hashtags. For example, less than 15% tweets contain at least one hashtag (Wang et al., 2011; Khabiri et al., 2012). Consequently, for a multitude of posts without human-annotated hashtags, there exists a pressing need for automating the hashtag annotation process for them.

Target post for hashtag generation

This *Azarenka* woman needs a talking to from the umpire her weird noises are totes inappropes professionally. ***#AusOpen***

Replying messages forming a conversation

[T1] How annoying is she. I just worked out what she sounds like one of those turbo charged cars when they change gear or speed.

[T2] On the topic of noises, I was at the *Nadal-Tomic* game last night and I loved how quiet *Tomic* was compared to *Nadal*.

[T3] He seems to have a shitload of talent and the postmatch press conf. He showed a lot of maturity and he seems nice.

[T4] *Tomic* has a fantastic *tennis* brain...

Table 1: A post and its conversation snippet about "Australian Open" on Twitter. "*#AusOpen*" is the human-annotated hashtag for the target post. *Words indicative of the hashtag* are in blue and italic type.

Most previous work in this field focuses on extracting phrases from target posts (Zhang et al., 2016, 2018) or selecting candidates from a pre-

defined list (Gong and Zhang, 2016; Huang et al., 2016; Zhang et al., 2017). However, hashtags usually appear in neither the target posts nor the given candidate list. The reasons are two folds. For one thing, microblogs allow large freedom for users to write whatever hashtags they like. For another, due to the wide range and rapid change of social media topics, a vast variety of hashtags can be daily created, making it impossible to be covered by a fixed candidate list. Prior research from another line employs topic models to generate topic words as hashtags (Gong et al., 2015; Zhang et al., 2016). These methods, ascribed to the limitation of most topic models, are nevertheless incapable of producing phrase-level hashtags.

In this paper, we approach hashtag annotation from a novel *sequence generation* framework. In doing so, we enable phrase-level hashtags beyond the target posts or the given candidates to be created. Here, hashtags are first considered as a sequence of tokens (e.g., "*#DeepLearning*" as "*deep learning*"). Then, built upon the success of sequence to sequence (seq2seq) model on language generation (Sutskever et al., 2014), we present a neural seq2seq model to generate hashtags in a *word-by-word* manner. To the best of our knowledge, *we are the first to deal with hashtag annotation in sequence generation architecture*.

In processing microblog posts, one major challenge we might face is the limited features to be encoded. It is mostly caused by the data sparsity exhibited in short and informal microblog posts.[2] To illustrate such challenge, Table 1 displays a sample Twitter post tagged with "*#AusOpen*", referring to Australian Open tennis tournament. Only given the short post, it is difficult to understand why it is tagged with "*#AusOpen*", not to mention that neither "*aus*" nor "*open*" appear in the target post. In such a situation, how shall we generate hashtags for a post with limited words?

To address the data sparsity challenge, we exploit conversations initiated by the target posts to enrich their contexts. Our approach is benefited from the nature that most messages in a conversation tend to focus on relevant topics. Content in conversations might hence provide contexts facilitating the understanding of the original post (Chang et al., 2013; Li et al., 2015). The effects of conversation contexts, useful on topic modeling (Li et al., 2016, 2018) and keyphrase extraction (Zhang et al., 2018), have never been explored on microblog hashtag generation. To show why conversation contexts are useful, we display in Table 1 a conversation snippet formed by some replies of the sample target post. As can be seen, key content words in the conversation (e.g., "*Nadal*", "*Tomic*", and "*tennis*") are useful to reflect the relevance of the target post to the hashtag "*#AusOpen*", because Nadal and Tomic are both professional tennis players. Concretely, our model employs a dual encoder (i.e., two encoders), one for the target post and the other for the conversation context, to capture the representations from the *two sources*. Furthermore, to capture their joint effects, we employ the bidirectional attention (**bi-attention**) (Seo et al., 2016) to explore the interactions between two encoders' outputs. Afterward, an attentive decoder is applied to generate the word sequence of the hashtag.

In experiments, we construct two large-scale datasets, one from English platform Twitter and the other from Chinese Weibo. Experimental results based on both information retrieval and text summarization metrics show that our model generates hashtags closer to human-annotated ones than all the comparison models. For example, our model achieves 45.03% ROUGE-1 F1 on Weibo, compared to 25.34% given by the state-of-the-art classification-based method. Further comparisons with classification-based models show that our model, in a sequence generation framework, can better produce rare and even new hashtags.

To summarize, our contributions are three-fold:

- We are the first to approach microblog hashtag annotation with *sequence generation* architecture.
- To alleviate data sparsity, we enrich context for short target posts with their *conversations* and employ a bi-attention mechanism for capturing their interactions.
- Our proposed model outperforms state-of-the-art models by large margins on two large-scale datasets, constructed as part of this work.

2 Neural Hashtag Generation Model

In this section, we describe our framework shown in Figure 1. There are two major modules: a dual encoder to encode both target posts and their conversations with a bi-attention to explore their interactions, and a decoder to generate hashtags.

---

[2] For instance, the eligible length of a post on Twitter or Weibo is up to 140 characters.

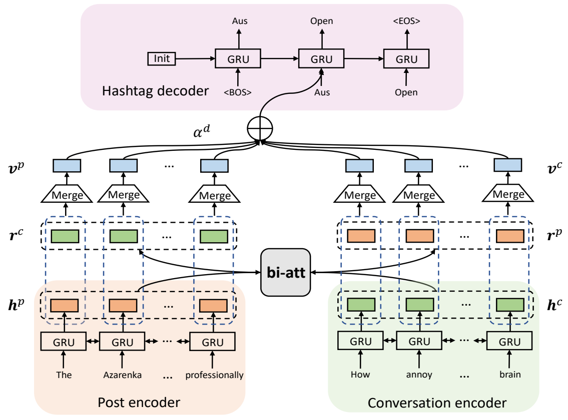

Figure 1: Our hashtag generation framework with a dual encoder, including a post encoder and a conversation encoder, where a bi-attention (bi-att) distills their salient features, followed by a merge layer to fuse them. An attentive decoder generates the hashtag sequence.

Input and Output. Formally, given a target post $\mathbf{x}^p$ formulated as word sequence $\langle x_1^p, x_2^p, ..., x_{|\mathbf{x}^p|}^p \rangle$ and its conversation context $\mathbf{x}^c$ formulated as word sequence $\langle x_1^c, x_2^c, ..., x_{|\mathbf{x}^c|}^c \rangle$, where $|\mathbf{x}^p|$ and $|\mathbf{x}^c|$ denote the number of words in the input target post and its conversation, respectively, our goal is to output a hashtag $\mathbf{y}$ represented by a word sequence $\langle y_1, y_2, ..., y_{|\mathbf{y}|} \rangle$. For training instances tagged with multiple gold-standard hashtags, we copy the instances multiple times, each with one gold-standard hashtag following Meng et al. (2017). All the input target posts, their conversations, and the hashtags share the same vocabulary V.

Dual Encoder. To capture representations from both target posts and conversation contexts, we design a dual encoder, composed of a post encoder and a conversation encoder, each taking the $\mathbf{x}^p$ and $\mathbf{x}^c$ as input, respectively.

For the post encoder, we use a bidirectional gated recurrent unit (Bi-GRU) (Cho et al., 2014) to encode the target post $\mathbf{x}^p$, where its embeddings $e(\mathbf{x}^p)$ are mapped into hidden states $\mathbf{h}^p = \langle \mathbf{h}_1^p, \mathbf{h}_2^p, ..., \mathbf{h}_{|\mathbf{x}^p|}^p \rangle$. Specifically, $\mathbf{h}_i^p = [\overrightarrow{\mathbf{h}_i^p}; \overleftarrow{\mathbf{h}_i^p}]$ is the concatenation of forward hidden state $\overrightarrow{\mathbf{h}_i^p}$ and backward hidden state $\overleftarrow{\mathbf{h}_i^p}$ for the i-th token:

$$\overrightarrow{\mathbf{h}_i^p} = GRU(e(\mathbf{x}_i^p), \overrightarrow{\mathbf{h}_{i-1}^p}), \tag{1}$$

$$\overleftarrow{\mathbf{h}_i^p} = GRU(e(\mathbf{x}_i^p), \overleftarrow{\mathbf{h}_{i+1}^p}). \tag{2}$$

Likewise, the conversation encoder converts conversations into hidden states $\mathbf{h}^c$ via another Bi-GRU. The dimensions of both $\mathbf{h}^p$ and $\mathbf{h}^c$ are d.

Bi-attention. To further distill useful representations from our two encoders, we employ the bi-attention to explore the interactions between the target posts and their conversations. The adoption of bi-attention is inspired by Seo et al. (2016), where the bi-attention was applied to extract query-aware contexts for machine comprehension. Our intuition is that the content concerning the key points in target posts might have their relevant words frequently appearing in their conversation contexts, and vice versa. In general, such content can reflect what the target posts focus on and hence effectively indicate what hashtags should be generated. For instance, in Table 1, names of tennis players (e.g., "*Azarenka*", "*Nadal*", and "*Tomic*") are mentioned many times in both target posts and their conversations, which reveals why the hashtag is "*#AusOpen*".

To this end, we first put a *post-aware* attention on the conversation encoder with coefficients:

$$\alpha_{ij}^c = \frac{\exp(f_{score}(\mathbf{h}_i^p, \mathbf{h}_j^c))}{\sum_{j'=1}^{|\mathbf{x}^c|} \exp(f_{score}(\mathbf{h}_i^p, \mathbf{h}_{j'}^c))}, \tag{3}$$

where the alignment score function $f_{score}(\mathbf{h}_i^p, \mathbf{h}_j^c) = \mathbf{h}_i^p \mathbf{W}_{bi-att} \mathbf{h}_j^c$ captures the similarity of the i-th word in the target post and the j-th word in its conversation. Here $\mathbf{W}_{bi-att} \in \mathbb{R}^{d \times d}$ is a weight matrix to be learned. Then, we compute a context vector $\mathbf{r}^c$ conveying post-aware conversation representations, where the i-th value is defined as:

$$\mathbf{r}_i^c = \sum_{j=1}^{|\mathbf{x}^c|} \alpha_{ij}^c \mathbf{h}_j^c. \tag{4}$$

Analogously, a *conversation-aware* attention on post encoder is used to capture the conversation-aware post representations as $\mathbf{r}^p$.

Merge Layer. Next, to further fuse representations distilled by the bi-attention on each encoder, we design a *merge* layer, a multilayer perceptron (MLP) activated by hyperbolic function:

$$\mathbf{v}^p = \tanh(\mathbf{W}_p[\mathbf{h}^p; \mathbf{r}^c] + \mathbf{b}_p), \tag{5}$$

$$\mathbf{v}^c = \tanh(\mathbf{W}_c[\mathbf{h}^c; \mathbf{r}^p] + \mathbf{b}_c), \tag{6}$$

where $\mathbf{W}_p, \mathbf{W}_c \in \mathbb{R}^{d \times 2d}$ and $\mathbf{b}_p, \mathbf{b}_c \in \mathbb{R}^d$ are trainable parameters.

Note that either $\mathbf{v}^p$ or $\mathbf{v}^c$ conveys the information from both posts and conversations, but with a different emphasis. Specifically, $\mathbf{v}^p$ mainly retains the contexts of posts with the auxiliary information from conversations, while $\mathbf{v}^c$ does the opposite. Finally, vectors $\mathbf{v}^p$ and $\mathbf{v}^c$ are concatenated and fed into the decoder for hashtag generation.

Decoder. Given the representations $\mathbf{v} = [\mathbf{v}^p; \mathbf{v}^c]$ produced by our dual encoder with bi-attention, we apply an attention-based GRU decoder to generate a word sequence $\mathbf{y}$ as the hashtag. The probability to generate the hashtag conditioned on a target post and its conversation is defined as:

$$Pr(\mathbf{y}|\mathbf{x}^p, \mathbf{x}^c) = \prod_{t=1}^{|\mathbf{y}|} Pr(y_t|\mathbf{y}_{<t}, \mathbf{x}^p, \mathbf{x}^c), \quad (7)$$

where $\mathbf{y}_{<t}$ refers to $(y_1, y_2, ..., y_{t-1})$.

Concretely, when generating the t-th word in hashtag, the decoder emits a hidden state vector $\mathbf{s}_t \in \mathbb{R}^d$ and puts a global attention over $\mathbf{v}$. The attention aims to exploit indicative representations from the encoder outputs $\mathbf{v}$ and summarizes them into a context vector $\mathbf{c}_t$ defined as:

$$\mathbf{c}_t = \sum_{i=1}^{|\mathbf{x}^p|+|\mathbf{x}^c|} \alpha^d_{ti} \mathbf{v}_i, \quad (8)$$

$$\alpha^d_{ti} = \frac{\exp(g_{score}(\mathbf{s}_t, \mathbf{v}_i))}{\sum_{i'=1}^{|\mathbf{x}^p|+|\mathbf{x}^c|} \exp(g_{score}(\mathbf{s}_t, \mathbf{v}_{i'}))}, \quad (9)$$

where $g_{score}(\mathbf{s}_t, \mathbf{v}_i) = \mathbf{s}_t \mathbf{W}_{att} \mathbf{v}_i$ is another alignment function ($\mathbf{W}_{att} \in \mathbb{R}^{d \times d}$) to measure the similarity between $\mathbf{s}_t$ and $\mathbf{v}_i$.

Finally, we map the current hidden state $\mathbf{s}_t$ of the decoder together with the context vector $\mathbf{c}_t$ to a word distribution over the vocabulary V via:

$$Pr(y_t|\mathbf{y}_{<t}, \mathbf{x}^p, \mathbf{x}^c) = softmax(\mathbf{W}_v[\mathbf{s}_t; \mathbf{c}_t] + \mathbf{b}_v), \quad (10)$$

which reflects how likely a word to be the t-th word in the generated hashtag sequence. Here $\mathbf{W}_v \in \mathbb{R}^{V \times 2d}$ and $\mathbf{b}_v \in \mathbb{R}^V$ are trainable weights.

Learning and Inferring Hashtags. During the training stage, we apply stochastic gradient descent to minimize the loss function of our entire framework, which is defined as:

$$\mathcal{L}(\Theta) = -\sum_{n=1}^{N} \log(Pr(\mathbf{y}_n|\mathbf{x}^p_n, \mathbf{x}^c_n; \Theta)). \quad (11)$$

Here N is the number of training instances and Θ denotes the set of all the learnable parameters.

Datasets	# of posts	Avg len of posts	Avg len of convs	Avg len of tags	# of tags per post
Twitter	44,793	13.27	29.94	1.69	1.14
Weibo	40,171	32.64	70.61	2.70	1.11

Table 2: Statistics of our datasets. Avg len of posts, convs, tags refer to the average number of words in posts, conversations, and hashtags, respectively.

Datasets	|Tagset|	$\mathcal{P}$	$\mathcal{C}$	$\mathcal{P} \cup \mathcal{C}$
Twitter	4,188	2.72%	5.58%	7.69%
Weibo	5,027	8.29%	6.21%	12.52%

Table 3: Statistics of the hashtags. |Tagset|: the number of distinct hashtags. $\mathcal{P}$, $\mathcal{C}$, and $\mathcal{P} \cup \mathcal{C}$: the percentage of hashtags appearing in their corresponding posts, conversations, and the union set of them, respectively.

In hashtag inference, based on the produced word distribution at each time step, word selection is conducted using beam search. In doing so, we generate a ranking list of output hashtags, where the top K hashtags serve as our final output.

3 Experiment Setup

Here we describe how we set up our experiments.

Datasets and Statistic Analysis. Two large-scale experiment datasets are *newly collected* from popular microblog platforms: an English Twitter dataset and a Chinese Weibo dataset. The Twitter dataset was built based on the TREC 2011 microblog track.[3] To recover the conversations, we used Tweet Search API to fetch "in-reply-to" relations in a recursive way. The Weibo dataset was collected from January to August 2014 using Weibo Search API via searching messages with the trending queries[4] as keywords. For gold-standard hashtags, we take the user-annotated hashtags, appearing before or after a post, as the reference.[5] The statistics of our datasets are shown in Table 2. We randomly split both datasets into three subsets, where 80%, 10%, and 10% of the data corresponds to training, development, and test sets, respectively.

To further investigate how challenging our problem is, we show some statistics of the hashtags in Table 3 and the distributions of hashtag frequency in Figure 2. In Table 3, we observe

---

[3] `https://trec.nist.gov/data/tweets/`

[4] `http://open.weibo.com/wiki/Trends/`

[5] Hashtags in the middle of a post are not considered here as they generally act as semantic elements (Zhang et al., 2016, 2018).

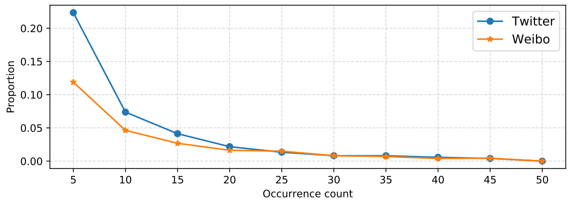

Figure 2: Distribution of hashtag frequency. The horizontal axis refers to the occurrence count of hashtags (shown with maximum 50 and bin 5) and the vertical axis denotes the data proportion.

the large size of hashtags in both datasets. Moreover, Figure 2 indicates that most hashtags only appear a few times. Given such a large and imbalanced hashtag space, hashtag selection from a candidate list, as many existing methods do, might not perform well. Table 3 also shows that only a small proportion of hashtags appearing in their posts, conversations, and either of them, making it inappropriate to directly extract words from the two sources to form hashtags.

Preprocessing. For tokenization and word segmentation, we employed the tweet preprocessing toolkit released by Baziotis et al. (2017) for Twitter, and the Jieba toolkit[6] for Weibo. Then, for both Twitter and Weibo, we further take the following preprocessing steps: First, single-character hashtags were filtered out for not being meaningful. Second, generic tags, i.e., links, mentions (@username), and numbers, were replaced with "URL" "MENTION", and "DIGIT", respectively. Third, inappropriate replies (e.g., retweet-only messages) were removed, and the remainder were chronologically ordered to form a sequence as conversation contexts. Last, a vocabulary was maintained with the $30K$ and $50K$ most frequent words, for Twitter and Weibo, respectively.

Comparisons. For experiment comparisons, we first consider a weak baseline RANDOM that randomly ranks hashtags seen from training data. Two unsupervised baselines are also considered, where words are ranked by latent topics induced with the latent Dirichlet allocation topic model (henceforth LDA), and by their TF-IDF scores (henceforth TF-IDF). Here for TF-IDF scores, we consider the N-gram TF-IDF ($N \leq 5$). Besides, we compare with *supervised* models below:

- EXTRACTOR: Following Zhang et al. (2018), we extract phrases from target posts as hashtags via sequence tagging and encode conversations with memory networks (Sukhbaatar et al., 2015).
- CLASSIFIER: We compare with the state-of-the-art model based on classification (Gong and Zhang, 2016), where hashtags are selected from candidates seen in training data. Here two versions of their classifier are considered, one only taking a target post as input (henceforth CLASSIFIER (*post only*)) and the other taking the concatenation of a target post and its conversation as input (henceforth CLASSIFIER (*post+conv*)).
- GENERATOR: A seq2seq generator (henceforth SEQ2SEQ) (Sutskever et al., 2014) is applied to generate hashtags given a target post. We also consider its variant augmented with copy mechanism (Gu et al., 2016) (henceforth SEQ2SEQ-COPY), which has proven effective in keyphrase generation (Meng et al., 2017) and also takes the post as input. The proposed seq2seq with the bi-attention to encode both the post and its conversation is denoted as OUR MODEL for simplicity.

Model Settings. We conduct model tunings on the development set based on grid search, where the hyper-parameters that give the lowest objective loss are selected. For the sequence generation models, the implementations are based on the OpenNMT framework (Klein et al., 2017). The word embeddings, with dimension set to 200, are randomly initialized. For encoders, we employ two layers of Bi-GRU cells, and for decoders, one layer of GRU cell is used. The hidden size of all GRUs is set to 300. In learning, we use the Adam optimizer (Kingma and Ba, 2014) with the learning rate initialized to 0.001. We adopt the early-stop strategy: the learning rate decreases by a decay rate of 0.5 till either it is below $1e^{-6}$ or the validation loss stops decreasing. The norm of gradients is rescaled to 1 if the $L2$-norm > 1 is observed. The dropout rate is 0.1 and the batch size is 64. In inference, we set the beam-size to 20 and the maximum sequence length of a hashtag to 10.

For CLASSIFIER and EXTRACTOR, lacking publicly available codes, we reimplement the models using Keras.[7] Their results are reproduced in their original experiment settings. For LDA, we employ an open source toolkit lda.[8]

Evaluation Metrics. Popular *information retrival* evaluation metrics F1 scores at K (F1@K)

Table 4: Comparison results on Twitter and Weibo datasets (in %). RG-1 and RG-4 refer to ROUGE-1 and ROUGE-SU4 respectively. The best results in each column are in bold. The "*" after numbers indicates significantly better results than all the other models ($p < 0.05$, paired t-test). Higher values indicate better performance.

and mean average precision (MAP) scores (Manning et al., 2008) are reported. Here, different K values are tested on F1@K and result in a similar trend, so only F1@1 and F1@5 are reported. MAP scores are also computed given the top 5 outputs. Besides, as we consider a hashtag as a sequence of words, ROUGE metrics for *summarization* evaluation (Lin, 2004) are also adopted. Here, we use ROUGE F1 for the top-ranked hashtag prediction computed by an open source toolkit pythonrouge,[9] with Porter stemmer used for English tweets. For Weibo posts, scores calculated at the Chinese character level following Li et al. (2018). We report the average scores for multiple gold-standard hashtags on ROUGE evaluation.

4 Experimental Results

In this section, we first report the main comparison results in Section 4.1, followed by an in-depth comparative study between classification and sequence generation models in Section 4.2. Further discussions are then presented to analyze our superiority and errors in Section 4.3.

4.1 Main Comparison Results

Table 4 reports the main comparison results. For Classifier, their outputs are ranked according to the logits after a $softmax$ layer. For Extractor, it is unable to produce ranked hashtags and thus no results are reported for F1@5 and MAP. For LDA, as it cannot generate bigram hashtags, no results are presented for ROUGE-SU4. In general, we have the following observations:

• ***Hashtag annotation is more challenging for Twitter than Weibo.*** Generally, all models perform worse on Twitter measured by different metrics. The intrinsic reason is the essential language difference between English and Chinese microblogs. English allows higher freedom in writing, resulting in more variety in Twitter hashtags (e.g., abbreviations are prominent like "*aus*" in "*#AusOpen*"). For statistical reasons, Twitter hashtags are more likely to be absent in either posts or conversations (Table 3), and have a more severe imbalanced distribution (Figure 2).

• ***Topic models and extractive models are ineffective for hashtag annotation***. The poor performance of all baseline models indicates that hashtag annotation is a challenging problem. LDA sometimes performs even worse than Random due to its inability to produce phrase-level hashtags. For extractive models, both Tf-Idf and Extractor fail to achieve good results. It is because most hashtags are absent in target posts, as we see in Table 3 that only 2.72% hashtags on Twitter and 8.29% on Weibo appear in target posts. This confirms that extractive models, relying on word selection from target posts, cannot well fit the hashtag annotation scenario. For the same reason, copy mechanism fails to bring noticeable improvements for the seq2seq generator on both datasets.

• ***Sequence generation models outperform other counterparts.*** When comparing Generators with other models, we find the former uniformly achieve better results, showing the superiority to produce hashtags with sequence generation framework. Classification models, though as

---

[9] `https://github.com/tagucci/pythonrouge`

the state of the art, expose their inferiority as they select labels from the large and imbalanced hashtag space (reflected in Table 3 and Figure 2).

- ***Conversations are useful for hashtag generation.*** Among the sequence generation models, OUR MODEL achieves the best performance across all the metrics. The observation indicates the usefulness of bi-attention in exploiting the joint effects of target posts and their conversations, which further helps in identifying indicative features from both sources for hashtag generation. However, interestingly, incorporating conversations fails to boost the classification performance. The reason why OUR MODEL better exploits conversations than CLASSIFIER (*post+conv*) might be that we can attend the indicative features when decoding each word in the hashtag, which is however not possible for classification models (considering hashtags to be inseparable).

4.2 Classification vs. Generation

From Table 4, we observe that the classifiers outperform topic models and extractive models by a large margin but exhibit generally worse results than sequence generation models. Here, we present a thorough study to compare hashtag classification and generation. Four models are selected for comparison: two classifiers, CLASSIFIER (*post only*) and CLASSIFIER (*post+conv*), and two sequence generation models, SEQ2SEQ and OUR MODEL. Below, we explore how they perform to predict rare and new hashtags.

Rare Hashtags. According to the hashtag distributions in Figure 2, we can see a large proportion of hashtags appearing only a few times in the data. To study how models perform to predict such hashtags, in Figure 3, we display their F1@1 scores in inferring hashtags with varying frequency. The lower F1 score on less frequent hashtags indicates the difficulty to yield rare hashtags. The reason probably comes from the overfitting issue caused by limited data to learn from.

We also observe that sequence generation models achieve consistently better F1@1 scores on hashtags with varying sparsity degree, while classification models suffer from the label sparsity issue and obtain worse results. The better performance of the former might result from the word-by-word generation manner in hashtag generation, which enables the internal structure of hashtags (how words form a hashtag) to be exploited.

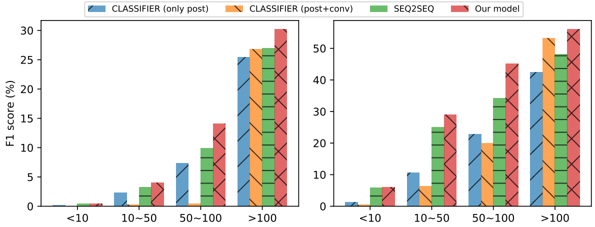

Figure 3: F1@1 on Twitter (the left subfigure) and Weibo (the right subfigure) in inferring hashtags with varying frequency. In each subfigure, from left to right shows the results of CLASSIFIER (*post only*), CLASSIFIER (*post+conv*), SEQ2SEQ, and OUR MODEL. Generation models consistently perform better.

New Hashtags. To further explore the extreme situation where hashtags are absent in the training set, we experiment to see how models perform in handling new hashtags. To this end, we additionally collect instances tagged with hashtags absent in training data and construct an external test set, with the same size as our original test set. Considering that classifiers will never predict unseen labels, to ensure comparable performance, we only adopt summarization metrics here for evaluation and report ROUGE-1 F1 scores in Table 5.

As can be seen, creating unseen hashtags is a challenging task, where unsurprisingly, all models perform poorly on this task. Nevertheless, sequence generation models perform much better on both datasets, e.g., at least 6.5x improvements over classification models observed on Weibo dataset. For Twitter dataset, the improvements are not that large, which confirms again that hashtag annotation on Twitter is more difficult due to the noisier data characteristics. In particular, compared to SEQ2SEQ, OUR MODEL achieves an additional performance gain in producing new hashtags by leveraging conversations with the bi-attention.

Model	**Twitter**	**Weibo**
CLASSIFIER (*post only*)	1.15	1.65
CLASSIFIER (*post+conv*)	1.13	1.52
SEQ2SEQ	1.33	10.84
OUR MODEL	**1.48**	**12.55**

Table 5: ROUGE-1 F1 scores (%) in producing unseen hashtags. Best results are in bold.

4.3 Further Discussions on Our Model

To further analyze our model, we conduct a quantitative ablation study, a qualitative case study, and an error analysis. We then discuss them in turn.

Ablation Study. We report the ablation study results in Table 6 to examine the relative contributions of the target posts and the conversation contexts. To this end, our model is compared with its five variants below: Seq2Seq (*post only*), Seq2Seq (*conv only*), and Seq2Seq (*post+conv*), using standard seq2seq to generate hashtags from their target posts, conversation contexts, and their concatenation, respectively; Our model (*post-att only*) and Our model (*conv-att only*), whose decoder only takes $\mathbf{v}^p$ and $\mathbf{v}^c$ defined in Eq. (5) and Eq. (6), respectively. The results show that solely encoding target posts is more effective than modeling the conversations alone, but exploring their joint effects can further boost the performance, especially combined with a bi-attention mechanism over them.

Model	Twitter	Weibo
Seq2Seq (*post only*)	10.44	26.00
Seq2Seq (*conv only*)	6.27	18.57
Seq2Seq (*post + conv*)	11.24	29.85
Our model (*post-att only*)	11.18	28.67
Our model (*conv-att only*)	10.61	28.06
Our model (*full*)	**12.29**	**31.96**

Table 6: F1@1 scores (%) for our variants.

Case Study. We further present a case study on the target post shown in Table 1, where the top five outputs of some comparison models are displayed in Table 7. As can be seen, only our model successfully generates "*aus open*", the gold standard. Particularly, it not only ranks the correct answer as the top prediction, but also outputs other semantically similar hashtags, e.g., sport-related terms like "*bbc football*", "*arsenal*", and "*murray*". On the contrary, Classifier and Seq2Seq tend to yield frequent hashtags, such as "*just saying*" and "*jan 25*". Baseline models also perform poorly: LDA produces some common single word, and TF-IDF extracts phrases in the target post, where the gold-standard hashtag is however absent.

Model	Top five outputs
LDA	found; stated; excited; card; apparently
TF-IDF	inappropes; umpire; woman need; azarenka woman; the umpire
Classifier	fail; facebook; just saying; quote; pro choice
Seq2Seq	fail; jan 25; yr; eastenders; facebook
Our model	***aus open*** ; bbc football ; bbc aus ; arsenal ; murray

Table 7: Model outputs for the target post in Table 1. "*aus open*" matches the gold-standard hashtag.

To analyze why our model obtains superior results in this case, we display the heatmap in Figure 4 to visualize our bi-attention weight matrix $\mathbf{W}_{bi-att}$. As we can see, bi-attention can identify the indicative word "*Azarenka*" in the target post, via highlighting its other pertinent words in conversations, e.g., "*Nadal*" and "*tennis*". In doing so, salient words in both the post and its conversations can be unveiled, facilitating the correct hashtag "*aus open*" to be generated.

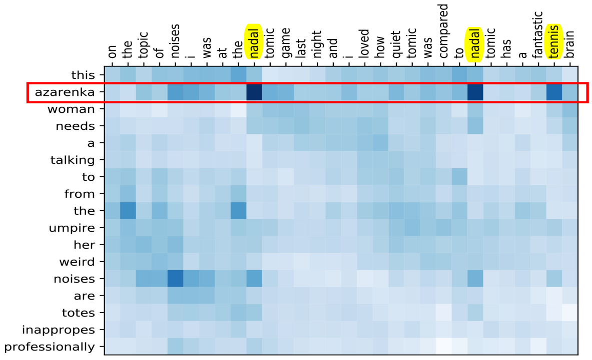

Figure 4: Visualization of bi-attention given the input case in Table 1. The horizontal axis denotes a snippet of a truncated conversation. The vertical axis shows the target post. Salient words are highlighted.

Error Analysis. Taking a closer look at our outputs, we find that one type of major errors comes from the unmatched outputs with gold standards, even as a close guess. For example, our model predicts "*super bowl*" for a post tagged with "*#steelers*", a team in super bowl. In future work, the semantic similarity should be considered in hashtag evaluation. Another primary type of error is caused by the non-topic hashtags, such as "*#fb*" (indicating the messages forwarded from Facebook). Such non-topic hashtags cannot reflect any content information from target posts and should be distinguished from topic hashtags in the future.

5 Related Work

Our work mainly builds on two streams of previous work — microblog hashtag annotation and neural language generation.

We are in the line of microblog hashtag annotation. Some prior work extracts phrases from target posts with sequence tagging models (Zhang et al., 2016, 2018). Another popular approach is to apply classifiers and select hashtags from a candidate list (Heymann et al., 2008; Weston et al., 2014; Sedhai and Sun, 2014; Gong and Zhang, 2016;

Huang et al., 2016; Zhang et al., 2017). Unlike them, we generate hashtags with a language generation framework, where hashtags in neither the target posts nor the pre-defined candidate list can be created. Topic models are also widely applied to induce topic words as hashtags (Krestel et al., 2009; Ding et al., 2012; Godin et al., 2013; Gong et al., 2015; Zhang et al., 2016). However, these models are usually unable to produce phrase-level hashtags, which can be achieved by ours via generating hashtag word sequences with a decoder.

Our work is also closely related to neural language generation, where the encoder-decoder framework (Sutskever et al., 2014) acts as a springboard for many sequence generation models. In particular, we are inspired by the keyphrase generation studies for scientific articles (Meng et al., 2017; Ye and Wang, 2018; Chen et al., 2018, 2019), incorporating word extraction and generation using a seq2seq model with copy mechanism. However, our hashtag generation task is inherently different from theirs. As we can see from Table 4, it is suboptimal to directly apply keyphrase generation models on our data. The reason mostly lies in the informal language style of microblog users in writing both target posts and their hashtags. To adapt our model on microblog data, we explore the effects of conversation contexts on hashtag generation, which has never been studied in any prior work before.

6 Conclusion

We have presented a novel framework of hashtag generation via jointly modeling of target posts and conversation contexts. To this end, we have proposed a neural seq2seq model with bi-attention over a dual encoder for capturing indicative representations from the two sources. Experimental results on two newly collected datasets have demonstrated that our proposed model significantly outperforms existing state-of-the-art models. Further studies have shown that our model can effectively generate rare and even unseen hashtags.

Abstract

Visual modifications to text are often used to obfuscate offensive comments in social media (e.g., "!d10t") or as a writing style ("1337" in "leet speak"), among other scenarios. We consider this as a new type of adversarial attack in NLP, a setting to which humans are very robust, as our experiments with both simple and more difficult visual perturbations demonstrate. We investigate the impact of visual adversarial attacks on current NLP systems on character-, word-, and sentence-level tasks, showing that both neural and non-neural models are, in contrast to humans, extremely sensitive to such attacks, suffering performance decreases of up to 82%. We then explore three shielding methods—visual character embeddings, adversarial training, and rule-based recovery—which substantially improve the robustness of the models. However, the shielding methods still fall behind performances achieved in non-attack scenarios, which demonstrates the difficulty of dealing with visual attacks.

1 Introduction

For humans, visual similarity can play a decisive role for assessing the meaning of characters. Some evidence for these are: the frequent swapping of similar looking characters in Internet slang or abusive comments, creative trademark logos, and attack scenarios such as domain name spoofing (see examples in Table 1).

Internet slang writing style	n00b, w!k!p3d!4, 1337
Toxic comments	pi§§, ṇiggers, ḟucking
Trademark logos/artwork	SΛMSUNG
Domain name spoofing	http://wíkipedia.org

Table 1: Examples of text in which characters have been changed to visually similar ones.

Recently, some NLP systems have exploited visual features to capture visual relationships among characters in compositional writing systems such as Chinese or Korean (Liu et al., 2017). However, in more general cases, current neural NLP systems have no built-in notion of visual character similarity. Rather, they either treat characters as discrete units forming a word or they represent characters by randomly initialized embeddings and update them during training—typically in order to generate a character-based word representation that is robust to morphological variation or spelling mistakes (Ma and Hovy, 2016). Intriguingly, this marked distinction between human and machine processing can be exploited as a blind spot of NLP systems. For example, spammers might send malicious emails or post toxic comments to online discussion forums (Hosseini et al., 2017) by visually 'perturbing' the input text in such a way that it is still easily recoverable by humans.

The issue of exposing and addressing the weaknesses of deep learning models to *adversarial inputs*, i.e., perturbed versions of original input samples, has recently received considerable attention. For instance, Goodfellow et al. (2015) showed that small perturbations in the pixels of an image can mislead a neural classifier to predict an incorrect label for the image. In NLP, Jia and Liang (2017) inserted grammatically correct but semantically irrelevant paragraphs to stories to fool neural reading comprehension models. Singh et al. (2018) showed significant drops in the performance of neural models for question answering when using simple paraphrases of the original questions.

Unlike previous NLP attack scenarios, visual attacks, i.e., the exchange of characters in the input with visually similar alternatives, have the following 'advantages': 1) They do not require *any* linguistic knowledge beyond the character level, making the attacks straightforwardly applicable across languages, domains, and tasks. 2) They are al-

Proceedings of NAACL-HLT 2019, pages 1634–1647
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

legedly less damaging to human perception and understanding than, e.g., syntax errors or the insertion of negations (Hosseini et al., 2017). 3) They do not require knowledge of the attacked model's parameters or loss function (Ebrahimi et al., 2018).

In this work, we investigate to what extent recent state-of-the-art (SOTA) deep learning models are sensitive to visual attacks and explore various shielding techniques. Our contributions are:

- We introduce VIPER, a Visual Perturber that randomly replaces characters in the input with their visual nearest neighbors in a visual embedding space.
- We show that the performance of SOTA deep learning models substantially drops for various NLP tasks when attacked by VIPER. On individual tasks (e.g., Chunking) and attack scenarios, our observed drops are up to 82%.
- We show that, in contrast to NLP systems, humans are only mildly or not at all affected by visual perturbations.
- We explore three methods to shield from visual attacks, *viz.*, visual character embeddings, adversarial training (Goodfellow et al., 2015), and rule-based recovery. We quantify to which degree and in which circumstances these are helpful.

We point out that integrating visual knowledge with deep learning systems, as our visual character embeddings do, aims to make NLP models behave more like humans by taking cues directly from sensory information such as vision.[1]

2 Related Work

Our work connects to two strands of literature: adversarial attacks and visually informed character embeddings.

Adversarial Attacks are modifications to a classifier's input, that are designed to fool the system into making an incorrect decision, while the original meaning is still understood by a human observer. Different forms of attacks have been studied in NLP and computer vision (CV), including at a character, syntactic, semantic and, in CV, the visual level. Ebrahimi et al. (2018) propose a character flipping algorithm to generate adversarial examples and use it to trick a character-level neural classifier. They show that the accuracy decreases significantly after a few manipulations if certain characters are swapped. Their character flipping approach requires very strong knowledge in the form of the attacked networks' gradients in a so-called white box attack setup. Chen et al. (2018) find that reading comprehension systems often ignore important question terms, thus giving incorrect answers when these terms are replaced. Belinkov and Bisk (2018) show that neural machine translation systems break for all kinds of noise to which humans are robust, such as reordering characters in words, keyboard typos and spelling mistakes. Alzantot et al. (2018) replace words by synonyms to fool text classifiers. Iyyer et al. (2018) reorder sentences syntactically to generate adversarial examples.

In contrast to those related works which perform attacks on the character level, our attacks allow perturbation of any character in a word while potentially minimizing impairment for humans. For example, the strongest attack in Belinkov and Bisk (2018) is random shuffling of all characters, which is much more difficult to restore for humans.

To cope with adversarial attacks, *adversarial training* (Goodfellow et al., 2015) has been proposed as a standard remedy in which training data is augmented with data that is similar to the data used to attack the neural classifiers. Rodriguez and Rojas-Galeano (2018) propose simple rule-based corrections to address a limited number of attacks, including obfuscation (e.g., "idiots" to "!d10ts") and negation (e.g., "idiots" to "NOT idiots"). Most other approaches have been explored in the context of CV, such as adding a stability objective during training (Zheng et al., 2016) and distillation (Papernot et al., 2016). However, methods to increase the robustness in CV have been shown to be less effective against more sophisticated attacks (Carlini and Wagner, 2017).

Visual Character Embeddings were originally proposed to address large character vocabularies in 'compositional' languages like Chinese and Japanese. Shimada et al. (2016) and Dai and Cai (2017) employ a convolutional autoencoder to generate image-based character embeddings (ICE) for Japanese and Chinese text and show improvement on author and publisher identification tasks. Similarly, Liu et al. (2017) create ICEs from a CNN and show that ICEs carry more semantic content and are more suitable for rare characters. However,

---

[1] Code and data available from `https://github.com/UKPLab/naacl2019-like-humans-visual-attacks`

existing work on visual character embeddings has not used visual information to attack NLP systems or to them.

3 Approach

To investigate the effects of visual attacks and propose methods for shielding, we introduce 1) a visual text perturber, 2) three character embedding spaces, and 3) methods for obtaining word embeddings from character embeddings, used as input representations in some of our experiments.

3.1 Text perturbations

Our visual perturber VIPER disturbs an input text in such a way that (ideally) it is still readable by humans but causes NLP systems to fail blatantly. We parametrize VIPER by a probability p and a character embedding space, CES:[2] For each character c in the input text a flip decision is made (i.i.d. Bernoulli distributed with probability p), and if a replacement takes place, one of up to 20 nearest neighbors in the CES is chosen.[3] Thus, we denote VIPER as taking two arguments:

$$\mathsf{VIPER} = \mathsf{VIPER}(p, \mathrm{CES}).$$

Note that VIPER is a black-box attacker as it does not require any knowledge of the attacked system. It would also be possible to design a more intelligent perturber that only disturbs content words (or "hot" words), similar to Ebrahimi et al. (2018), but this would increase the difficulty for realizing VIPER as a black-box attacker because different types of hot words may be relevant for different tasks.

3.2 Character Embeddings

We consider three different character embedding spaces. The first is continuous, assigning each character a dense 576 dimensional representation, which allows, e.g., for computing cosine similarities between any two characters as well as nearest neighbors for each input character. The other two are discrete and merely used as arguments to VIPER. Thus, they are only required to specify nearest neighbors for standard input characters. For them, each character c in a selected range (e.g., standard English alphabet a-zA-Z) is assigned a set of nearest neighbors, and all nearest neighbors are equidistant to c. All three CES carry visual information, i.e., nearest neighbors are visually similar to the character in question. For practical reasons, we limit all our perturbations to the first 30k Unicode characters throughout.

Image-based character embedding space (ICES) provides a continuous image-based character embedding (ICE) for each Unicode character. We retrieve a 24×24 image representation of the character (using Python's PIL library), then stack the rows of this matrix (with entries between 0 and 255) to form a $24 \cdot 24 = 576$ dimensional embedding vector.

Description-based character embedding space (DCES) is based on the textual descriptions of Unicode characters. We first obtain descriptions of each character from the Unicode 11.0.0 final names list (e.g., LATIN SMALL LETTER A for the character 'a'). Then we determine a set of nearest neighbors by choosing all characters whose descriptions refer to the same letter in the same case, e.g., an alternative to LATIN SMALL LETTER A is LATIN SMALL LETTER A WITH GRAVE as it contains the keywords SMALL and A.

Easy character embedding space (ECES) provides manually selected simple visual perturbations. It contains exactly one nearest neighbor for each of the 52 characters a-zA-Z, chosen as a diacritic below or above a character, such as $\hat{c}$ for the character c.

Differences between the CESs The three embedding spaces play different roles in our experiments. We use ICES as character representations in deep learning systems. DCES and ECES are used as input to VIPER to perturb our test data.[4] ECES models a 'minimal perturbance with maximal impact' scenario: we assume that ECES perturbations do not or only minimally affect human perception but may still have a large impact upon NLP systems. Indeed, we could have chosen an even simpler embedding space, e.g., by considering visually identical characters in different alphabets, such as the Cyrillic 'a' (Unicode 1072) for a Latin 'a' (Unicode 97). DCES is a more difficult

---

[2] CES may be any 'embedding space' that can be used to identify the nearest neighbors of characters.

[3] The probability of choosing one of the 20 neighbors of c is proportional to its distance to c.

[4] We do not attack with ICES because we also shield with ICES and this would be a (very unrealistic) white box defense scenario. Besides, ICES is also more difficult to restore for humans (see below), making it less desirable for an attacker.

test-bed designed for evaluating our approaches under more realistic conditions with more varied and stronger attacks.

Table 2 exemplifies the differences between ICES, DCES, and ECES by comparing the nearest neighbors of a given character. As expected, ICES contains neighbors of characters which are merely visually similar without representing the same underlying character (such as Λ as a neighbor of A, or ı as a neighbor of i). In contrast, DCES sometimes has neighbors with considerable visual dissimilarity to the original character such as Cyrillic small letter i (и) which rather resembles a mirror-inverted n. The overlap between ICES and DCES is modest: out of 20 neighbors, a character has on average only four to five common neighbors in ICES and DCES.

3.3 Word Embeddings

Most neural NLP architectures encode text either on a character or word level. For the latter, word embeddings are needed. In this work, we use the ELMo architecture (Peters et al., 2018) to obtain (contextualized) word embeddings based on characters, i.e., there exists no fixed vocabulary and there will be no (word-level) out-of-vocabulary issues due to perturbation. In the following, we outline our ELMo variant and a visual extension that includes visual signals from the input characters.

SELMo: ELMo as proposed by Peters et al. (2018) first retrieves embeddings for every character in the input, which are learned as part of the network. ELMo then infers non-contextualized word embeddings by applying CNNs over all character embeddings in a word. Two layers of a deep bidirectional language model further process the word embeddings in their local sentential context and output contextualized word embeddings.

We slightly extend ELMo to include character embeddings for the first 30k Unicode characters (instead of the default 256). We call this variant SELMo ("Standard ELMo"). It is worth pointing out that the learned character embeddings of SELMo carry almost no visual information, as illustrated in Table 2. That is, except for a few very standard cases, nearest neighbors of characters do not visually resemble the orginal characters, even when trained on the 1 billion word benchmark (Chelba et al., 2013).[5]

VELMo: To obtain a visually informed variant of ELMo, we replace learned character embeddings with the ICEs and keep the character embeddings fixed during training. This means that during training, the ELMo model learns to utilize visual features of the input, thus potentially being more robust against visual attacks. We call this variant VELMo ("Visually-informed ELMo").

To keep training times of SELMo and VELMo feasible, we use an output dimensionality of 512 instead of the original ELMo's 1024d output. Our detailed hyperparameter setup is given in §A.1.

4 Human annotation experiment

We asked 6 human annotators, university employees and students with native or near-native English language skills, to recover the original underlying English sentences given some perturbed text (data taken from the POS tagging and Chunking tasks, see Table 4). We considered different conditions:

(i) `clean`: $\mathsf{VIPER}(0,\_)$, i.e., no perturbation;
(ii) $\mathsf{VIPER}(p,\text{ICES})$ for $p = 0.2, 0.4, 0.6, 0.8$;
(iii) $\mathsf{VIPER}(p,\text{DCES})$ for $p = 0.2, 0.4, 0.6, 0.8$;
(iv) `easy`: $\mathsf{VIPER}(p,\text{ECES})$ for $p = 0.4, 0.8$.

For each condition, we used 60-120 sentences, where at most 20 sentences of one condition were given to an annotator. Examples of selected conditions are shown in Table 3. Our rationale for including this recovery task is to test robustness of human perception under (our) visual perturbations. We focus on recovery instead of an extrinsic task such as POS because the latter would have required expert/trained annotators.

We evaluate by measuring the normalized edit distance between the recovered sentence and the underlying original, averaged over all sequence pairs and all human annotators. We normalize by the maximum lengths of the two sequences. In our case, this metric can be interpreted as the fraction of characters that have been, on average, wrongly recovered by human annotators. We refer to the metric as "error rate".

Results are shown in Figure 1. In `easy`, there is almost no difference between perturbation levels $p = 0.4$ and $p = 0.8$, so we merge the two conditions.

Humans make copy mistakes even when the input is not perturbed, as evidenced by a positive

---

[5] We believe SELMo nearest neighbors are more likely to be Chinese/Japanese/Korean (CJK) characters because these nearest neighbors are largely random and there are far more CJK characters in our subset of Unicode.

error rate in `clean`. Such mistakes are typically misspellings or the wrong type of quotation marks (” vs. “). We observe a slightly higher error rate in `easy` than in `clean`. However, on average 75% of all sentences are (exactly) correctly recovered in `easy` while this number is lower (72.5%) in `clean`. By chance, `clean` contains fewer sentences with quotation marks than `easy`, for which a copy mistake was more likely. This may explain `easy`’s higher error rate.

As we increase the perturbation level, the error rate increases consistently for DCES/ICES. It is noteworthy that DCES perturbations are easier to parse for humans than ICES perturbations. We think this is because DCES perturbations always retain a variant of the same character, while ICES may also disturb one character to another character (such as *h* to *b*). Another explanation is that ICES, unlike DCES and ECES, also disturbs numbers and punctuation. Numbers, especially, are more difficult to recover. However, even at 80% disturbance level, humans can, on average, correctly recover at least 93% of all characters in the input text in all conditions.

In summary, humans appear very good at understanding visual perturbations, and are almost perfectly robust to the easy perturbations of ECES. Since adversarial attacks should have minimal impact on humans (Szegedy et al., 2014), the good performance of humans especially on ECES and DCES makes these two spaces ideal candidates for attacks on NLP systems.

5 Computational Experiments

We now evaluate the capabilities of SOTA neural network models to deal with visual attacks in four extrinsic evaluation tasks described in §5.1 and illustrated in Table 4. Hyperparameters of all our models are given in §A.2. We first examine the robustness of all architectures to visual perturbations in §5.2 and then evaluate different shielding approaches in §5.3.

5.1 Tasks

G2P: As our first task, we consider the character-level task of grapheme-to-phoneme (G2P) conversion. It consists of transcribing a character input stream into a phonetic representation. As our dataset, we choose the Combilex pronunciation dataset of American English (Richmond et al.,

Task	**Task Type**	**Input**	**Target / Label(s)**	**Train/Dev/Test**
G2P	char-lvl	ẉṙḛŧchȩđlȳ	r E < @ d 5 i	5K/1K/1K
POS	word-lvl	… exᴛȇ’nɖíng itŝ contraᶝẗ …	… VBG PRP NN …	212K/44K/47K
Chunking	word-lvl	… exᴛȇ’nɖíng itŝ contraᶝẗ …	… B-VP B-NP I-NP …	212K/44K/47K
Toxic Comments	sent-lvl	Ḟǔĉǩ ôḟḟ , yoǔ âňtî - ŝeḿîẗîĉ ĉǔňẗ .	toxic, obscene, insult	149K/10K/64K

Table 4: NLP tasks considered in this work, along with (perturbed) examples and data split statistics.

2009). We frame G2P as a sequence tagging task. To do so, we first hard-align input and output sequences using a 1-0,1-1,1-2 alignment scheme (Schnober et al., 2016) in which an input character is matched with zero, one, or two output characters. Once this preprocessing is done, input and output sequences have equal lengths and we can apply a standard BiLSTM on character-level to the aligned sequences (Reimers and Gurevych, 2017).

POS & Chunking: We consider two word-level tasks. POS tagging associates each token with its corresponding word class (e.g., *noun, adjective, verb*). Chunking groups words into syntactic chunks such as noun and verb phrases (NP and VP), assigning a unique tag to each word, which encodes the position and type of the syntactic constituent, e.g., begin-noun-phrase (B-NP). We use the training, dev and test splits provided by the CoNLL-2000 shared task (Sang and Buchholz, 2000) and use the same BiLSTM architecture as above with SELMo/VELMo embeddings.

Toxic comment (TC) classification: A very realistic use case for adversarial attacks is the toxic comment classification task. One could easily think of a scenario where a person with malicious intent explicitly aims to fool automated methods for detecting toxic comments or insults by obfuscating text with non-standard characters that are still human-readable. We conduct experiments on the TC classification task provided by Kaggle.[6] It is a multi-label sentence classification task with six classes, i.e., *toxic*, *severe toxic*, *obscene*, *threat*, *insult*, *identity hate*. We use average SELMo/VELMo embeddings as input to an MLP.

5.2 VIPER attacks

In Figure 2, we plot how various SOTA systems degrade as we perturb the test data using DCES. We do not only include our own systems, but also existing SOTA models: Marmot (Müller et al., 2013) and Stanford POS tagger (SPT) (Manning et al., 2014). Marmot is a feature-based POS tagger and trained on our data splits. SPT is a bi-directional dependency network tagger that mostly employs lexical features. For SPT, we used the pretrained English model provided by the toolkit. Further, we include a FastText TC classifier which has achieved SOTA performance.[7] We additionally experiment with word level dependency embeddings for POS tagging and TC classification (Komninos and Manandhar, 2016).

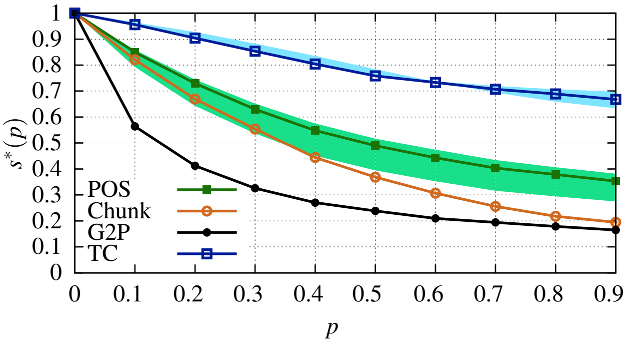

Figure 2: Degradation of SOTA systems for different perturbation levels when attacked by VIPER(p,DCES). The colored regions show how the performance of other SOTA systems relate to ours (i.e., they all suffer from similar degradation).

To compare the performance of different tasks, Figure 2 shows scores computed by:

$$s^*(p) = \frac{s(p)}{s(0)},$$

where p is the perturbation level and $s(p)$ is the score for each task at p, measured in edit distance for G2P, accuracy for POS tagging, micro-F1 for chunking, and AUCROC for TC classification. We invert the scores g of G2P by $1/g$ since lower scores are better for edit distance. Thus, $s^*(0)$ is always 1 and $s^*(p)$ is the relative performance compared to the clean case of no perturbations.

We see that all systems degrade considerably. For example, all three POS taggers have a performance of below 60% of the clean score when 40%

---

[6] https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/

[7] https://www.kaggle.com/yekenot/pooled-gru-fasttext

of the input characters are disturbed. Chunking degrades even more strongly, and G2P has the highest drop: 10% perturbation level causes a 40% performance deterioration. This may be because G2P is a character-level task and the perturbation of a single character is analogous to perturbing a complete word in the word-level tasks. Finally, TC classification degrades least, i.e., only at $p = 0.9$ do we see a degradation of 30% relative to the clean score. These results appear to suggest that character-level tasks suffer the most from our VIPER attacks and sentence-level tasks the least. However, it is worthwhile pointing out that lower-bounds for individual tasks may depend on the evaluation metric (e.g., AUCROC always yields 0.5 for majority class voting) as well as task-specific idiosyncrasies such as the size of the label space.

We note that the degradation curves look virtually identical for both DCES or ECES perturbations (given in §A.3). This is in stark contrast to human performance, where ECES was much easier to parse than DCES, indicating the discrepancies between human and machine text processing.

5.3 Shielding

We study four forms of shielding against VIPER attacks: adversarial training (**AT**), visual character embeddings (**CE**), **AT+CE**, and rule-based recovery (**RBR**). For **AT**, we include visually perturbed data at train time. We do not augment the training data, but replace clean examples using VIPER in the same way as for the test data. Based on preliminary experiments with the G2P task, we apply VIPER to the training data using $p_{\text{train}} = 0.2$. Higher levels of p_{train} did not appear to improve performance. For **CE**, we use fixed ICEs, either fed directly into a model (G2P) or via VELMo (all other tasks). For **AT+CE**, we combine adversarial training with visual embeddings. Finally, for **RBR**, we replace each non-standard character in the input stream with its nearest standard neighbor in ICES, where we define the standard character set as a-zA-Z plus punctuation.

Rather than absolute scores, we report differences between the scores in one of the shielding treatments and original scores:

$$\Delta_\tau := \sigma^*(p) - s^*(p), \quad \sigma^*(p) := \sigma(p)/s(0)$$

where $\sigma(p)$ is the score for each task using a form of shielding. The value Δ_τ denotes the improvement of the scores from shielding method τ over the original scores without shielding. We normalize $\sigma(p)$ by the score $s(0)$ of the systems without shielding on clean data. We also note that our test perturbations are unseen during training for DCES; for ECES this would not make sense, because each character has only one nearest neighbor. In the following, we report results mostly for DCES and show the ECES results in §A.3. We highlight marked differences between the results, however.

All tasks typically profit considerably from **AT** (Figure 3 left). Chunking scores improve most; e.g., at $p = 0.5$, σ^* is 17 percent points (pp) higher than s^*. AT does not help for G2P in the DCES setting but it does help for ECES (see §A.3), where test perturbations may have been seen during training. We conjecture that AT makes systems generally aware that the input can be broken in some way and forces them to shield against such situations, an effect similar to dropout. However, such shielding appears more difficult in character-level tasks, where a missing token is considerably more damaging than in word- or sentence-level tasks.

In Figure 3 (right), we observe that **CE** helps a lot for G2P, but much less particularly for POS and Chunking. We believe that for G2P, the visual character embeddings restore part of the input and thus have considerable effect. It is surprising, however, that visual embeddings have no positive effect for both word-level tasks, and instead lead to small deteriorations. A possible explanation is that, as the character embeddings are fed into the ELMo architecture, their effect is dampened. Indeed, we performed a sanity check (see §A.5) to test how (cosine) similar a word or sentence w is to a perturbed version w' of w under both SELMo and VELMo. We found that VELMo assigns consistently better similarities but the overall gap is small.

We observe that the combined effect of AT and CE (**AT+CE**, Figure 4 left) is always substantially better than either of the two alone. For instance, at $p = 0.5$, POS improves by about 20pp, while AT alone had an effect of only 12pp and the effect of CE was even negative. Thus, it appears that AT is able to kick-start the benefits of CE, especially in the case when they alone are not effective.

RBR is excellent for ECES (see §A.3). It has a small negative effect on clean data, meaning that there is some foreign material in English texts which gets corrupted by RBR, but for any $p > 0$ the performance under RBR is almost on the level of $p = 0$ for ECES. RBR is also consistently better

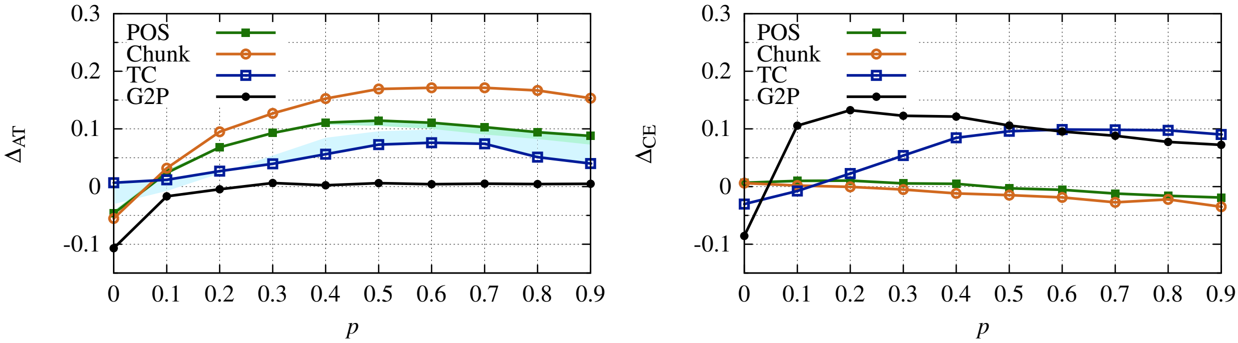

Figure 3: AT (with ICES replacements) and CE tested on DCES perturbed data. The colored regions show AT (with random replacements).

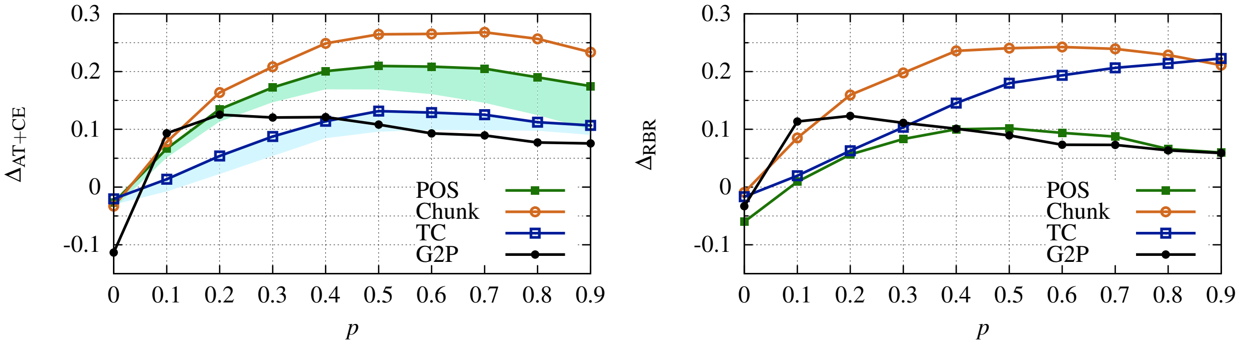

Figure 4: AT+CE (with ICES replacements) and RBR on DCES perturbed data. The colored regions show AT (with random replacements).

than CE, even though both depend on ICES: CE in a 'soft' way and RBR in a 'hard' way. Our best explanation is that RBR is analogous to 'machine translating' a foreign text into English and then applying a trained classifier, while CE is analogous to a direct transfer approach (McDonald et al., 2011) which trains in one domain and is then applied to another. This causes a form of domain shift to which neural nets are quite vulnerable (Ruder and Plank, 2018; Eger et al., 2018a).

For DCES, RBR is outperformed by AT+CE, which better mitigates the domain shift than CE, except for TC.

We note that even with all our shielding approaches, the performance of the shielded systems is still considerably below the performance on clean data at some perturbation levels. E.g., at $p = 0.9$, AT+CE shielded Chunking has a score of less than 60% of the clean performance. While it may be partially due to our character embeddings not being optimal (i.e., they assign low similarity to major and minor variants of the same letter such as ˢ and s, which could be improved by size-invariant CNNs), a main reason for this could be the domain-shift induced by the perturbations, for which even AT cannot always help when attacks are unseen during training. This is another major distinction between human and machine processing.

6 Discussion

Random AT. We discussed that the effect of AT may be similar to dropout. If so, AT with random rather than visual character replacements should be similarly effective. Indeed, the graphs in Figures 3 and 4 show that injecting random noise generally improves the robustness, but not to the level of visually informed AT (exemplarily for POS/TC).

Error analysis. We analyze the cases in which our perturbation with VIPER changes the prediction to a wrong class. We perform our analysis for TC as it represents a real-world attack scenario. We define the *toxicity level* (TL) of a comment x for a class $y \in \{1,\ldots,6\}$ and model θ as $\text{TL}(x) = \sum_y \theta(x,y)$, e.g., a comment x which has been classified as *insult* (probability 0.8) and *obscene* (probability 0.7) gets a TL of 1.5. We consider a successful attack to decrease TL after perturbation. VIPER with DCES and $p = 0.1$ achieves a success rate of 24.1%—i.e., roughly one fourth of the *toxic* comments receive a lower TL. In contrast, the

Perturbation (CES)	Perturbed Text	Toxicity Level	No Shielding	AT	CE	AT+CE	RBR
clean	u are a gigantic faggot	4.00	3.29	3.16	2.93	3.11	3.57
VIPER(p, ECES)	u are â gigantic faggoẗ	4.00	0.11	1.05	1.37	2.05	3.57

clean	he is also a faggot .	4.00	3.26	3.68	2.81	2.14	3.79
VIPER(p, ECES)	ĥe is also a faggot .	4.00	3.39	3.70	2.64	2.23	3.79
VIPER(p, DCES)	he is alşo a fagᶢof .	4.00	0.48	1.48	1.55	1.78	0.40

Table 5: Two examples of toxic/non-toxic comments that show the effects of the different shielding methods. We report the averaged sum over the six toxicity classes, e.g., 4.00 is equal to a positive example in four classes. $p = 0.1$.

impact on *non-toxic* comments is small—TL increased in only 3.2% of the cases.

Table 5 shows sample comments and their TL for different shielding and perturbation methods. As can be seen, perturbing specific words (*hot words* for TC) substantially reduces the TL score of a non-shielded approach (e.g., from 3.29 to 0.11), while perturbing 'non-hot' words like 'he' has little effect. The shielding approaches help in these show-cased examples to various degrees and the shielding with AT+CE is more robust to stronger attacks (higher visual dissimilarity) than RBR.

This illustrates that a malicious attacker may aim to increase the success rate of an attack by only perturbing offensive words (in the TC task). To test whether VIPER benefits from perturbing such hot words, we manually compiled a list of 20 hand-selected offensive words (see §A.6) which we believe are indicators of toxic comments. We then analyzed how often a perturbation of a word from this list co-occurs with a successful attack. We observe that in 55% of successful attacks, a word from our list was among the perturbed words of the comment. As our list is only a small subset of all possible offensive words, the perturbation of hot words may have an even stronger effect.

7 Conclusion

In this work, we considered visual modifications to text as a new type of adversarial attack in NLP and we showed that humans are able to reliably recover visually perturbed text. In a number of experiments on character-, word-, and sentence-level, we highlighted the fundamental differences between humans and state-of-the-art NLP systems, which sometimes blatantly fail under visual attack, showing that visual adversarial attacks can have maximum impact. This calls for models that have richer biases than current paradigm types do, which would allow them to bridge the gaps in information processing between humans and machines. We have explored one such bias, visual encoding, but our results suggest that further work on such shielding is necessary in the future.

Our work is also important for system builders, such as of toxic comment detection models deployed by, e.g., Facebook and Twitter, who regularly face visual attacks, and who might face even more such attacks once visual character perturbations are easier to insert than via the keyboard. From the opposite viewpoint, VIPER may help users retain privacy in online engagements and when trying to avoid censorship (Hiruncharoenvate et al., 2015) by suggesting visually similar spellings of words.

Finally, our work shows that the 'brittleness' (Belinkov and Bisk, 2018) of NLP extends beyond MT and beyond word reordering or replacements, a recognition that we hope inspires others to investigate more ubiquitous shielding techniques.

A Appendices

A.1 SELMo and VELMo Hyperparameters

Differences to the original ELMo as in (Peters et al., 2018) are:

- We exclude CNN filters of size 6 and 7.
- The maximum characters per token is 20 (instead of 50).
- The LSTM dimensionality is 2048 (instead of 4096).
- Our projection dimensionality is 256 (instead of 512).
- We train the models for 5 epochs (instead of training it for 10 epochs).

A.2 Task Settings

G2P: We randomly draw most hyperparameters for the sequence tagging BiLSTM architecture (Reimers and Gurevych, 2017) that we use for G2P, e.g., those concerning the optimizer used, learning and dropout rates. We hand-set the number of hidden recurrent layers to 1, and its size to 50. We use early stopping and set the maximum number of epochs for training to 50. As our dataset, we choose the Combilex pronunciation dataset of American English (Richmond et al., 2009). We randomly draw our train/dev/test splits from the whole corpus. Examples and split sizes are given in Table 4. We report **edit distance** between desired pronunciations and predicted pronunciations as metric. We report the edit distance averaged across all 1k test strings, averaged over 5 random initializations of all weight matrices.

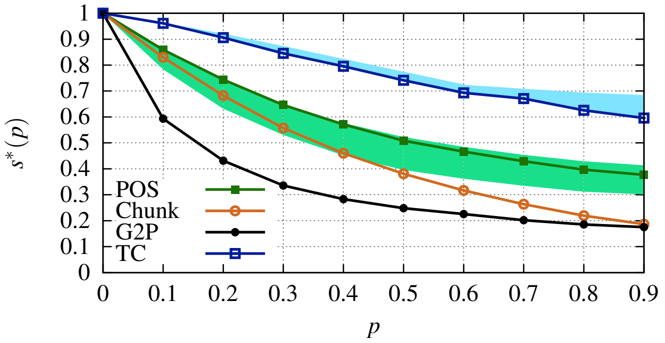

Figure 5: Degradation of SOTA systems for different perturbation levels when attacked by VIPER(p,ECES). The colored regions show how the performance of other SOTA systems relate to ours.

POS & Chunking: We use the training, dev and test splits provided by the CoNLL-2000 shared task (Sang and Buchholz, 2000) for both tasks. We have used a readily available LSTM-CRF sequence tagger (Reimers and Gurevych, 2017) as above, but adapted for ELMo-type input embeddings, with default hyperparameter settings. We run each experimental setting 10 times, and report the average, measured as **accuracy** for POS and **micro-F1** for Chunking. For both tasks, we have used two stacked BiLSTM-layers with 100 recurrent units and dropout probability of 0.5. Mini-batch size is chosen as 32. We used gradient clipping and early stopping to prevent overfitting. Adam is used as the optimizer.

Toxic comment classification: We use the train and test splits provided by the task organizers. For tuning our models, we split off a development set of 10k sentences from the training data. As in POS&Chunking, we train models on clean and perturbed data using SELMo and VELMo representations. We obtain the sentence representation for a single sentence by averaging ELMo word embeddings over all tokens. We then train an MLP which we tune separately for each SELMo and VELMo embedding using random grid search with 100 different configurations. We tune the following hyperparameters separately for each hidden layer: the depth of the neural network, i.e., one, two, or three hidden layers; the size of the hidden layer (128, 256, 512, or 1024); the amount of dropout after each layer (0.1 - 0.5); the activation functions for each hidden layer (*tanh*, *sigmoid*, or *relu*) (Eger et al., 2018b). Both models are trained for 100 epochs with an early stopping after 10 epochs without any substantial improvement and use Nesterov-accelerated Adaptive Moment Estimation (Dozat, 2016) for optimization. Model performance is measured as proposed by the task organizers using the *area under the receiver operating characteristics curve* (**AUCROC**).

A.3 ECES Results

Figure 5 shows how the performances of various SOTA systems degrade on ECES settings. Figures 6 and 7 show our shielding results on ECES perturbed data. As indicated in the main paper, RBR is able to recover ECES data almost perfectly regardless of the perturbation level. This is because ECES only perturbs with a single nearest neighbor, which in addition is visually extremely similar to the underlying original, and thus, RBR can almost completely undo the perturbations.

A.4 AT+CE *vs.* AT or CE

Figure 8 compares AT+CE against either AT or CE. For this, we compute the difference in the performance decrease normalized by the test performance on the clean data. As can be seen, AT+CE almost constantly outperforms either one of both, especially on word- and sentence-level tasks.

A.5 Intrinsic Evaluation

To analyze the differences between VELMo and SELMo, we investigate whether the models learn similar word embeddings for a clean sentence and its visually perturbed counterpart. We compare sentence embeddings which we obtain by averaging over the SELMo or VELMo word embeddings of a sentence (clean or perturbed).

Setup Given a sentence embedding σ of a clean sentence and an embedding σ' of its visually perturbed counterpart, obtained by either averaging over VELMo (indicated by subscript v) or SELMo (indicated by subscript s) word embeddings, we test if the condition

$$\cos(\sigma_v, \sigma'_v) > \cos(\sigma_s, \sigma'_s) \qquad (1)$$

is met (with cos being the cosine similarity).

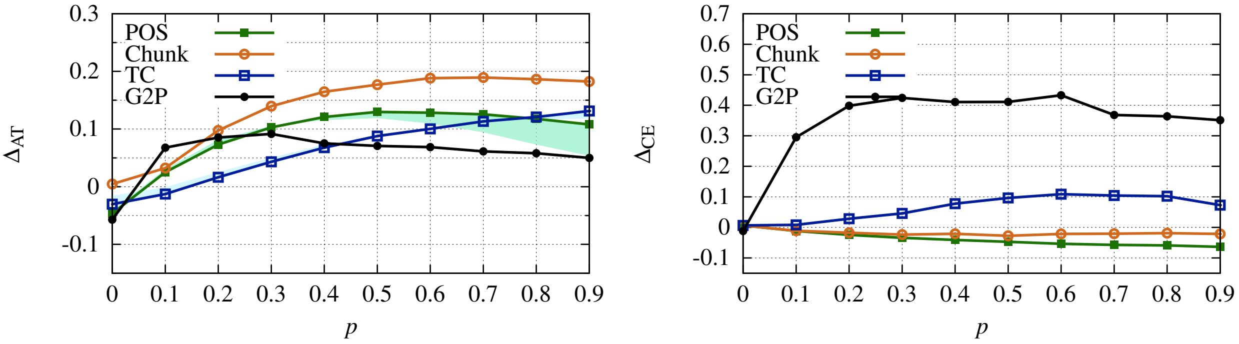

Figure 6: AT (ICES) and CE tested on ECES perturbed data. The colored regions show AT (Random). The y axis of Δ_{AT} spans -0.15-0.3 for better visualization.

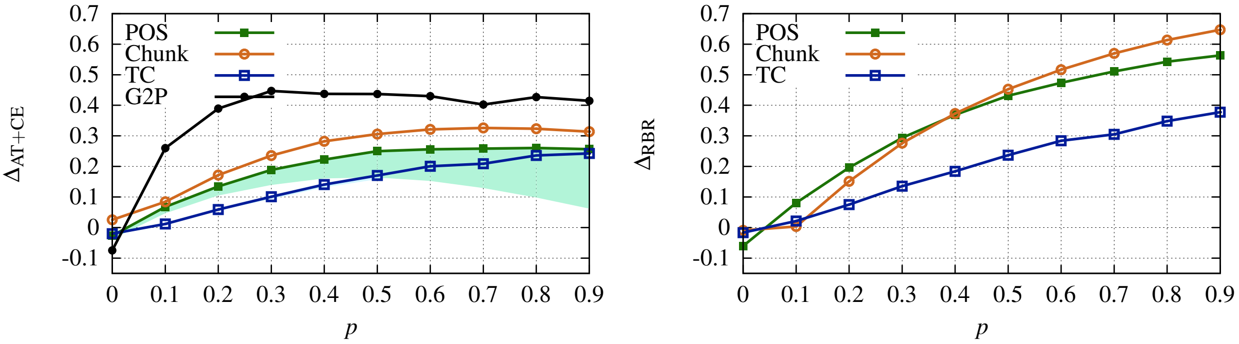

Figure 7: AT+CE (ICES) and RBR on ECES perturbed data. The colored regions show AT (Random).

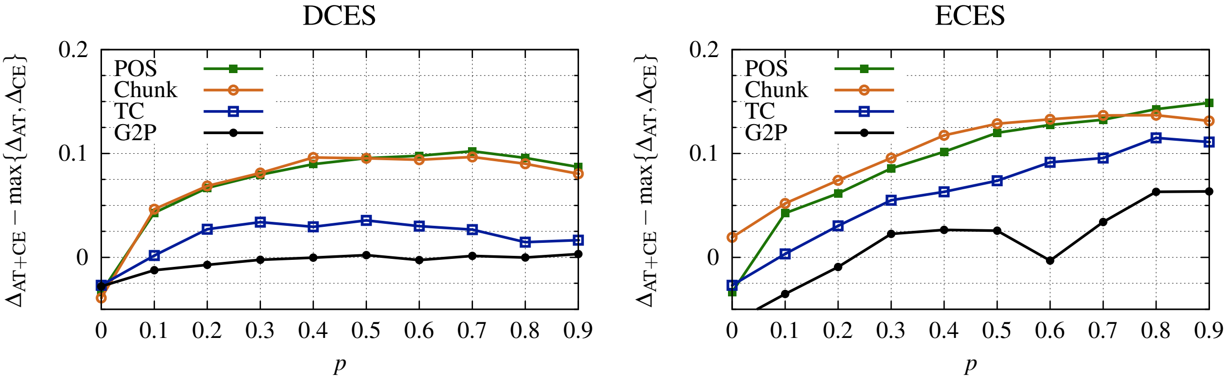

Figure 8: AT+CE (ICES) vs max(AT,CE) for DCES and ECES perturbed test data.

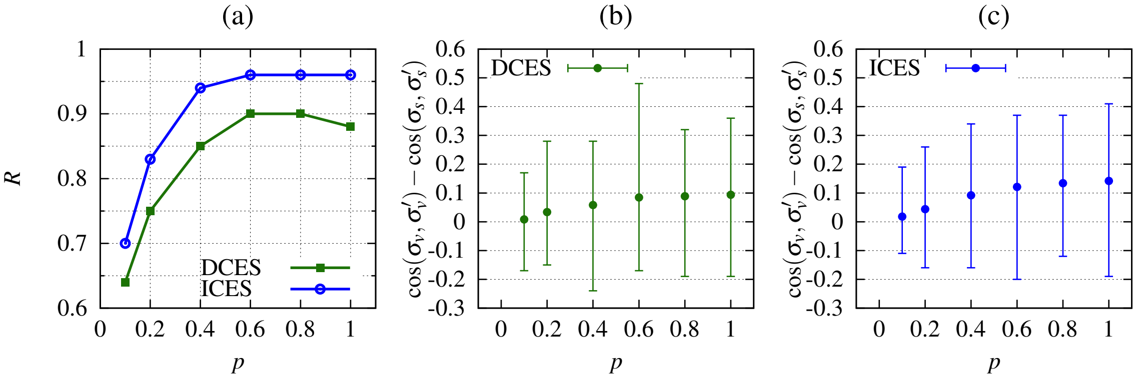

Figure 9: Results of the intrinsic evaluation. (a) shows the ratio of cases in which the condition in Eq. (1) is met (‘R’). (b) and (c) show the average difference of the cosine similarities when sentences are perturbed with (b) DCES and (c) ICES.

For our experiments, we randomly sample 1000 sentences from the Toxic Comments dataset (see §5.1) and perturb them with VIPER(p, CES) where CES $\in$ {ICES, DCES}. We then count the number N of cases in which the above condition is met with regards to the chosen CES and the value of p, and report the ratio $R = N/1000$.

Results The results are given in Figure 9. In Figure 9(a) we observe that the VELMo embeddings of a clean sentence and its perturbed counterpart are in many cases more similar than the ones of SELMo. For larger values of p, this ratio substantially increases from 70% to 95% (with ICES), which shows that VELMo is better suited to capture the similarity to the source sentence, especially in cases with a strong perturbation.

In Figures 9(b) and (c) we show the (mean) difference $\cos(\sigma_v, \sigma'_v) - \cos(\sigma_s, \sigma'_s)$. Here, we only observe a small positive effect in favor of VELMo, showing that the advantage of VELMo over SELMo is not substantial. We hypothesize that this is due to the contextual information which is utilized throughout the ELMo architecture, allowing SELMo to infer individual characters from the context of the word and the sentence. However, our results also show that the advantage of VELMo over SELMo is consistent.

Differences in similarities can also be affected by model training or the model architecture—e.g., in an extreme case a model could output the same embedding for every word/sentence. This would result in a ‘perfect’ cosine similarity, which would be advantageous in the previous experiment. Thus, we perform an additional experiment where we examine if

$$\cos(\sigma_v, \sigma'_v) > \cos(\sigma_v, \rho_v) \tag{2}$$

holds, where ρ is a randomly sampled sentence from the Toxic Comments dataset (with no perturbation). The same experiment is also performed for SELMo.

	DCES		**ICES**	
p	**VELMo**	**SELMo**	**VELMo**	**SELMo**
0.1	0.99	0.98	1.00	0.97
0.2	0.98	0.84	0.98	0.77
0.4	0.81	0.38	0.85	0.25
0.6	0.60	0.10	0.63	0.07
0.8	0.42	0.04	0.49	0.03
1.0	0.34	0.01	0.39	0.01

Table 6: Results of the intrinsic evaluation where we compare clean sentences to their perturbed counterparts as well as randomly chosen sentences. The numbers show the ratio of cases where clean sentences are more similar to their perturbed counterparts than the randomly chosen sentences.

The results in Table 6 show that for both models with $p = 0.1$ the original sentence is in 97–100% of the cases more similar to its perturbed counterpart than the randomly chosen sentence. As the perturbation probability increases, VELMo has a clear advantage over SELMo. E.g., if we perturb all characters in a sentence ($p = 1.0$), the SELMo embeddings of the perturbed sentence are in 1% of the cases more similar to the original sentence whereas this is the case for more than 34–39% for VELMo. Thus, VELMo embeddings better capture similarity between visually similar words.

A.6 List of Hand-selected Curse Words

arrogant, ass, bastard, bitch, dick, die, fag, fat, fuck, gay, hate, idiot, jerk, kill, nigg*[8], shit, stupid, suck, troll, ugly

---

[8] Due to several variations in the data, we match against *nigg** instead of the whole word.

Something's Brewing!
Early Prediction of Controversy-causing Posts from Discussion Features

Jack Hessel
Cornell University
`jhessel@cs.cornell.edu`

Lillian Lee
Cornell University
`llee@cs.cornell.edu`

Abstract

Controversial posts are those that split the preferences of a community, receiving both significant positive and significant negative feedback. Our inclusion of the word "community" here is deliberate: what is controversial to some audiences may not be so to others. Using data from several different communities on `reddit.com`, we predict the ultimate controversiality of posts, leveraging features drawn from both the textual content and the tree structure of the early comments that initiate the discussion. We find that even when only a handful of comments are available, e.g., the first 5 comments made within 15 minutes of the original post, discussion features often add predictive capacity to strong content-and-rate only baselines. Additional experiments on domain transfer suggest that conversation-structure features often generalize to other communities better than conversation-content features do.

1 Introduction

Controversial content — that which attracts both positive and negative feedback — is not necessarily a bad thing; for instance, bringing up a point that warrants spirited debate can improve community health.[1] But regardless of the nature of the controversy, detecting potentially controversial content can be useful for both community members and community moderators. Ordinary users, and in particular new users, might appreciate being warned that they need to add more nuance or qualification to their earlier posts.[2] Moderators could be alerted that the discussion ensuing from some content might need monitoring. Alternately, they could draw community attention to issues possibly needing resolution: indeed, some sites already provide explicit sorting by controversy.

We consider the controversiality of a piece of content in the context of the community in which it is shared, because what is controversial to some audiences may not be so to others (Chen and Berger, 2013; Jang et al., 2017; Basile et al., 2017). For example, we identify "break up" as a controversial concept in the relationships subreddit (a subreddit is a subcommunity hosted on the Reddit discussion site), but the same topic is associated with a *lack* of controversy in the AskWomen subreddit (where questions are posed for women to answer). Similarly, topics that are controversial in one community may simply not be discussed in another: our analysis identifies "crossfit", a type of workout, as one of the most controversial concepts in the subreddit Fitness.

However, while controversial topics may be community-specific, community moderators still may not be able to determine a priori which posts will attract controversy. Many factors cannot be known ahead of time, e.g., a fixed set of topics may not be dynamic enough to handle a sudden current event, or the specific set of users that happen to be online at a given time may react in unpredictable ways. Indeed, experiments have shown that, to a certain extent, the influence of early opinions on subsequent opinion dynamics can override the influence of an item's actual content (Salganik et al., 2006; Wu and Huberman, 2008; Muchnik et al., 2013; Weninger et al., 2015).

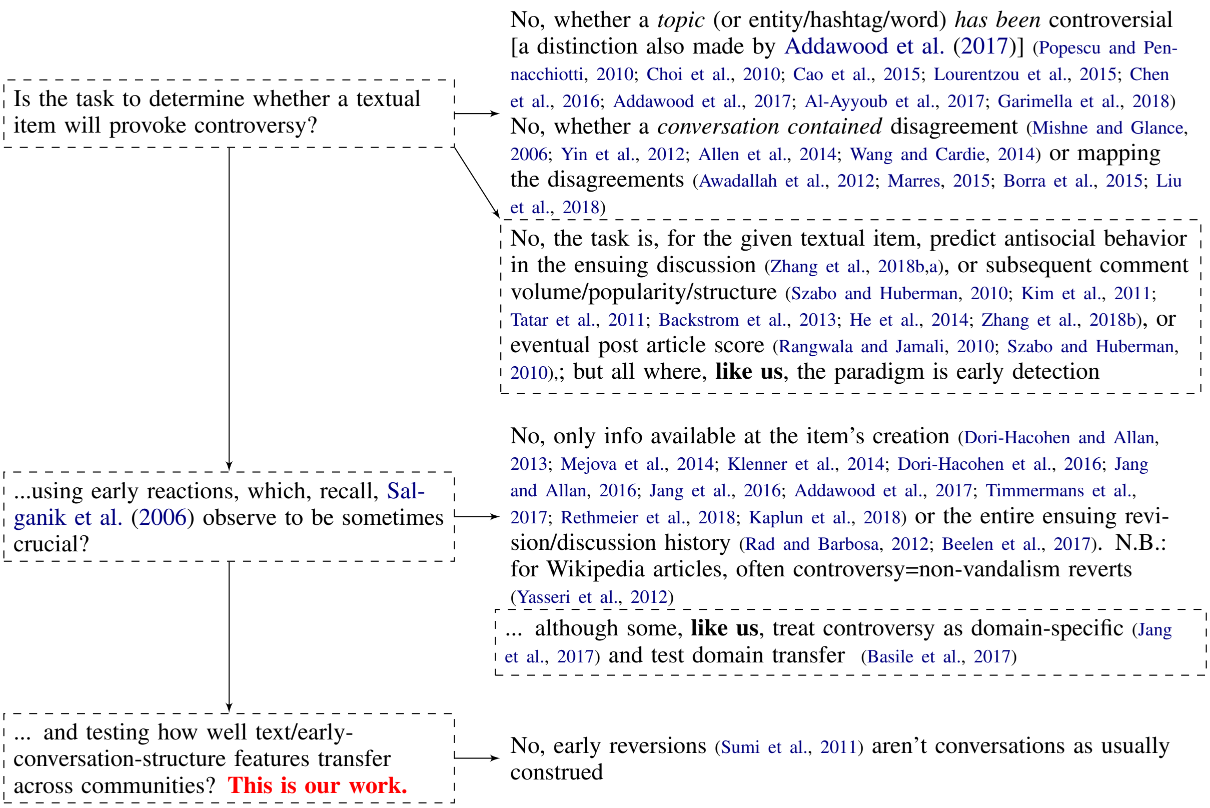
Hence, we propose an early-detection approach that uses not just the content of the initiating post, but also the content and structure of the initial responding comments. In doing so, we unite streams of heretofore mostly disjoint research programs: see Figure 1. Working with over 15,000 discus-

---

[1] Coser (1956); Jehn (1995); De Dreu and Weingart (2003) discuss how disagreement interacts with group makeup, group-task type, and outcome. Chen and Berger (2013) demonstrate a non-linear relationship between controversy and amount of subsequent discussion.

[2] We set aside the issue of *trolls* whose intent is solely to divide a community.

Proceedings of NAACL-HLT 2019, pages 1648–1659
Minneapolis, Minnesota, June 2 - June 7, 2019.



Is the task to determine whether a textual item will provoke controversy?

No, whether a *topic* (or entity/hashtag/word) *has been* controversial [a distinction also made by Addawood et al. (2017)] (Popescu and Pennacchiotti, 2010; Choi et al., 2010; Cao et al., 2015; Lourentzou et al., 2015; Chen et al., 2016; Addawood et al., 2017; Al-Ayyoub et al., 2017; Garimella et al., 2018) No, whether a *conversation contained* disagreement (Mishne and Glance, 2006; Yin et al., 2012; Allen et al., 2014; Wang and Cardie, 2014) or mapping the disagreements (Awadallah et al., 2012; Marres, 2015; Borra et al., 2015; Liu et al., 2018)

No, the task is, for the given textual item, predict antisocial behavior in the ensuing discussion (Zhang et al., 2018b,a), or subsequent comment volume/popularity/structure (Szabo and Huberman, 2010; Kim et al., 2011; Tatar et al., 2011; Backstrom et al., 2013; He et al., 2014; Zhang et al., 2018b), or eventual post article score (Rangwala and Jamali, 2010; Szabo and Huberman, 2010).; but all where, **like us**, the paradigm is early detection

...using early reactions, which, recall, Salganik et al. (2006) observe to be sometimes crucial?

No, only info available at the item's creation (Dori-Hacohen and Allan, 2013; Mejova et al., 2014; Klenner et al., 2014; Dori-Hacohen et al., 2016; Jang and Allan, 2016; Jang et al., 2016; Addawood et al., 2017; Timmermans et al., 2017; Rethmeier et al., 2018; Kaplun et al., 2018) or the entire ensuing revision/discussion history (Rad and Barbosa, 2012; Beelen et al., 2017). N.B.: for Wikipedia articles, often controversy=non-vandalism reverts (Yasseri et al., 2012)

... although some, **like us**, treat controversy as domain-specific (Jang et al., 2017) and test domain transfer (Basile et al., 2017)

... and testing how well text/early-conversation-structure features transfer across communities? **This is our work.**

No, early reversions (Sumi et al., 2011) aren't conversations as usually construed

Figure 1: How our research relates to prior work.

sion trees across six subreddits, we find that incorporating structural and textual features of budding comment trees improves predictive performance relatively quickly; for example, in one of the communities we consider, adding features taken from just the first 15 minutes of discussion significantly increases prediction performance, even though the average thread only contains 4 comments by that time ($\sim$4% of all eventual comments).

Additionally, we study feature transferability across domains (in our case, communities), training on one subreddit and testing on another. While text features of comments carry the greatest predictive capacity in-domain, we find that discussion-tree and -rate features are less brittle, transferring better between communities.

Our results not only suggest the potential usefulness of granting controversy-prediction algorithms a small observation window to gauge community feedback, but also demonstrate the utility of our expressive feature set for early discussions.

2 Datasets

Given our interest in community-specific controversiality, we draw data from `reddit.com`, which hosts several thousand discussion subcommunities (subreddits) covering a variety of interests. Our dataset, which attempts to cover all public posts and comments from Reddit's inception in 2007 until Feb. 2014, is derived from a combination of Jason Baumgartner's posts and comments sets and our own scraping efforts to fill in dataset gaps. The result is a mostly-complete set of posts alongside associated comment trees.[3] We focus on six text-based[4] subreddits ranging over a variety of styles and topics: two Q&A subreddits: AskMen (AM) and AskWomen (AW); a special-interest community, Fitness (FT); and three advice communities: LifeProTips (LT), personalfinance (PF), and relationships (RL). Each comprises tens of thousands of posts and hundreds of thousands to millions of comments.

In Reddit (similarly to other sites allowing explicit negative feedback, such as YouTube, imgur, 9gag, etc.), users can give posts *upvotes*, increas-

---

[3] Data hosted at `pushshift.io`, an open data initiative. Scraping was performed using Reddit's API or `github.com/pushshift/api`. Roughly 10% of comments and 20% of posts are deleted by users and/or moderators; also, authorship information is not available for many posts due to deletion of accounts.

[4] We ignore subreddits devoted to image sharing.

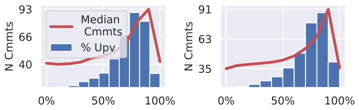
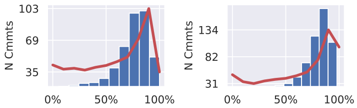
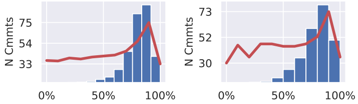
Figure 2: Examples of two controversial and one non-controversial post from three communities. Also shown are the text of the first reply, the number of comments the post received, and its percent-upvoted.



(a) AM (b) AW



(c) FT (d) LT



(e) PF (f) RL

Figure 3: For each community, a histogram of percent-upvoted and the median number of comments per bin.

ing a post's score, or *downvotes*, decreasing it.[5] While the semantics of up/down votes may vary based on community (and, indeed, each user may have their own views on what content should be upvoted and what downvoted), in aggregate, posts that split community reaction fundamentally differ from those that produce agreement. Thus, in principle, posts that have unambiguously received both many upvotes *and* many downvotes should be deemed the most controversial.

Percent Upvoted on Reddit. We quantify the relative proportion of upvotes and downvotes on a post using *percent-upvoted*, a measure provided by Reddit that gives an estimate of the percent of all votes on a post that are upvotes. In practice, exact values of percent-upvoted are not directly available; the site adds "vote fuzzing" to fight vote manipulation.[6] To begin with, we first discard posts with fewer than 30 comments.[7] Then, we query for the noisy percent-upvoted from each post ten times using the Reddit API, and take a mean to produce a final estimate.

Post Outcomes. To better understand the interplay between upvotes and downvotes, we first explore the outcomes for posts both in terms of percent-upvoted and the number of comments; doing so on a per-community basis has the potential to surface any subreddit-specific effects. In addition, we compute the median number of comments for posts falling into each bin of the histogram. The resulting plots are given in Figure 3.

In general, posts receive mostly positive feedback in aggregate, though the mean percent-upvoted varies between communities (Table 1). There is also a positive correlation between a post's percent-upvoted and the number of comments it receives. This relationship is unsurprising, given that Reddit displays higher rated posts to more users.

A null hypothesis, which we compare to empirically in our prediction experiments, is that popularity and percent-upvoted simply carry the same information. However, we have reason to doubt this null hypothesis, as quite a few posts receive significant attention despite having a low percent-upvoted (Figure 2).

Assigning Controversy Labels To Posts. We assign binary controversy labels (i.e., relatively controversial vs. relatively non-controversial) to posts according to the following process: first, we discard posts where the observed variability across 10 API queries for percent-upvoted exceeds 5%; in these cases, we assume that there are too few total votes for a stable estimate. Next, we discard posts where neither the observed upvote ratio nor the observed score[8] vary at all; in these cases, we cannot be sure that the upvote ratio is insensitive to the vote fuzzing function.[9] Fi-

---

[5] Vote timestamps are not publicly available.

[6] Prior to Dec. 2016, vote information was fuzzed according to a different algorithm; however, vote statistics for all posts were recomputed according to a new algorithm that, according to a reddit moderator, can "actually be trusted;" `https://goo.gl/yHWeJp`

[7] The intent is to only consider posts receiving enough community attention for us to reliably compare upvote counts with downvotes. We use number of comments as a proxy for aggregate attention because Reddit does not surface the true number of votes.

[8] A score is the (noised) upvotes minus the downvotes.

[9] We validate our filtration process in a later section by directly comparing to Reddit's rank-by-controversy function.

	# posts	# cmnts	μ_{up} cont	μ_{up} noncont
AM	3.3K	474K	66%	90%
AW	3.0K	417K	67%	91%
FT	3.9K	625K	66%	91%
LT	1.6K	208K	68%	91%
PF	1.0K	95K	72%	92%
RL	2.2K	221K	68%	93%

Table 1: Dataset statistics: number of posts, number of comments, mean percent-upvoted for the controversial and non-controversial classes.

nally, we sort each community's surviving posts by upvote percentage, and discard the small number of posts with percent-upvoted below 50%.[10] The top quartile of posts according to this ranking (i.e., posts with mostly only upvotes) are labeled "non-controversial." The bottom quartile of posts, where the number of downvotes cannot exceed but may approach the number of upvotes, are labeled as "controversial." For each community, this process yields a balanced, labeled set of controversial/non-controversial posts. Table 1 contains the number of posts/comments for each community after the above filtration process, and the percent-upvoted for the controversial/non-controversial sets.

2.1 Quantitative Validation of Labels

Reddit provides a sort-by-controversy function, and we wanted to ensure that our controversy labeling method aligned with this ranking.[11] We contacted Reddit itself, but they were unable to provide details. Hence, we scraped the 1K most controversial posts according to Reddit (1K is the max that Reddit provides) for each community over the past year (as of October 2018). Next, we sampled posts that *did not* appear on Reddit's controversial list in the year prior to October 2018 to create a 1:k ratio sample of Reddit-controversial posts and non-Reddit-controversial posts for $k \in \{1, 2, 3\}$, $k = 3$ being the most difficult setting. Then, we applied the filtering/labeling method described above, and measured how well our process matched Reddit's ranking scheme, i.e., the "controversy" label applied by our method matched the "controversy" label assigned by Reddit.

Our labeling method achieves high precision in identifying controversial/non-controversial posts. While a large proportion of posts are discarded, the labels assigned to surviving posts match those assigned by Reddit with the following F-measures at $k = 3$ (the results for $k = 1, 2$ are higher):[12]

	AM	AW	FT	LT	PF	RL
F-measure	97	96	88	90	94	96

In all cases, the precision for the non-controversial label is perfect, i.e., our filtration method never labeled a Reddit-controversial post as non-controversial. The precision of the controversy label was also high, but imperfect; errors could be a result of, e.g., Reddit's controversy ranking being limited to 1K posts, or using internal data, etc.

2.2 Qualitative Validation of Labels

Figure 2 gives examples of controversial and non-controversial posts from three of the communities we consider, alongside the text of the first comment made in response to those posts.

Topical differences. A priori, we expect that the topical content of posts may be related to how controversial they become (see prior work in Fig. 1). We ran LDA (Blei et al., 2003) with 10 topics on posts from each community independently, and compared the differences in mean topic frequency between controversial and non-controversial posts. We observe community-specific patterns, e.g., in relationships, posts about family (top words in topic: "family parents mom dad") are less controversial than those associated with romantic relationships (top words: "relationship, love, time, life"); in AskWomen, a gender topic ("women men woman male") tends to be associated with more controversy than an advice-seeking topic ("im dont feel ive")

Wording differences. We utilize Monroe et al.'s (2008) algorithm for comparing language usage in two bodies of text; the method places a Dirichlet prior over n-grams (n=1,2,3) and estimates Z-scores on the difference in rate-usage between controversial and non-controversial posts.

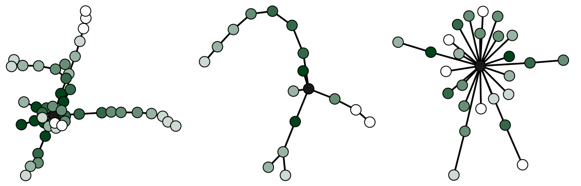
This analysis reveals many community-specific patterns, e.g., phrases associated with controversy include "crossfit" in Fitness, "cheated on my" in relationships, etc. What's controversial in one community may be non-controversial in another, e.g., "my parents" is associated with controversy

---

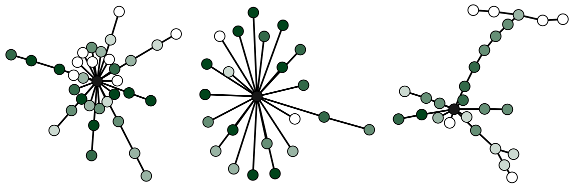
[10] Reddit provides less information for posts with more upvotes than downvotes.

[11] This validation step rules out the possibility that percent-upvoted is uncorrelated with Reddit's official definition of controversy.

[12] There were communities that we did not consider because the correlation between our filter and Reddit's ranking was lower, e.g., PoliticalDiscussion.



(a) Discussions on controversial posts



(b) Discussions on non-controversial posts

Figure 4: Early conversation trees from AskMen; nodes are comments and edges indicate reply structure. The original post is the black node, and as node colors lighten, comment timing increases from zero minutes to sixty minutes.

in personalfinance (e.g., "live with my parents") but strongly associated with lack of controversy in relationships (e.g., "my parents got divorced"). We also observe that some communities share commonalities in phrasing, e.g., "do you think" is associated with controversy in both AskMen and AskWomen, whereas "what are some" is associated with a lack of controversy in both.

3 Early Discussion Threads

We now analyze comments posted in early discussion threads for controversial vs. non-controversial posts. In this section, we focus on comments posted within one hour of the original submission, although we consider a wider range of times in later experiments.

Comment Text. We mirrored the n-gram analysis conducted in the previous section, but, rather than the text of the original post, focused on the text of comments. Many patterns persist, but the conversational framing changes, e.g., "I cheated" in the *posts* of relationships is mirrored by "you cheated" in the *comments*. Community differences again appear: e.g., "birth control" indicated controversy when it appears in the comments for relationships, but not for AskWomen.

Comment Tree Structure. While prior work in early prediction mostly focuses on measuring rate of early responses, we postulate that more expressive, structural features of conversation trees may also carry predictive capacity.

Figure 4 gives samples of conversation trees that developed on Reddit posts within one hour of the original post being made. There is significant diversity among tree size and shape. To quantify these differences, we introduce two sets of features: C-RATE features, which encode the rate of commenting/number of comments;[13] and C-TREE features, which encode structural aspects of discussion trees.[14] We then examine whether or not tree features correlate with controversy after controlling for popularity.

Using binary logistic regression, after controlling for C-RATE, C-TREE features extracted from comments made within one hour of the original post improve model fit in all cases except for personalfinance ($p < .05$, LL-Ratio test). We repeated the experiment, but also controlled for *eventual* popularity[15] in addition to C-RATE, and observed the same result. This provides evidence that *structural* features of conversation trees are predictive, though *which* tree feature is most important according to these experiments is community-specific. For example, for the models without eventual popularity information, the C-TREE feature with largest coefficient in AskWomen and AskMen was the max-depth ratio, but it was the Wiener index in Fitness.

4 Early Prediction of Controversy

We shift our focus to the task of predicting controversy on Reddit. In general, tools that predict controversy are most useful if they only require information available at the time of submission or as soon as possible thereafter. We note that while the causal relationship between vote totals and comment threads is not entirely clear (e.g., perhaps the comment threads cause more up/down votes on the post), predicting the ultimate *outcome* of posts is still useful for community moderators.

Experimental protocols. All classifiers are bi-

---

[13] Specifically: total number of comments, the logged time between OP and the first reply, and the average logged parent-child reply time over pairs of comments.

[14] Specifically: max depth/total comment ratio, proportion of comments that were top-level (i.e., made in direct reply to the original post), average node depth, average branching factor, proportion of top-level comments replied to, Gini coefficient of replies to top-level comments (to measure how "clustered" the total discussion is), and Wiener Index of virality (which measures the average pairwise path-length between all nodes in the conversation tree (Wiener, 1947; Goel et al., 2015)).

[15] We added in the logged number of eventual comments, and also whether or not the post received an above-median number of comments.

nary (i.e., controversial vs. non-controversial) and, because the classes are in 50/50 balance, we compare algorithms according to their accuracy. Experiments are conducted as 15-fold cross validation with random 60/20/20 train/dev/test splits, where the splits are drawn to preserve the 50/50 label distribution. For non-neural, feature-based classifiers, we use linear models.[16] For BiLSTM models,[17] we use Tensorflow (Abadi et al., 2015). Whenever a feature is ill-defined (e.g., if it is a comment text feature, but there are no comments at time t) the column mean of the training set for each cross-validation split is substituted. Similarly, if a comment's body is deleted, it is ignored by text processing algorithms. We perform both Wilcoxon signed-rank tests (Demšar, 2006) and two-sided corrected resampled t-tests (Nadeau and Bengio, 2000) to estimate statistical significance, taking the maximum of the two resulting p-values to err on the conservative side and reduce the chance of Type I error.

4.1 Comparing Text Models

The goal of this section is to compare text-only models for classifying controversial vs. non-controversial posts. Algorithms are given access to the full post titles and bodies, unless stated otherwise.

HAND. We consider a number of hand-designed features related to the textual content of posts inspired by Tan et al. (2016).[18]

TFIDF. We encode posts according to tfidf feature vectors. Words are included in the vocabulary if they appear more than 5 times in the corresponding cross-validation split.

W2V. We consider a mean, 300D word2vec (Mikolov et al., 2013) embedding representation, computed from a GoogleNews corpus.

ARORA. A slight modification of W2V, proposed by Arora et al. (2017), serves as a "tough to beat" baseline for sentence representations.

LSTM. We train a Bi-LSTM (Graves and Schmidhuber, 2005) over the first 128 tokens of titles + post text, followed by a mean pooling layer, and then a logistic regression layer. The LSTM's embedding layer is initialized with the same word2vec embeddings used in W2V. Markdown formatting artifacts are discarded.

BERT-LSTM. Recently, features extracted from fixed, pretrained, neural language models have resulted in high performance on a range of language tasks. Following the recommendations of §5.4 of Devlin et al. (2019), we consider representing posts by extracting BERT-Large embeddings computed for the first 128 tokens of titles + post text; we average the final 4 layers of the 24-layer, pretrained Transformer-decoder network (Vaswani et al., 2017). These token-specific vectors are then passed to a Bi-LSTM, a mean pooling layer, and a logistic classification layer. We keep markdown formatting artifacts because BERT's token vocabulary are WordPiece subtokens (Wu et al., 2016), which are able to incorporate arbitrary punctuation without modification.

BERT-MP. Instead of training a Bi-LSTM over BERT features, we mean pool over the first 128 tokens, apply L2 normalization to the resulting representations, reduce to 100 dimensions using PCA,[19] and train a linear classifier on top.

BERT-MP-512. The same as BERT-MP, except the algorithm is given access to 512 tokens (the maximum allowed by BERT-Large) instead of 128.

Results: Table 2 gives the performance of each text classifier for each community. In general, the best performing models are based on the BERT features, though HAND+W2V performs well, too. However, no performance gain is achieved when adding hand designed features to BERT. This may be because BERT's subtokenization scheme incorporates punctuation, link urls, etc., which are similar to the features captured by HAND. Adding an LSTM over BERT features is comparable to mean pooling over the sequence; similarly, considering 128 tokens vs. 512 tokens results in comparable

---

[16] We cross-validate regularization strength 10^(-100,-5,-4,-3,-2,-1,0,1), model type (SVM vs. Logistic L1 vs. Logistic L2 vs. Logistic L1/L2), and whether or not to apply feature standardization for each feature set and cross-validation split separately. These are trained using `lightning` (`http://contrib.scikit-learn.org/lightning/`).

[17] We optimize using Adam (Kingma and Ba, 2014) with LR=.001 for 20 epochs, apply dropout with $p = .2$, select the model checkpoint that performs best over the validation set, and cross-validate the model's dimension (128 vs. 256) and the number of layers (1 vs. 2) separately for each cross-validation split.

[18] Specifically: for the title and text body separately, length, type-token ratio, rate of first-person pronouns, rate of second-person pronouns, rate of question-marks, rate of capitalization, and Vader sentiment (Hutto and Gilbert, 2014). Combining the post title and post body: number of links, number of Reddit links, number of imgur links, number of sentences, Flesch-Kincaid readability score, rate of italics, rate of boldface, presence of a list, and the rate of word use from 25 Empath wordlists (Fast et al., 2016), which include various categories, such as politeness, swearing, sadness, etc.

[19] Values of 50 and 150 both work well, too.

	AM	AW	FT	LT	PF	RL
HAND	55.4	52.2	61.9	59.7	54.5	60.8

Table 3: Post-time only results: the effect of incorporating timing and author identity features.

performance. Based on the results of this experiment, we adopt BERT-MP-512 to represent text in experiments for the rest of this work.

4.2 Post-time Metadata

Many non-content factors can influence community reception of posts, e.g., Hessel et al. (2017) find that *when* a post is made on Reddit can significantly influence its eventual popularity.

TIME. These features encode when a post was created. These include indicator variables for year, month, day-of-week, and hour-of-day.

AUTHOR. We add an indicator variable for each user that appears at least 3 times in the training set, encoding the hypothesis that some users may simply have a greater propensity to post controversial content.

The results of incorporating the metadata features on top of TEXT are given in Table 3. While incorporating TIME features on top of TEXT results in consistent improvements across all communities, incorporating author features on top of TIME+TEXT does not. We adopt our highest performing models, TEXT+TIME, as a strong post-time baseline.

4.3 Early Discussion Features

Basic statistics of early comments. We augment the post-time features with early-discussion feature sets by giving our algorithms access to comments from increasing observation periods. Specifically, we train linear classifiers by combining our best post-time feature set (TEXT+TIME) with features derived from comment trees available after t minutes, and sweep t from $t = 15$ to $t = 180$ minutes in 15 minute intervals.

Figure 6 plots the median number of comments available per thread at different t values for each community. The amount of data available for the early-prediction algorithms to consider varies significantly, e.g., while AskMen threads have a median 10 comments available at 45 minutes, LifeProTips posts do not reach that threshold even after 3 hours, and we thus expect that it will be a harder setting for early prediction. We see, too, that even our maximal 3 hour window is still early in a post's lifecycle, i.e., posts tend to receive significant attention afterwards: only 15% (LT) to 32% (AW) of all eventual comments are available per thread at this time, on average. Figure 7 gives the distribution of the number of comments available for controversial/non-controversial posts on AskWomen at $t = 60$ minutes. As with the other communities we consider, the distribution of number of available posts is not overly-skewed, i.e., most posts in our set (we filtered out posts with less than 30 comments) get at least *some* early comments.

We explore a number of feature sets based on early comment trees (comment feature sets are prefixed with "C-"):

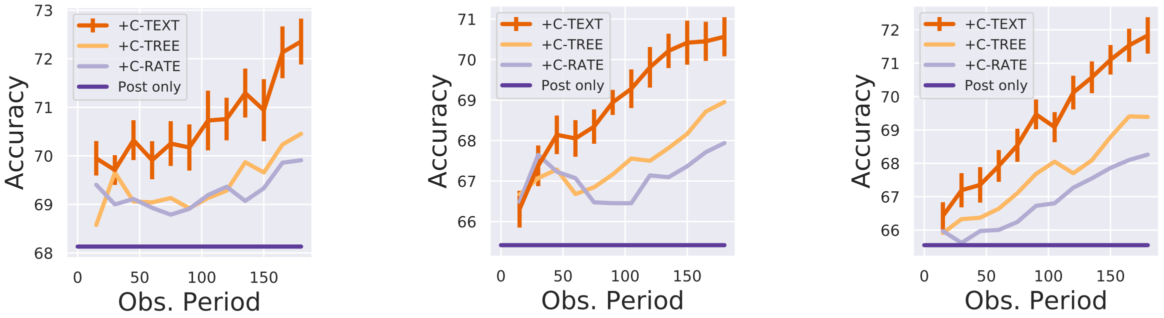
C-RATE and C-TREE. We described these in §3.

C-TEXT. For each comment available at a given observation period, we extract the BERT-MP-512 embedding. Then, for each conversation thread, we take a simple mean over all comment representations. While we tried several more expressive means of encoding the text of posts in comment trees, this simple method proved surprisingly effective.[20]

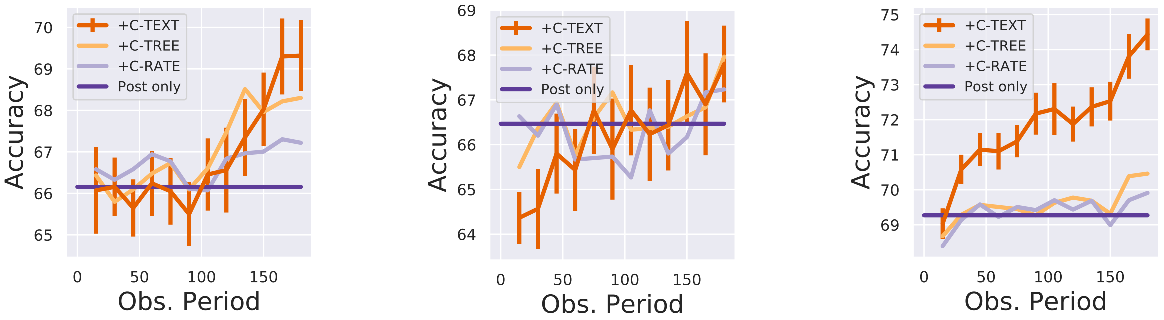
Sweeping over time. Figure 5 gives the performance of the post-time baseline combined with comment features while sweeping t from 15 to 180 minutes. For five of the six communities we consider, the performance of the comment feature classifier significantly ($p < .05$) ex-

---

[20] We do not claim that this is the *best* way to represent text in comment trees. However, this simple method produces performance improvements over strong post-time baselines; exploring better models is a promising avenue for future work.



(a) AskMen ($t_s = 15$) (b) AskWomen ($t_s = 45$) (c) Fitness ($t_s = 60$)



(d) LifeProTips ($t = 165$) (e) personalfinance (N/A) (f) relationships ($t_s = 45$)

Figure 5: Classifier accuracy for increasing periods of observation; the "+" in the legend indicates that a feature set is combined with the feature sets below. t_s, the time the full feature set first achieves statistical significance over the post-time only baseline, is given for each community (if significance is achieved).

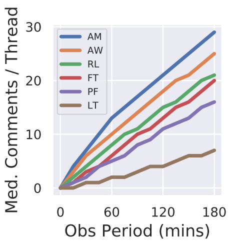


Figure 6: Observation period versus median number of comments available.

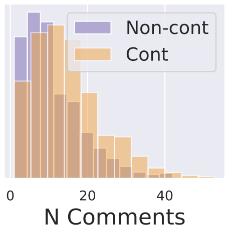

Figure 7: Histogram of the number of comments available per thread at $t = 60$ minutes in AskWomen.

ceeds the performance of the post-time baseline in less than three hours of observation, e.g., in the case of AskMen and AskWomen, significance is achieved within 15 and 45 minutes, respectively.

In general, C-RATE improves only slightly over post only, even though rate features have proven useful in predicting popularity in prior work (He et al., 2014). While adding C-TREE also improves performance, comment textual content is the biggest source of predictive gain. These results demonstrate i) that incorporating a variety of early conversation features, e.g., structural features of trees, can improve performance of controversy prediction over strong post-time baselines, and ii) the text content of comments contains significant complementary information to post text.

Controversy prediction $\neq$ popularity prediction. We return to a null hypothesis introduced in §2: that the controversy prediction models we consider here are merely learning the same patterns that a popularity prediction algorithm would learn. We train popularity prediction algorithms, and then attempt to use them at test-time to predict controversy; under the null hypothesis, we would expect little to no performance degradation when training on these alternate labels.

We 1) train binary popularity predictors using post text/time + comment rate/tree/text features available at $t = 180$,[21] and use them to predict controversy at test-time; and 2) consider an oracle that predicts the true popularity label at test-time; this oracle is *quite* strong, as prior work suggests that perfectly predicting popularity is impossible (Salganik et al., 2006).

---

[21] We predict whether or not a post eventually receives an above-median number of comments. We force the popularity predictors to predict 50/50 at test time, which improves their performance.

	AM	AW	FT	LT	PF	RL
Pop Pred	53.9	55.2	60.1	54.2	52.9	52.8
Pop Oracle	65.8	67.0	70.3	68.1	64.0	63.3

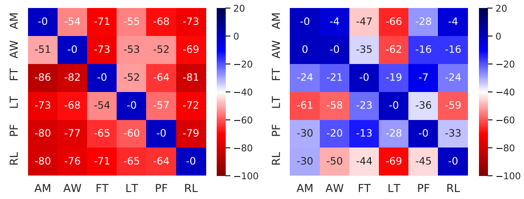
In all cases, the best popularity predictor does not achieve performance comparable to even the post-only baseline. For 3 of 6 communities, even the popularity oracle does not beat post time baseline, and in all cases, the mean performance of the controversy predictor exceeds the oracle by $t = 180$. Thus, in our setting, controversy predictors and popularity predictors learn disjoint patterns.

4.3.1 Domain Transfer

We conduct experiments where we train models on one subreddit and test them on another. For these experiments, we discard all posting time features, and compare C-(TEXT+TREE+RATE) to C-(TREE+RATE); the goal is to empirically examine the hypothesis in §1: that controversial text is community-specific.

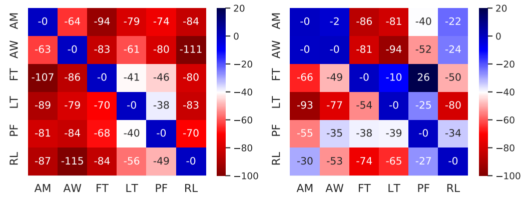
To measure performance differences in the domain transfer setting, we compute the percentage accuracy drop relative to a constant prediction baseline when switching the training subreddit from the matching subreddit to a different one. For example, at $t = 60$, we observe that raw accuracy drops from $65.6 \rightarrow 55.8$ when training on AskWomen and testing on AskMen when considering text, rate, and tree features together; given that the constant prediction baseline achieves 50% accuracy, we compute the percent drop in accuracy as: $(55.8 - 50)/(65.6 - 50) - 1 = -63\%$.

The results of this experiment (Figure 8) suggest that while text features are quite strong in-domain, they are brittle and community specific. Conversely, while rate and structural comment tree features do not carry as much in-domain predictive capacity on their own, they generally transfer better between communities, e.g., for RATE+TREE, there is very little performance drop-off when training/testing on AskMen/AskWomen (this holds for all timing cutoffs we considered). Similarly, in the case of training on Fitness and testing on PersonalFinance, we sometimes observe a performance *increase* when switching domains (e.g., at $t = 60$); we suspect that this could be an effect of dataset size, as our Fitness dataset has the most posts of any subreddit we consider, and PersonalFinance has the least.



(a) TEXT+RATE+TREE $t = 180$

(b) RATE+TREE $t = 180$



(c) TEXT+RATE+TREE $t = 60$

(d) RATE+TREE $t = 60$

Figure 8: Average cross-validated performance degradation for transfer learning setting at $t = 180$ and $t = 60$; the y-axis is the training subreddit and the x-axis is testing. For a fixed test subreddit, each column gives the percent accuracy drop when switching from the matching training set to a domain transfer setting. In general, while incorporating comment text features results in higher accuracy overall, comment rate + tree features transfer between communities with less performance degradation.

5 Conclusion

We demonstrated that early discussion features are predictive of eventual controversiality in several reddit communities. This finding was dependent upon considering an expressive feature set of early discussions; to our knowledge, this type of feature set (consisting of text, trees, etc.) hadn't been thoroughly explored in prior early prediction work.

One promising avenue for future work is to examine higher-quality textual representations for conversation trees. While our mean-pooling method did produce high performance, the resulting classifiers do not transfer between domains effectively. Developing a more expressive algorithm (e.g., one that incorporates reply-structure relationships) could boost predictive performance, and enable textual features to be less brittle.

Abstract

Understanding the dynamics of international politics is important yet challenging for civilians. In this work, we explore unsupervised neural models to infer relations between nations from news articles. We extend existing models by incorporating shallow linguistics information and propose a new automatic evaluation metric that aligns relationship dynamics with manually annotated key events. As understanding international relations requires carefully analyzing complex relationships, we conduct in-person human evaluations with three groups of participants. Overall, humans prefer the outputs of our model and give insightful feedback that suggests future directions for human-centered models. Furthermore, our model reveals interesting regional differences in news coverage. For instance, with respect to US-China relations, Singaporean media focus more on "strengthening" and "purchasing", while US media focus more on "criticizing" and "denouncing".

1 Introduction

In the context of growing globalization (Baylis et al., 2017), understanding complex international relations is increasingly relevant to our daily life. Yet this is a challenging task due to the inherently dynamic nature of international relations. As Kissinger famously said, "America has no permanent friends or enemies, only interests." Staying informed becomes even harder in the continuous streams of information from news outlets and social media.

This very availability of such information, however, opens up exciting opportunities for natural language processing to support individuals in understanding international relations. Supervised extraction has been incredibly useful at identifying pre-defined relations and events (Doddington et al., 2004; Mintz et al., 2009) but fails to capture emerging or complex information needs. Topic models and neural models have been proposed to explore relations between entities without supervision (O'Connor et al., 2013; Chaney et al., 2016; Iyyer et al., 2016). In particular, Iyyer et al. (2016) introduces an unsupervised neural model for tracking relations between fictional characters, and this approach outperforms baselines from topic models and hidden Markov models. In this work, we incorporate linguistic insights into this model to track relation dynamics between nations from news articles.

Our model reconstructs textual information in the embedding space using relation embeddings, as proposed in Iyyer et al. (2016). We integrate simple yet effective linguistic insights: verbal predicates often describe the relationship between entities,[1] while nouns and proper nouns provide the context of this relationship. For example, in "U.S. denounces Russia for its interference in the 2016 election", *denounce* describes the relation, and *election* and *interference* provide the context. We show that this intuition leads the model to discover relation descriptors that are easier to interpret and less noisy.

Evaluating these exploratory models for subjective tasks poses a challenge as there are no gold labels. Along with the model, we propose new approaches for evaluation. We introduce a quantitative metric which aligns pre-annotated key events with the temporal trends of relationships produced by the models. Since this task requires careful analysis of complex international relations, we conduct in-person user studies with NLP researchers and undergraduate students recruited from political science and linguistics courses. Both quantitative evaluation and human evaluation indicate that our model better rep-

---

[1] We use entities, countries, and nations interchangeably in this work.

Proceedings of NAACL-HLT 2019, pages 1660–1676
Minneapolis, Minnesota, June 2 - June 7, 2019.

resents the dynamic relationships between nations than the prior model (Iyyer et al., 2016): 75.9% of participants preferred our model for finding natural language words describing international relations and 85.5% preferred temporal trends generated by our model.

Finally, we qualitatively explore the context of relations provided by an attention-based mechanism and demonstrate a practical application of our model by studying regional differences in news coverage of relationships between two countries. We conclude with discussions on future directions for buildings models that can support individuals in navigating a large collection of news articles. Our code is available at `https://github.com/BoulderDS/LARN`.

2 Data

We start by introducing our dataset of news articles, the shallow linguistic information that we extract, and our annotation of key events.

News article collection. Our dataset is derived from the NOW corpus, the largest corpus of news articles that is available in full-text format.[2] The NOW corpus collects the news articles that are available on Google News in 20 English-speaking countries and thus include news articles that span a wide variety of topics, ranging from politics, to sports, to celebrity news from 23K media outlets. In this work, we consider the news articles in recent years, i.e., from January 2016 to June 2018, to facilitate human evaluation.

We consider 12 nations (U.S., Russia, China, UK, Germany, Canada, France, India, Japan, Iran, Israel, and Syria) and the 66 nation pairs between them. To identify mentions of each nation in news articles, we manually construct a set of aliases for each nation to cover common abbreviations and the names of political leaders (e.g., Trump, Putin). On average, each nation has 3.5 aliases. We then use these aliases to find sentences that contain a pair of nations under consideration and obtain 1.2M sentences associated with 634K articles.

Adding Shallow Linguistic Information. To incorporate shallow linguistic knowledge, we process the news article collection for each nation pairs to extract (1) verbal predicates and (2) nouns and proper nouns from each sentence. Specifically, we use a dependency parser to detect verbal predicates and their subjects and objects, and only include predicates for which both subjects and objects were found. For sentences with such predicates, we find nouns and proper nouns using part of speech tags. All data processing was done in spaCy (Honnibal and Montani, 2017) and full details can be found in the appendix.

Total # of months considered	30
Total # of articles	7.7M
Total # of articles with valid nation pairs	634K
Avg. # of articles per nation pair	9.6K
Avg. # of sentences per nation pair	18.2K
Avg. # of predicates per nation pair	21.6K
Avg. # of nouns & proper nouns per nation pair	201K
Avg. # of key events per nation pair (8 pairs)	4.9

Table 1: Data statistics.

Key events annotation. The main goal of our model is to support the exploration of international relations, which is very challenging to evaluate. To derive quantitative evaluation measures and provide the basic context of international relations, we manually identify key events over the 30 months for 8 most frequently mentioned nation pairs (i.e. US-[China, Russia, UK, India, Canada, Japan, Syria], China-India) by reading through the top Google search results for each two countries and each month.[3] We identified roughly five key events per nation pair. For example, one key event for US-China relation is Chairman Xi's visit to the US in April 2017. A complete list of key events is shown in the appendix. Table 1 summarizes the data statistics.

3 Model

In this section, we formally introduce our model that builds on Relation Modeling Network (*RMN*) (Iyyer et al., 2016). Our main contribution is to integrate shallow linguistic information (i.e., verbal predicates and nouns/proper nouns) and identify the context of relations.

3.1 Overview

The intuition behind our model follows RMN, i.e., inferring relation embeddings by reconstruct-

---

[2] The dataset can be obtained from `https://www.corpusdata.org/now_corpus.asp`.

[3] This annotation is done by the first author and is thus inherently subjective. We add a robustness check in the appendix based on another set of independently annotated key events by the third author. Automatic evaluation shows a similar trend holds for the two sets of annotations.

ing textual information in the embedding space. Specifically, we learn a fixed set of relation embeddings and use a convex combination of these relation embeddings to reconstruct information in sentences that mention both entities.

Our main hypothesis is that relation information is often encoded in verbal predicates and we can obtain more interpretable and robust relations if we focus on predicates. For each pair of entities, we extract information from the predicates in sentences with both entities and reconstruct these predicates using shared relation embeddings. In addition, we use nouns to provide the context for the relations. We refer to our model as Linguistically Aware Relationship Networks (*LARN*).

We now formally define our problem. The input of our model is a collection of news articles. For each entity pair e_i, e_j, we obtain a set of articles, $\mathcal{A}_{e_i,e_j}$, containing at least one sentence mentioning both entities. We identify sentences where both e_i and e_j occur based on any alias associated with an entity (nation). We extract all the verbal predicates from these sentences in article $a \in \mathcal{A}_{e_i,e_j}$ as $\{p_1^{a,e_i,e_j}, \ldots, p_N^{a,e_i,e_j}\}$, as well as the proper nouns or nouns as $\{n_1^{a,e_i,e_j}, \ldots, n_M^{a,e_i,e_j}\}$. Preprocessing details could be found in the appendix. We then use GloVe embeddings to represent these words, i.e., $v_{p_k^{a,e_i,e_j}}$ for p_k^{a,e_i,e_j} and $v_{n_k^{a,e_i,e_j}}$ for n_k^{a,e_i,e_j} (Pennington et al., 2014). These word embeddings are static in the entire learning process.

Our model learns relation embeddings $\mathbf{R} \in \mathbb{R}^{K \times d}$, where K is a hyperparameter for the number of relations and d is the dimension of the relation embedding as well as the word embedding. Following Iyyer et al. (2016), we obtain a list of natural language descriptors for each relation using the nearest neighbors of the relation embedding within the 500 most common predicates.[4] The model also provides (1) a probability distribution over relations for each article, (2) a probability distribution over nouns for each relation between each entity pair, and (3) an embedding for each entity.

Figure 1 describes the overall architecture. We will describe the construction of v^a_{label} in §3.2, a reconstruction of v^a_{label} through a weighted sum of relation embeddings in §3.3, and finally the learning in §3.4.

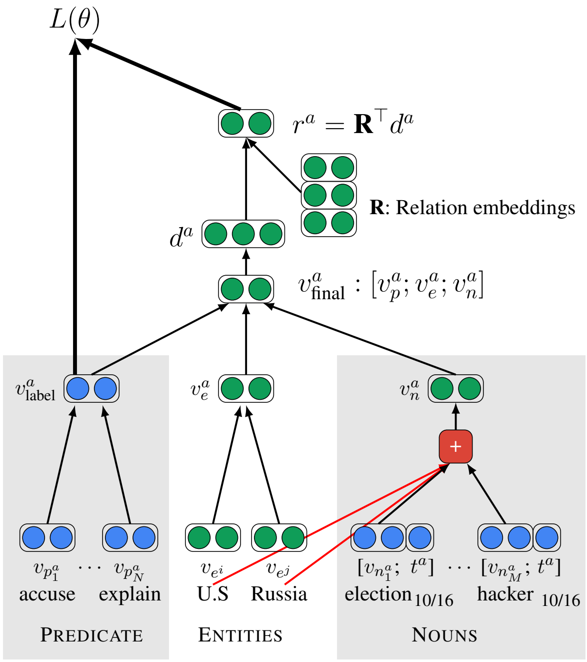

Figure 1: Model overview of an article with respect to a pair of nations. Our model approximates the predicates from the input article v^a_{label} as a weighted sum of relation embeddings from $\mathbf{R}$. The blue embeddings are fixed and the green ones are trained. The red cell indicates our attention mechanism. The shaded area is our extension: we use only predicates as the label and provide the context of relations via nouns.

3.2 Modeling Text with Predicates

We compute the representation for each article to be reconstructed as the sum of bag-of-words embeddings. While Iyyer et al. (2016) considers all the words in a window in which both entities occur, we only consider predicates in the sentences where both entities show up:

$$v_{\text{label}}^{a,e_i,e_j} = \sum_{k=1}^{N} v_{p_k^{a,e_i,e_j}}.$$

$v_{\text{label}}^{a,e_i,e_j}$ depends on both the news article and the entity pair. In the rest of the paper, We omit e_i, e_j in the superscript here for simplicity, i.e., v^a_{label}.

3.3 Reconstructing Text with Relation Embeddings

We represent each article as a weighted sum of relation embeddings. Assuming d^a represents a weight vector over the K relation embeddings that

---

[4] Refer to the appendix for a version that include all words. The relation descriptors from *RMN* required a manual filtering step in Iyyer et al. (2016), and become unintelligible without the 500 common words constraint. Note that our model produces intelligible descriptors even without the 500 most common predicates constraint.

sums to 1 for an article a with respect to a pair of entities (e_i, e_j), we obtain r^a as follows:

$$r^a = \mathbf{R}^\top d^a.$$

d^a can also be thought of as a distribution over relations. This distribution over relations depends on entity pair (v^a_e), predicate information (v^a_p), and noun information (v^a_n). While *RMN* simply takes the average of all words in the sentence, *LARN* focuses on verbal predicates and nouns to capture our intuition that predicates describe the main relations, whereas nouns provide background information to explain the relations. We now describe these three components in details.

Representing predicates and entity pair. We follow *RMN* to construct embedding for each entity pair and for the predicates. The entity pair vector, v^a_e, simply adds the embedding of the two entities. The predicate vector, v^a_p, is equivalent to v^a_{label} except for word dropout during training, i.e., setting b^a_k to be 0 or 1 with a probability of 0.5.

$$\begin{aligned} v^a_e &= v_{e_i} + v_{e_j}, \\ v^a_{\text{p}} &= \sum_{k=1}^{N} b^a_k \cdot v_{p^a_k}. \end{aligned}$$

Representing context with nouns. To understand relations between an entity pair in a sentence, nouns should be considered in addition to predicates. For example, *tariff* is indicative of the relation between US and China in "Originally, Trump favoured the simple imposition of a tariff on products from selected countries, especially China and Mexico", despite the seemingly positive predicate *favour*. As nouns are much more common than predicates (see Table 1) and not all of them are meaningful for understanding international relations, we employ a weighted sum of noun vectors. We use an attention mechanism (Conneau et al., 2017; Bahdanau et al., 2015) and consider each entity pair as a unique key to compute the attention weights, since the same noun can be interpreted differently across different entity pairs. To this end, we train an attention query embedding q_{e_i,e_j} for each entity pair separately. We further encode the temporal information by concatenating a one-hot vector t^a that indicates the month when the article was published with the noun representation $v_{n^a_k}$. This allows us to capture the shifts in a word's meaning over time.

$$\begin{aligned} h_{n^a_k} &= \tanh(W_{\text{proj}} \cdot [v_{n^a_k}; t^a]), \\ \alpha_{n^a_k} &= \frac{\exp(h_{n^a_k} \cdot q_{e_i,e_j})}{\sum_{k'=1}^{M} \exp(h_{n^a_{k'}} \cdot q_{e_i,e_j})}, \\ v^a_n &= \sum_{k=1}^{M} \alpha_{n^a_k} h_{n^a_k}. \end{aligned}$$

Finally, we concatenate the three representations as the input to a feedforward network and pass to a softmax layer to create the weight vector d^a.

$$\begin{aligned} v^a_{\text{final}} &= \text{ReLU}(W_{\text{cat}} \cdot [v^a_p; v^a_e; v^a_n]), \\ d^a &= \text{Softmax}(W_{\text{final}} \cdot v^a_{\text{final}}). \end{aligned}$$

This d^a is multiplied with the descriptor matrix $\mathbf{R}$ to get the final representation r^a. Different from *RMN*, we do not consider temporal dependencies between time steps in our model because it is important to understand sudden shifts in international relations rather than assuming that the relations slowly evolve. We also found the temporal dependencies were not helpful empirically in our domain but rather computationally expensive.

3.4 Learning Objective and Summary

The reconstruction objective pushes r^a to resemble v^a_{label}. Our formulation is identical to *RMN*: the loss function consists of a contrastive max-margin loss term, J, and an auxiliary loss term, X, to encourage unique relation embeddings.

$$\begin{aligned} L(\theta) =& J(\theta) + \lambda X(\theta), \\ J(\theta) =& \sum_{a \in \mathcal{A}_{e_i,e_j}} \sum_{v^a_{\text{label}'} \in \mathcal{N}} \max(0, \\ & 1 - \frac{r_a \cdot v^a_{\text{label}}}{||r_a|| \cdot ||v^a_{\text{label}}||} + \frac{r_a \cdot v^a_{\text{label}'}}{||r_a|| \cdot ||v^a_{\text{label}'}||}), \\ X(\theta) =& \|RR^\top - I\|, \end{aligned}$$

where v'_{label} is a randomly sampled negative example, $\mathcal{N}$ is a collection of them, and λ is a hyperparameter for balancing two loss terms.

4 Evaluation

In this section, we compare our model to *RMN*. For both models, we fixed the number of descriptors to 30 following Iyyer et al. (2016). As tracking dynamic international relations requires careful analysis, we hosted onsite user studies for quality control and in-person feedback. We first describe the model outputs, and then present both quantitative and qualitative evaluation results.

LARN (Linguistically Aware Relationship Network)	Weight	*RMN* (Relationship Modeling Network)	Weight
denounce, undermine, condemn, punish, oppose	5.46%	seem, thing, though, too, especially	11.79%
leave,tell,ask,know,want	4.93%	range, information, supply, infrastructure, value	9.42%

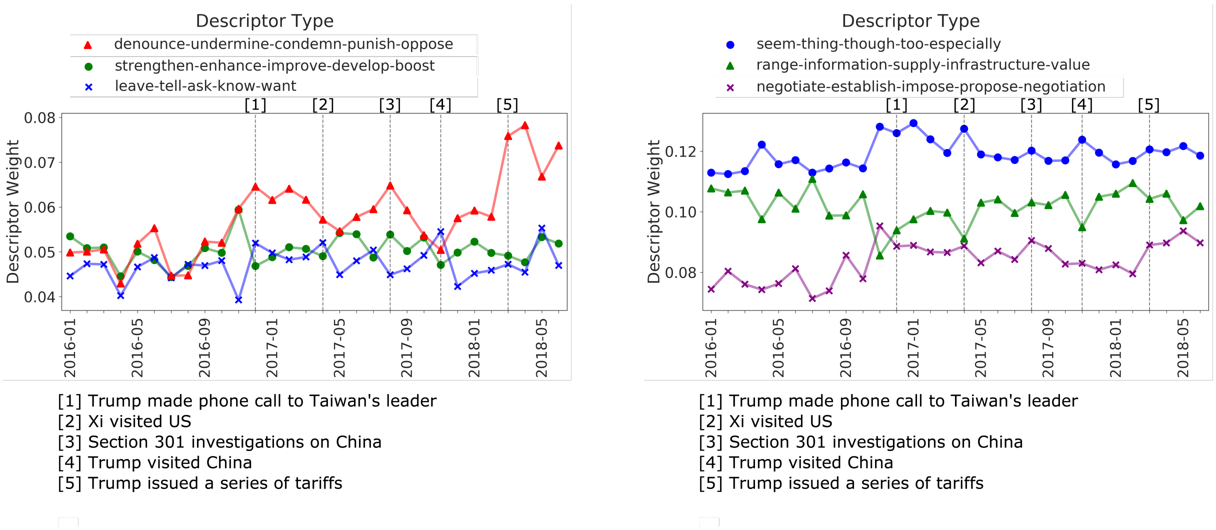
Table 2: Relation descriptors of the most/least frequent five relations by *LARN* and *RMN* and their average weights in news articles. The relations generated from *LARN* are more semantically meaningful.



(a) US-China's relation trends by *LARN*.

(b) US-China's relation trends by *RMN*.

Figure 2: Temporal trends of top three relations between US and China based on *LARN* (Figure 2a), in comparison with results from *RMN* (Figure 2b). We highlight key events during this time period under the x-axes. Similar visualizations are also used in human evaluations. More figures are provided in the appendix.

4.1 Understanding Model Outputs

Given a set of time-stamped news articles and a list of nations of interest, both models provide a set of relation descriptors, where each one **defines** a type of relation and a temporal trend analysis of these descriptors that shows how the relation **evolves**.

Relation descriptors. Table 2 shows the top five and bottom five descriptors from *LARN* and *RMN* sorted by the average weights over all news articles related to the most frequently mentioned eight nation pairs.[5] By using predicates to describe relations, our descriptors seem to contain more semantically meaningful words. For instance, the top relation in *RMN* consists of exclusively non-content words. Another interesting advantage of our model is that the five relations with the lowest weight have much higher weights in *LARN* than in *RMN*. This suggests that *RMN* tends to generate "useless" relations that do not show up in the data, while even bottom relations in *LARN* remain useful for describing the data.

Temporal trends. We visualize the temporal trends of the most prominent relations between nation pairs. We further provide our annotated key events as the context to interpret these temporal trends. Figure 2 gives an example for US and China. The top three relations based on *LARN* are "denounce", "strengthen", and "leave",[6] while the top three based on *RMN* are "seem", "range", and "negotiate". We find our model generally aligns better with the key events: for instance, the "denounce" relation peaked around the time that Trump started issuing a series of tariffs based on

---

[5] We focus on the top eight nation pairs to be consistent with human evaluation.

[6] For space reasons, we only include the top word in the relation descriptor.

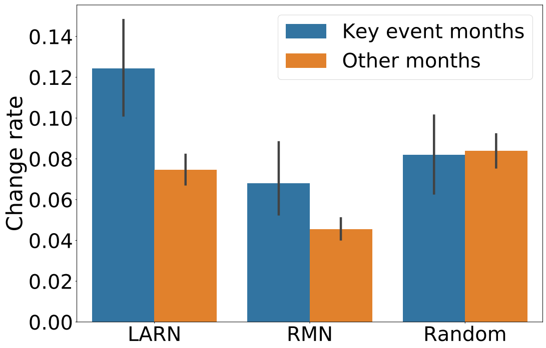


Figure 3: Change rate at key event months vs. other months. Our model demonstrates a clearer relative difference between key event months and other months (66.9%) than *RMN* (50.1%). For the random baseline, we randomly choose the same number of key events and we observe no differences as expected.

our model (Figure 2a), while there do not exist similar fluctuations in Figure 2b based on *RMN*.

4.2 Quantitative Evaluation

We leverage our manually annotated key events to develop a novel automatic metric to evaluate how well the temporal trends from our model are aligned with key events. We define a change rate at each month Δ_t as the weighted average of changes in relation weights in the top three relations:

$$\Delta_t = \sum_{i \in \text{top 3 relations}} w_{t,i} * \frac{|d_{t,i} - d_{t_{prev},i}|}{d_{t_{prev},i}},$$

where $d_{t,i}$ is the average weight for the i-th relation in all the articles published at t, $d_{t_{prev},i}$ is the average weight before t in a window of W preceding months ($\frac{1}{W}\sum_{w=1}^{W} d_{(t-w),i}$), and weight $w_{t,i}$ is the normalized weight for top three descriptors ($\frac{d_{t,i}}{\sum_{j \in \text{top 3 relations}} d_{t,j}}$). Our results are robust to the choices of W, and we set it to 6 for presentation.

We expect change rates to be greater when significant events happen in international politics. Figure 3 compares the change rate at months where key events occurred with other months for eight nation pairs for which we annotated key events. Both models present more abrupt changes when key events occurred. Unlike *RMN*, our model does not have temporal dependencies between relation distributions over time,[7] and thus has a higher discontinuity in general. However, even in relative terms, our model fluctuated more substantially than *RMN* when key events occurred.

	Model		P Value
	LARN	*RMN*	
Descriptor	22	7	8.1e-3
Temporal Trend	106	18	2.3e-16
Nation Pair Matching	38.0 %	45.2 %	0.33

Table 3: Human evaluation results: The first two rows represents the number of votes, while the last row represents % of nation pairs matched correctly with its temporal trend. We did a two-tail binomial test for the relation descriptor and temporal trend evaluation and an independent t-test for the nation pair matching evaluation. We show the p-values in the last column.

We also did a robustness check with another set of independently annotated key events and the results can be found in the appendix. This measure captures whether the model can detect the change points, but does not measure whether the model correctly captures the **semantics** of the key events, i.e., did a negative relation increase after hostile events such as war? To this end, we performed human evaluations.

4.3 Human Evaluation

We hosted three human evaluations with participants from different demographics: undergraduate students from political science classes, graduate students from a computer science department (mostly in NLP), and undergraduate students taking a linguistics class. The total number of participants was 29, roughly equally divided among the three groups. The participants were shown outputs from *RMN* and *LARN*, and asked to choose the output that better aligns with their intuitions. Each participant answered about 10 questions and provided justification for their answers to each question, taking roughly 30 minutes to an hour. Table 3 summarizes the results of our human evaluations.

Relation descriptor evaluation. The participants were shown a list of top five descriptors (as in Table 2) from two models, and prompted to select a set which adequately covers possible relationships that can occur between countries. 75.9% of participants preferred our model.

Temporal trends evaluation. We showed temporal trends between nation pairs annotated with key events, one from *RMN* and the other from *LARN* (as in Figure 2). We asked them to evaluate whether the temporal trends accurately reflect the dynamics in nation-to-nation relationships. Each participant evaluated four randomly chosen nation

---

[7] Please refer to Iyyer et al. (2016)'s Section 3.2.3 for more details on how they incorporated previous time steps.

pairs. The temporal trend from our model was preferred more frequently (85.5% of total responses).

Nation pair matching. We designed a novel task where we showed the participants the other four temporal trends without annotated key events and asked them to match each trend with the corresponding nation pair from the four candidates, based on their world knowledge about nation-nation relations. Each participant did the matching twice, once for *RMN* and once for *LARN*. The participants found correct temporal trends for 45.2% of entity pairs for *RMN*, and 38.0% of entity pairs for *LARN*, when random pairing would yield 25.0%. The difference between two models here is not statistically significant. Most participants found this task very challenging, as they did not know much about the relationship between certain entity pairs (e.g., a participant said “As an American, there’s no way to know the relation between China and India.”). Even political science students do not perform better than the other two groups.

Discussion. Overall the output from our model is preferred by the participants. We found that political science students paid more attention to detail, took a longer time to finish, and were more ambivalent between the performance of the two models. For example, for temporal trends, they preferred our model for 71.4% of the examples, compared to other groups which preferred our model for 90% of the examples. They also preferred *RMN*’s relation descriptors slightly (42.9% selected our model) and commented that a few concepts from *RMN*, like “infrastructure, supply, and value”, are more concrete (e.g., a participant said “I chose the left one (*RMN*), because it is easy to determine and remember the positive of items such as infrastructure, value, and supply. Those have more positive undertones, while it is easy to gauge negative sentiments with ‘terrorism,’ ‘condemn’ and those.”). As *LARN* encodes the background context specific to each nation pair separately, our relation descriptors do not contain such “concrete” concepts. In the next section, we will discuss **contexts** for relations, where these concepts appear in *LARN*.

5 Further Exploration

We present additional qualitative results to showcase the applications of our model. First, we examine the context (nouns) associated with a relation between two nations based on an attention-based mechanism, which *RMN* does not handle. Second, we perform an in-depth analysis to show how our model can reveal regional differences in news coverage on the same topic.

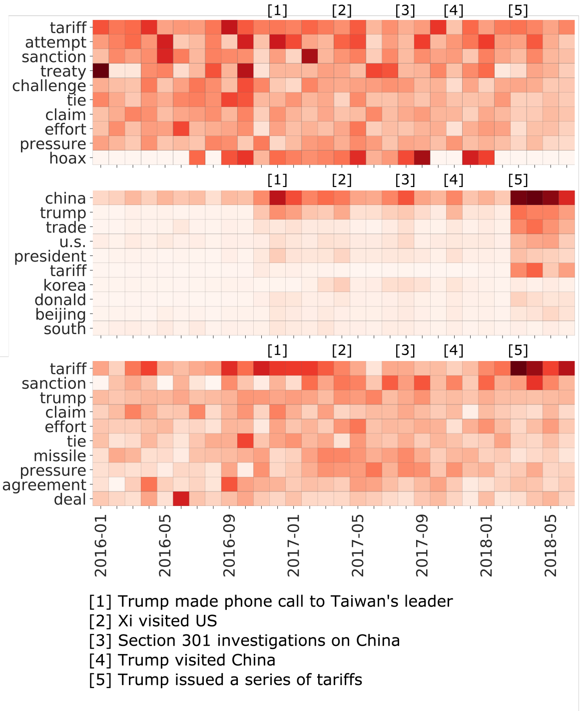

Figure 4: Top contextual words for US-China’s “denounce” relation derived from three approaches. *Top*: Showing word’s avg. attention score in all “denounce” articles each month. *Middle*: Showing word’s frequency in all “denounce” articles each month. *Bottom*: Showing word’s average attention score multiplied by $\log(\text{appearance})$ in each month. All figures are normalized by the global maximum score in the figure.

5.1 Context for Relations

To help users better understand the inferred relations, we offer specific contexts that relate to the inferred relations based on the attention-based mechanism introduced in §3. For each relation, we find articles that place the most weight in that relation, and rank the nouns and proper nouns in those articles by their average attention score (i.e., $\alpha_{n_i^a}$ in §3.3).

The top part of Figure 4 shows the top 10 words for the “denounce” relation in Figure 2a, the temporal trend for US-China relations. Since *RMN* does not support such mechanism, we show the most frequent nouns that occurred in the documents that mention both entities as a baseline (middle part).[8] We find that the attended nouns from our model are more informative than frequent nouns: "tariff" is the most attended word; words such as "sanction", "treaty", and "pressure" also show up, while the frequency baseline centers around words like "China" and "president". As we noticed that the frequency baseline can capture alignment with key events, we incorporate attention score and frequency in the bottom part of Figure 4. This augmented version captures informative words (e.g., "tariff", "sanction", and "missile") [9] and closely aligns with the key events.

5.2 Regional Differences in News Coverage

To further demonstrate the utility of our model, we explore regional differences in news coverage, as "it is possible to build real knowledge by comparing perspectives from different social contexts."[10] This also relates to the longstanding literature on framing in news coverage, i.e., "selecting some aspects of a perceived reality and make them more salient to promote problem definition/interpretation" (Entman, 1993; Chong and Druckman, 2007).

We picked two countries, Singapore and US, to study US-China relations.[11] Using country source of media outlets in the NOW corpus, we found 10K articles from Singaporean media and 5.7K articles from US media on US and China.

Table 4 shows the top five relations sorted by their absolute weight differences between US media outlets and Singaporean media outlets. Singaporean media more frequently use "positive" descriptors such as "strengthen" and "purchase", whereas US media report negative relations such as "denounce" and "criticize" more frequently. Table 5 shows two example sentences from articles with the most weight in the "denounce" relation. Even though two media sources are focusing on events leading to the same type of relation, a reader who mainly consume news articles in Singapore would get a clearly different impression of US-China relations from those who read US news.

Relation descriptor	US	Singapore
strengthen, enhance, improve, develop, boost	4.62%	**5.42%**
purchase, sell, pay, buy, cost	3.18%	**3.86%**
denounce, undermine, condemn, punish, oppose	**6.21%**	5.66%
wag, criticise, accuse, tell, criticize	**3.81%**	3.29%
flee, destroy, invade, unmake, expel	**3.70%**	3.32%

Table 4: Top five relations between US and China sorted by absolute weight differences between US media outlets and Singaporean media outlets.

US media: "President Donald Trump is preparing to *impose* a *package* of $60 billion in annual *tariffs* against Chinese products, following through on a longtime *threat* that he says will *punish* China for intellectual property theft and *create* more American jobs."
Singaporean media: It does not look like just a *trade war*, but rather the US is trying to *bully* China and the rest of the world in order to make China *concede* economic resources and development *opportunities* to the US and make the US forever big and strong.

Table 5: Example sentences in top-scoring articles on US-China's "denounce" relation in March 2018. We italicize key predicates (red color) and three most attended nouns (cyan color).

6 Related Work

Prior work (Chambers et al., 2015; Choi et al., 2016; Rashkin et al., 2017) studied entity-entity relations in terms of positive and negative sentiments between them. Similarly, literature on relation extraction (Riedel et al., 2010; Gardner and Krishnamurthy, 2017; Elson et al., 2010; Srivastava et al., 2016) focused on pre-defined relations between a pair of entities in the database schema. In comparison, our work discovers descriptors for relations between entity pairs instead of finding entity pairs matching pre-defined relation schema.

Topic modeling has been an important method to grasp important concepts from a large collection of documents in an unsupervised fashion (Blei et al., 2003; Das et al., 2015; Chang et al., 2009; Schein et al., 2015). Similar to our work, O'Connor et al. (2013) incorporates linguistic insights with topic models to identify event classes and detect conflicts. Our work additionally models

---

[8] We had a comparison between the top figure and the middle figure in the human evaluation, but we found an error in visualization and thus focus on qualitative comparisons.

[9] "missile" points us to another event related to US deploying missile defense system in South Korea, which also impacts US-China relations.

[10] https://www.publicbooks.org/why-an-age-of-machine-learning-needs-the-humanities/

[11] China is not an English speaking country and is thus not in the NOW corpus. Singapore contained the most articles containing both US and China.

the context of relations through nouns and focuses on exploring the potential of neural models.

Most relevant to our work is Iyyer et al. (2016), which suggests *RMN* better capture dynamic relationships in literature than hidden Markov model (Gruber et al., 2007) and LDA (Blei et al., 2003). Recent work extended and applied *RMN* to other settings such as studying user roles in online communities (Wang et al., 2016; Fremann and Szarvas, 2017). Notably, Chaturvedi et al. (2017) suggests HMM with shallow linguistic features (i.e., frame net parses) and global constraints can outperform *RMN* for modeling relations in literature. In this work, we incorporate linguistic insights with *RMN* and apply it to news domain.

Last but not least, researchers have studied the dynamics of media coverage from a wide range of perspectives, ranging from framing (Card et al., 2015; Field et al., 2018), to relationship between ideas (Tan et al., 2017), to quotes of politicians (Niculae et al., 2015; Tan et al., 2018; Leskovec et al., 2009). There is also significant effort for building event databases in political science (Leetaru and Schrodt, 2013), and assisting journalists with tools (Handler and O'Connor, 2017), and dating historical text (Niculae et al., 2014).

7 Conclusion

We investigate the promise of unsupervised neural models for automatically inferring relations between nations. We find that incorporating shallow linguistic information is a simple yet effective strategy for deriving robust and interpretable relations. We develop a novel quantitative evaluation metric for understanding international relations and in-depth human evaluation also confirms the effectiveness of our model. We further show that our models can provide the background of relations using attention score and reveal regional differences for future studies on media framing.

Meanwhile, our work suggests important future directions for using NLP technologies to support individuals in navigating a large collection of news articles. Our participants often find it challenging to infer information simply from temporal dynamics of our inferred relations based on natural language descriptors. It is thus important to incorporate human cognitive preferences in developing such models and provide narratives beyond words such as key events. Furthermore, different populations pay attention to different parts of information. We need to understand the diversity when developing NLP technologies for end users and provide helpful personalized hints to lower the barrier of benefiting from model outputs.

Acknowledgments

We thank the anonymous reviewers, Dallas Card, and Mohit Iyyer for helpful feedback and discussion. We thank all the participants in our human evaluation from LING 3813 at Georgia Tech by Lelia Glass, students at X-lab at University of Washington, and undergraduate students at University of Colorado Boulder. We also thank Andy Baker and Sven Steinmo for recruiting students in their classes. Choi is supported by a Facebook Fellowship.

A Appendix

Data: Aliases and Key Events

We use a dictionary of nation aliases to find relevant sentences in the corpus that mentioned at least one nation pair.[12] Table A1 shows the full alias dictionary we used. Table A5 shows the complete list of key events used in this paper.

Nation	Aliases
U.S.	U.S., US, USA, Trump, Obama
China.	China, Chinese, Xi
Syria	Syria, Syrian, Assad
France	France, French, Macron, Hollande
Germany.	Germany, German, Merkel
Canada	Canada, Canadian, Trudeau
Russia	Russia, Russian, Putin
U.K.	U.K., UK, British, Britain, Cameron
India	India, Indian, Modi
Japan	Japan, Japanese, Abe
Iran	Iran, Iranian, Khamenei, Rouhani
Israel	Israel, Israeli, Netanyahu

Table A1: Aliases used for detecting nation mentions.

Preprocessing

We use spaCy to preprocess all sentences (Honnibal and Montani, 2017). We then use a rule based extractor[13] to get verbal predicates with detectable subjects and objects. When verbal predicate has a negation, we take its antonym in WordNet (Fellbaum, 1998) if it exists, ignored otherwise. We also extract nouns and proper nouns in sentences using spaCy's part-of-speech tagging.

We follow the preprocessing steps in Iyyer et al. (2016) for *RMN*. The original *RMN*, which used a fiction dataset, removes the 500 most frequently occurring words and words that occur in fewer than 100 books. We also remove the 500 most frequent words for the input to *RMN*. However, since our news dataset doesn't have the notion of "books", we remove 5000 least common words (out of a 200K vocabulary) for *RMN*. Note that this is not done for our model *LARN*.

Implementation Details

We show all hyperparameters used in our study in Table A2. We generally use the same hyperparameter values as *RMN*, except a few model-specific hyperparameters in Table A2. We also use Xavier initialization (Glorot and Bengio, 2010) for all trainable layers as in the original *RMN*.

Hyperparameter	Value
v_{label}, v_p, v_n dimension	300
p_{drop}	0.5
v_e dimension	50
h_n (*LARN*) dimension	300 + 30
v_{final} dimension	300
recurrent enforcement α (*RMN*)	0.5
number of relations K	30
number of training epochs	15
learning rate	1e-3
orthogonal penalty λ	1e-1
number of negative samples	15
batch size	256

Table A2: Hyperparameters.

Relation Descriptors Postprocessing

In addition to finding the nearest neighboring words to the relation embeddings, the orginal *RMN* also requires a manual filtering process to achieve an interpretable definition of the relation descriptor. To prevent introducing bias in this manual filtering step, we define each relation descriptor directly as its five nearest neighboring words in the input vocabulary. However, since the full vocabulary would contain many uncommon words which could hinder the interpretation of relation descriptors, we limit both models to choose descriptor words from the most frequently occurring 500 words in their own processed input vocabulary (i.e., verb predicates only for *LARN* and all words for *RMN*).

In Table A3, we present the descriptor set by *RMN* and *LARN* without the most common 500 words constraint on descriptor word selection. We find that the descriptor set of our model is robust to this change and does not suffer from a lowered interpretability as much as *RMN*.

Additional Temporal Relation Trends: US-Russia, US-India, US-Syria

See Figure A2, Figure A3, and Figure A4 for three more examples of temporal relation trends between nation pairs.

Additional Influential Background Words:US-Russia, US-India, US-Syria

In Figure A5, Figure A6, and Figure A7, we further show the corresponding attended background words for the top relation descriptor in each of the

offer, provide, deliver, ideal, cater	2.46%	ricoh, powe, mw, sy, hamill	2.94e-10
launch, relaunch, announce, debut, unveil	2.36%	tunstall, booksellers, seiko, pring, reflation	2.21e-10

Table A3: Relation descriptors of the most/least frequent five relations by *RMN* and *LARN* and their average weights in news articles (without constraint on most common words).

three nation pair relations shown in the previous section.

Robustness Check: Another Set of Key Events Annotations

Apart from the key events annotated by the first author, which were used in the change rate analysis in the main paper, the third author also did an independent annotation of the key events as a robustness check. The details of this annotation could found in Table A6. Figure A1 shows the change rate evaluation with respect to this annotation. A similar trend holds for both sets of annotations.

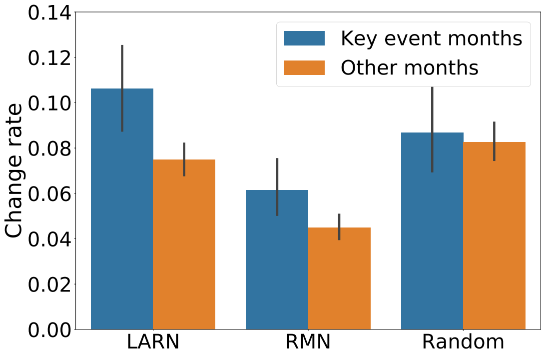

Figure A1: Change rate at key event months vs. other months using an additional set of key events annotations. Our model demonstrates a clearer relative difference between key event months and other months (41.74%) than *RMN* (36.75%). For the random baseline, we randomly choose the same number of key events and we observe no differences as expected.

A Simpler Baseline: Term-frequency Trend of Verbal Predicates

In addition to the comparison with *RMN*, we also checked a simpler baseline by replacing the descriptor weights with term-frequency values of each verbal predicates for each document. Specifically, the term-frequency of a predicate p in document d is $\frac{count(p)}{length(d)}$. Note that *document* refers to all sentences where a nation pair is mentioned. We show some temporal trend examples in Figure A8 and also the change rate evaluation result in Table A4. Note that the scales of these results are different from *LARN* and *RMN*, since the predicate words are much more sparse than the 30 descriptors used in *LARN* and *RMN*.

	Change rate		Δ
	key months	other months	
LARN	12.44 %	7.45 %	66.91 %
RMN	6.81 %	4.53 %	50.07 %
Predicate TF	69.86 %	62.36 %	12.02 %

Table A4: Change rate at key event months vs. other months with the predicate term-frequency baseline, compared to *LARN* and *RMN*.

Nation pair	Key events
U.S.-China	(2016-12) Trump made phone call to Taiwan's leader; (2017-04) Xi visited U.S.; (2017-08) Section 301 investigations on China; (2017-11) Trump visited China; (2018-03) Trump started issuing a series of tariffs.
U.S.-Russia	(2016-10) U.S. officially accused Russia's hacking; (2017-04) Syria airstrike; (2017-07) Trump and Putin's first meeting; (2017-11) Trump and Putin's meeting at APEC; (2018-02) Dozens of Russians killed by U.S.-backed Syria attack.
U.S.-Syria	(2016-10) U.S. suspended Syria ceasefire talk; (2017-04) Khan Shaykhun chemical attack and Shayrat missile strike; (2017-10) ISIS 'capital' captured; (2017-11) ISIS's defeat and aftermath; (2018-02) Battle of Khasham.
U.S.-U.K.	(2016-06) U.K. Brexit vote; (2017-01) Therasa May visited U.S.; (2017-12) Trump set a controversial visit to U.K.
U.S.-Canada	(2017-01) Trump said Nafta renegotiation to be started; (2017-04) Trump imposed tariff on Canadian lumber; (2018-06) Canada fought back with retaliatory tariff on U.S. products.
U.S.-India	(2016-06) Modi visited U.S. and met Obama; (2016-12) Trump made a complimentary phone call to Pakistan; (2017-06) Modi visited U.S. and met Trump; (2017-10) U.S. Secretary Of State Tillerson visited India; (2018-06) India imposed retaliatory tariffs on U.S.
U.S.-Japan	(2016-05) Obama gave memorial speech at Hiroshima with Japanese PM Abe; (2016-12) Abe visited Pearl Harbor; (2017-02) Abe visited Washington and met Trump; (2017-11) Trump visited Japan and met Abe; (2018-03) Trump accepted North Korea's invitation for direct nuclear talks.
China-India	(2016-04) Minister of Foreign Affairs meeting; (2016-11) China and India's joint military drill; (2017-02) India to develop a new missile; (2017-05) India refused to attend Belt and Road Summit; (2017-06) Doklam border standoff started; (2017-08) Doklam border standoff ended; (2017-11) China and India's WMCC meeting; (2018-03) China and India to boost trade.

Abstract

Titles of short sections within long documents support readers by guiding their focus towards relevant passages and by providing anchor-points that help to understand the progression of the document. The positive effects of section titles are even more pronounced when measured on readers with less developed reading abilities, for example in communities with limited labeled text resources. We, therefore, aim to develop techniques to generate section titles in low-resource environments. In particular, we present an extractive pipeline for section title generation by first selecting the most salient sentence and then applying deletion-based compression. Our compression approach is based on a Semi-Markov Conditional Random Field that leverages unsupervised word-representations such as ELMo or BERT, eliminating the need for a complex encoder-decoder architecture. The results show that this approach leads to competitive performance with sequence-to-sequence models with high resources, while strongly outperforming it with low resources. In a human-subjects study across subjects with varying reading abilities, we find that our section titles improve the speed of completing comprehension tasks while retaining similar accuracy.

1 Introduction

Section titles in long documents that explain the content of the section improve the recall of content (Dooling and Lachman, 1971; Smith and Swinney, 1992) while simultaneously increasing the reading speed (Bransford and Johnson, 1972). Additionally, they can provide a context to allow ambiguous words to be understood more easily (Wiley and Rayner, 2000) and to better understand the overall text (Kintsch and Van Dijk, 1978). However, most documents do not include titles for short segments or only provide a very abstract description of their topics, e.g. "Geography" or "Introduction". This makes them more inaccessible especially to readers with less developed reading skills, who have trouble identifying relevant information in text (Englert et al., 2009) and therefore more strongly rely on text-markups (Bell and Limber, 2009).

Lascaux cave complex discovered	When another old cave is discovered in the south of France, it is not usually news. Rather, it is an ordinary event. Such discoveries are so frequent these days that hardly anybody pays heed to them. However, when the *Lascaux cave complex* was *discovered* in 1940, the world was amazed. Painted directly on its walls were hundreds of scenes showing how people lived thousands of years ago. The scenes show people hunting animals, such as bison or wild cats. Other images depict birds and, most noticeably, horses, which appear in more than 300 wall images, by far outnumbering all other animals.
Paintings exposed to destructive action	Early artists drawing these animals accomplished a monumental and difficult task. They did not limit themselves to the easily accessible walls but carried their painting materials to spaces that required climbing steep walls or crawling into narrow passages in the Lascaux complex. Unfortunately, the *paintings* have been *exposed to* the *destructive action* of water and temperature changes, which easily wear the images away. Because the Lascaux caves have many entrances, air movement has also damaged the images inside. Although they are not out in the open air, where natural light would have destroyed them long ago, many of the images have deteriorated and are barely recognizable.
Site closed to tourists	To prevent further damage, the *site* was *closed to tourists* in 1963, 23 years after it was discovered.

Figure 1: Output example from our model (left) for an out-of-domain text (right).

This paper introduces an approach to generate section titles by extractively compressing the most salient sentence of each paragraph, as shown in Figure 1. While there has been much recent work on abstractive headline generation from a single sentence (Nallapati et al., 2016), abstractive models require larger datasets, which are not available in many domains and languages. Moreover, abstractive text-generation models tend to generate incorrect information for complex inputs (See et al., 2017; Wiseman et al., 2017). Misleading headlines can have unintended effects, affecting readers' memory and reasoning skills and even bias them (Ecker et al., 2014; Chesney et al., 2017). Especially in times of sensationalism and click-baiting, the unguided generation of titles can be considered unethical and we thus focus on the investigation of deletion-only approaches to title-generation. While this restricts this approach to languages that, similar to English, do not

Proceedings of NAACL-HLT 2019, pages 1677–1688
Minneapolis, Minnesota, June 2 - June 7, 2019.

lose grammatical soundness when clauses are removed, this approach is highly data-efficient and preserves the original meaning in most cases.

We approach the problem with a two-part pipeline where we aim to generate a title for each paragraph of a text, as illustrated in Figure 2. First, a SELECTOR selects the most salient sentence within a paragraph and then the COMPRESSOR compresses the sentence. The selector is an extractive summarization algorithm that assigns a score to each sentence corresponding to its likelihood to be used in a summary (Gehrmann et al., 2018). Algorithms for word deletion typically rely on linguistic features within a tree-pruning algorithm that identifies which phrases can be excluded (Filippova and Altun, 2013). Following recent work that shows the efficiency of contextual span-representations (Lee et al., 2016; Peters et al., 2018), we develop an alternative approach based on a Semi-Markov Conditional Random Field (SCRF) (Sarawagi and Cohen, 2005). The SCRF is further extended by a language model that ranks multiple compression candidates to generate grammatically correct compressions.

We evaluate this approach by comparing it to strong sequence-to-sequence baselines on an English sentence-compression dataset and show that our approach performs almost as well on large datasets while outperforming the complex models with limited training data. We further show the results of a human study to compare the effects of showing no section titles, human-generated titles, and titles generated with our method. The results corroborate previous findings in that we find a significant decrease in time required to answer questions about a text and an increase in the length of summaries written by test subjects. We also observe that the extractive algorithmic titles have a stronger effect on question answering tasks, whereas abstractive human titles have a stronger effect on the summarization task. This indicates that the inherent differences in how humans and our approach summarize the content of a section play a major role in how reading comprehension is affected.

2 Methods

2.1 SELECTOR

To select the most important sentence, we adapt an approach to the problem of content-selection in summarization, which has been shown to be effective and data-efficient (Gehrmann et al., 2018). An advantage of this approach over other extractive summarizers (e.g. Zhou et al. (2018)) is that those often model dependencies between selected sentences, which is not applicable to this problem since we only aim to extract a single sentence.

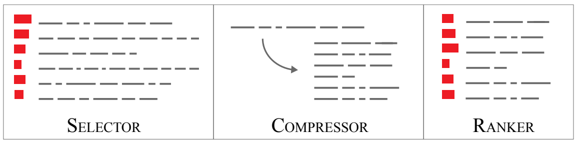

Figure 2: Overview of the three steps. The SELECTOR detects the most salient sentence. Then, the COMPRESSOR generates compressions and the RANKER scores the them.

Let $x = x_1, \dots, x_n$ denote a sequence of words within a paragraph, and $y = y_1, \dots, y_m$ a multi-sentence summary with $n \gg m$. Further, let $t = t_1, \dots, t_n$ be a binary alignment variable where t_i=1 iff $x_i \in y$. Using this alignment, the word-saliency problem is defined as learning a SELECTOR model that maximizes $\log p(t|x) = \sum_{i=1}^{n} \log p(t_i|x)$. Using this model, we calculate the relevance of a sentence $sent := x_{start}, \dots, x_{end}$, with $1 \leq start < end \leq n$, with a saliency function defined as

$$\text{saliency}(sent) = \frac{1}{|sent|} \sum_{i=1}^{|sent|} p(t_i|sent).$$

The sentence selection problem thus reduces to sentence with the most relevant words within a paragraph $para$,

$$\underset{\text{sent} \in \text{para}}{\text{argmax}} \ \text{saliency}(sent).$$

We first represent each word using two different embedding channels. The first is a contextual word representation using ELMo (Peters et al., 2018), and the second one uses GloVe (Pennington et al., 2014). Preliminary experiments corroborated the findings by Peters et al. that the combination of the embeddings help the model converge faster, and perform better with limited training data. Both embeddings for a word x_i are concatenated into one vector e_i, and used as input to a bidirectional LSTM (Hochreiter and Schmidhuber, 1997). Finally, the output of the LSTM h_i is used to compute the probability that a word is selected $\sigma(W_s^T h_i + b_s)$ with the trainable parameters W_s and b_s.

2.2 COMPRESSOR

We next define the problem of deletion-only compression of a single sentence. For simplicity of notation, let $x_1, \ldots, x_n$ refer to the words within a single sentence, and $y_1, \ldots, y_n$ be a binary indicator whether a word is kept in the compressed form. The compression $c(x, y)$ becomes

$$\mathrm{c}(x, y) = x_i \forall (x_1, y_1), \ldots, (x_n, y_n) \text{ iff } y_i = 1.$$

The challenge here is that choices are not made independently from another. Consider the sentence *The round ball flew into the net last weekend*, which should be compressed to *Ball flew into net*. Here, the choice to include *into* depends on first selecting the corresponding verb *flew*. One approach to this problem is to use an autoregressive sequence-to-sequence model, in which choices are conditioned on preceding ones. However, these models typically require too many training examples for many languages or domains. Therefore, we relax the problem by assuming that it obeys the Markov property of order L, and train a COMPRESSOR model to maximize $p(y|x) = \sum_{i=1}^{n} \log p(y_i | \mathbf{x}, y_{i-L:i-1})$. To still retain grammaticality, we define the additional problem of estimating the likelihood of a compression $p(\mathbf{y})$ with a RANKER model, described below.

We compare multiple approaches to deletion-based sentence compression. Throughout, we apply the same embedding as for the SELECTOR. Since a grammatical compression problem relies on the underlying linguistic features (Filippova and Altun, 2013), we process the source documents with spaCy (Honnibal and Montani, 2017) to include the following features in addition to contextualized word embeddings: (1) Part-of-speech tags, (2) Syntactic dependency tags, (3) original word shape, (4) Named entities. Each of these information is encoded in an additional embedding that is concatenated to the word embeddings. Over the final embedding vector, we use a bidirectional LSTM to compute the hidden representations $h_1, \ldots, h_n$ for this task.

Naive Tagger The simplest approach we consider is a naive tagger similar to the SELECTOR. We assume full independence between values in y. The probability $p(y_i{=}1|x)$ is computed as $\sigma(W_c^T w_1 + b_c)$ with trainable parameters W_c and b_c.

Conditional Random Field Compressed sentences have to remain grammatical, which implies a dependence between values in y. Without any restrictions on the dependence between choices, it is intractable to marginalize over all possible y with a scoring function for a given (x, y) pair,

$$p(y|x) = \frac{\exp \mathrm{Score}(x, y)}{\sum_{y'} \exp \mathrm{Score}(x, y')}. \tag{1}$$

Therefore, we assume that only neighboring values in y are dependent, and apply a linear-chain CRF (Lafferty et al., 2001) that uses h as its features to this problem.

We define a scoring function $\mathrm{Score}(x, y) = \sum_i \log \phi_i(x, y)$ that computes the (log) potentials at a position i using a function ϕ. The emission potential for a word x_i is computed as $\phi_i^{\mathrm{E}}(x, y) = W_{e2}(\tanh(W_{e1} h_i + b_{e1})) + b_{e2}$, using only the local information. The transition potential ϕ_i^{T} depends on the previous and current choice (y_{i-1}, y_i), and can be looked up in a 2 × 2 matrix that is learned during training. The complete scoring function can be expressed as

$$\mathrm{Score}(x, y) = \sum_{i}^{|y|} \left(\phi_i^{\mathrm{E}}(x, y) + \phi_i^{\mathrm{T}}(y_{i-1}, y_i) \right).$$

During training, we can minimize the negative log-likelihood in which the partition function is computed with the forward-backward algorithm. During inference, this formulation allows for exact inference with the Viterbi algorithm.

Semi-Markov Conditional Random Field Although compressed sentences should often include entire phrases, the CRF does not take into account local dependencies beyond neighboring words. Therefore, we relax the Markov assumption and score longer spans of words. This can be achieved with a SCRF (Sarawagi and Cohen, 2005). Following a similar approach as Ye and Ling (2018), let $s = \{s_1, s_2, \ldots, s_p\}$ denote the segmentation of x. Each segment s_i is represented as a tuple $\langle start, end, \tilde{y}_i \rangle$, where $start$ and the end denote the indices of the boundaries of the phrase, and $\tilde{y}$ the corresponding label for the entire phrase. To ensure the validity of the representation, we impose the restrictions that $start_1 = 1$, $end_p = |x|$, $start_{i+1} = end_i + 1$, and $start_i \leq end_i$. Additionally, we set a fixed maximum length L. We extend Eq. 1 to account for a segmentation s instead of individual tags such that

$$p(s|x) = \frac{\exp \text{Score}(s, x)}{\sum_{s'} \exp \text{Score}(s', x)},$$

marginalizing over all possible segmentations. The CRF represents a special case of the SCRF with $L = 1$. To account for the segment-level information, we extend the emission potential function to

$$\phi_i^{\text{E}}(x, \langle \tilde{y}, \mathit{start}, \mathit{end} \rangle) = \sum_{i=\mathit{start}}^{\mathit{end}} W_e^T h_i', \qquad (2)$$

where h_i' is the concatenation of h_i, $h_{start} - h_{end}$, and a span length embedding e_{len} to account for both individual words and global segment information. We also extend ϕ^T to include transitions to and from longer tagged sequences by representing targets as BIEUO tags (Ratinov and Roth, 2009). This formulation allows for similar training by minimizing the negative log-likelihood.

2.3 RANKER

The inference of the CRF and the SCRF require an estimation of the best possible segmentation $s^* = p(s|x)$, which can be computed using the Viterbi algorithm. However, CRFs and SCRFs are typically employed in sequence-level tagging with no inter-segment dependencies. The sentence compression task differs since a resulting compressed sentence should be grammatical. Therefore, we employ a language model (LM) to rank compression candidates based on the likelihood of the compressed sentence compress(x, s). Namely, we extend the inference target to

$$s_{LM}^* = \underset{s}{\text{argmax}} \; \left(p(s|x) + \lambda p(\text{compress}(x, s))\right),$$

using a weighting parameter λ. Since exact inference for this target is intractable, we approximate this inference by constraining the re-ranking to the K best segmentations according to a K-best Viterbi algorithm.

The RANKER uses the same word embeddings as the COMPRESSOR, and a bidirectional LSTM in order to maximize the probability of a sequence $\sum_i p(x_i|x_{1:i-1}) + p(x_i|x_{i+1:n})$. Using the hidden representation h_i, we compute a distribution over the vocabulary as softmax$(W_l h_i + b_l)$. We additionally use the same weights for word embeddings and W_l, which has been shown to improve language model performance (Inan et al., 2016). We prevent affording an advantage to shorter compressions c during the inference by applying length normalization (Wu et al., 2016) with a length penalty α.

2.4 Sequence-to-Sequence Baselines

The most common approach to summarization and sentence compression uses sequence-to-sequence (S2S) models that learn an alignment between source and target sequences (Sutskever et al., 2014; Bahdanau et al., 2014). S2S models are autoregressive and generate one word at a time by maximizing the probability $p(y|x) = \sum_i p(y_i|x, y_{1:i-1})$. Since this condition is stronger than that of CRF-based approaches, we hypothesize that S2S models perform better with unlimited training data. However, since S2S models need to jointly learn the alignment and generate words, they typically perform worse with limited data.

To test this hypothesis, we define two S2S baselines we compare to our models. First, we use a standard S2S model with attention as described by Luong et al. (2015). In contrast to the other approaches, this model is abstractive and has the ability to paraphrase and re-order words. We constrain these abilities in a second S2S approach as described by Filippova et al. (2015). This model is a sequential pointer-network (Vinyals et al., 2015) and can only generate words from the source sentence. Instead of using an attention mechanism to compute which word to copy, the model enforces a monotonically increasing index of copied words to prevent the re-ordering. We compare both against their reported numbers and our own implementation.

3 Data and Experiments

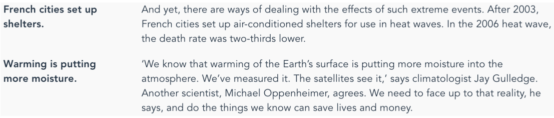
The SELECTOR is trained on the CNN-DM corpus (Hermann et al., 2015; Nallapati et al., 2016), which is the most commonly used corpus for news summarization (Dernoncourt et al., 2018). Each summary comprises a number of bullet points for an article, with an average length of 66 tokens and 4.9 bullet points. The COMPRESSOR is trained on the Google sentence compression dataset (Filippova and Altun, 2013), which comprises 200,000 sentence-headline pairs from news articles. The deletion-only version of the headlines was created by pruning the syntactic tree of the sentence and aligning the words with the headline. The largest comparable corpus Gigaword (Rush et al., 2015) does not include deletion-only headlines.

We limit the vocabulary size to 50,000 words for both corpora. Both SELECTOR and COMPRESSOR use a two-layer bidirectional LSTM with 64 hidden dimensions for each direction, and a word-embedding size of 200. Each linguistic feature is embedded into 30-dimensional space. During training, the dropout probability is set to 0.5 (Srivastava et al., 2014). The model is trained for up to 50 epochs or until the validation loss does not decrease for three consecutive epochs. We additionally halve the learning rate every time the validation loss does not decrease for two epochs. We use Adam (Kingma and Ba, 2014) with AMSGrad (Reddi et al., 2018), an initial learning rate of 0.003, and a $l2$-penalty weight of 0.001. The RANKER uses the same LSTM configuration, but we optimize it with SGD with 0.9 momentum, and an initial learning rate of 0.25.

The S2S models have 64 hidden dimensions for each direction of the encoder, and 128 dimensions for the decoder LSTM. They use one layer, and the decoder is initialized with the final state of the encoder. Our optimizer for this task is adagrad with an initial learning rate of 0.15, and an accumulator value of 0.1 (Duchi et al., 2011).

3.1 Automated Evaluation

In the automated evaluation, we focus on the compression models and first conduct experiments with the full dataset to compute an upper bound on the performance of our approach. This experiment functions as a benchmark to investigate how much better the S2S based approaches perform with sufficient data. The next experiment investigates a scenario, in which data availability is limited and ranges from 100 to 1000 training examples. We compare results with and without linguistic features to further evaluate whether these features improve the performance or whether contextual embeddings are a sufficient representation. In each experiment, we measure precision, recall, and F1-score of the predictions compared to the human reference, as well as the ROUGE-score. We additionally measure the length of the compressions to investigate whether methods delete a sufficient number of words.



French cities set up shelters.

And yet, there are ways of dealing with the effects of such extreme events. After 2003, French cities set up air-conditioned shelters for use in heat waves. In the 2006 heat wave, the death rate was two-thirds lower.

Warming is putting more moisture.

'We know that warming of the Earth's surface is putting more moisture into the atmosphere. We've measured it. The satellites see it,' says climatologist Jay Gulledge. Another scientist, Michael Oppenheimer, agrees. We need to face up to that reality, he says, and do the things we know can save lives and money.

Figure 3: Two paragraphs within the interface of our human evaluation with titles in the left-top margin of a paragraph. A side-effect of the data-efficient deletion-only approach, some titles look ungrammatical, as shown in the second example "*Warming is putting more moisture.*"

3.2 Human Evaluation

We evaluated the effect of our generated titles in a between-subjects study on Amazon Mechanical Turk. We compared three different conditions: no titles, human-generated titles, and algorithmically generated titles by our SCRF+Ranking model. Every participant kept their randomly assigned condition throughout all tasks. We defined the following three tasks to approximately measure the effect of short section titles on (1) retention of text, (2) comprehension of text, and (3) retrieval of information. **(Retention)** We first presented a text and then asked participants three questions about facts in the text. **(Comprehension)** We showed a text and then asked the participants to generate a three-sentence summary of the text. **(Retrieval)** We first presented two questions and then the text, prompting participants to find the answers.

Previous findings indicate that titles help with retention only when presented towards the beginning of a text (Dooling and Mullet, 1973). Thus, we place texts in the left margin at the top of a paragraph as shown in the example in Figure 3. This further avoids interrupting the reading flow of the long text while being integrated into the natural left-to-right reading process. Although reading comprehension is well studied in natural language processing, most datasets focus on machine comprehension (Richardson et al., 2013; Rajpurkar et al., 2016). Therefore, we adapted texts from the interactive reading practice by National Geographic, written by Helen Stephenson[1]. The 33 texts are based on articles and comprise three versions for each story; elementary, intermediate, and advanced, from which we selected intermediate and advanced versions. Topics of the

Table 1: Results of our models on the large dataset comprising 200,000 compression examples.

texts include Geography, Science, Anthropology, and History; their length ranges from four to seven paragraphs. Each text is accompanied by reading comprehension questions, which we utilized in the retention and retrieval tasks. We first excluded those questions where the answer was part of either human- or algorithmically generated summary. Of the remaining questions, we randomly selected three questions for each of the retention and retrieval tasks. The same questions were shown in either of the conditions.

Every participant completed six tasks, two for every possible task, one with intermediate and one with advanced difficulty. To account for the different backgrounds of participants, we also asked participants about their perceived difficulty for each task on a 5-point Likert scale. The total time to complete all tasks was limited to 30 minutes, and Turkers were paid $5. In total, we recruited 144 participants who self-reported that they fluently spoke English, uniformly distributed over the three conditions. They answered on average 68.25% of questions correctly and took 16.5 minutes to complete all six tasks. This is approximately 30% faster than the fastest graduate student we recruited for pilot-testing, indicating that Turkers aimed to complete the tasks as fast as possible, possibly by only skimming the text. We omitted results from participants with an answer accuracy of less than 25% (n=21), and excluded individual replies given in under 15 seconds (n=10) or over 10 minutes (n=5), leaving a total of 701 completed tasks. After excluding outliers, the correct answer average was 75.64%, while the time to completion increased by 15 seconds to 16.75 minutes.

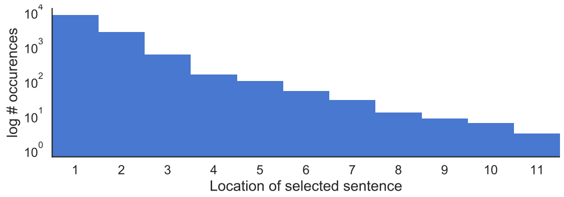

Figure 4: Index of extraction within a paragraph.

4 Results

Selector We compare the performance of the selector against the LEAD-1 baseline that naively selects the first sentence of a news article. This provides a strong comparison since a news article typically aims to summarize its content in the first sentence. LEAD-1 achieves ROUGE (1/2/L)-scores of 27.5/9.6/23.7 respectively. In contrast, our selector achieves scores of 30.2/12.2/26.45 which presents an improvement of over 10% in each category. We illustrate the source of this improvement in Figure 4, which shows the locations of selected sentences and observe a negative correlation between a later location within a text and the probability of being selected. However, in most cases, the first sentence is not the most relevant according to the model.

Unrestricted Data Table 1 shows the results of the different approaches on the large dataset. As expected, the copy-model performs best due to its larger modeling potential. It is closely followed by SCRF+Ranking, which comes within 0.2 F1-score when using additional features. This difference is not statistically significant, given the high variance of the results. Compared to the best reported re-

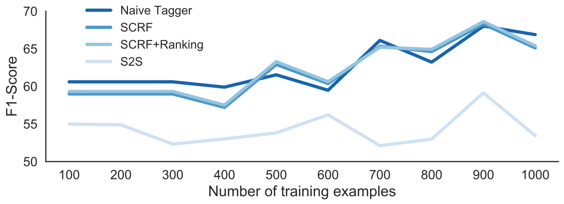

Figure 5: F1-scores of the different models with an increasing number of training examples.

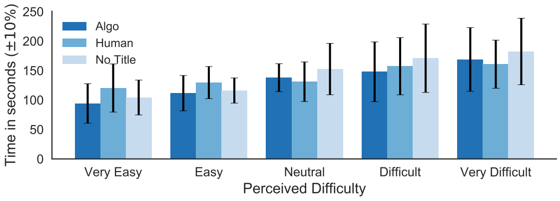

Figure 6: Mean and the 90% confidence interval of the time taken by Turkers to complete the tasks, grouped by the perceived difficulty.

sult in the literature by Filippova et al. (2015), our models perform almost as well, despite the fact that their model is trained on 2,000,000 unreleased datapoints compared to our 200,000. We further observe that all models generate compressed sentences of almost the same length between 8.7 and 9.5 tokens per compression.

The Naive Tagger also achieves comparable performance to the SCRF in F1-Score. To test whether our model leads to a higher fluency compared to it, we additionally measure the ROUGE score. In ROUGE-2, we find that the SCRF+Ranking leads to an increase from 58.1 to 60.1, with an increase in bigram precision by 5 points from 64.5 to 69.3. The Naive Tagger is more efficient at identifying individual words, with a ROUGE-1 of 71.3 when the ranking approach only achieves 68.7. While these differences lead to similar ROUGE-L scores between 69.9 and 70.2, the fact that the ranking-based approach matches longer sequences indicates higher fluency. In an analysis of samples from the Naive Tagger, we found that it commonly omits crucial verb-phrases from compressed sentences.

We show compressions from two paragraphs in the NatGeo data in Figure 3. This example illustrates the robustness of the compression approach to out-of-domain data when including linguistic features. Despite the fact that the example text is not a news article like the training data, it performs well and generates mostly grammatical compressions.

Limited Data We present results on limited data in Figure 5. The results show the major advantage of the simpler training objective. All of the tagging-based models outperform the S2S baselines by a large margin due to their data-efficiency. We did not observe a significant difference between the different tagging approaches in the limited data condition. In our experiments, we found that the S2S models start outperforming the simpler models at around 20,000 training examples. Despite its high F1-Score, the Naive Tagger suffers from ungrammatical output in this condition as well, with the readability scoring significantly lower than the SCRF outputs. We argue that the SCRF+Ranking approach represents the best trade-off of our presented models since it performs well with limited data while performing almost as well as complex models in unlimited data situations. This makes it most flexible to apply to a wide range of tasks.

Human Evaluation In the human study, we notice an immediate effect of the difficulty of texts. Between the intermediate and advanced versions of the texts, the mean time to complete the tasks increases by 8 seconds (from 125 to 133 seconds). Additionally, the mean perceived difficulty increases from 2.40 to 2.55 (in between Easy and Neutral). The largest observed effect of text difficulty is on the accuracy of answers, which decreases from 84.4% to 67.5%, indicating that within a similar time frame, the difficult texts were harder to understand.

We present a breakdown of time spent on a task by perceived difficulty for each of the conditions in Figure 6. There is a positive correlation between perceived difficulty and time spent on a task across all conditions. Interestingly, tasks rated Very Easy and Easy were completed slower in the human condition than in the no-title condition, but faster with the algorithmically generated ones. This effect alleviates in the higher difficulties, in which the no-title condition takes longest. Indeed, a comparison between the algorithmic and no title conditions reveals a decrease in time by 19.8 seconds in the retention task, significant with $p < 0.005$ according to a χ^2 test. Interestingly, we can observe opposite effects in the human condition. Here, the comprehension task is completed 15.4 seconds faster ($p < 0.005$), but the other tasks only show minor effects.

Task	Measure	Intervention	Effect Size	p-value
Retention	Time Taken (sec)	Human	-2.2	0.63
		Algo	-27.1	0.01*
	Accuracy	Human	-0.01	0.07
		Algo	-0.01	0.13
Retrieval	Time Taken (sec)	Human	-0.9	0.87
		Algo	-4.5	0.03*
	Accuracy	Human	+0.01	0.20
		Algo	-0.01	0.15
Comprehension	Time Taken (sec)	Human	-20.9	0.03*
		Algo	-2.6	0.04*
	Summary Length (words)	Human	+8.6	0.02*
		Algo	+5.3	0.03*
	Readability	Human	-0.1	0.24
		Algo	-0.1	0.50
	Relevance	Human	-0.02	0.92
		Algo	+0.01	0.63

Table 2: The causal effects of the human and algorithmic section titles on different measures differ across tasks. All the shown effect sizes are measured in comparison to the baseline without any shown titles. Significant p-values at a 0.05 level are marked with a *.

To further investigate these effects, we analyze the causal effect of our three conditions by measuring the average treatment effect while controlling for both actual and perceived difficulty of the tasks with an Ordinary Least Squares analysis. Whenever possible, we additionally condition on the total time taken. An overview of our tests is presented in Table 2. In the causal tests, we observe similar effects in the retention task – the algorithmically generated titles lead to a decrease in time required for the task with an effect size of 27.1 seconds. In contrast, human-generated titles only lead to a non-significant 2.2-second decrease. We observe a non-significant decrease of approximately 4% in accuracy with added titles. We observed no effect of adding titles on the perceived difficulty of this task. In the retrieval task, added titles result in a weaker effect. The algorithmic titles decrease time by only 4.5 seconds, and the human titles by non-significant 0.9 seconds. Similar to the retention task, there is no significant change in accuracy, with all accuracy levels within 1% from another and we observe no effect on the perceived difficulty.

In the comprehension task, it is not possible to measure accuracy. Instead, we evaluate readability and relevance as judged by human raters on a five-point Likert scale, two commonly used metrics for abstractive summarization (Paulus et al., 2017). We present the average ratings in Table 3 and observe that there is almost no difference in relevance and only a minor (not significant) decrease in readability with either condition. Curiously, the previous effect on speed reverses in this task – algorithmic titles only lead to a 2.6-second decrease in time, while human titles lead to a 20.9-second decrease. Both conditions additionally lead to longer summaries; algorithmic titles by 5.3 words and human titles by 8.6 words. One potential explanation for this behavior could be that subjects copied the presented section titles into the summary text field. This was not the case, since, on average, only 2.8-3.7% of the bigrams in the titles were used in the summaries, across both conditions and difficulties (0.6-1.5% of trigrams, 0.1-0.8% of 4-grams).

	Readability		Relevance	
Condition	μ	σ	μ	σ
No title	4.66	0.65	4.11	0.86
Human	4.55	0.76	4.09	0.95
Algo	4.52	0.72	4.12	1.02

Table 3: Human ratings for human-generated summaries while showing different section titles.

Given the similar relevance scores, we thus argue that presenting the titles leads to more detailed descriptions of the texts. Similarly to the other tasks, the perceived difficulty does not change significantly. However, we note that some subjects noted that there were some ungrammatical generated titles, which is an artifact of the deletion-only approach. Future work may investigate how abstractive approaches that are not restricted to deletion-based approaches can be applied to the same problem.

Overall, the results of the human-subject study reveal an effect that is well studied in the literature. Namely, that the type of title influences what is being remembered about a text (Schallert, 1975), and that different headline styles affect readers in different ways (Lorch Jr et al., 2011). Kozminsky (1977) found that the immediate free recall of information is biased towards topics emphasized in titles. The better performance in memorization tasks in the algorithmic condition can be explained by the fully extractive approach that immediately shows information judged most relevant by the model. In contrast, human-generated titles show a higher level of abstraction and generalization, which is more helpful for the overall comprehension but does not emphasize any piece of information.

5 Related Work

The aim of SCRFs is to learn a segmentation of a sequential input and assigning the same label to an entire segment. While they were originally developed for information extraction (Sarawagi and Cohen, 2005), it is most commonly applied to speech recognition within the acoustic model to improve segmentation between different words (He and Fosler-Lussier, 2015; Lu et al., 2016; Kong et al., 2015). Similar to this work, it has also been shown that coupling an LM with an SCRF can improve segmentation through multi-task training (Lu et al., 2017; Liu et al., 2017). SCRFs have also been applied to sequence tagging tasks, for example, the extraction of phrases that indicate opinions (Yang and Cardie, 2012). In this work, we built upon an approach by Ye and Ling (2018) who recently introduced a hybrid SCRF that uses both word- and phrase-level information. Alternative approaches for similar tasks are CRFs that estimate pairwise potentials rather than using a fixed transition matrix (Jagannatha and Yu, 2016) or high-order CRFs which outperform SCRFs in some sequence labeling tasks (Cuong et al., 2014).

While this work is the first to apply SCRFs to sentence compression, Grootjen et al. (2018) also use extractive summarization techniques to improve reading comprehension by highlighting relevant sentences. Most similar to our compression approach is Hedge Trimmer (Dorr et al., 2003), which compresses sentences through deletion, but uses an iterative shortening algorithm based on linguistic features. Extending this work, Filippova and Altun (2013) apply a similar approach on linguistic features, but learn weights for the shortening algorithm. Both approaches also do not consider the selection of the sentence to be compressed, unlike our proposed model.

6 Conclusion

In this work, we have presented a novel approach to section title generation that uses an efficient sentence compression model. We demonstrated that our approach performs almost as well as sequence-to-sequence approaches with unlimited training data while outperforming sequence-to-sequence approaches in low-resource domains. A human evaluation showed that our section titles lead to strong improvements across multiple reading comprehension tasks. Future work might investigate end-to-end approaches, or develop alternative approaches that generate titles more similar to how humans write titles.

Unifying Human and Statistical Evaluation for Natural Language Generation

Abstract

How can we measure whether a natural language generation system produces both high quality and diverse outputs? Human evaluation captures quality but not diversity, as it does not catch models that simply plagiarize from the training set. On the other hand, statistical evaluation (i.e., perplexity) captures diversity but not quality, as models that occasionally emit low quality samples would be insufficiently penalized. In this paper, we propose a unified framework which evaluates both diversity and quality, based on the optimal error rate of predicting whether a sentence is human- or machine-generated. We demonstrate that this error rate can be efficiently estimated by combining human and statistical evaluation, using an evaluation metric which we call HUSE. On summarization and chit-chat dialogue, we show that (i) HUSE detects diversity defects which fool pure human evaluation and that (ii) techniques such as annealing for improving quality actually decrease HUSE due to decreased diversity.

1 Introduction

Generating text is a core part of many NLP tasks such as image captioning (Lin et al., 2014), open-domain dialogue (Sordoni et al., 2015), story generation (Roemmele, 2016), and summarization (Nallapati et al., 2016). However, proper evaluation of natural language generation has proven difficult (Liu et al., 2016; Novikova et al., 2017; Chaganty et al., 2018). A good evaluation metric should not only capture the *quality* of generation, but also the *diversity* of generation, which is especially crucial for creative, open-ended tasks like dialogue or story generation.

Human evaluation, which is often viewed as the gold standard evaluation, captures quality but fails to capture diversity. As an example, for language modeling, a model that directly plagiarizes sentences from the training set would pass the human quality bar but would have zero generalization ability and thus have inadequate diversity. On the other hand, *statistical evaluation*—i.e., perplexity on a reference test set—captures diversity, as it ensures a model must assign reasonable probability to novel sentences, but perplexity provides an inadequate measure of quality (Theis et al., 2015). For example, modifying a perfect model by removing its ability to generate even a single test sentence results in *infinite* perplexity even though the model is still near-perfect. Automatic metrics such as BLEU (Papineni et al., 2002) and ROUGE (Lin and Rey, 2004) capture quality better than perplexity but still correlate poorly with human evaluation and fail to capture diversity (Novikova et al., 2017; Chaganty et al., 2018).

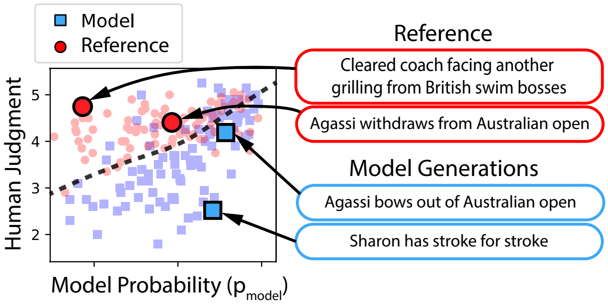

Figure 1: HUSE is twice the classification error of distinguishing reference and generated text based on human judgment scores and model probabilities. HUSE identifies samples with defects in quality (Sharon has stroke . . .) and diversity (Cleared coach facing . . .).

Existing approaches to combining statistical and human evaluation have been ad-hoc, leading to misleading performance measures. A common approach is to measure diversity through the perplexity of a probabilistic model and quality through human evaluation on beam-searched out-

Proceedings of NAACL-HLT 2019, pages 1689–1701
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

puts. This gives the illusion that a single model is high-quality and diverse, while the reality is that it shows we can have either a diverse model (when sampling from the distribution used to compute perplexity) *or* a high-quality model (when beam-searching).

In this paper, we define the idealized evaluation metric as twice the error of the *optimal discriminator* for classifying sentences as coming from the reference distribution or the model (Section 2). If a model generates gibberish (low quality), the optimal discriminator can classify these accurately as coming from the model. If the reference distribution contains sentences the model cannot generate (low diversity), the optimal discriminator can classify these accurately as coming from the reference.

Unfortunately, the optimal discriminator is unavailable. Human discriminators cannot capture diversity effectively, and learned discriminators—e.g., from a Generative Adversarial Network (Goodfellow et al., 2014) or one trained on human judgments (Lowe et al., 2017)—are too unreliable to use for rigorous evaluation.

Our key result (Section 3) is based on the observation that the optimal classifier depends only on two numbers: the probability of a sentence under the model and the probability under the reference distribution. The former can be computed directly from the model, and we show that the latter can be well-approximated by human judgment scores. The resulting two-dimensional space is illustrated in Figure 1. We apply a simple k-nearest neighbor classifier in this space and define Human Unified with Statistical Evaluation (HUSE) as twice the leave-one-out error of this classifier.

We apply HUSE to four natural language generation tasks (Section 5): language modeling, chitchat dialogue, story generation, and summarization. First, we show that human evaluation alone is insufficient to discriminate model generations from the references, leading to inflated estimates of model performance. In contrast, HUSE is able to reveal deficiencies of current models. We also show that common techniques for improving sample quality such as annealing actually increase distinguishability between the model and reference due to losses in diversity.

2 Optimal Discriminator

Consider a natural language generation task where the model is given a context x (e.g., a dialogue history) drawn from some prior $p(x)$ and must output a distribution over possible sentences $p_{\text{model}}(y \mid x)$. We define an idealized evaluation metric based on whether p_{model} is close to a *reference distribution* p_{ref}, which is generally human-generated.[1] Specifically, consider a random variable y drawn from either the reference or the model based on an indicator $z \sim \text{Bernoulli}\left(\frac{1}{2}\right)$:

$$y \mid x, z \sim \begin{cases} p_{\text{ref}}(y \mid x) & \text{if } z = 1 \\ p_{\text{model}}(y \mid x) & \text{if } z = 0. \end{cases} \tag{1}$$

Define L^* to be twice the lowest possible error over any discriminator f that attempts to determine z based on x and y:

$$L^* \overset{\text{def}}{=} 2 \inf_f \mathbb{P}[f(x, y) \neq z]. \tag{2}$$

L^* measures similarity between p_{model} and p_{ref}; it is 0 if p_{model} and p_{ref} are disjoint and 1 if they are identical.[2]

Obstacles. Unfortunately, L^* is unattainable because it requires computing the optimal discriminator. In the spirit of the Turing Test, we could consider using the error rate of a human discriminator f_{hum} instead, often considered the gold standard for evaluation. However, while humans might have knowledge of p_{ref}, they do not have full knowledge of p_{model} and thus would have difficulties determining which sentences a model *cannot* generate.

As a concrete example, suppose p_{ref} placed a uniform distribution over some set S. Without knowledge of p_{model} the most sensible discriminator is to predict $z = 1$ (reference) when $y \in S$. This discriminator achieves the same classification error of 0.5 for both the perfect model $p_{\text{model}} = p_{\text{ref}}$ and one which can only return a single $y \in S$. We could try to reveal p_{model} to humans by showing multiple samples simultaneously, but this is expensive and, as we will later see, unnecessary.

Another option is to learn f over an expressive class of functions such as neural networks on data

---

[1] While some tasks only care about quality and thus only require p_{model} to place mass on *some* high quality y, we demand that p_{model} places mass on *all* high quality y as given by p_{ref}. This diversity is important for open-ended tasks such as dialogue or story generation. Also note that p_{ref} need not be the human distribution, or match the training distribution. It can be defined as the distribution given by experts.

[2] Note that L^* is a linear function of the total variational divergence: $\|p_{\text{model}} - p_{\text{ref}}\|_{\text{TV}} \overset{\text{def}}{=} \sum_{x,y} p(x) \left|p_{\text{model}}(y \mid x) - p_{\text{ref}}(y \mid x)\right| = 1 - L^*$. See Appendix A.1 for details.

sampled from p_{model} and p_{ref}. This is analogous to learning the discriminator in a Generative Adversarial Network (GAN) (Goodfellow et al., 2014) or learning an evaluation metric from human judgments (Lowe et al., 2017). However, as (x, y) are high-dimensional objects, training a good classifier is extremely difficult (and perhaps not significantly easier than solving the original generation problem). Indeed, learned evaluation metrics do not generalize very well (Lowe et al., 2017; Chaganty et al., 2018). Unlike these approaches which seek to replace human evaluation, our focus will instead be on combining human and automatic statistical evaluation to estimate the *optimal* classifier error.

3 Human Unified with Statistical Evaluation (HUSE)

Our key result is that the optimal discriminator depends on (x, y) only through a two-dimensional sufficient statistic (Section 3.1), motivating an approximation which we call HUSE (Section 3.2).

For any feature map ϕ that maps (x, y) to $\phi(x, y) \in \mathbb{R}^d$, define the evaluation score $L(\phi)$ to be twice the error rate of the optimal discriminator that depends on (x, y) *only* through ϕ:

$$L(\phi) \overset{\text{def}}{=} 2 \inf_f \mathbb{P}[f(\phi(x, y)) \neq z]. \tag{3}$$

Note that the evaluation score $L(\phi)$ given by a feature map ϕ optimizes over all functions that depend on ϕ (3). Thus, the more information ϕ contains, the lower $L(\phi)$ is. This has two implications: First, any feature map ϕ yields an (optimistic) *upper bound* on L^* (2), meaning that $L(\phi)$ might be able detect when a model is poor but cannot certify that it is good. Second, adding features to ϕ can only improve this bound.

3.1 Two features suffice

Let us consider the following two-dimensional feature map:

$$\phi_{\text{opt}}(x, y) \overset{\text{def}}{=} \left[p_{\text{ref}}(y \mid x), p_{\text{model}}(y \mid x)\right]. \tag{4}$$

From the arguments above, it is clear that $L(\phi_{\text{opt}}) \geq L^*$, but perhaps more surprisingly, we actually have equality:

Proposition 1. *The two-dimensional feature map* ϕ_{opt} *achieves the optimal discriminator score:* $L(\phi_{opt}) = L^*$.

Proof We compute the true posterior over z given x, y. Since $p(z = 1) = p(z = 0) = \frac{1}{2}$, $p(y \mid x, z = 1) = p_{\text{ref}}(y \mid x)$ and $p(y \mid x, z = 0) = p_{\text{model}}(y \mid x)$, by Bayes' rule:

$$p(z = 1 \mid x, y) = \frac{p_{\text{ref}}(y \mid x)}{p_{\text{ref}}(y \mid x) + p_{\text{model}}(y \mid x)}.$$

The optimal discriminator simply predicts $z = 1$ if $p_{\text{ref}}(y \mid x) > p_{\text{model}}(y \mid x)$ and $z = 0$ otherwise. In other words, the decision boundary is given by $\phi_{\text{opt}}(x, y)_1 > \phi_{\text{opt}}(x, y)_2$. $\square$

More generally, we can obtain this equality with a wider class of ϕ. It will hold exactly for any invertible transformation of ϕ_{opt} (Appendix Corollary 1), and approximately for any ϕ which has high mutual information with ϕ_{opt} (Appendix Theorem 1). This means that we can substitute p_{ref} with noisy, possibly un-normalized estimates and still obtain accurate estimates of L^*.

3.2 HUSE features

While we can directly compute $p_{\text{model}}(y \mid x)$ for many probabilistic models, $p_{\text{ref}}(y \mid x)$ is unattainable, so $L(\phi_{\text{opt}})$ is not computable. However, the *wisdom of the crowds* (Surowiecki, 2004; Ungar et al., 2012) suggests that pooling together the judgments of many humans can often produce surprisingly reliable estimates of real-world probabilities such as $p_{\text{ref}}(y \mid x)$, even if no individual human is particularly reliable. With this motivation, we ask Amazon Mechanical Turk workers to rate a sentence from 1–5 based on how "typical" it is as a way to estimate $p_{\text{ref}}(y \mid x)$. (see Appendix A.3 for more details). We define HJ(x, y) to be the average response over 20 crowdworkers. Figure 2 shows that for a language modeling task on the Reddit corpus,[3] HJ(x, y) strongly correlates with the actual log-frequency of y in the corpus. The high correlation suggests that human judgments HJ(x, y) are a good surrogate for $\log p_{\text{ref}}$.

In addition, we found that rather than using the model probability $p_{\text{model}}(y \mid x)$ directly as a feature, normalizing by sentence length len(y) yielded lower (tighter) scores. We therefore define the HUSE features as follows:

$$\phi_{\text{huse}}(x, y) \overset{\text{def}}{=} \left[\frac{\log p_{\text{model}}(y \mid x)}{\text{len}(y)}, \text{HJ}(x, y)\right], \tag{5}$$

---

[3] We used the Reddit corpus due to crowdworker familiarity, corpus size, and short average sentence length, which results in a wide range of sentence frequencies.

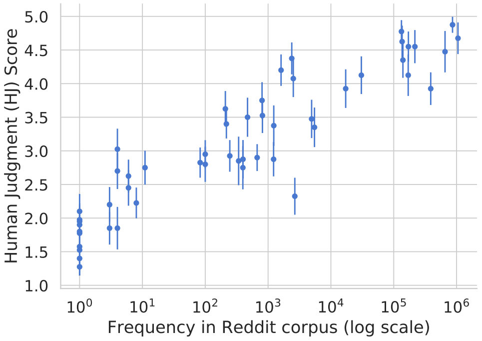

Figure 2: On the Reddit corpus, human judgment (HJ) of the "typicality" of a sentence y correlates strongly ($r = 0.92$) with its frequency in the corpus, suggesting that HJ is a good surrogate for $\log p_{\text{ref}}$. Error bars at the 90% confidence interval.

and define the (population) *HUSE score* as $L(\phi_{\text{huse}})$.

3.3 Guarantees derived from HUSE

We now show that the HUSE score satisfies two nice properties: (i) HUSE does at least as well as human evaluation and (ii) a low HUSE score is *sufficient* to show that a model is far from the reference distribution.

To show (i), consider a feature map that only includes human evaluation: $\phi_{\text{hj}}(x, y) \overset{\text{def}}{=} [\text{HJ}(x, y)]$. Because ϕ_{huse} also incorporates human evaluation, $L(\phi_{\text{huse}})$ is always tighter (lower) than the human discriminator error $L(\phi_{\text{hj}})$:

Proposition 1 (Relationship between HUSE, human evaluation, and optimal scores)**.**

$$L(\phi_{hj}) \geq L(\phi_{huse}) \geq L^*. \tag{6}$$

Furthermore, the main difference between $L(\phi_{\text{huse}})$ and L^* is that the former uses $\text{HJ}(x, y)$ and the latter uses p_{ref}. But as we argued using Figure 2, $\text{HJ}(x, y)$ is strongly correlated with p_{ref}, and good approximations to p_{ref} provide approximation guarantees for $L(\phi_{\text{huse}})$ (Appendix Theorem 1).

4 Evaluating models with HUSE

In this section, we show how we can estimate the error rate $L(\phi)$ from finite data (Section 4.1). We then show how the HUSE estimate $(\hat{L}(\phi_{\text{huse}}))$ can be decomposed into a score that measures quality (HUSE-Q) and a score that measures diversity (HUSE-D), which allows us to study quality-diversity tradeoffs (Section 4.2).

4.1 Learning a discriminator

For any feature map ϕ, we show how to produce an estimate of $L(\phi)$. Fix n contexts $x_1, \ldots, x_n$. First, we draw n examples $y_1, \ldots, y_n$ from the reference distribution $p_{\text{ref}}(y \mid x)$, which are usually human-generated sentences from a test set. We also draw n examples $y'_1, \ldots, y'_n$ from the model $p_{\text{model}}(y \mid x)$ we wish to evaluate. Next, for each of the $2n$ examples (x, y), we compute the feature map $\phi(x, y)$, which might involve evaluating the model probability $p_{\text{model}}(y \mid x)$ as well as collecting human judgments $\text{HJ}(x, y)$ from crowdworkers.

Finally, we compute the leave-one-out error of a classifier that tries to predict whether a given example (x, y) comes from the reference distribution $(z = 1)$ or the model $(z = 0)$.

The classification problems for HUSE are two-dimensional, which allows us to accurately estimate error rates using a k-nearest neighbors classifier. We opt to use nearest neighbors classifiers as they are simple, require no training, and can asymptotically capture arbitrary continuous decision boundaries. Specifically, we set $k = 16$ and define neighbors using L_2 distances over the feature vectors $\phi(x, y)$ scaled componentwise to have unit variance. The overall procedure for computing the estimate $\hat{L}(\phi)$ is formally defined in Algorithm 1.

Algorithm 1 Estimating error rates under ϕ

```
Require: Feature map $\phi$, number of neighbors $k$
    Contexts $x_1, \ldots, x_n$
    Reference outputs $y_1, \ldots, y_n$
    Model outputs $y'_1, \ldots, y'_n$
Construct dataset:
    $\mathcal{D} = \bigcup_{i=1}^{n} \{(\phi(x_i, y_i), 1), (\phi(x_i, y'_i), 0)\}$
$\hat{L}(\phi) \overset{\text{def}}{=}$ leave-one-out error of $k$-NN on $\mathcal{D}$
```

4.2 Quality-diversity decomposition

We now define the (empirical) *HUSE score* using the feature map ϕ_{huse}:

$$\text{HUSE} \overset{\text{def}}{=} \hat{L}(\phi_{\text{huse}}). \tag{7}$$

We define the quality component of HUSE (HUSE-Q) similarly using human judgments alone:

$$\text{HUSE-Q} \overset{\text{def}}{=} \hat{L}(\phi_{\text{hj}}). \quad (8)$$

Since humans can detect quality defects in a model, any increase in error from removing p_{model} must come from a model's lack of diversity. Therefore, we define the diversity component (HUSE-D) as follows:

$$\text{HUSE-D} \overset{\text{def}}{=} 1 + \text{HUSE} - \text{HUSE-Q}, \quad (9)$$

which implies the decomposition $(1-\text{HUSE-D})+(1-\text{HUSE-Q}) = 1-\text{HUSE}$. As long as the discriminators are non-degenerate (obtaining better performance than chance and HUSE $>$ HUSE-Q), all scores are contained in $[0, 1]$. Here, HUSE-D $= 1$ implies that the model suffers no diversity defects, while HUSE-D $= 0$ indicates that the examples could be discriminated perfectly due to a lack of diversity.

5 Experiments

5.1 Experimental setup

We use HUSE to evaluate three different types of single-sentence natural language generation tasks: (i) unconditional and high entropy (language modeling); (ii) conditional and high entropy (story generation, chit-chat dialogue); and (iii) conditional and low entropy (summarization). We show that HUSE provides a direct and interpretable measure of diversity on high-entropy tasks, while also serving as a useful model diagnostic on low-entropy ones.

The four tasks along with the datasets and models are as follows:

- **Summarization**: Giganews story to headline dataset and the pre-trained model from Gehrmann et al. (2018). The dataset consists of 3.8 million news story-headline pairs. Examples from this dataset are shown in Table 2.

- **Story generation**: Last sentence generation for ROC stories (Mostafazadeh et al., 2016) consisting of 96,198 examples of partially written four-sentence stories as input, and a single sentence which completes the story as the target. We use a standard OpenNMT model with global attention (Klein et al., 2017).

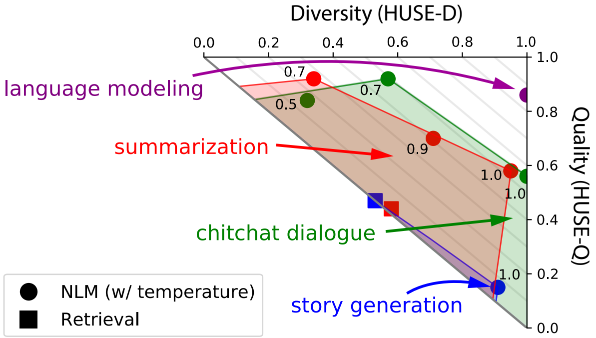

Figure 3: Tradeoffs between HUSE-D and HUSE-Q. Points are models and color indicates task. Neural models (circle) generate using temperature annealing (point labels indicate temperature). Models closer to the top right are superior, and gray diagonal lines indicate equivalent HUSE. A shaded region for a task indicates models which are strictly dominated (worse HUSE with the same HUSE-D-HUSE-Q proportion). Annealing can trade-off between diversity and quality but cannot easily increase the underlying model performance (HUSE).

- **Language modeling**: One billion word benchmark pre-trained language model from Jozefowicz et al. (2016). The task consists of generating a single sentence from the one billion word newswire text distribution.

- **Chit-chat dialogue**: Two-turn chit-chat dialogue dataset consisting of 37.3 million comment-response pairs from Reddit (Appendix A.4). Comments are generally short (5–15 tokens) and cover a single topic (e.g. given "wow how did i not notice that", the response is "you were focusing on other things its understandable"). We train a convolutional model using fairseq (Gehring et al., 2017).

For all the tasks, we train neural models and evaluate their diversity-quality tradeoffs as we change the decoding scheme for generation. Our primary evaluation concerns diversity trade-offs involving **temperature annealing** which is a generation technique applicable to any probabilistic model that generates words sequentially. In temperature annealed models, we sample a word w proportional to $p^{1/t}(w)$ where p is the model probability of w given previous words and t is the temperature parameter. We excluded beam search since it qualitatively behaves similarly to temperature annealing with low temperatures and HUSE ≈ 0 due to beam search being extremely

Score	Summarization $t = 1.0$	Summarization $t = 0.7$	Story generation $t = 1.0$	Story generation Retrieval	Chit-chat dialogue $t = 1.0$	Chit-chat dialogue $t = 0.7$	LM $t = 1.0$
HUSE	**0.53**	0.26	**0.06**	0.00	**0.56**	0.49	**0.86**
HUSE-Q	0.58	**0.92**	0.15	**0.47**	0.56	**0.92**	**0.88**
HUSE-D	**0.95**	0.34	**0.91**	0.53	**1.00**	0.57	**1.02**

Table 1: Performance achieved by the best models on the four tasks, as measured by overall goodness-of-fit (HUSE), sample quality (HUSE-Q) and diversity (HUSE-D). The scale for HUSE and HUSE-Q ranges from 0.0 (completely distinguishable from reference) to 1.0 (indistinguishable from reference) where the implied classification error is HUSE$/2$. HUSE-D may exceed 1.0 with small sample sizes when HUSE-Q $>$ HUSE.

under diverse.

As a non-neural baseline, we also consider retrieval based models based on Apache `solr` on a few tasks. For this approach, we retrieve the single most relevant response from the training set using the BM25 similarity metric on inputs. Such models are known to perform well in tasks with complex outputs such as program generation (Hayati et al., 2018; Hashimoto et al., 2018) and style transfer (Li et al., 2018).

For cost reasons, we did not measure certain combinations of task and generation mechanisms. We did not measure retrieval for chit-chat dialogue, as we observed its outputs were lower quality than a low-temperature neural model. We also did not anneal language models, as the generation quality from the language model was already high, and our goal was to show that they achieved high HUSE. Our set of measurements, while not comprehensive, generally covers the available quality-diversity tradeoffs for conditional tasks.

Finally, we collect human judgments HJ(x, y) as per Section 4.1 where we query 20 Amazon Mechanical Turk crowdworkers for typicality ratings on 100 reference and 100 model sentences. Since our models generate UNK (unknown and out-of-vocabulary) tokens, we instructed crowdworkers to treat UNK tokens as rare, but appropriate words for the context.

5.2 Overall results

The HUSE scores across the four tasks vary widely. Table 1 shows that single-sentence language models are nearly indistinguishable, with HUSE $= 0.86$ and implied discriminator error of 43%.

In contrast, both summarization and dialogue are highly distinguishable (HUSE ≈ 0.5) with relatively low quality when sampled from $t = 1.0$. Human evaluation alone (HUSE-Q) would suggest that using temperature annealing $(t = 0.7)$ to emphasize high-probability outputs substantially improves the model (HUSE-Q goes from 0.58 to 0.92 for summarization and 0.56 to 0.92 for dialogue). However, we find that this increase in sample quality comes at the cost of diversity (HUSE-D goes from 0.95 to 0.34 for summarization and 1.0 to 0.57 for dialogue). Examining the achievable HUSE and diversity tradeoffs in Figure 3 shows that mechanisms such as annealing which improve sample quality actually degrade HUSE due to severe losses in diversity.

We find that all generation schemes and models are inadequate for story generation on ROC stories. The original model $(t = 1.0)$ is very easily distinguishable by a human (HUSE-Q $= 0.15$), corresponding to a discriminator error of 7%. The retrieval models can improve this to HUSE-Q $=$ 0.47, but this comes at the expense of diversity.

Finally, we observe that directly sampling from the model $(t = 1.0)$ is always diverse. This suggests that human evaluation is an appropriate evaluation for generation systems that are directly sampled (rather than beam-searched).

5.3 Model error analysis with HUSE

Since HUSE is estimated from a two-dimensional classification problem, we can directly visualize the classification problem to understand defects in both model quality and diversity.

Figure 4 shows both reference points $\phi_{\text{huse}}(x_i, y_i)$ (blue squares) and model points $\phi_{\text{huse}}(x_i, y'_i)$ (red circles) for the summarization task. The shaded areas indicate the decision boundary of the 16-nearest neighbor classifier.

At temperature $t = 1.0$, we find that the classification boundary is mostly horizontal, implying that human judgment alone can distinguish model outputs from references. There is a cluster of sentences with high HJ and high p_{model} which are es-

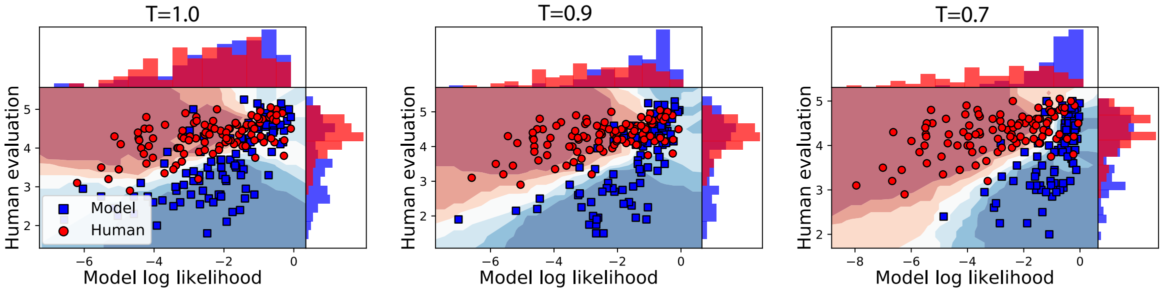

Figure 4: The two-dimensional classification problem in Algorithm 1 on the summarization task with different softmax temperatures (three panels). Each point represents a reference sentence $\phi_{\text{huse}}(x_i, y_i)$ or model-generated sentence $\phi_{\text{huse}}(x_i, y'_i)$. The color denotes the source of the sentence (z), shading is the classification confidence of the nearest neighbor classifier.

sentially indistinguishable. Examining the samples in this top-right region reveals that these are news stories with short headlines such as "Nadal pulls out of Sydney International" which can be reliably generated even at $t = 1.0$. However, the model frequently generates low quality samples that can easily be distinguished such as "two new vaccines in the poor countries were effective against go-it-alone study says" (Table 2).

At lower temperatures of $t = 0.9$ and $t = 0.7$, the boundary shifts towards becoming diagonal. Although the distribution is no longer directly separable on human judgment, the two distributions are clearly separable with the inclusion of p_{model}.

Using Figure 4, we can identify individual examples which were correctly and incorrectly classified based on p_{model} and HJ. Table 2 shows examples of both quality failures and diversity failures identified by HUSE. For example, the "diversity failure" table shows that the summarization model ($t = 0.7$) has an extremely low probability of generating some reference sentences ("NFL's bills shake up front office") and is thus under-diverse. Closer examination of the model shows that the probability of generating "front office" is low, since it is an unusual way to refer to the president and general manager. Improving these models on the diversity failures will require that the model understand more subtle paraphrases. We can also identify model successes, where the model outputs are indistinguishable from the reference in terms of quality ("Agassi bows out of Australian Open after injury"), and the model assigns high probability to the reference ("Agassi withdraws from Australian Open").

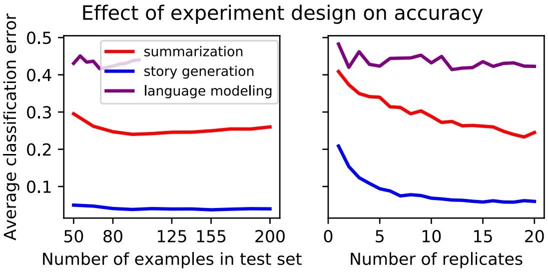

Figure 5: Estimates of HUSE are robust to small test set size, but generally require ≈ 20 crowdworker measurements for each example.

5.4 HUSE stability

Since HUSE depends on human crowdworker annotations, one might ask if it is possible to reduce either the number of annotated examples, or number of distinct crowdworkers for each example. We show that for low-quality models, substantially fewer annotations are needed.

Figure 5 shows the result of subsampling our original data of 200 sentences and 20 crowdworkers and estimating HUSE. First, we find that using 50 test set examples (Figure 5, left) is often sufficient to give accurate estimates of HUSE. Next, we find that the necessary number of crowdworkers per example depends heavily on the task. Easily distinguishable tasks (story generation), require only 10 crowdworkers, while less distinguishable tasks (summarization) require more than 20 crowdworkers to obtain accurate estimates.

6 Related work

The current state of NLG evaluation. Existing approaches to NLG evaluation use a hodgepodge mix of quality and diversity measures. Out of the 26 NLG papers at ACL 2018, six perform only hu-

Table 2: Example reference and model outputs (capitalization added for readability) corresponding to Figure 4 (summarization task) that were shown to crowdworkers (left column). Crowdworkers were shown samples from the model (including the <UNK> token) and returned human judgments (right column). Using human judgments and the model probability, we can identify several types of failures. Quality failures are examples that are classified by human judgment. Diversity failures are examples that are classified by model probabilities. Finally some examples are not easily classified, as they have similar human judgment and model probability scores.

man evaluation, fourteen measure human evaluation and a diversity metric such as perplexity or n-gram diversity, and six do not evaluate using human judgments.

While perplexity and n-gram counts can *in principle* evaluate diversity, their practical implementations suffer from serious drawbacks. When human evaluation and perplexity are both evaluated, they are almost always done on separate models—human evaluations are done on beam-searched output, while perplexity is computed on the softmax outputs. This makes it appear as if the models can simultaneously generate high quality outputs while also being diverse, when in fact they can only be one at a time based on whether they sample or run beam search.

On the other hand, n-gram diversity was proposed by Li et al. (2016) to identify models with the generic utterance problem where models repeat phrases such as 'I don't know'. Unfortunately, n-gram diversity is computed *across* contexts by counting the number of unique n-grams generated, and so does not measure a model's ability to generate multiple valid utterances at any single context. In particular, a model which only outputs a single memorized utterance per context (e.g., via memorization or retrieval) can still have high n-gram diversity as long as the memorized sentences differ across contexts.

Finally, *all* existing diversity measures are computed separately from human evaluation. This results in two incomparable evaluation metrics, which prevent us from reasoning about tradeoffs between diversity and quality. In contrast, HUSE allows us to make precise statements about the tradeoffs between model quality and diversity because it is a single metric which decomposes into diversity and quality terms.

Related evaluations of diversity. The importance of diverse responses has previously been acknowledged for summarization (Nenkova et al., 2007) and information retrieval (Clarke et al., 2008). Our work differs in considering a *single* evaluation measure that captures quality and diversity applicable to *any* generation task.

Automated metrics based on n-gram overlap such as BLEU, METEOR, ROUGE (Papineni et al., 2002; Lavie and Denkowski, 2009; Lin and Rey, 2004) work well for machine translation but do not generalize well to domains with a diverse spectrum of correct responses. While variants (Sun and Zhou, 2012; Galley et al., 2015; Shima and Mitamura, 2011) have adapted such metrics to high entropy generative environments, they are still significantly inferior to the human judgments they attempt to mimic.

Caccia et al. (2018) recently examined the diversity and quality tradeoffs for different language model architectures on synthetic datasets. However, as their approach relies on measuring log-likelihoods under both the model and reference distributions, it *cannot* be applied to real data where p_{ref} is unavailable. Our main conceptual contribution overcomes this by showing that HJ is an acceptable proxy for p_{ref}.

Sajjadi et al. (2018) also examines diversity and quality (which they call precision and recall) in the context of generative image models. However, they rely on assuming that p_{ref} and p_{model} can be estimated accurately using the Fréchet Inception Distance (FID) (Heusel et al., 2017). HUSE avoids such assumptions and instead directly leverages human judgments, resulting in a simple and reliable metric more suitable for use as a gold-standard.

Estimating optimal classification error. Evaluating a model by estimating its optimal classification error has been considered by several earlier works (Olsson et al., 2018; Kannan and Vinyals, 2016; Li et al., 2017; Bruni and Fernandez, 2017; Bowman et al., 2016). However, these methods have focused on classifying sentences directly, which is quite challenging to do reliably. Existing adversarial evaluation methods do not yet reliably outperform human classification (Kannan and Vinyals, 2016; Bruni and Fernandez, 2017). We propose the use of both human evaluation and model probabilities as part of the adversarial evaluation framework, and demonstrate that the resulting classifier reliably outperforms humans and captures both the sample quality and diversity of a model.

Distributional divergence estimation. Our proposed evaluation metric is closely related to the total variation distance which has been studied extensively in the distribution testing literature. It is known that total variation distance estimates have pessimistic minimax estimation rates in high dimensions (Balakrishnan and Wasserman, 2017). Our work overcomes this by utilizing p_{model} and an estimate of p_{ref}. Other approaches to distributional testing include the maximum mean discrepancy (MMD) and Wasserstein distances, but these approaches require knowledge of a ground truth metric or kernel space (Tolstikhin et al., 2016; Singh et al., 2018). Although such divergences are easier to estimate than the total variation distance from samples, the implied convergence rates are still too slow to be practically useful.

7 Discussion

In this paper, we demonstrate that the current gold standard of human evaluation does not penalize under-diverse models. To remedy this, we propose HUSE, a general purpose evaluation strategy which can be applied to any model for which we can calculate a model's sampling probabilities. HUSE is an upper bound on the optimal classification error of distinguishing reference and model-generated text, and *never* does worse than human classification. HUSE leverages both model probabilities and human judgments, ensuring that models which do well on the metric are both high-quality and diverse.

Our work can be viewed as a "superhuman version" of the classic Turing Test (Turing, 1950). Instead of relying on just a human classifier, we approximate the *optimal* classifier, which can utilize information about the model in addition to the reference. We also modify the classification problem and seek to identify whether a sample comes from a (potentially superhuman) reference distribution, rather than the human distribution. These two changes lead to tractable, rigorous estimators which can quantify tradeoffs between model quality and diversity on a wide range of generation tasks.

A Appendix

A.1 Relationship between total variation distance and optimal discriminator error

This is a standard result, replicated here for completeness:

Proposition 2. *The total variation distance is related to the optimal discriminator error as follows:* $\|p_{model} - p_{ref}\|_{TV} = 1 - L^*$.

Proof Fix any x. Define $a_y \overset{\text{def}}{=} p_{\text{ref}}(y \mid x)$ and $b_y \overset{\text{def}}{=} p_{\text{model}}(y \mid x)$. Let $S \overset{\text{def}}{=} \{y : a_y < b_y\}$ be the y where the p_{model} assigns higher probability than p_{ref}, and define $A \overset{\text{def}}{=} \sum_{y \in S} a_y$ and $B \overset{\text{def}}{=} \sum_{y \in S} b_y$ be the aggregated probabilities. On S, the optimal discriminator should return $z = 0$ (model). This is an error when $z = 1$, which occurs with probability $\frac{1}{2}A$. Analogously, on the complement of S, the error probability (when $z = 0$) is $\frac{1}{2}(1 - B)$. The total contribution to L^* is thus $A + (1 - B)$. The rest follows from algebra:

$$\|p_{\text{model}} - p_{\text{ref}}\|_{\text{TV}} = \frac{1}{2}\|p_{\text{model}} - p_{\text{ref}}\|_1 \quad (10)$$

$$= \frac{1}{2}[(B - A) + (1 - A) - (1 - B)] \quad (11)$$

$$= B - A = (1 - L^*). \quad (12)$$

□

A.2 Approximation error from ϕ features

Theorem 1. *Let* L^* *and* $L(\phi)$ *be the optimal classification error and optimal error under feature map* ϕ *respectively. Then,*

$$L^* \leq L(\phi) \leq L^* + 2(1 - 2^{-I})$$

where $I \overset{\text{def}}{=} I(Z_{opt}; \phi_{opt}(X, Y) \mid \phi(X, Y))$ *is the conditional mutual information in bits and* Z_{opt} *is the prediction of the optimal classifier.*

Proof The lower bound falls out of the definition of L^*. To prove the upper bound, a variant of the entropy lower bound by Feder and Merhav (Feder and Merhav, 1994) shows that the error rate for predicting Z_{opt}, via the optimal $f(\phi(X, Y))$ follows

$$P(f(\phi(X, Y)) \neq Z_{opt}) \leq 1 - 2^{I(Z_{opt};\phi(X,Y)) - H(Z_{opt})}. \quad (13)$$

Now expand the mutual information using the chain rule

$$\begin{aligned} I(Z_{opt}; \phi(X, Y)) &= I(Z_{opt}; \phi_{opt}(X, Y), \phi(X, Y)) \\ &\quad - I(Z_{opt}; \phi_{opt}(X, Y) \mid \phi(X, Y)) \\ &= -I(Z_{opt}; \phi_{opt}(X, Y) \mid \phi(X, Y)) + H(Z_{opt}). \end{aligned}$$

The last line follows from the fact that Z_{opt} is a deterministic function of ϕ_{opt} (Proposition 1). Substituting this into the inequality gives the bound,

$$P(f(\phi(X, Y)) \neq Z_{opt}) \leq 1 - 2^{-I}$$

with $I = I(Z_{opt}; \phi_{opt}(X, Y) \mid \phi(X, Y))$.

Finally, note that Z_{opt} incurs $L^*/2$ error, and we disagree with Z_{opt} at most a $P(f(\phi(X, Y)) \neq Z_{opt})$ fraction of time. Assuming that we get every one of these disagreements wrong gives an upper bound of $L^*/2 + P(f(\phi(X, Y)) \neq Z_{opt})$ on $L(\phi)/2$. □

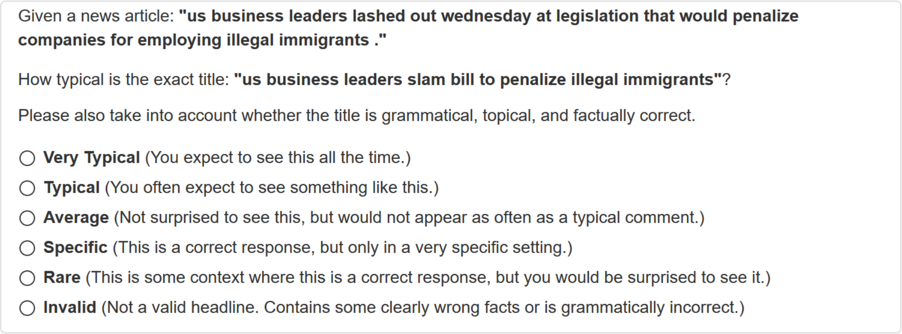
A straightforward corollary is that whenever ϕ is an invertible function of ϕ_{opt}, the conditional mutual information is zero, and therefore the above inequalities become an equality.

Corollary 1. *Whenever* ϕ *is an invertible function of* ϕ_{opt}, $L(\phi) = L^*$.

A.3 Amazon Mechanical Turk for human judgments

In order to show that HUSE can be reliably estimated even with simple crowdsourcing techniques, we used a single uniform task design where we asked Amazon Mechanical Turk workers to rate the typicality of a sentence from 0–5. We defined 0 as invalid (grammatically or factually incorrect) and 5 as 'very typical'. HJ(x, y) is defined as the average score that crowdworkers assign to a response y given the context x. We did not perform substantial filtering or qualification checks beyond HIT acceptance rate (HIT Approval rate greater than 95 percent and number of HITs approved greater than 50 and location is USA). We constructed each HIT to be 25 examples, and paid one dollar per HIT.

We observe that measuring many replicates is sufficient to get low-variance estimates of HJ. For classification tasks where the model is straightforward to identify from references (such as story generation) we require five to ten replicates, while



Given a news article: **"us business leaders lashed out wednesday at legislation that would penalize companies for employing illegal immigrants ."**

How typical is the exact title: **"us business leaders slam bill to penalize illegal immigrants"**?

Please also take into account whether the title is grammatical, topical, and factually correct.

○ **Very Typical** (You expect to see this all the time.)
○ **Typical** (You often expect to see something like this.)
○ **Average** (Not surprised to see this, but would not appear as often as a typical comment.)
○ **Specific** (This is a correct response, but only in a very specific setting.)
○ **Rare** (This is some context where this is a correct response, but you would be surprised to see it.)
○ **Invalid** (Not a valid headline. Contains some clearly wrong facts or is grammatically incorrect.)

Figure 6: Amazon Mechanical Turk survey design for eliciting human judgment scores HJ in the summarization task.

for hard tasks such as summarization at least twenty replicates are needed (Section 5.4). Manual inspection suggests that up to 20% of the collected data are low-quality but that this noise is uncorrelated with the sentence being rated and outweighed by a larger majority of honest and reasonably accurate data. Even if the data quality is low, HUSE is still a valid upper bound (i.e. models with low HUSE are guaranteed to be distinguishable from humans). Thus the models which we identify as having low-HUSE are reliably distinguishable regardless of the crowdworker quality.

A.4 Reddit Dataset

We use a subset of Reddit comments from 2006-2018 scraped from https://pushshift.io/. We construct a dictionary containing the 10,000 most popular words and preprocess the dataset by removing deleted posts, out-of-vocabulary tokens, profanity, comments with less than 10 upvotes, and comments with over 400 tokens.

What makes a good conversation?
How controllable attributes affect human judgments

Abstract

A good conversation requires balance – between simplicity and detail; staying on topic and changing it; asking questions and answering them. Although dialogue agents are commonly evaluated via human judgments of overall quality, the relationship between quality and these individual factors is less well-studied. In this work, we examine two controllable neural text generation methods, conditional training and weighted decoding, in order to control four important attributes for chitchat dialogue: repetition, specificity, response-relatedness and question-asking. We conduct a large-scale human evaluation to measure the effect of these control parameters on multi-turn interactive conversations on the PersonaChat task. We provide a detailed analysis of their relationship to high-level aspects of conversation, and show that by controlling combinations of these variables our models obtain clear improvements in human quality judgments.

1 Introduction

Neural generation models for dialogue, despite their ubiquity in current research, are still poorly understood. Well known problems, such as the genericness and repetitiveness of responses (Serban et al., 2016a), remain without a de facto solution. Strikingly, the factors that determine human judgments of overall conversation quality are almost entirely unexplored. Most works have been limited to the next utterance prediction problem, whereas a multi-turn evaluation is necessary to evaluate the quality of a full conversation.

In this work we both (i) conduct a large-scale study to identify the fine-grained factors governing human judgments of full conversations, and (ii) develop models that apply our findings in practice, leading to state-of-the-art performance. Specifically, we identify and study eight aspects of conversation that can be measured by human judgments, while varying four types of low-level attributes that can be algorithmically controlled in neural models; see Figure 1. To control the low-level model attributes, we consider two simple but general algorithms: conditional training, in which the neural model is conditioned on additional control features, and weighted decoding, in which control features are added to the decoding scoring function at test time only.

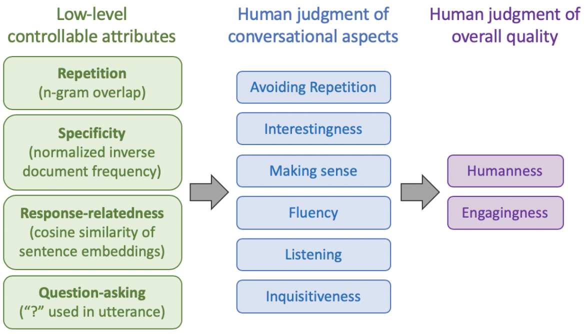

Figure 1: We manipulate four low-level attributes and measure their effect on human judgments of individual conversational aspects, as well as overall quality.

One major result of our findings is that existing work has ignored the importance of conversational flow, as standard models (i) repeat or contradict previous statements, (ii) fail to balance specificity with genericness, and (iii) fail to balance asking questions with other dialogue acts. Conducting experiments on the PersonaChat task (Zhang et al., 2018b), we obtain significantly higher engagingness scores than the baseline by optimizing control of repetition, specificity and question-asking over multiple turns. Using these findings, our best model matches the performance of the winning entry in the recent NeurIPS ConvAI2 competition (Dinan et al., 2019), which was trained on much

more data but had no control (see Section 8.1). Our code, pretrained models, and full chatlogs, are available at `https://parl.ai/projects/controllable_dialogue`.

2 Related Work

Dialogue Dialogue evaluation is relatively well understood in goal-oriented tasks, where automated approaches can be coded by measuring task completion (Bordes et al., 2017; El Asri et al., 2017; Hastie, 2012; Henderson et al., 2014; Wen et al., 2017). Task success combined with dialogue cost can be linked to human judgments like user satisfaction via the PARADISE framework (Walker et al., 1997).

However in chitchat tasks, which we study in this work, automatic metrics and their relation to human ratings are less well-understood. While word-overlap metrics are effective for question-answering and machine translation, for dialogue they have little to no correlation with human judgments (Liu et al., 2016; Novikova et al., 2017) – this is due to the open-ended nature of dialogue. There are more recent attempts to find better automatic approaches, such as adversarial evaluation (Li et al., 2017b) and learning a scoring model (Lowe et al., 2017), but their value is still unclear.

Nevertheless, a number of studies only use automatic metrics, with no human study at all (Lowe et al., 2015; Parthasarathi and Pineau, 2018; Serban et al., 2016b). Other works do use human evaluations (Dinan et al., 2018; Li et al., 2016a,b; Venkatesh et al., 2017; Vinyals and Le, 2015; Zhang et al., 2018b), typically reporting just one type of judgment (either quality or appropriateness) via a Likert scale or pairwise comparison. Most of those works only consider single turn evaluations, often with a shortened dialogue history, rather than full multi-turn dialogue.

A more comprehensive evaluation strategy has been studied within the scope of the Alexa prize (Venkatesh et al., 2017; Guo et al., 2018) by combining multiple automatic metrics designed to capture various conversational aspects (engagement, coherence, domain coverage, conversational depth and topical diversity). Though these aspects have some similarity to the aspects studied here, we also focus on lower-level aspects (e.g. avoiding repetition, fluency), to understand how they correspond to both our controllable attributes, and to overall quality judgments.

Controllable neural text generation Researchers have proposed several approaches to control aspects of RNN-based natural language generation such as sentiment, length, speaker style and tense (Fan et al., 2018; Ficler and Goldberg, 2017; Ghazvininejad et al., 2017; Hu et al., 2017; Kikuchi et al., 2016; Peng et al., 2018; Wang et al., 2017). In particular, several works use control to tackle the same common sequence-to-sequence problems we address here (particularly genericness and unrelated output), in the context of single-turn response generation (Baheti et al., 2018; Li et al., 2016a, 2017a; Shen et al., 2017; Xing et al., 2017; Zhang et al., 2018a; Zhou et al., 2017). By contrast, we focus on developing controls for, and human evaluation of, *multi*-turn interactive dialogue – this includes a new method (described in Section 5) to control attributes at the *dialogue* level rather than the utterance level.

In this work, we require a control method that is both general-purpose (one technique to simultaneously control many attributes) and easily tunable (the control setting is adjustable after training). Given these constraints, we study two control methods: conditional training (variants of which have been described by Fan et al. (2018); Kikuchi et al. (2016); Peng et al. (2018)) and weighted decoding (described by Ghazvininejad et al. (2017) as a general technique, and by Baheti et al. (2018) to control response-relatedness). To our knowledge, this work is the first to systematically compare the effectiveness of two general-purpose control methods across several attributes.

3 The PersonaChat dataset

PersonaChat (Zhang et al., 2018b) is a chitchat dialogue task involving two participants (two humans or a human and a bot). Each participant is given a *persona* – a short collection of personal traits such as *I'm left handed* or *My favorite season is spring* – and are instructed to get to know each other by chatting naturally using their designated personas, for 6–8 turns. The training set contains 8939 conversations and 955 personas, collected via crowdworkers, plus 1000 conversations and 100 personas for validation, and a similar number in the hidden test set. The PersonaChat task was the subject of the NeurIPS 2018 ConvAI2 Challenge (Dinan et al., 2019), in which competitors were first evaluated with respect to automatic metrics (perplexity, hits@1 and F1 score), and then with respect to human judgment via the question *"How much did you enjoy talking to this user?"* on a scale of 1–4.

4 Baseline model

Our baseline model is a 2-layer LSTM sequence-to-sequence model with attention. On any dialogue turn, the input x to the encoder is the entire dialogue history (separated using unique speaker-identifying tokens), with the model's own persona prepended. Conditioned on this input sequence x, the decoder generates a response y. Except when stated otherwise, all our models decode using beam search with beam size 20.

We initialized the word embedding matrix with 300-dimensional GloVe embeddings (Pennington et al., 2014). Using the ParlAI framework (Miller et al., 2017), we pretrained the model on a dataset of 2.5 million Twitter message-response pairs,[1] then fine-tuned it on PersonaChat. On the PersonaChat validation set, the baseline model has a perplexity of 26.83 and F1 of 17.02, which would have placed us 4th out of 26 models in the ConvAI2 competition (Dinan et al., 2019). We attempt to improve over this baseline using control.

5 Controllable text generation methods

Suppose we have a sequence-to-sequence model which gives $P(y|x) = \Pi_t P(y_t|x, y_1, \dots, y_{t-1})$, the conditional probability of a response y (the model's next utterance) given input x (the context, which in our case includes the model's own persona and the dialogue history).

Contrary to most previous work, which controls *at the sentence level*, we wish to control attributes of the output y *at the dialogue level* – meaning that a single control setting is used for a whole dialogue. For example, to control question-asking, we provide a control setting at the beginning of each dialogue (e.g. *20% questions* or *70% questions*) rather than providing a control setting for each utterance (e.g. *is a question* or *isn't a question*). With this approach, the sequence-to-sequence model is able to choose what value the controlled attribute should take for any particular utterance, but we are able to choose the overall distribution. We find that this approach works well – for example, the sequence-to-sequence model is generally good at detecting when to ask a question. In particular, this is easier than the alternative: developing a separate process to decide, for each utterance, whether to ask a question.

In this section, we describe the two methods – which we call Conditional Training (CT) and Weighted Decoding (WD) – that we use to control attributes of the output y at the dialogue level.

5.1 Conditional Training (CT)

Conditional Training (Fan et al., 2018; Kikuchi et al., 2016; Peng et al., 2018) is a method to learn a sequence-to-sequence model $P(y|x, z)$, where z is a discrete *control variable*. If the control attribute is naturally continuous (for example in our work, repetitiveness, specificity and response-relatedness), we use z to represent bucketed ranges. For a binary attribute like question-asking, z represents an overall probability (as explained in Section 5).

To train a CT model, we first automatically annotate every (x, y) pair in the training set with the attribute we wish to control (for example, whether y contains a question mark). During training, for each example we determine the corresponding z value (for continuous attributes, this simply means sorting into the correct bucket; for question-asking, see Section 6.4). Next, the control variable z is represented via an embedding (each of the possible values of z has its own embedding). For all our experiments, the embedding is of length 10; this was determined via hyperparameter tuning. There are several possible ways to condition the sequence-to-sequence model on z – for example, append z to the end of the input sequence, or use z as the START symbol for the decoder. We find it most effective to concatenate z to the decoder's input on every step.[2] Lastly, the CT model learns to produce $y = y_1, \dots, y_T$ by optimizing the cross-entropy loss:

$$\text{loss}_{\text{CT}} = -\frac{1}{T}\sum_{t=1}^{T}\log P(y_t|x, z, y_1, \dots, y_{t-1})$$

Our CT models are initialized with the parameters from the baseline sequence-to-sequence model $P(y|x)$ (the new decoder parameters are initialized with small random values), then fine-tuned to optimize loss_{CT} on the PersonaChat training set, until convergence of loss_{CT} on the validation set.

---

[1] The Twitter dataset is provided in ParlAI; details can be found here: `https://parl.ai/docs/tasks.html`

[2] To build a CT model $P(y|x, z_1, \dots, z_n)$ conditioned on *multiple* controls $\{z_1, \dots, z_n\}$, we can simply concatenate multiple control embeddings to the decoder inputs.

5.2 Weighted Decoding (WD)

Weighted Decoding (Ghazvininejad et al., 2017) is a decoding method that increases or decreases the probability of words with certain features. The technique is applied only at test time, requiring no change to the training method. A limitation of WD is that the controllable attribute must be defined at the word-level; any desired utterance-level attribute must be redefined via word-level features.

In weighted decoding, on the t^{th} step of decoding, a partial hypothesis $y_{<t} = y_1, \dots, y_{t-1}$ is expanded by computing the score for each possible next word w in the vocabulary:

$$\begin{aligned}\text{score}(w, y_{<t}; x) &= \text{score}(y_{<t}; x) \\ + \log P_{\text{RNN}}(w|y_{<t}, x) &+ \sum_i w_i * f_i(w; y_{<t}, x).\end{aligned}$$

Here, $\log P_{\text{RNN}}(w|y_{<t}, x)$ is the log-probability of the word w calculated by the RNN, $\text{score}(y_{<t}; x)$ is the accumulated score of the already-generated words in the hypothesis $y_{<t}$, and $f_i(w; y_{<t}, x)$ are *decoding features* with associated weights w_i. There can be multiple features f_i (to control multiple attributes), and the weights w_i are hyperparameters to be chosen.

A decoding feature $f_i(w; y_{<t}, x)$ assigns a real value to the word w, in the context of the text generated so far $y_{<t}$ and the context x. The feature can be continuous (e.g. the unigram probability of w), discrete (e.g. the length of w in characters), or binary (e.g. whether w starts with the same letter as the last word in $y_{<t}$). A positive weight w_i increases the probability of words w that score highly with respect to f_i; a negative weight decreases their probability.

Note that weighted decoding and conditional training can be applied simultaneously (i.e. train a CT model then apply WD at test time) – a strategy we use in our experiments.

6 Controlling conversational attributes

In this section, we describe how we use conditional training and weighted decoding to control four attributes: repetition, specificity, response-relatedness and question-asking. We evaluate the effectiveness of both control methods via automatic metrics (i.e., measuring how well the attribute was controlled), and use our findings to select control methods and control settings to be explored further via human evaluation (Section 8).

6.1 Repetition

Our baseline model exhibits three types of repetition, which we call *external repetition* (self-repetition across utterances), *internal repetition* (self-repetition within utterances), and *partner repetition* (repeating the conversational partner).

To control repetition with weighted decoding,[3] we define five n-gram based decoding features (see Appendix D). Three of these features (`extrep_bigram`, `intrep_bigram` and `partnerrep_bigram`) identify repeating bigrams for the three repetition types. The other two features (`extrep_unigram` and `intrep_unigram`) identify repeating content words. By applying a negative weight to these features, we can reduce repetition. In particular, if the weight is $-\infty$, our method is equivalent to *n-gram blocking* as described by Kulikov et al. (2018). We observe that repetition control is very important, thus all further control experiments include repetition control.

6.2 Specificity

Like many sequence-to-sequence models using beam search decoding, our baseline frequently asks generic questions such as *What music do you like?* and gives dull, unspecific responses, such as *I like all kinds of music*.

We control specificity using Normalized Inverse Document Frequency (NIDF) as a measure of word rareness.[4] The Inverse Document Frequency of a word w is $\text{IDF}(w) = \log(R/c_w)$ where R is the number of responses in the dataset, and c_w is the number of those responses that contain w. Normalized IDF (which ranges from 0 to 1) is

$$\text{NIDF}(w) = \frac{\text{IDF}(w) - \texttt{min\_idf}}{\texttt{max\_idf} - \texttt{min\_idf}} \quad (1)$$

where `min_idf` and `max_idf` are the minimum and maximum IDFs, taken over all words in the vocabulary. To control specificity with weighted decoding, we use NIDF as a decoding feature. As shown in Table 1, this method produces reasonable outputs when the feature weight is within a certain range, but at the extremes the outputs are

---

[3] We also tried controlling repetition with conditional training, defining z as the (bucketed) maximum ROUGE-L precision between the response y and the bot's previous utterances. However, this method was unsuccessful because there are not enough repetitive examples in the training data for the model to learn the control. Experimenting with data augmentation to solve this problem is an area for future work.

[4] Note that our NIDF specificity features are similar to the NIRF and NIWF features used by Zhang et al. (2018a).

Input: *Yes, I'm studying law at the moment*
Baseline Response: *That sounds like a lot of fun!*

Wt	**NIDF**	**Weighted Decoding Response**
-5.0	0.6%	*Oh......................................*
0.0	17.1%	*That sounds like a lot of fun!*
3.0	18.3%	*That sounds like a lot of fun. How long have you been studying?*
7.0	38.5%	*I majored in practising my spiritual full time philosophy test*
10.0	71.9%	*Oh wow! Merna jean isa paino yi hao hui bu acara sya gila* [. . .]

z	**NIDF**	**Conditional Training Response**
0	16.8%	*Sounds like you are a great person!*
2	18.3%	*So you are a law student?*
4	18.4%	*That sounds like a lot of fun*
6	22.8%	*That sounds like a rewarding job!*
8	24.4%	*That sounds like a rewarding career!*

Table 1: Middle: Example of controlling specificity (NIDF) via weighted decoding. At the extremes, the model produces only the most rare or the most common tokens. Bottom: Example of controlling specificity via conditional training. This gives a narrower NIDF range, but all the responses are appropriate.

Input: *Do you go get coffee often*
Baseline Response: *I do, when I am not playing the piano.*

Wt	**Sim**	**Weighted Decoding Response**
-10.0	-0.05	*I am a musician.*
0.0	-0.02	*I do, when I am not playing the piano.*
5.0	0.40	*I do, usually at starbucks.*
8.0	0.59	*Not usually, especially when you drink latte.*
11.0	0.72	*Not often, usually with drinks, espresso, latte, tea, etc.*

Table 2: Example of controlling response-relatedness (cosine similarity to input) via weighted decoding. Positive weights (e.g. 5.0) can yield more on-topic responses, but higher weights (e.g. 11.0) can result in nonsensical lists of topically related words.

nonsensical. The boundary for nonsensical output differs from example to example.

To control specificity with conditional training, we define the specificity of an utterance y to be the mean NIDF of the words in y. Thus our control variable z is mean NIDF (discretized into 10 equal-sized buckets). As shown in Table 1, this method gives outputs with a narrower NIDF range, but overall produces less nonsensical outputs.

6.3 Response-relatedness

In conversation, it's generally desirable to produce a response that is related to the partner's last utterance; for example if the partner says *My grandfather died last month*, it is appropriate to say *I'm so sorry. Were you close to your grandfather?* However, our baseline model frequently responds with unrelated utterances like *Do you have any pets?*

To control response-relatedness with weighted decoding, we use the decoding feature $\texttt{resp\_rel}$:

$$\texttt{resp\_rel}(w; y_{<t}, x) = \texttt{cos\_sim}(\texttt{word\_emb}(w), \texttt{sent\_emb}(\ell))$$

where $\texttt{word\_emb}(w)$ is the GloVe embedding for the word w, $\texttt{sent\_emb}(\ell)$ is the sentence embedding for the partner's last utterance ℓ (note ℓ is part of the context x), and $\texttt{cos\_sim}$ is the cosine similarity between the two. In particular, the sentence embedding $\texttt{sent\_emb}(s)$ for an utterance s is a weighted average of the GloVe embeddings of the words in s, with the first principal component projected out; for full details, see Arora et al. (2017). This method of controlling response-relatedness is similar to that described in (Baheti et al., 2018). We find that weighted decoding is effective to control the semantic relatedness of the model's response to the partner's last utterance (see Table 2). As before, we find that extreme weights lead to nonsensical output.

To control response-relatedness with conditional training, we try defining the control variable z to be $\texttt{cos\_sim}(\texttt{sent\_emb}(y), \texttt{sent\_emb}(\ell))$, the overall cosine similarity between the partner's last utterance ℓ and the model's response y (again, we discretize z). However, we find this method ineffective – the CT model learns only a very weak connection between z and the semantic relatedness of the output (see Section 7 for more details).

6.4 Question-asking

Considerate chitchat requires a reciprocal asking and answering of questions – asking too few or too many can appear self-centered or nosy. We control question-asking in order to study these trade-offs.

To control question-asking with weighted decoding, we use the binary decoding feature $\texttt{is\_qn\_word}(w)$, which is equal to 1 if and only if the word w is in a pre-defined list of interrogative words (*how, what, when, where, which, who, whom, whose, why, ?*). We find this is a somewhat effective method to encourage or discourage questions, but with unintended side-effects: a negative weight can discourage valid non-question utterances that happen to contain interrogative words (such as *I'm learning **how** to knit*) and a positive weight can result in degenerate utterances (such as

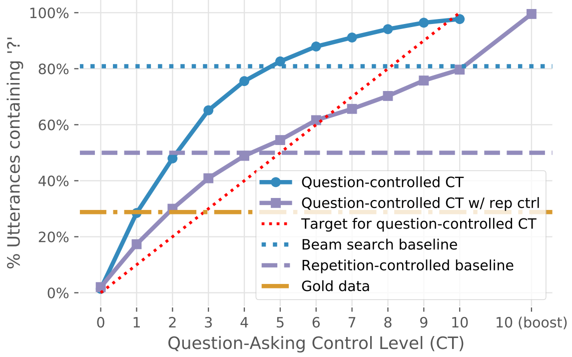

Figure 2: Controlling question-asking via conditional training. Exact numbers can be found in Appendix F.

What??????? or *Who? When? How?*).

For conditional training, we regard an utterance y as containing a question if and only if y contains a question mark. We train our CT model on a control variable z with 11 possible values: $\{0, \ldots, 10\}$. As discussed in Section 5, we wish to control question-asking at the distributional, dialogue level, rather than at the binary, utterance level. Thus the setting $z = i$ means that the model should produce, on average, utterances containing '?' with probability $i/10$. During training we randomly assign examples to buckets such that each bucket i is trained on examples with the correct proportion of questions ($i/10$), and all buckets have the same amount of training examples.

We find that conditional training is effective to control question-asking – as shown in Figure 2, by increasing z from 0 to 10, we obtain a range of question-asking rates from 1.40% to 97.72%. However, when we introduce repetition control, question-asking is reduced – in particular, the $z = 10$ setting (which should produce 100% questions) now only produces 79.67% questions. The primary problem is the weighted decoding feature `extrep_bigram`, which discourages bigrams that have appeared in previous utterances – this prevents the model from producing bigrams that commonly occur in many questions, such as *do you* and *what is*. To fix this, we introduce an extra setting $z = 10$ *(boost)*, in which we do not use the feature `extrep_bigram` for weighted decoding during beam search, but we do use it to rerank the candidates after beam search. This setting, which allows the model to produce necessary question-asking bigrams, yields a 99.54% question-asking rate, at the cost of slightly increased external bigram repetition (see Appendix F).

For controlling question-asking, conditional training is preferable to weighted decoding for two reasons. Firstly, it allows us to achieve (close to) 0% questions, 100% questions, or anything in between, without introducing the risk of degenerate output. Secondly, presence-of-a-question-mark captures the true attribute of interest (question-asking) more exactly and directly than presence of interrogative words. For these reasons, only the CT method is considered in the human evaluation.

7 Comparison of control methods

The previous section shows that conditional training and weighted decoding are both useful techniques, with different strengths and weaknesses.

The primary disadvantage of conditional training is that it sometimes fails to learn the connection between the control variable z and the target output y. In practice, we find the model can learn simple attributes of the output (such as the presence of '?', and overall genericness), but not relationships between the input and output (such as semantic relatedness). By contrast, weighted decoding can force the desired feature to appear in the output by raising the weight arbitrarily high (though this may have unintended side-effects).

The primary disadvantage of weighted decoding is that it risks going off-distribution when the weight is too strong. By contrast, conditional training produces mostly well-formed, in-distribution outputs. This highlights the importance of learned control – it is safer to learn to produce output that both satisfies the control variable and is appropriate, than to alter the decoding process to satisfy the control variable, potentially trading off appropriateness in the process.

Other considerations include: (1) Convenience: conditional training requires retraining; weighted decoding doesn't, but is slower at test time. (2) Data availability: conditional training requires training examples of the controllable attribute, whereas weighted decoding can control any computable feature without requiring examples. (3) Attribute definition: conditional training can control sentence-level attributes, but they must be discrete. By contrast, weighted decoding requires word-level features, but they can be continuous.

8 Human evaluation results

In order to study the effect of our controllable attributes, we conduct a large-scale human evaluation of 28 model configurations (see Appendix E), plus human-human conversations for comparison.

Approach In our evaluation, a crowdworker chats with a model (or in the human-human case, another crowdworker) for six conversational turns, then answers eight multiple-choice questions which each capture different aspects of conversational quality: avoiding repetition, interestingness, making sense, fluency, listening, inquisitiveness, humanness and engagingness. The eight questions are Likert questions on a 1-4 scale, where higher is better.[5] To match the ConvAI2 Challenge, we also add a persona retrieval question, in which the crowdworker is asked to select which of two possible personas was the model's persona. For full details of the evaluation design, see Appendix B.

Our evaluation is the same as the ConvAI2 Challenge evaluation, but more detailed – ConvAI2 includes only engagingness and persona retrieval.[6] As in the ConvAI2 challenge, each of our 28 model configurations was evaluated by over 100 crowdworkers, and the results were adjusted for annotator variance via a Bayesian calibration (Kulikov et al., 2018).

In designing our evaluation, we aimed to capture the four aspects we expected to directly improve via control (avoiding repetition, interestingness, listening, inquisitiveness), two important error classes we thought would be affected by our controls (fluency, making sense), and two overall quality measures (engagingness, humanness).

8.1 Main findings

In this section we summarize the main findings of our human evaluation – whose full results can be found in Appendices G and H, with sample conversations in Appendix C.

As Figure 3 shows, controlling for repetition, specificity and question-asking all lead to large engagingness improvements over the greedy and beam-search baseline models. In particular, we find that controlling for multi-turn (self) repetition is important and should be incorporated alongside other attribute control methods. We found no improvement by controlling response-relatedness.

To better understand these overall engagingness improvements, we consider the full set of human judgments, shown in Figure 4. We find that reducing repetition leads to improvements across all our aspects of conversational quality. Increasing specificity shows improvements in interestingness and listening ability over the repetition-controlled baseline, while increasing question-asking shows improvements in inquisitiveness and interestingness over the repetition-controlled baseline.

Our most engaging model, which controls both repetition and question-asking – marked 'Question (CT)' in Figure 3 (left) – matches the engagingness of the winning entry in the ConvAI2 competition, as both models achieve a raw score[7] of 3.1 (Dinan et al., 2019). However, the ConvAI2 winner, Lost in Conversation, was trained on approximately 12× as much data as our model. Lost in Conversation is based on the OpenAI GPT Language Model (Radford et al., 2018), which is pretrained on the BookCorpus (Zhu et al., 2015), which contains approximately 985 million words, whereas our model is pretrained on the Twitter dataset (approximately 79 million words).

Altogether, our evaluation clearly shows that controlling low-level attributes over multiple turns leads to improved overall quality.

8.2 Effect of controlled attributes

Repetition (WD) We observe that self-repetition across utterances (*external repetition*) is by far the most severe form of repetition in our beam search baseline model. We evaluate several settings of the `extrep_bigram` weighted decoding feature, and find that an aggressive repetition-reduction setting (reducing bigram repetition rate to below gold data levels) is rated best. We also find that blocking repeated content words improves the avoiding repetition score. See Appendices E, F and G for full details.

As shown in Figure 3 (left) and Figure 4, our repetition-controlled model improves hugely

---

[5] Exceptions: Avoiding repetition is a 1-3 scale, as we found this gave clearer instructions. Inquisitiveness has an optimal score of 3; 1 and 2 represent too little question-asking, and 4 represents too much.

[6] There are three other minor differences between our evaluation and ConvAI2's: (1) We fix capitalization and spacing before showing the chatbot's utterances to crowdworkers, while ConvAI2 show the raw lowercase tokenized form. We found the latter interferes with fluency evaluation. (2) We conduct 6 dialogue turns, while ConvAI2 conducts 4-6. This was necessary to evaluate repetitiveness. (3) We use (publicly-available) validation set personas, while ConvAI2 uses (hidden) test set personas. This enables us to release our evaluation chatlogs.

[7] Although the same Bayesian calibration method was applied both in our study and in the ConvAI2 competition, calibrated scores are not comparable across the two; thus we compare raw scores (viewable in Table 7).

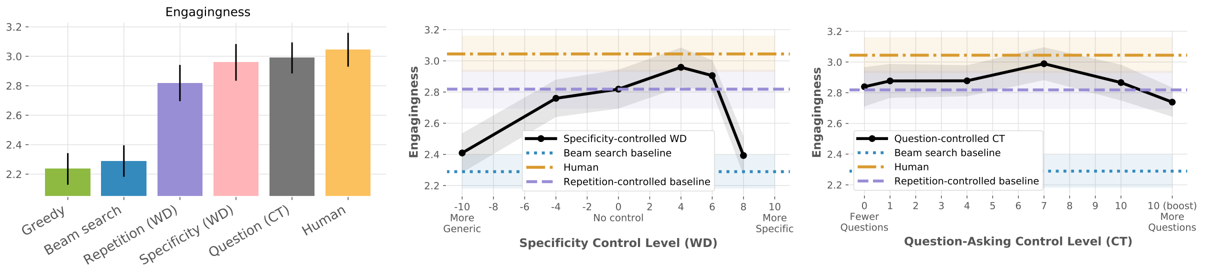

Figure 3: Calibrated human judgments of engagingness for the baselines and best controlled models (left); for different specificity control settings (middle); and for different question-asking control settings (right).

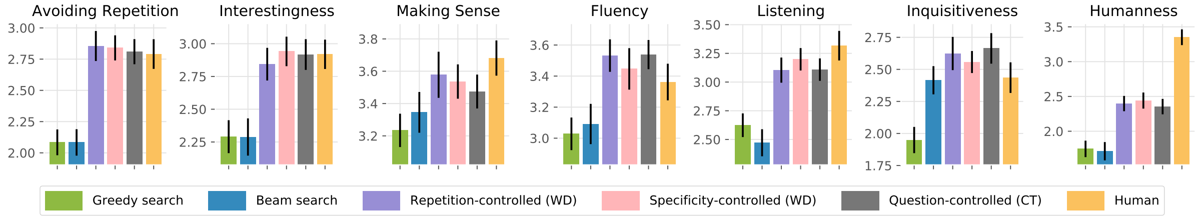

Figure 4: Calibrated human judgments of conversational aspects for the baselines and best controlled models. Note: In Figure 3 and here, the Specificity and Question controlled models both include Repetition control, but Question control doesn't include Specificity control, or vice versa.

over the beam search baseline in all metrics, and achieves close-to-human scores on all metrics except humanness. This striking result demonstrates that repetition is by far the biggest limiting quality factor for naive sequence-to-sequence dialogue agents. The result also emphasizes the importance of *multi-turn* dialogue evaluation to detect the problem. We refer to this model as the *repetition-controlled baseline*, and use it as a basis for all remaining experiments (i.e., we control specificity, response-relatedness and question-asking on top of these repetition-control settings).

Specificity (WD, CT) For our weighted decoding models, the extreme settings (very generic and very specific) score poorly in engagingness due to the frequent presence of degenerate output – see Figure 3 (middle). We find that the weight $= 4$ setting (which is more specific than the repetition-controlled baseline and about as specific as the gold data) maximizes engagingness. As shown in Figure 3 (left) and Figure 4, this more-specific model is rated more interesting, engaging, and a better listener than the repetition-controlled baseline, but at the cost of reduced fluency and making sense. Our CT model with $z = 7$ (which has a similar NIDF level as WD with weight $= 4$) shows similar results, but the improvements are smaller. For further discussion on the interestingness of our specificity models, see Section 8.3.

Response-relatedness (WD) We evaluated several control settings (weight $= -10, 5, 10, 13$) and found that none scored better than weight $= 0$ (no response-relatedness control); see Appendix H. This is surprising – prior to running the human evaluation, we annotated 100 examples ourselves to determine the best control settings. While we identified a more responsive setting (weight $= 5$) as less likely than the uncontrolled model to ignore the user, crowdworkers rated it as a slightly *worse* listener than the uncontrolled model. One explanation for this discrepancy is that the more responsive model takes more risks, using more rare words (0.197 NIDF, up from 0.178), and thus receives a lower makes-sense score (3.41, down from 3.70). We hypothesize that, compared to us, the crowdworkers are less tolerant of slightly nonsensical output, and more tolerant of generic unrelated utterances.

Question-asking (CT) As shown in Figure 3 (right), a question-asking rate of 65.7% ($z = 7$) maximizes engagingness. This setting, which asks more questions than both the repetition-controlled baseline (50.0%) and the human-produced gold data (28.8%), brings us closest to human-level engagingness – see Figure 3 (left). Although we find that a rate of approximately 65.7% question-asking is the most engaging, a lower level (48.9%, or $z = 4$) is rated the best listener. Lastly, we find

Model	Win%	Top 3 reasons for preferring model
Specificity WD (weight $= 6$)	84.1%	*More information; Better flow; More descriptive*
Specificity WD (weight $= 4$)	75.5%	*More information; They describe their life in more detail; Funny*
Specificity CT ($z = 7$)	56.2%	*More information; Better flow; Seems more interested*

Table 3: A/B tests comparing various specificity-controlled models to the repetition-controlled baseline on interestingness. We find all comparisons are significant ($p < .05$; binomial test).

that although asking too many questions is less engaging, most crowdworkers will not directly criticize a chatbot that asks questions on every turn – only 11.9% of crowdworkers judged the $z = 10$ *(boost)* setting, which asks 99.5% questions, as asking too many questions.[8] For full details of these scores, see Appendix F and H.

For time and budget reasons, we did not evaluate any models controlling both question-asking and specificity. However, we expect it is possible to obtain further improvements by doing so.

8.3 A/B tests for interestingness

Though our more-specific models yielded significant improvements in engagingness, we were surprised that they did not yield clearer improvements in interestingness. To investigate further, we conducted an A/B interestingness evaluation of three specificity-controlled models, compared to the repetition-controlled baseline. Crowdworkers were shown two conversations (from the main human evaluation) and asked to choose which model was more interesting (see Figure 7 for details). We collected 500 samples per comparison, plus 200 additional human vs repetition-controlled baseline samples, which were used to filter for quality control. After discarding low-quality crowdworkers, we have roughly 300 evaluations per comparison, with an average Cohen's $\kappa = 0.6$.

As shown in Table 3, all three models were rated significantly more interesting than the repetition-controlled baseline. This convincingly shows that producing utterances with more rare words is a valid strategy to improve interestingness. We have two explanations for why these interestingness differences did not materialize in our main evaluation. Firstly, interestingness is a particularly subjective metric (unlike more tangible metrics such as avoiding repetition and making sense) – this makes it hard to calibrate across crowdworkers. Secondly, we suspect that in our original evaluation, the crowdworkers may have evaluated the interestingness of the *task* rather than the *chatbot*. This could account for why subtle increases in conversational ability did not result in higher interestingness ratings – the PersonaChat task itself has a natural interestingness limit.

9 Conclusion

What makes a good conversation? Through our evaluation, we showed that a good conversation is about balance – controlling for the right level of repetition, specificity and question-asking is important for overall quality. We also found that conversational aspects such as interestingness, listening, and inquisitiveness are all important – though optimizing these can introduce a trade-off against certain types of errors (such as repetitive, disfluent, or nonsensical output). Secondly, multi-turn evaluation is essential to study what makes a good conversation – multiple turns are required to reveal issues such as repetition, consistency, and question-asking frequency. Lastly, what do we mean by 'good'? Although humanness and engagingness are both commonly used as overall quality metrics, the two are very different. While our models achieved close-to-human scores on engagingness, they failed to get close on humanness – showing that a chatbot need not be human-like to be enjoyable. This striking result also demonstrates the importance of measuring more than one quality metric when evaluating dialogue agents.

Outlook Our work shows that neural generative systems have systemic problems when applied to open-ended dialogue, some of which (e.g. repetition) are only observable in the multi-turn setting. Furthermore, control of low-level attributes offers a practical way to correct these problems, yielding large improvements to overall quality – in our case, comparable to systems trained on much more data. Future work includes optimizing control settings automatically, and building more convincingly human-like chatbots.

---

[8] Though this conclusion may hold true for the PersonaChat task – a synthetic chatting task that instructs participants to get to know each other – in real-life social conversations, incessant question-asking may be less tolerated.

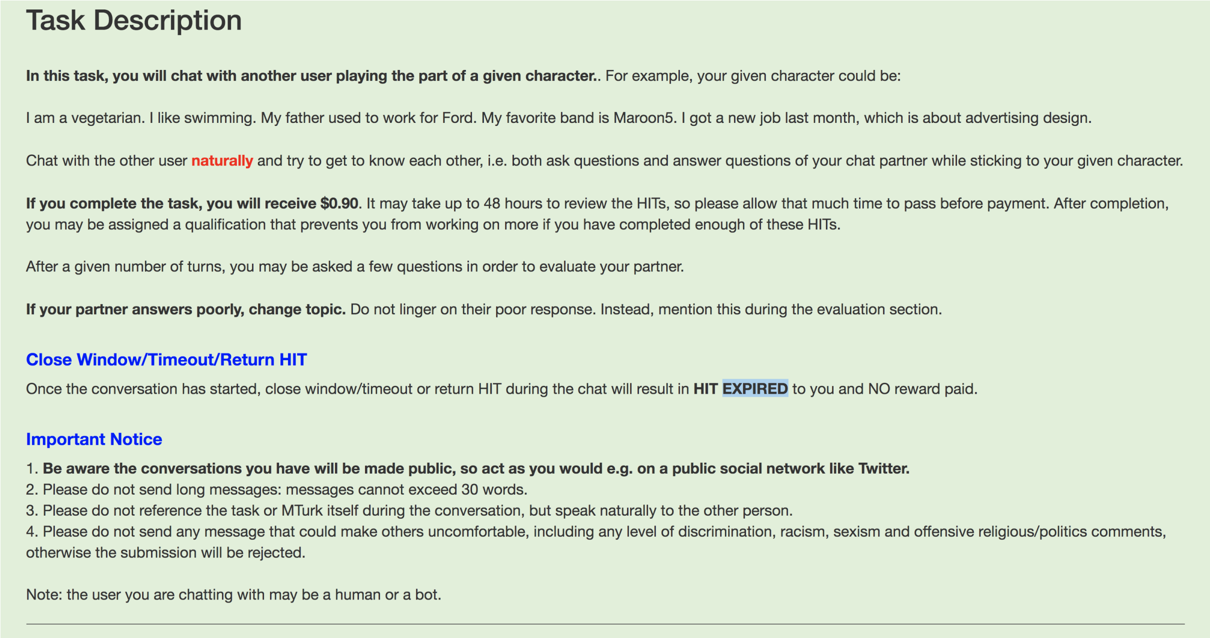
Supplementary Material

A Screenshots of human evaluation interface



Task Description

In this task, you will chat with another user playing the part of a given character.. For example, your given character could be:

I am a vegetarian. I like swimming. My father used to work for Ford. My favorite band is Maroon5. I got a new job last month, which is about advertising design.

Chat with the other user **naturally** and try to get to know each other, i.e. both ask questions and answer questions of your chat partner while sticking to your given character.

If you complete the task, you will receive $0.90. It may take up to 48 hours to review the HITs, so please allow that much time to pass before payment. After completion, you may be assigned a qualification that prevents you from working on more if you have completed enough of these HITs.

After a given number of turns, you may be asked a few questions in order to evaluate your partner.

If your partner answers poorly, change topic. Do not linger on their poor response. Instead, mention this during the evaluation section.

Close Window/Timeout/Return HIT

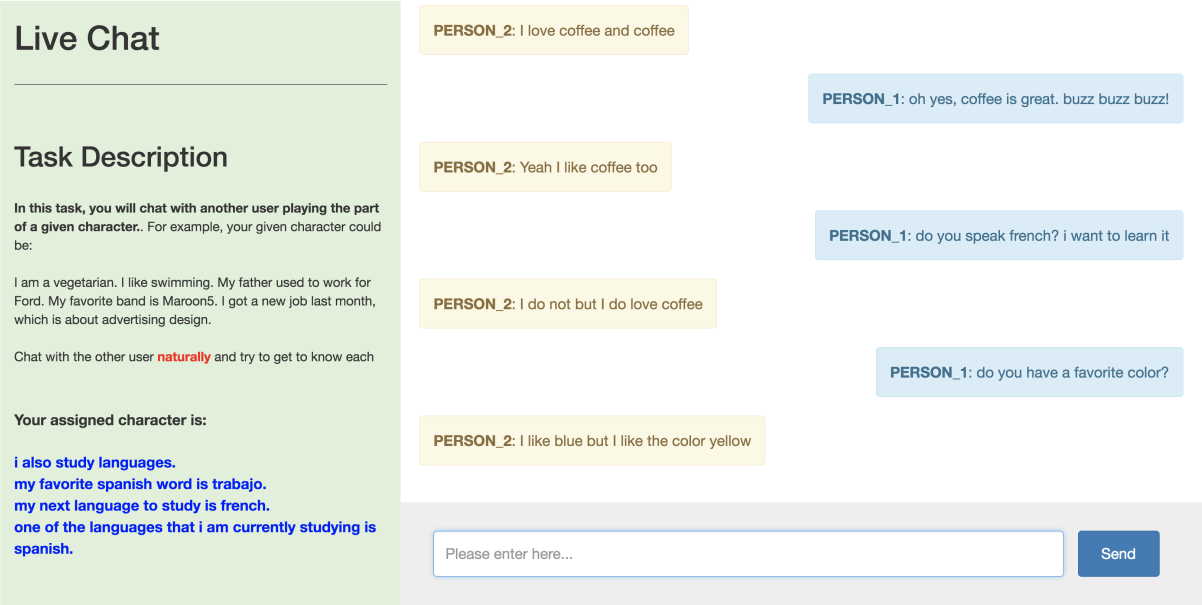
Once the conversation has started, close window/timeout or return HIT during the chat will result in **HIT EXPIRED** to you and NO reward paid.

Important Notice

1. **Be aware the conversations you have will be made public, so act as you would e.g. on a public social network like Twitter.**
2. Please do not send long messages: messages cannot exceed 30 words.
3. Please do not reference the task or MTurk itself during the conversation, but speak naturally to the other person.
4. Please do not send any message that could make others uncomfortable, including any level of discrimination, racism, sexism and offensive religious/politics comments, otherwise the submission will be rejected.

Note: the user you are chatting with may be a human or a bot.

Figure 5: Screenshot of the Task Description



Live Chat

Task Description

In this task, you will chat with another user playing the part of a given character.. For example, your given character could be:

I am a vegetarian. I like swimming. My father used to work for Ford. My favorite band is Maroon5. I got a new job last month, which is about advertising design.

Chat with the other user **naturally** and try to get to know each

Your assigned character is:

i also study languages.
my favorite spanish word is trabajo.
my next language to study is french.
one of the languages that i am currently studying is spanish.

PERSON_2: I love coffee and coffee

PERSON_1: oh yes, coffee is great. buzz buzz buzz!

PERSON_2: Yeah I like coffee too

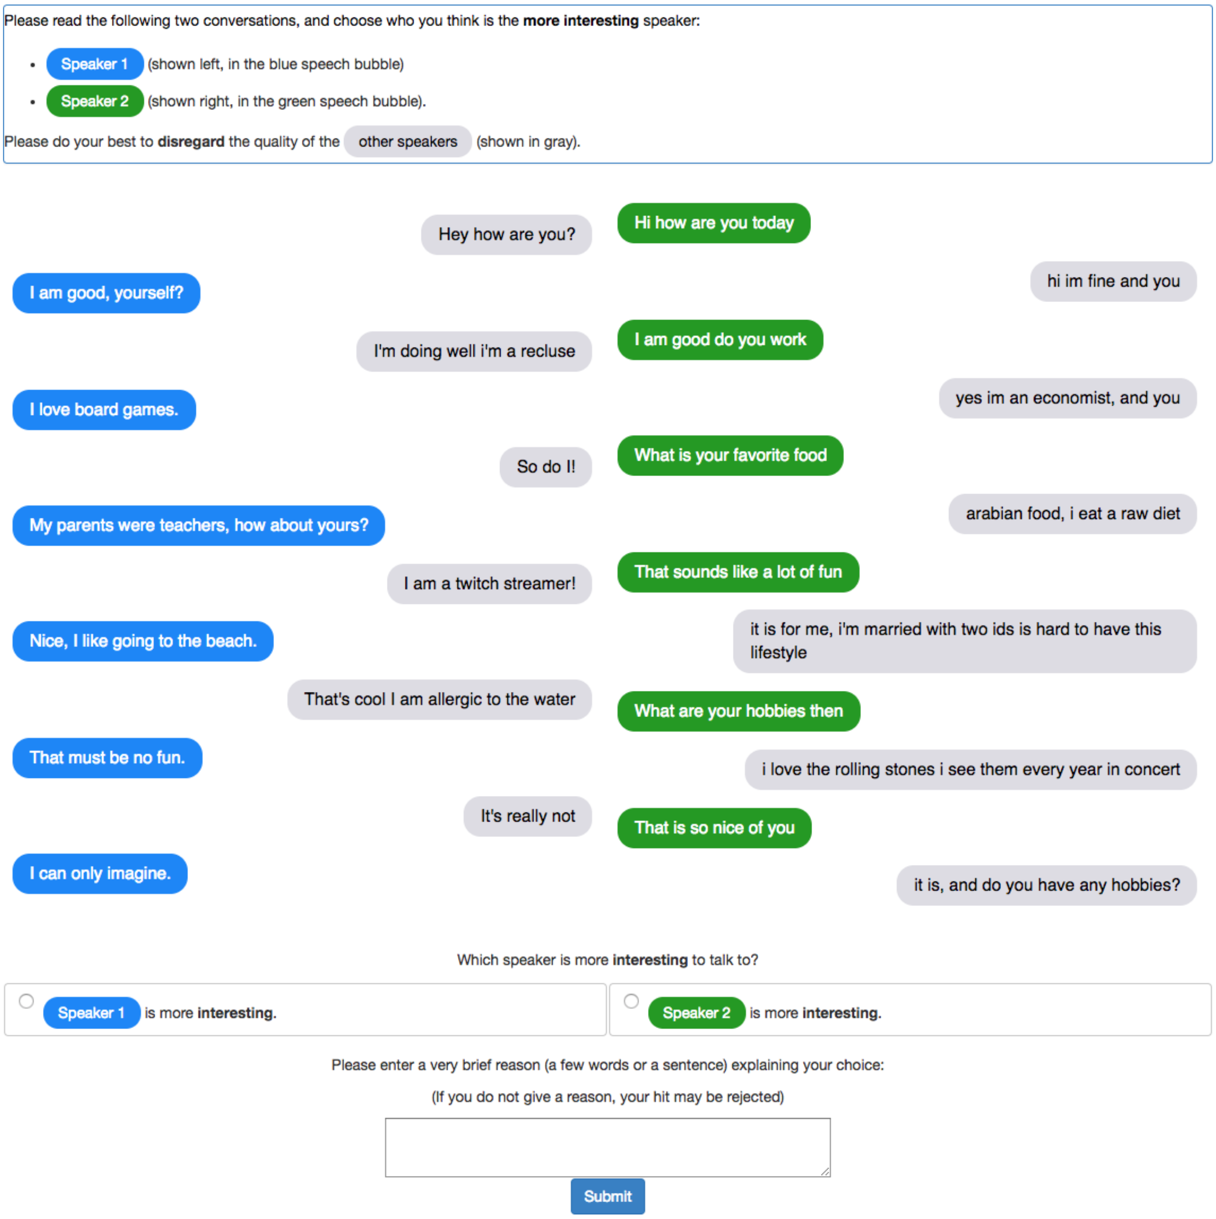
PERSON_1: do you speak french? i want to learn it

PERSON_2: I do not but I do love coffee

PERSON_1: do you have a favorite color?

PERSON_2: I like blue but I like the color yellow

Figure 6: Screenshot of the chat UI, talking with the beam search baseline model.



Please read the following two conversations, and choose who you think is the **more interesting** speaker:

- Speaker 1 (shown left, in the blue speech bubble)
- Speaker 2 (shown right, in the green speech bubble).

Please do your best to **disregard** the quality of the other speakers (shown in gray).

Hey how are you?

I am good, yourself?

I'm doing well i'm a recluse

I love board games.

So do I!

My parents were teachers, how about yours?

I am a twitch streamer!

Nice, I like going to the beach.

That's cool I am allergic to the water

That must be no fun.

It's really not

I can only imagine.

Hi how are you today

hi im fine and you

I am good do you work

yes im an economist, and you

What is your favorite food

arabian food, i eat a raw diet

That sounds like a lot of fun

it is for me, i'm married with two ids is hard to have this lifestyle

What are your hobbies then

i love the rolling stones i see them every year in concert

That is so nice of you

it is, and do you have any hobbies?

Which speaker is more **interesting** to talk to?

○ Speaker 1 is more **interesting**.

○ Speaker 2 is more **interesting**.

Please enter a very brief reason (a few words or a sentence) explaining your choice:

(If you do not give a reason, your hit may be rejected)

Figure 7: Screenshot of the A/B test UI, comparing a human-human conversation (left) and a Repetition-controlled baseline model (right).

B Human evaluation questionnaire design

Here are the questions and multiple-choice options used in the human evaluation, in the order presented:

[Engagingness] How much did you enjoy talking to this user?
• Not at all • A little • Somewhat • A lot

[Interestingness] How interesting or boring did you find this conversation?
• Very boring • A little boring • A little interesting • Very interesting

[Inquisitiveness] How much did the user try to get to know you?
• Didn't ask about me at all • Asked about me some
• Asked about me a good amount • Asked about me too much

[Listening] How much did the user seem to pay attention to what you said?
• Always ignored what I said • Mostly ignored what I said
• Mostly paid attention to what I said • Always paid attention to what I said

[Avoiding Repetition] How repetitive was this user?
• Repeated themselves over and over • Sometimes said the same thing twice
• Always said something new

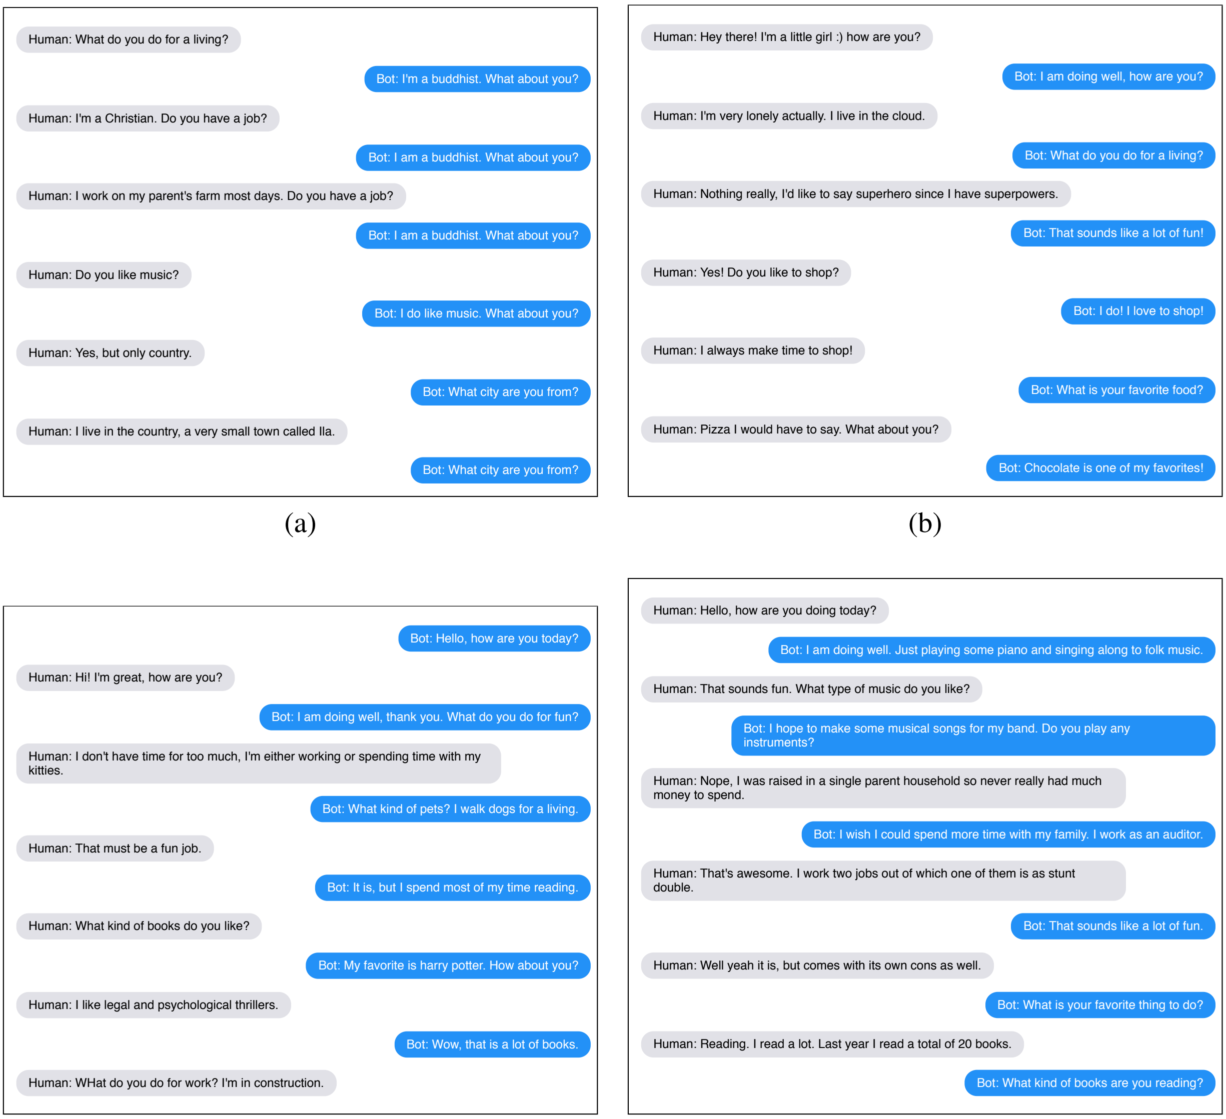
[Fluency] How naturally did this user speak English?
• Very unnatural • Mostly unnatural • Mostly natural • Very natural

[Making sense] How often did this user say something which did NOT make sense?
• Never made any sense • Most responses didn't make sense
• Some responses didn't make sense • Everything made perfect sense

[Humanness] Do you think this user is a bot or a human?
• Definitely a bot • Probably a bot • Probably a human • Definitely a human

[Persona retrieval] Which prompt (character) do you think the other user was given for this conversation?
Respondent chooses one of two provided personas

C Example conversations from human evaluation



Human: What do you do for a living?

Bot: I'm a buddhist. What about you?

Human: I'm a Christian. Do you have a job?

Bot: I am a buddhist. What about you?

Human: I work on my parent's farm most days. Do you have a job?

Bot: I am a buddhist. What about you?

Human: Do you like music?

Bot: I do like music. What about you?

Human: Yes, but only country.

Bot: What city are you from?

Human: I live in the country, a very small town called Ila.

Bot: What city are you from?

(a)

Human: Hey there! I'm a little girl :) how are you?

Bot: I am doing well, how are you?

Human: I'm very lonely actually. I live in the cloud.

Bot: What do you do for a living?

Human: Nothing really, I'd like to say superhero since I have superpowers.

Bot: That sounds like a lot of fun!

Human: Yes! Do you like to shop?

Bot: I do! I love to shop!

Human: I always make time to shop!

Bot: What is your favorite food?

Human: Pizza I would have to say. What about you?

Bot: Chocolate is one of my favorites!

(b)

Bot: Hello, how are you today?

Human: Hi! I'm great, how are you?

Bot: I am doing well, thank you. What do you do for fun?

Human: I don't have time for too much, I'm either working or spending time with my kitties.

Bot: What kind of pets? I walk dogs for a living.

Human: That must be a fun job.

Bot: It is, but I spend most of my time reading.

Human: What kind of books do you like?

Bot: My favorite is harry potter. How about you?

Human: I like legal and psychological thrillers.

Bot: Wow, that is a lot of books.

Human: WHat do you do for work? I'm in construction.

(c)

Human: Hello, how are you doing today?

Bot: I am doing well. Just playing some piano and singing along to folk music.

Human: That sounds fun. What type of music do you like?

Bot: I hope to make some musical songs for my band. Do you play any instruments?

Human: Nope, I was raised in a single parent household so never really had much money to spend.

Bot: I wish I could spend more time with my family. I work as an auditor.

Human: That's awesome. I work two jobs out of which one of them is as stunt double.

Bot: That sounds like a lot of fun.

Human: Well yeah it is, but comes with its own cons as well.

Bot: What is your favorite thing to do?

Human: Reading. I read a lot. Last year I read a total of 20 books.

Bot: What kind of books are you reading?

(d)

Figure 8: Example conversation with (a) Baseline (b) Repetition-controlled baseline (c) Question-controlled CT ($z = 7$), (d) Specificity-controlled WD (weight $= 4$).

D Repetition-control decoding features

Feature	**Condition**
`extrep_bigram`$(w, y_{<t}, x)$	Adding w to the hypothesis $y_{<t}$ would create a 2-gram that appears in a previous utterance by the model
`extrep_unigram`$(w, y_{<t}, x)$	w is a non-stopword **and** w appears in a previous utterance by the model
`intrep_bigram`$(w, y_{<t}, x)$	Adding w to the hypothesis $y_{<t}$ would create a 2-gram that appears earlier in the hypothesis $y_{<t}$
`intrep_unigram`$(w, y_{<t}, x)$	w is a non-stopword **and** w appears earlier in the hypothesis $y_{<t}$
`partnerrep_bigram`$(w, y_{<t}, x)$	Adding w to the hypothesis $y_{<t}$ would create a 2-gram that appears in a previous utterance by the partner

Table 4: We define five binary features for controlling different types of repetition via weighted decoding (see Section 5.2). Each feature depends on the word w, the partial hypothesis $y_{<t}$, and the context x (which includes the model's own persona and the dialogue history). Each of these features is equal to 1 if and only if the condition on the right is true; otherwise 0.

E Control settings for all configurations

	Repetition					**Specificity**	**Response-rel**	**Questions**
	External		**Internal**		**Partner Rep.**			
	Bigram	**Unigram**	**Bigram**	**Unigram**	**Bigram**	**NIDF**	**Cos sim**	**Has '?'**
Baselines								
Greedy Search								
Beam Search (beam size 20)								
Repetition control (WD)								
Extrep bigram WD -0.5	wt -0.5							
Extrep bigram WD -1.25	wt -1.25							
Extrep bigram WD -3.5	wt -3.5							
Extrep bigram WD -inf	wt $-\infty$							
Repetition-controlled baseline	wt -3.5	wt $-\infty$		wt $-\infty$				
Question control (CT)								
Question-controlled CT 0	wt -3.5	wt $-\infty$		wt $-\infty$				$z = 0$
Question-controlled CT 1	wt -3.5	wt $-\infty$		wt $-\infty$				$z = 1$
Question-controlled CT 4	wt -3.5	wt $-\infty$		wt $-\infty$				$z = 4$
Question-controlled CT 7	wt -3.5	wt $-\infty$		wt $-\infty$				$z = 7$
Question-controlled CT 10	wt -3.5	wt $-\infty$		wt $-\infty$				$z = 10$
Question-controlled CT 10 (boost)	wt 0 *	wt $-\infty$		wt $-\infty$				$z = 10$
Specificity control (CT)								
Specificity-controlled CT 0	wt -3.5	wt $-\infty$		wt $-\infty$		$z = 0$		
Specificity-controlled CT 2	wt -3.5	wt $-\infty$		wt $-\infty$		$z = 2$		
Specificity-controlled CT 4	wt -3.5	wt $-\infty$		wt $-\infty$		$z = 4$		
Specificity-controlled CT 7	wt -3.5	wt $-\infty$		wt $-\infty$		$z = 7$		
Specificity-controlled CT 9	wt -3.5	wt $-\infty$		wt $-\infty$		$z = 9$		
Specificity control (WD)								
Specificity-controlled WD -10	wt -3.5	wt $-\infty$		wt $-\infty$		wt -10		
Specificity-controlled WD -4	wt -3.5	wt $-\infty$		wt $-\infty$		wt -4		
Specificity-controlled WD 4	wt -3.5	wt $-\infty$		wt $-\infty$		wt 4		
Specificity-controlled WD 6	wt -3.5	wt $-\infty$		wt $-\infty$		wt 6		
Specificity-controlled WD 8	wt -3.5	wt $-\infty$		wt $-\infty$		wt 8		
Response-related control (WD) **								
Response-related controlled WD -10	wt -3.5	wt $-\infty$	wt $-\infty$	wt $-\infty$	wt $-\infty$		wt -10	
Response-related controlled WD 0	wt -3.5	wt $-\infty$	wt $-\infty$	wt $-\infty$	wt $-\infty$		wt 0	
Response-related controlled WD 5	wt -3.5	wt $-\infty$	wt $-\infty$	wt $-\infty$	wt $-\infty$		wt 5	
Response-related controlled WD 10	wt -3.5	wt $-\infty$	wt $-\infty$	wt $-\infty$	wt $-\infty$		wt 10	
Response-related controlled WD 13	wt -3.5	wt $-\infty$	wt $-\infty$	wt $-\infty$	wt $-\infty$		wt 13	

Table 5: Control settings for all configurations that were human-evaluated. 'wt' means the weight used for a weighted decoding feature and '$z =$' means the setting (i.e. bucket) for the control variable in conditional training.

* In the setting Question-controlled CT 10 (boost), the feature `extrep_bigram` is *not* used for weighted decoding during beam search, but it *is* used to rerank the candidates after beam search. See Section 6.4 for details.

** Note that the Response-related controlled models additionally introduce repetition controls to block internal bigram repetition and partner bigram repetition. This was necessary to prevent the model from parroting the partner's last utterance. In Table 8, we find that just adding these extra repetition controls (here called Response-related controlled WD 0, i.e. increased repetition control but no response-relatedness control) outperforms our canonical Repetition-controlled baseline. However, given that we discovered this later, our specificity and question controlled models are built on top of the canonical Repetition-controlled baseline.

Table 7: Raw scores (mean ± std.) for all models and human evaluation metrics.

The first eight columns are Likert metrics on a 1-4 scale (except Avoiding Repetition, which is a 1-3 scale), where higher is better (except Inquisitiveness, which has an optimal score of 3). The last column, Persona Retrieval, is on a scale from 0 to 1 where higher is better.

The maximum of each column (excluding Human row) is in bold.

Abstract

Globally normalized neural sequence models are considered superior to their locally normalized equivalents because they may ameliorate the effects of label bias. However, when considering high-capacity neural parametrizations that condition on the whole input sequence, both model classes are theoretically equivalent in terms of the distributions they are capable of representing. Thus, the practical advantage of global normalization in the context of modern neural methods remains unclear. In this paper, we attempt to shed light on this problem through an empirical study. We extend an approach for search-aware training via a continuous relaxation of beam search (Goyal et al., 2017b) in order to enable training of *globally normalized* recurrent sequence models through simple backpropagation. We then use this technique to conduct an empirical study of the interaction between global normalization, high-capacity encoders, and search-aware optimization. We observe that in the context of inexact search, globally normalized neural models are still more effective than their locally normalized counterparts. Further, since our training approach is sensitive to warm-starting with pre-trained models, we also propose a novel initialization strategy based on self-normalization for pre-training globally normalized models. We perform analysis of our approach on two tasks: CCG supertagging and Machine Translation, and demonstrate the importance of global normalization under different conditions while using search-aware training.

1 Introduction

Neural encoder-decoder models have been tremendously successful at a variety of NLP tasks, such as machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), parsing (Dyer et al., 2016, 2015), summarization (Rush et al., 2015), dialog generation (Serban et al., 2015), and image captioning (Xu et al., 2015). With these models, the target sequence is generated in a left-to-right step-wise manner with the predictions at every step being conditioned on the input sequence and the whole prediction history. This long-distance memory precludes exact search for the maximally scoring sequence according to the model and therefore, approximate algorithms like greedy search or beam search are necessary in practice during decoding. In this scenario, it is natural to resort to search-aware learning techniques for these models which makes the optimization objective sensitive to any potential errors that could occur due to inexact search in these models.

This work focuses on comparison between search-aware locally normalized sequence models that involve projecting the scores of items in the vocabulary onto a probability simplex at each step and globally normalized/unnormalized sequence models that involve scoring sequences without explicit normalization at each step. When conditioned on the the full input sequence and the entire prediction history, both locally normalized and globally normalized conditional models should have same expressive power under a high-capacity neural parametrization in theory, as they can both model same set of distributions over all finite length output sequences (Smith and Johnson, 2007). However, locally normalized models are constrained in how they respond to search errors during training since the scores at each decoding step must sum to one. To let a search-aware training setup have the most flexibility, abandoning this constraint may be useful for easier optimization.

In this paper, we demonstrate that the interaction between approximate inference and non-convex parameter optimization results in more robust training and better performance for models with global normalization compared to those with

Proceedings of NAACL-HLT 2019, pages 1724–1733
Minneapolis, Minnesota, June 2 - June 7, 2019.

the more common locally normalized parametrization. We posit that this difference is due to *label bias* (Bottou, 1991) arising from the interaction of approximate search and search-aware optimization in locally normalized models. A commonly understood source of label bias in *locally normalized* sequence models is an effect of conditioning only on partial input (for example, only the history of the input) at each step during decoding (Andor et al., 2016; Lafferty et al., 2001; Wiseman and Rush, 2016). We discus another potential source of label bias arising from approximate search with locally normalized models that may be present even with access to the full input at each step. To this end, we train search-aware globally and locally normalized models in an end-to-end (sub)-differentiable manner using a continuous relaxation to the discontinuous beam search procedure introduced by Goyal et al. (2017b). This approach requires initialization with a suitable globally normalized model to work in practice. Hence, we also propose an initialization strategy based upon self-normalization for pre-training globally normalized models.

We demonstrate the effect of both sources of label bias through our experiments on two common sequence tasks: CCG supertagging and machine translation. We find that label bias can be eliminated by both, using a powerful encoder, and using a globally normalized model. We observe that global normalization yields performance gains over local normalization and is able to ameliorate label bias especially in scenarios that involve a very large hypothesis space.

2 Recurrent Sequence Models and Effects of Normalization

We now introduce the notation that we will use in the remainder of the paper for describing locally and globally normalized neural sequence-to-sequence models. We are interested in the probability of output sequence, $\mathbf{y}$, conditioned on input sequence, $\mathbf{x}$. Let $s(\mathbf{x}, y_{1:i-1}, y_i)$ be a non negative score of output label y at time-step i for the input x and the prediction history $y_{1:i-1}$, let V be the label space, and let $\mathcal{Y}_{\mathbf{x}}$ be the space of all finite sequences for $\mathbf{x}$.[1] A neural encoder (e.g. a bidirectional LSTM) encodes information about $\mathbf{x}$ and a recurrent neural decoder generates the output $\mathbf{y}$ (typically step-by-step from left-to-right) conditioned on the encoder.

2.1 Locally normalized models

Under a locally normalized model $\mathcal{M}_L$, the probability of $\mathbf{y}$ given $\mathbf{x}$ is:

$$p_{\mathcal{M}_L}(\mathbf{y} \mid \mathbf{x}) = \prod_{i=1}^{n} p(y_i \mid \mathbf{x}, y_{1:i-1}) = \prod_{i=1}^{n} \frac{s(\mathbf{x}, y_{1:i-1}, y_i)}{Z_{L,i}(\mathbf{x}, y_{1:i-1})}$$

where $Z_{L,i}(\mathbf{x}, y_{1:i-1}) = \sum_{y \in V} s(\mathbf{x}, y_{1:i-1}, y)$, is the local normalizer at each time step and n is the number of prediction steps. Since, the local normalizer is easy to compute, likelihood maximization based training is a standard approach for training these models.

2.2 Globally normalized models

In contrast, under a globally normalized model $\mathcal{M}_G$, the probability of $\mathbf{y}$ given $\mathbf{x}$ is:

$$p_{\mathcal{M}_G}(\mathbf{y} \mid \mathbf{x}) = \frac{\prod_{i=1}^{n} s(\mathbf{x}, y_{1:i-1}, y_i)}{Z_G(\mathbf{x})}$$

where $Z_G(\mathbf{x}) = \sum_{\mathbf{y} \in \mathcal{Y}} \prod_{i=1}^{n} s(\mathbf{x}, y_{1:i-1}, y_i)$, is the global log-normalizer. $Z_G(\mathbf{x})$ is intractable to estimate for most problems of interest due to the large search space therefore, an exact likelihood maximization training approach is intractable for these models.

2.3 Label Bias with partial input

It was shown in Andor et al. (2016); Lafferty et al. (2001), locally normalized conditional models *with access to only partial input*, $x_{1:i-1}$, at each decoding step are biased towards labeling decisions with low-entropy transition probabilities at each decoding step and, as a result, suffer from a weakened ability to revise previous decisions based upon future input observations. This phenomenon has been referred to as *label bias*, and presents itself as an arbitrary allocation of probability mass to unlikely or undesirable label sequences despite the presence of well-formed sequences in training data. Andor et al. (2016) prove that this class of locally normalized models that relies on the structural assumption of access to only left-to-right partial input at each step,

$$\prod_{i=1}^{n} p(y_i \mid \mathbf{x}, y_{1:i-1}) = \prod_{i=1}^{n} p(y_i \mid x_{1:i-1}, y_{1:i-1}),$$

---

[1] For notational convenience we suppress the dependence of the score s on model parameters θ.

is strictly less expressive than its globally normalized counterpart.

However, the standard sequence-to-sequence models used most often in practice and presented in this paper actually condition the decoder on a summary representation of the *entire input sequence*, $\mathbf{x}$, computed by a neural encoder. Hence, depending on the power of the encoder, it is commonly thought that such models avoid this type of label bias. For these models, both locally normalized and globally normalized conditional models are equally expressive, in principle, with a sufficiently powerful encoder.

However, as we suggest in the next section and show empirically in experiments, this does not necessarily mean that both parametrizations are equally amenable to gradient-based training in practice, particularly when the search space is large and search-aware training techniques are used. We will argue that they suffer from a related, but distinct, form of bias introduced by inexact decoding.

2.4 Search-aware training

To improve performance with inexact decoding methods (e.g. beam search), search-aware training techniques take into account the decoding procedure that will be used at test time and adjust the parameters of the model to maximize prediction accuracy under the decoder. Because of the popularity of beam search as a decoding procedure for sequence models, in this paper we focus on beam search-aware training. While many options are available, including beam-search optimization (BSO) (Wiseman and Rush, 2016), in Section 3.1 we will describe the particular search-aware training strategy we use in experiments (Goyal et al., 2017b), chosen for its simplicity.

2.5 Label Bias due to approximate search

We illustrate via example how optimization of locally normalized models may suffer from a new kind of label bias when using beam search-aware training, and point to reasons why this issue might be mitigated by the use of globally normalized models. While the scores of successors of a single candidate under a locally normalized model are constrained to sum to one, scores of successors under a globally normalized model need only be positive. Intuitively, during training, this gives the globally normalized model more freedom to downweight undesirable intermediate candidates in order avoid search errors.

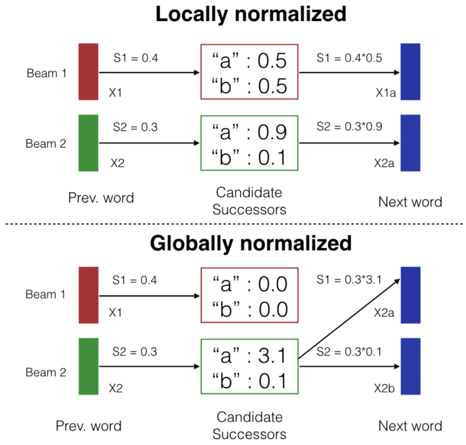

Figure 1: Illustrative example of bias arising in locally normalized models due to beam search. Red indicates the candidate that optimization should learn to discard and green indicates the candidate that should be propagated. Locally normalized models are constrained to return normalized scores for the successors of each candidate, while globally normalized models are unconstrained and can more easily learn to drop successors of the red candidate.

In the example beam search decoding problem in Figure 1, we compare the behavior of locally and globally normalized models at a single time step for a beam size of two. In this example, we assume that the score for beams in both the models is exactly the same until the step shown in Figure 1. Suppose that the lower item on the beam(X2) is correct, and thus, for more effective search, we would prefer the models scores to be such that only successors of the lower beam item are present on the beam at the next step. However, since, the scores at each step for a locally normalized model are constrained to sum to one, the upper beam item(X1) generates successors with scores comparable to those of the lower beam item. As we see in the example, due to the normalization constraint, search-aware training of the locally normalized model might find it difficult to set the parameters to prevent extension of the poorer candidate. In contrast, because the scores of a *globally normalized* model are not constrained to sum to one, the parameters of the neural model can be set such that *all* the successors of the bad candidate have a very low score and thus do not compete for space on the beam. This illustrates a mechanism by which search-aware training of globally normalized models in a large search spaces might

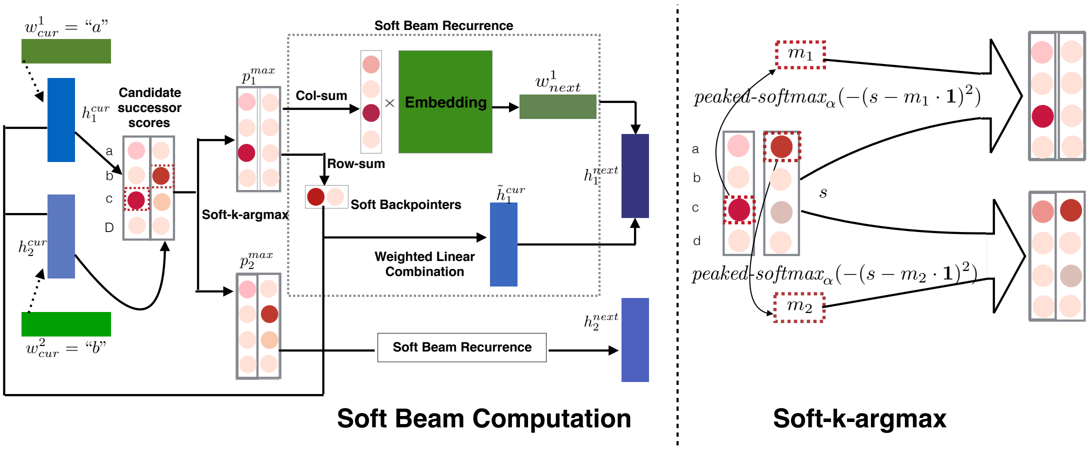

Figure 2: **Left:** Computing LSTM hidden states at a subsequent step using continuous relaxation to beam search for beam size of 2. **Right:** Illustration of top-k-argmax. m_1 and m_2 are the maximum and second maximum candidate scores.

be more effective. However as discussed earlier, if we can perform *exact search* then this *label bias* ceases to exist because both the models have the same expressive power with a search-agnostic optimization scheme. In experiments, we will explore this trade-off empirically.

3 Search-aware Training for Globally Normalized Models

In order to conduct an empirical study with meaningful comparisons, we devise an extension of the relaxed beam-search based optimization proposed by Goyal et al. (2017b) that allows us to train both the search-aware globally and locally normalized models in a similar manner with the same underlying architecture.

3.1 Continuous Relaxation to Beam Search

Following Goyal et al. (2017b), we train a beam-search aware model by optimizing a continuous surrogate approximation to a *direct loss* objective, J, defined as a function of the output of beam search and the ground truth sequence $\mathbf{y}^*$:

$$\min_\theta J(\mathbf{x}, \theta, \mathbf{y}^*) = \min_\theta \ell(\mathit{Beam}(\mathbf{x}, \mathcal{M}(\theta)), \mathbf{y}^*)$$

Here ℓ is a function that computes the loss of the model's prediction produced by beam search , and $\mathcal{M}$ refers to the model parametrized by θ. While this objective is search-aware, it is discontinuous and difficult to optimize because beam search involves discrete *k-argmax* operations. Therefore, Goyal et al. (2017b) propose a continuous surrogate, $\tilde{J}$, by defining a continuous approximation (*soft-k-argmax*) of the discrete *k-argmax* and using this to compute an approximation to a composition of the loss function and the beam search function.

$$\min_\theta \tilde{J}(\mathbf{x}, \theta, \mathbf{y}^*) \approx \min_\theta (\ell \circ \mathit{Beam})(\mathbf{x}, \mathcal{M}(\theta), \mathbf{y}^*)$$

The *soft-k-argmax* procedure involves computing distances between the scores of the successors and the k^{th}-max score and using the temperature based argmax operation (Maddison et al., 2017; Jang et al., 2016; Goyal et al., 2017a) to get an output peaked on the k^{th}-max value as shown in the right panel of Figure 2. The temperature is a hyperparameter which is typically annealed toward producing low entropy distributions during optimization. As shown in the left panel of Figure 2, the *soft candidate vectors* and the *soft backpointers* are computed at every decoding step using this *soft-k-argmax* operation in order to generate the embeddings and recurrent hidden states of the LSTM at each step of the *soft beam search* procedure. With a locally decomposable loss like Hamming loss, both *soft loss* and *soft scores* for the relaxed procedure are iteratively computed so that the end-to-end objective computation can be described by a computation graph that is amenable to backpropagation.

Using this relaxation, point-wise convergence of the surrogate objective to the original objective can be established (α is the inverse temperature):

$$\tilde{J}_\alpha(\mathbf{x}, \theta, \mathbf{y}^*) \xrightarrow[p]{\alpha \to \infty} J(\mathbf{x}, \theta, \mathbf{y}^*)$$

Goyal et al. (2017b) demonstrated empirically that optimizing the surrogate objective, $\tilde{J}$ – which can be accomplished via simple backpropagation for decomposable losses like Hamming distance – leads to improved performance at test time.

In experiments, for training locally normalized models, we use *log-normalized* successor scores. However, for training globally normalized models, we will directly use *unnormalized scores*, which are $\in \mathrm{R}_+$.

3.2 Initialization for training globally normalized models

Goyal et al. (2017b) reported that *initialization* with a locally normalized model pre-trained with teacher-forcing was important for their continuous beam search based approach to be stable and hence they used the locally normalized log-scores for their search-aware training model. In this work, we experimented with the unnormalized candidate successor scores and found that initializing the optimization for a globally normalized objective with a cross-entropy trained locally normalized model resulted in unstable training. This is expected because the locally normalized models are parametrized in a way such that using the scores before the softmax normalization results in a very different outcome than using scores after local normalization. For example, the locally normalized Machine Translation model in Table 1, that gives a BLEU score of 27.62 when decoded with beam search using locally normalized scores, results in BLEU of 4.30 when beam search decoding is performed with unnormalized scores. Pre-training a truly globally normalized model for initialization is not straghtforward because no exact likelihood maximization techniques exist for globally normalized models as the global normalizer is intractable to compute.

Therefore, we propose a new approach to initialization for search-aware training of globally normalized models: we pre-train a locally normalized model that is parametrized like a globally normalized model. More specifically, we train a locally normalized model with its distribution over the output sequences denoted by $p_L(\mathcal{Y})$ such that we can easily find a globally normalized model with a distribution $p_G(\mathcal{Y})$ that matches $p_L(\mathcal{Y})$. Following the notation in Section 2, for a locally normalized model, the log-probability of a sequence is:

$$\sum_{i=1}^{n} [\log s(\mathbf{x}, y_{1:i-1}, y_i) - \log Z_{L,i}(\mathbf{x}, y_{1:i-1})]$$

and for a globally normalized model it is:

$$\left[\sum_{i=1}^{n} \log s(\mathbf{x}, y_{1:i-1}, y_i)\right] - \log Z_G(\mathbf{x})$$

3.2.1 Self Normalization

One way to find a locally normalized model that is parametrized like a globally normalized model is to ensure that the local normalizer at each step, $\log\ Z_{L,i}(\mathbf{x}, y_{1:i-1})$, is 0. With the local normalizer being zero it is straightforward to see that the log probability of a sequence under a locally normalized model can easily be interpreted as log probability of the sequence under a globally normalized model with the global log-normalizer, $\log\ Z_G(\mathbf{x}) = 0$. This training technique is called *self-normalization* (Andreas and Klein, 2015) because the resulting models' unnormalized score at each step lies on a probability simplex. A common technique for training self-normalized models is L2-regularization of local log normalizer which encourages learning a model with $\log\ Z = 0$ and was found to be effective for learning a language model by Devlin et al. (2014)[2]. The L2-regularized cross entropy objective is given by:

$$\min_{\theta} \sum_{\mathbf{x}, \mathbf{y}^* \in \mathcal{D}} -\sum_{i=1}^{n} \log\ p(y_i^* \mid \mathbf{x}, y_{1:i-1}) \\ +\lambda \cdot (\log\ Z_{L,i}(\mathbf{x}, y_{1:i-1}))^2$$

In Table 1, we report the mean and variance of the local log normalizer on the two different tasks using L2-regularization (*L2*) based self normalization and no self normalization (*CE*). We observe that *L2* models are competitive performance-wise to the cross-entropy trained locally normalized models while resulting in a much smaller local log-normalizer on average. Although, we couldn't minimize $\log\ Z$ exactly to 0, we observe in Section 4 that this is sufficient to train a reasonable initializer for the search-aware optimization of globally normalized models. It is important to note that these approaches yield a *globally normalized* model that is equivalent to a locally normalized model trained via teacher-forcing and hence these are only used to *warm-start* the search-aware optimization of globally normalized models. Our search-aware training approach is

---

[2] Noise Contrastive Estimation (Mnih and Teh, 2012; Gutmann and Hyvärinen, 2010) is also an alternative to train unnormalized models but our experiments with NCE were unstable and resulted in worse models.

free to adjust the parameters of the models such that the final globally normalized model has a non-zero log-normalizer Z_G over the data.

		Train logZ		Dev logZ		Acc/BLEU
		Mean	Var	Mean	Var	
CCG	CE	21.08	9.57	21.96	9.18	93.3
	L2	0.6	0.29	0.26	0.08	91.9
MT	CE	24.7	115.4	25.8	129.1	27.62
	L2	0.65	0.18	0.7	0.29	26.63

Table 1: Comparison of logZ between cross entropy trained models (CE) and self normalized models (L2) for CCG supertagging and Machine Translation tasks.

Other possible approaches to project locally normalized models onto globally normalized models include distribution matching via knowledge distillation (Hinton et al., 2015). We leave exploration of warm-starting of search aware optimization with this approach to future work.

4 Experiments and Empirical Analysis

To empirically analyze the interaction between label bias arising from different sources, search-aware training, and global normalization, we conducted experiments on two tasks with vastly different sizes of output space: CCG supertagging and Machine Translation. As described in the next section, the task of tagging allows us to perform controlled experiments which explicitly study the effect of amount of input information available to the decoder at each step, we analyze the scenarios in which search aware training and global normalization are expected to improve the model performance.

In all our experiments, we report results on training with standard teacher forcing optimization and self-normalization as our baselines. We report results with both search-aware locally and globally normalized models (Section 3.1) after warm starting with both cross entropy trained models and self-normalized models to study the effects of search-aware optimization and global normalization. We follow Goyal et al. (2017b) and use the decomposable Hamming loss approximation with search-aware optimization for both the tasks and decode via *soft beam search decoding* method which involves continuous beam search with soft backpointers for the LSTM Beam search dynamics as described in Section 3, but using identifiable backpointers and labels (using MAP estimates of soft backpointers and labels) to decode.

We tune hyperparameters like learning rate and annealing schedule by observing performance on development sets for both the tasks. We performed at least three random restarts for each class and report results based on best development performance.

4.1 CCG supertagging

We used the standard splits of CCG bank (Hockenmaier and Steedman, 2002) for training, development, and testing. The label space of supertags is 1,284 and the labels are correlated with each other based on their syntactic relations. The distribution of supertag labels in the training data exhibits a long tail distribution. This task is sensitive to the long range sequential decisions because it encodes rich syntactic information about the sentence. Hence, this task is ideal to analyze the effects of label bias and search effects. We perform minor preprocessing on the data similar to the preprocessing in Vaswani et al. (2016). For experiments related to search aware optimization, we report results with beam size of 5.[3]

4.1.1 Tagging model for ablation study

We changed the standard sequence-to-sequence model to be more suitable for the tagging task. This change also lets us perform controlled experiments pertaining to the amount of input sequence information available to the decoder at each time step.

In a standard encoder-decoder model with attention, the initial hidden state of the decoder is often some function of the final encoder state so that the decoder's predictions can be conditioned on the full input. For our tagging experiments, instead of influencing the initial decoder state with the encoder, we set it to a vector of zeros. Thus the information about input for prediction is *only* available via the attention mechanism. In addition to the change above, we also forced the model to attend to only the i^{th} input representation while predicting the i^{th} label. This is enforceable because the output length is equal to the input length and it is also a more suitable structure for a tagging model. With these changes in the decoder, we can precisely control the amount of information about the input available to the decoder at each prediction step. For example, with a unidirectional LSTM encoder, the decoder at i^{th} step

---

[3] We observed similar results with beam size 10

only has access to input till the i^{th} token and the prediction history:

$$p(y_i \mid \mathbf{x}, y_{1:i-1}) = p(y_i \mid x_{1:i}, y_{1:i-1})$$

This setting lets us clearly explore the classical notion of *label bias* arising out of access to partial input at each prediction step (Section 2.3). A bidirectional LSTM encoder, however provides access to all of the input information to the decoder at all the prediction steps.

	Unidirectional	Bidirectional
pretrain-greedy	76.54	92.59
pretrain-beam	77.76	93.29
locally normalized	83.9	**93.76**
globally normalized	**83.93**	93.73

Table 2: **Accuracy results on CCG supertagging when initialized with a regular teacher-forcing model**. Reported using *Unidirectional* and *Bidirectional* encoders respectively with fixed attention tagging decoder. *pretrain-greedy* and *pretrain-beam* refer to the output of decoding the initializer model. *locally normalized* and *globally normalized* refer to search-aware soft-beam models

	Unidirectional	Bidirectional
pretrain-greedy	73.12	91.23
pretrain-beam	73.83	91.94
locally normalized	83.35	**92.78**
globally normalized	**85.50**	92.63

Table 3: **Accuracy results on CCG supertagging when initialized with a self normalized model**.

4.2 Machine Translation

We use the same dataset (the German-English portion of the IWSLT 2014 machine translation evaluation campaign (Cettolo et al., 2014)), preprocessing and data splits as Ranzato et al. (2016) for our Machine Translation experiments. The output label/vocabulary size is 32000 and unlike tagging, the length of output sequences cannot be deterministically determined from the length of the input sequence. Moreover, the output sequence does not necessarily align monotonically with the input sequence. Hence the output sequence space for MT is much larger than that for tagging and the effects of inexact search on optimization are expected to be even more apparent for MT. We use a standard LSTM-based encoder/decoder model with a standard attention mechanism (Bahdanau et al., 2016) for our MT experiments. For search-aware optimization experiments, we report results with beam size 3.[4]

Init-scheme →	Regular	Self-normalized
pretrain-greedy	26.24	25.42
pretrain-beam	27.62	26.63
locally-normalized	**29.28**	27.71
globally-normalized	26.24	**29.27**

Table 4: **BLEU results on de-en Machine Translation.** *Regular* and *Self-normalized* refer to the initization scheme for soft beam search training. *pretrain-greedy* and *pretrain-beam* refer to the output of decoding the initializer model. *locally normalized* and *globally normalized* refer to search-aware soft-beam models

4.3 Results and Analysis

The results reported in Tables 2, 3 and 4 allow us to analyze the effect of interaction of label bias, inexact search and global normalization in detail.

4.3.1 Label bias with partial input

First, we analyze the effect of label bias that arises from conditioning on partial input (Section 2.3) during decoding on optimization of the models. The unidirectional encoder based tagging experiments suggest that conditioning on partial input during decoding results in poor models when trained with cross entropy based methods. Interestingly, all techniques improve upon this: (i) search-aware locally and globally normalized models are able to train for accuracy directly and eliminate exposure bias that arises out of the mismatch between train-time and test-time prediction methods, and, (ii) the bidirectional tagging model which provides access to all of the input is powerful enough to learn a complex relationship between the decoder and the input representations for the search space of the CCG supertagging task and results in a much better performance.

4.3.2 Initialization of search-aware training

Next, we analyze the importance of appropriate initialization of search-aware optimization with pretrained models. Across all the results in Tables 2, 3 and 4, we observe that search-aware optimization for locally normalized models always improves upon the pre-trained locally

---

[4] We observed similar results beam size of 5.

normalized models used for initialization. But when the search-aware optimization for globally normalized models is initialized with locally normalized CE models, the improvement is not as pronounced and in the case of MT, the performance is actually *hurt* by the improper initialization for training globally normalized models – probably a consequence of large search space associated with MT and incompatibility between unnormalized scores for search-aware optimization and locally normalized scores of the *CE* model used for pre-training. When the *self-normalized* models are used for initialization, optimization for globally normalized models always improves upon the pre-trained self-normalized model. It is interesting to note that we see improvements for the globally normalized models even when $logZ$ is not exactly reduced to 0 indicating that the scores used for search-aware training initially are comparable to the scores of the pre-trained self-normalized model. We also observe that self-normalized models perform slightly worse than CE-trained models but search aware training for globally normalized models improves the performance significantly.

4.3.3 Search-aware training

Next, we analyze the effect of search-aware optimization on the performance of the models. Search-aware training with locally normalized models improves the performance significantly in *all* our experiments which indicates that accounting for exposure bias and optimizing for predictive performance directly is important. We also observe that the bidirectional model for tagging is quite powerful and seems to account for both *exposure bias* and *label bias* to a large extent. We reckon that this may be because the greedy decoding itself is very close to *exact search* for this well-trained tagging model over a search space that is much simpler than that associated with MT. Therefore, the impact of search-aware optimization on the bidirectional tagger is marginal. However, it is much more pronounced on the task of MT.

4.3.4 Global normalization and label bias

We analyze the importance of training globally normalized models. In the specific setup for tagging with the unidirectional encoder, globally normalized models are actually *more expressive* than the locally normalized models (Andor et al., 2016) as described in Section 2.3 and this is reflected in our experiments (table 3) with tagging. The globally normalized model (warm started with a self-normalized model) performs the best among all the models in the unidirectional tagger case which indicates that it is ameliorating something beyond exposure bias which is fixed by the search-aware locally normalized model.

For MT (table 4), both globally normalized and locally normalized models are equally expressive in theory because the decoder is conditioned on the full input information at each step, but we still observe that the globally normalized model improves significantly over the self-normalized pre-trained model and the search-aware locally normalized model. This indicates that it might be ameliorating the label bias associated with inexact search (discussed in Section 2.5). As discussed in Section 3.2, the globally normalized model, when initialized with a CE trained model, performs worse because of improper initialization of the search aware training. The self-normalized model starts off 1 BLEU point worse than the CE model point but global normalization, initialized with the self-normalized model improves the performance and is competitive with the best model for MT. This suggests that a better technique for initializing the optimization for globally normalized models should be helpful in improving the performance.

4.3.5 Global normalization and sentence length

In tables 5 and 6, we analyze the source of improvement from global normalization for MT. In table 5, we report the ngram overlap scores and ratio of length of the predictions to length of hypothesis for the case when the search-aware training is initialized with a self-normalized model. We observe that the globally normalized model produces longer predictions than the locally normalized model. More interestingly, it seems to have better 3 and 4-gram overlap and slightly worse unigram and bigram overlap score than the locally normalized model. These observations suggest that globally normalized models are better able to take longer range effects into account and are also cautious about predicting the *end-of-sentence* symbol too soon. Moreover, in table 6, we observe

	N-gram overlap	Length ratio
pretrain-beam	63.5/35.7/21.8/13.7	0.931
locally-normalized	66.9/39.4/22.7/14.0	0.918
globally-normalized	65.0/39.1/23.2/14.7	0.959

Table 5: **Breakdown of BLEU results on de-en Machine Translation dev set.** Reported on Self-normalized initialization

Src sent-length →	**0-20**	**20-30**	**30-40**	**40+**
pretrain-beam	29.36	25.73	24.71	24.50
locally-normalized	32.35	26.95	25.39	25.2
globally-normalized	33.21	28.08	26.75	26.41

Table 6: **BLEU scores with different length inputs on dev set** Reported on Self-normalized initialization. The header specifies the range of length of the input sentences

that globally normalized models perform better on all the length ranges but especially so on long sentences.

5 Related Work

Much of the existing work on search-aware training of globally normalized neural sequence models uses some mechanism like early updates (Collins and Roark, 2004) that relies on explicitly tracking if the gold sequence falls off the beam and is not end-to-end continuous. Andor et al. (2016) describe a method for training globally normalized neural feedforward models, which involves optimizing a CRF-based likelihood where the normalizer is approximated by the sum of the scores of the final beam elements. They describe label bias arising out of conditioning on partial input and hence focused on the scenario in which locally normalized models can be less expressive than globally normalized models, whereas we also consider another source of label bias which might be affecting the optimization of equally expressive locally and globally normalized conditional models. Wiseman and Rush (2016) also propose a beam search based training procedure that uses unnormalized scores similar to our approach. Their models achieve good performance over CE baselines – a pattern that we observe in our results as well. In this work, we attempt to empirically analyze the factors affecting this boost in performance with end-to-end continuous search-aware training (Goyal et al., 2017b) for globally normalized models.

Smith and Johnson (2007) proved that locally normalized conditional PCFGs and unnormalized conditional WCFGs are equally expressive for finite length sequences and posit that Maximum Entropy Markov Models (MEMMs) are weaker than CRFs because of the structural assumptions involved with MEMMs that result in label bias.

Recently, energy based neural structured prediction models (Amos et al., 2016; Belanger and McCallum, 2016; Belanger et al., 2017) were proposed that define an energy function over candidate structured output space and use gradient based optimization to form predictions making the overall optimization search aware. These models are designed to model global interactions between the output random variables without specifying strong structural assumptions.

6 Conclusion

We performed empirical analysis to analyze the interaction between label bias, search-aware optimization and global normalization in various scenarios. We proposed an extension to the continuous relaxation to beam search proposed by Goyal et al. (2017b) to train search-aware globally normalized models and comparable locally normalized models. We find that in the context of inexact search over large output spaces, globally normalized models are more effective than the locally normalized models in spite of them being equivalent in terms of their expressive power.

Pun Generation with Surprise

He He[1*] and **Nanyun Peng**[2*] and **Percy Liang**[1]

Abstract

We tackle the problem of generating a pun sentence given a pair of homophones (e.g., "*died*" and "*dyed*"). Supervised text generation is inappropriate due to the lack of a large corpus of puns, and even if such a corpus existed, mimicry is at odds with generating novel content. In this paper, we propose an unsupervised approach to pun generation using a corpus of unhumorous text and what we call the *local-global surprisal principle*: we posit that in a pun sentence, there is a strong association between the pun word (e.g., "*dyed*") and the distant context, as well as a strong association between the alternative word (e.g., "*died*") and the immediate context. This contrast creates surprise and thus humor. We instantiate this principle for pun generation in two ways: (i) as a measure based on the ratio of probabilities under a language model, and (ii) a retrieve-and-edit approach based on words suggested by a skip-gram model. Human evaluation shows that our retrieve-and-edit approach generates puns successfully 31% of the time, tripling the success rate of a neural generation baseline.

1 Introduction

Generating *creative* content is a key requirement in many natural language generation tasks such as poetry generation (Manurung et al., 2000; Ghazvininejad et al., 2016), story generation (Meehan, 1977; Peng et al., 2018; Fan et al., 2018; Yao et al., 2019), and social chatbots (Weizenbaum, 1966; Hao et al., 2018). In this paper, we explore creative generation with a focus on puns. We follow the definition of puns in Aarons (2017); Miller et al. (2017): "A pun is a form of wordplay in which one sign (e.g., a word or a phrase) suggests two or more meanings by exploiting polysemy, homonymy, or phonological similarity to another sign, for an intended humorous or rhetorical effect." We focus on a typical class of puns where the ambiguity comes from two (near) homophones. Consider the example in Figure 1: "*Yesterday I accidentally swallowed some food coloring. The doctor says I'm OK, but I feel like I've dyed (died) a little inside.*". The *pun word* shown in the sentence ("*dyed*") indicates one interpretation: the person is colored inside by food coloring. On the other hand, an *alternative word* ("*died*") is implied by the context for another interpretation: the person is sad due to the accident.

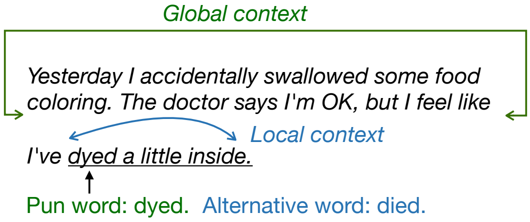

Figure 1: An illustration of a homophonic pun. The *pun word* appears in the sentence, while the *alternative word*, which has the same pronunciation but different meaning, is implicated. The *local context* refers to the immediate words around the pun word, whereas the *global context* refers to the whole sentence.

Current approaches to text generation require lots of training data, but there is no large corpus of puns. Even such a corpus existed, learning the distribution of existing data and sampling from it is unlikely to lead to truly novel, creative sentences. Creative composition requires deviating from the norm, whereas standard generation approaches seek to mimic the norm.

Recently, Yu et al. (2018) proposed an unsupervised approach that generates puns from a neural language model by jointly decoding conditioned on both the pun and the alternative words, thus injecting ambiguity to the output sentence. However, Kao et al. (2015) showed that ambiguity alone is insufficient to bring humor; the two mean-

[*] Equal contribution.

Proceedings of NAACL-HLT 2019, pages 1734–1744
Minneapolis, Minnesota, June 2 - June 7, 2019.

ings must also be supported by distinct sets of words in the sentence.

Inspired by Kao et al. (2015), we propose a general principle for puns which we call *local-global surprisal principle*. Our key observation is that the strength for the interpretation of the pun and the alternative words flips as one reads the sentence. For example, in Figure 1, "*died*" is favored by the immediate (local) context, whereas "*dyed*" is favored by the global context (i.e. "*...food coloring...*"). Our surprisal principle posits that the pun word is much more surprising in the local context than in the global context, while the opposite is true for the alternative word.

We instantiate our local-global surprisal principle in two ways. First, we develop a quantitative metric for surprise based on the conditional probabilities of the pun word and the alternative word given local and global contexts under a neural language model. However, we find that this metric is not sufficient for generation. We then develop an unsupervised approach to generate puns based on a retrieve-and-edit framework (Guu et al., 2018; Hashimoto et al., 2018) given an unhumorous corpus (Figure 2). We call our system SURGEN (SURprisal-based pun GENeration).

We test our approach on 150 pun-alternative word pairs.[1] First, we show a strong correlation between our surprisal metric and funniness ratings from crowdworkers. Second, human evaluation shows that our system generates puns successfully 31% of the time, compared to 9% of a neural generation baseline (Yu et al., 2018), and results in higher funniness scores.

2 Problem Statement

We assume access to a large corpus of raw (unhumorous) text. Given a pun word w^{p} (e.g., "*dyed*") and an alternative word w^{a} (e.g., "*died*") which are (near) homophones, we aim to generate a list of pun sentences. A pun sentence contains only the pun word w^{p}, but both w^{p} and w^{a} should be evoked by the sentence.

3 Approach

3.1 Surprise in Puns

What makes a good pun sentence? Our key observation is that as a reader processes a sentence, he or she expects to see the alternative word at the pun word position, and are tickled by the relation between the pun word and the rest of the sentence. Consider the following cloze test: "*Yesterday I accidentally swallowed some food coloring. The doctor says I'm OK, but I feel like I've _____ a little inside.*". Most people would expect the word in the blank to be "*died*" whereas the actual word is "*dyed*". Locally, "*died a little inside*" is much more likely than "*dyed a little inside*". However, globally when looking back at the whole sentence, "*dyed*" is evoked by "*food coloring*".

Formally, w^{p} is more surprising relative to w^{a} in the local context, but much less so in the global context. We hypothesize that this contrast between local and global surprisal creates humor.

3.2 A Local-Global Surprisal Measure

Let us try to formalize the local-global surprisal principle quantitatively. To measure the amount of surprise due to seeing the pun word instead of the alternative word in a certain context c, we define surprisal S as the log-likelihood ratio of the two events:

$$S(c) \stackrel{\text{def}}{=} -\log \frac{p(w^{\text{p}} \mid c)}{p(w^{\text{a}} \mid c)} = -\log \frac{p(w^{\text{p}}, c)}{p(w^{\text{a}}, c)}. \quad (1)$$

We define the local surprisal to only consider context of a span around the pun word, and the global surprisal to consider context of the whole sentence. Letting $x_1, \ldots, x_n$ be a sequence of tokens, and x_p be the pun word w^{p}, we have

$$S_{\text{local}} \stackrel{\text{def}}{=} S(x_{p-d:p-1}, x_{p+1:p+d}), \quad (2)$$

$$S_{\text{global}} \stackrel{\text{def}}{=} S(x_{1:p-1}, x_{p+1:n}), \quad (3)$$

where d is the local window size.

For puns, both the local and global surprisal should be positive because they are unusual sentences by nature. However, the global surprisal should be lower than the local surprisal due to topic words hinting at the pun word. We use the following unified metric, *local-global surprisal*, to quantify whether a sentence is a pun:

$$S_{\text{ratio}} \stackrel{\text{def}}{=} \begin{cases} -1 & S_{\text{local}} < 0 \text{ or } S_{\text{global}} < 0, \\ S_{\text{local}}/S_{\text{global}} & \text{otherwise.} \end{cases} \quad (4)$$

We hypothesize that larger S_{ratio} is indicative of a good pun. Note that this hypothesis is invalid when either S_{local} or S_{global} is negative, in which case we consider the sentences equally unfunny by setting S_{ratio} to -1.

---

[1] Our code and data are available at `https://github.com/hhexiy/pungen`.

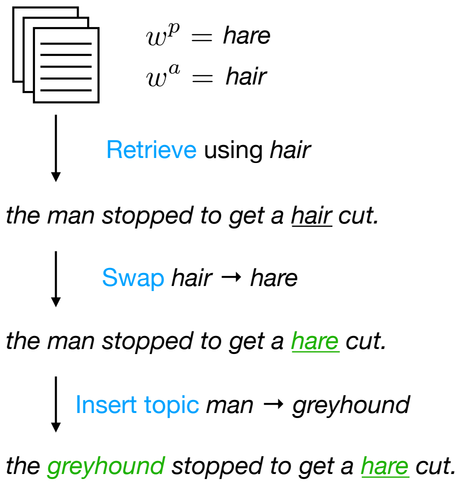

Figure 2: Overview of our pun generation approach. Given a pair of pun/alternative word, we first retrieve sentences containing w^{a} from a generic corpus. Next, w^{a} is replaced by w^{p} to increase local surprisal. Lastly, we insert a topic word at the beginning of the sentence to create global associations supporting w^{p} and decrease global surprisal.

3.3 Generating Puns

The surprisal metric above can be used to assess whether a sentence is a pun, but to generate puns, we need a procedure that can ensure grammaticality. Recall that the surprisal principle requires (1) a strong association between the alternative word and the local context; (2) a strong association between the pun word and the distant context; and (3) both words should be interpretable given local and global context to maintain ambiguity.

Our strategy is to model puns as deviations from normality. Specifically, we mine *seed sentences* (sentences with the potential to be transformed into puns) from a large, generic corpus, and edit them to satisfy the three requirements above.

Figure 2 gives an overview of our approach. Suppose we are generating a pun given $w^{\mathrm{p}} =$ "*hare*" and $w^{\mathrm{a}} =$ "*hair*". To reinforce $w^{\mathrm{a}} =$ "*hair*" in the local context despite the appearance of "*hare*", we retrieve sentences containing "*hair*" and replace occurrences of it with "*hare*". Here, the local context strongly favors the alternative word ("*hair cut*") relative to the pun word ("*hare cut*"). Next, to make the pun word "*hare*" more plausible, we insert a "*hare*"-related topic word ("*greyhound*") near the beginning of the sentence. In summary, we create local surprisal by putting w^{p} in common contexts for w^{a}, and connect w^{p} to a distant topic word by substitution. We describe each step in detail below.

Local surprisal. The first step is to retrieve sentences containing w^{a}. A typical pattern of pun sentences is that the pun word only occurs once towards the end of the sentence, which separates local context from pun-related topics at the beginning. Therefore, we retrieve sentences containing exactly one w^{a} and rank them by the position of w^{a} in the sentence (later is better). Next, we replace w^{a} in the retrieved sentence with w^{p}. The pun word usually fits in the context as it often has the same part-of-speech tag as the alternative word. Thus the swap creates local surprisal by putting the pun word in an unusual but acceptable context. We call this step RETRIEVE+SWAP, and use it as a baseline to generate puns.

Global surprisal. While the pun word is locally unexpected, we need to foreshadow it. This global association must not be too strong that it eliminates the ambiguity. Therefore, we include a single *topic word* related to the pun word by replacing one word at the beginning of the seed sentence. We see this simple structure in many human-written puns as well. For example, "*Old butchers never die, they only meat their fate.*", where pun words and their corresponding topic words are underlined.

We define relatedness between two words w_i and w_j based on a "distant" skip-gram model $p_\theta(w_j \mid w_i)$, where we train p_θ to maximize $p_\theta(w_j \mid w_i)$ for all w_i, w_j in the same sentence between d_1 to d_2 words apart. Formally:

$$\sum_{j=i-d_1}^{i-d_2} \log p_\theta(w_j \mid w_i) + \sum_{j=i+d_1}^{i+d_2} \log p_\theta(w_j \mid w_i). \tag{5}$$

We take the top-k predictions from $p_\theta(w \mid w^{\mathrm{p}})$, where w^{p} is the pun word, as candidate topic words w to be further filtered next.

Type consistent constraint. The replacement must maintain acceptability of the sentence. For example, changing "*person*" to "*ship*" in "*Each person must pay their fare share*" does not make sense even though "*ship*" and "*fare*" are related. Therefore, we restrict the deleted word in the seed sentence to nouns and pronouns, as verbs have more constraints on their arguments and replacing them is likely to result in unacceptable sentences.

In addition, we select candidate topic words that are type-consistent with the deleted word, e.g., replacing "*person*" with "*passenger*" as opposed to "*ship*". We define type-consistency (for nouns) based on WordNet path similarity.[2] Given two words, we get their synsets from WordNet constrained by their POS tags.[3] If the path similarity between any pair of senses from the two respective synsets is larger than a threshold, we consider the two words type-consistent. In summary, the first noun or pronoun in the seed sentence is replaced by a type-consistent topic word. We call this baseline RETRIEVE+SWAP+TOPIC.

Improve grammaticality. Directly replacing a word with the topic word may result in ungrammatical sentences, e.g., replacing "*i*" with "*negotiator*" and getting "*negotiator am just a woman trying to peace her life back together.*". Therefore, we use a sequence-to-sequence model to smooth the edited sentence (RETRIEVE+SWAP+TOPIC+SMOOTHER).

We smooth the sentence by deleting words around the topic word and train a model to fill in the blank. The smoother is trained in a similar fashion to denoising autoencoders: we delete immediate neighbors of a word in a sentence, and ask the model to reconstruct the sentence by predicting missing neighbors. A training example is shown below:

Original:	`the man slowly walked towards the woods .`
Input:	`<i> man </i> walked towards the woods .`
Output:	`the man slowly`

During training, the word to delete is selected in the same way as selecting the word to replace in a seed sentence, i.e. nouns or pronouns at the beginning of a sentence. At test time, the smoother is expected to fill in words to connect the topic word with the seed sentence in a grammatical way, e.g., "*the negotiator is just a woman trying to peace her life back together.*" (the part rewritten by the smoother is underlined).

4 Experiments

We first evaluate how well our surprisal principle predicts the funniness of sentences perceived by humans (Section 4.2), and then compare our pun generation system and its variations with a simple retrieval baseline and a neural generation model (Yu et al., 2018) (Section 4.3). We show that the local-global surprisal scores strongly correlate with human ratings of funniness, and all of our systems outperform the baselines based on human evaluation. In particular, RETRIEVE+SWAP+TOPIC (henceforth SURGEN) achieves the highest success rate and average funniness score among all systems.

4.1 Datasets

We use the pun dataset from 2017 SemEval task7 (Doogan et al., 2017). The dataset contains 1099 human-written puns annotated with pun words and alternative words, from which we take 219 for development. We use BookCorpus (Zhu et al., 2015) as the generic corpus for retrieval and training various components of our system.

4.2 Analysis of the Surprisal Principle

We evaluate the surprisal principle by analyzing how well the local-global surprisal score (Equation (4)) predicts funniness rated by humans. We first give a brief overview of previous computational accounts of humor, and then analyze the correlation between each metric and human ratings.

Prior funniness metrics. Kao et al. (2015) proposed two information-theoretic metrics: *ambiguity* of meanings and *distinctiveness* of supporting words. Ambiguity says that the sentence should support both the pun meaning and the alternative meaning. Distinctiveness further requires that the two meanings be supported by distinct sets of words.

In contrast, our metric based on the surprisal principle imposes additional requirements. First, surprisal says that while both meanings are acceptable (indicating ambiguity), the pun meaning is unexpected based on the local context. Second, the local-global surprisal contrast requires the pun word to be well supported in the global context.

Given the anomalous nature of puns, we also consider a metric for *unusualness* based on normalized log-probabilities under a language model (Pauls and Klein, 2012):

$$\text{Unusualness} \overset{\text{def}}{=} -\frac{1}{n}\log\left(p(x_1,\dots,x_n)/\prod_{i=1}^{n}p(x_i)\right). \tag{6}$$

Implementation details. Both ambiguity and distinctiveness are based on a generative model

---

[2] Path similarity is a score between 0 and 1 that is inversely proportional to the shortest distance between two word senses in WordNet.

[3] Pronouns are mapped to the synset `person.n.01`.

Type	Example	SEMEVAL		KAO	
		Count	Funniness	Count	Funniness
Pun	Yesterday a cow saved my life—it was bovine intervention.	33	1.13	141	1.09
Swap-pun	Yesterday a cow saved my life—it was divine intervention.	33	0.05	0	—
Non-pun	The workers are all involved in studying the spread of bovine TB.	64	-0.34	257	-0.53

Table 1: Dataset statistics and funniness ratings of SEMEVAL and KAO. Pun or alternative words are underlined in the example sentence. Each worker's ratings are standardized to z-scores. There is clear separation among the three types in terms of funniness, where pun $>$ swap-pun $>$ non-pun.

Metric	Pun and non-pun				Pun and swap-pun		Pun			
	SEMEVAL		KAO		SEMEVAL		SEMEVAL		KAO	
Surprisal (S_{ratio})	**0.46**	p=0.00	**0.58**	p=0.00	**0.48**	p=0.00	0.26	p=0.15	0.08	p=0.37
Ambiguity	**0.40**	p=0.00	**0.59**	p=0.00	0.18	p=0.15	0.00	p=0.98	0.00	p=0.95
Distinctiveness	-0.17	p=0.10	**0.29**	p=0.00	0.15	p=0.24	**0.41**	p=0.02	**0.27**	p=0.00
Unusualness	**0.37**	p=0.00	**0.36**	p=0.00	0.19	p=0.12	0.20	p=0.27	0.11	p=0.18

Table 2: Spearman correlation between different metrics and human ratings of funniness. Statistically significant correlations with p-value < 0.05 are bolded. Our surprisal principle successfully differentiates puns from non-puns and swap-puns. Distinctiveness is the only metric that correlates strongly with human ratings within puns. However, no single metric works well across different types of sentences.

of puns. Each sentence has a latent variable $z \in \{w^{\text{p}}, w^{\text{a}}\}$ corresponding to the pun meaning and the alternative meaning. Each word also has a latent meaning assignment variable f controlling whether it is generated from an unconditional unigram language model or a unigram model conditioned on z. Ambiguity is defined as the entropy of the posterior distribution over z given all the words, and distinctiveness is defined as the symmetrized KL-divergence between distributions of the assignment variables given the pun meaning and the alternative meaning respectively. The generative model relies on $p(x_i \mid z)$, which Kao et al. (2015) estimates using human ratings of word relatedness. We instead use the skip-gram model described in Section 3.3 as we are interested in a fully-automated system.

For local-global surprisal and unusualness, we estimate probabilities of text spans using a neural language model trained on WikiText-103 (Merity et al., 2016).[4] The local context window size (d in Equation (2)) is set to 2.

Human ratings of funniness. Similar to Kao et al. (2015), to test whether a metric can differentiate puns from normal sentences, we collected ratings for both puns from the SemEval dataset and *non-puns* retrieved from the generic corpus containing either w^{p} or w^{a}. To test the importance of surprisal, we also included *swap-puns* where w^{p} is replaced by w^{a}, which results in sentences that are ambiguous but not necessarily surprising.

We collected all of our human ratings on Amazon Mechanical Turk (AMT). Workers are asked to answer the question "*How funny is this sentence?*" on a scale from 1 (not at all) to 7 (extremely). We obtained funniness ratings on 130 sentences from the development set with 33 puns, 33 swap-puns, and 64 non-puns. 48 workers each read roughly 10–20 sentences in random order, counterbalanced for sentence types of non-puns, swap-puns, and puns. Each sentence is rated by 5 workers, and we removed 10 workers whose maximum Spearman correlation with other people rating the same sentence is lower than 0.2. The average Spearman correlation among all the remaining workers (which captures inter-annotator agreement) is 0.3. We z-scored the ratings of each worker for calibration and took the average z-scored ratings of a sentence as its funniness score.

Table 1 shows the statistics of our annotated dataset (SEMEVAL) and Kao et al. (2015)'s dataset (KAO). Note that the two datasets have different numbers and types of sentences, and the human ratings were collected separately. As expected, puns are funnier than both swap-puns and non-puns. Swap-puns are funnier than non-puns, possibly because they have inherit ambiguity brought by the RETRIEVE+SWAP operation.

---

[4] `https://dl.fbaipublicfiles.com/fairseq/models/wiki103_fconv_lm.tar.bz2`.

Automatic metrics of funniness. We analyze the following metrics: local-global surprisal (S_{ratio}), ambiguity, distinctiveness, and unusualness, with respect to their correlation with human ratings of funniness. For each metric, we standardized the scores and outliers beyond two standard deviations are set to $+2$ or -2 accordingly.[5] We then compute the metrics' Spearman correlation with human ratings. On KAO, we directly took the ambiguity scores and distinctiveness scores from the original implementation which requires human-annotated word relatedness.[6] On SEMEVAL, we used our reimplemention of Kao et al. (2015)'s algorithm but with the skip-gram model.

The results are shown in Table 2. For puns and non-puns, all metrics correlate strongly with human scores, indicating all of them are useful for pun detection. For puns and swap-puns, only local-global surprisal (S_{ratio}) has strong correlation, which shows that surprisal is important for characterizing puns. Ambiguity and distinctiveness do not differentiate pun word from the alternative word, and unusualness only considers probability of the sentence with the pun word, thus they do not correlate as significantly as S_{ratio}.

Within puns, only distinctiveness has significant correlation, whereas the other metrics are not fine-grained enough to differentiate good puns from mediocre ones. Overall, no single metric is robust enough to score funniness across all types of sentences, which makes it hard to generate puns by optimizing automatic metrics of funniness directly.

There is slight inconsistency between results on SEMEVAL and KAO. Specifically, for puns and non-puns, the distinctiveness metric shows a significant correlation with human ratings on KAO but not on SEMEVAL. We hypothesize that it is mainly due to differences in the two corpora and noise from the skip-gram approximation. For example, our dataset contains longer sentences with an average length of 20 words versus 11 words for KAO. Further, Kao et al. (2015) used human annotation of word relatedness while we used the skip-gram model to estimate $p(x_i \mid z)$.

Method	Success	Funniness	Grammar
NJD	9.2%	1.4	2.6
R	4.6%	1.3	**3.9**
R+S	27.0%	1.6	3.5
R+S+T+M	28.8%	**1.7**	2.9
SURGEN	**31.4%**	**1.7**	3.0
Human	78.9%	3.0	3.8

Table 3: Human evaluation results of all systems. We show average scores of funniness and grammaticality on a 1-5 scale and success rate computed from yes/no responses. We compare with two baselines: NEURALJOINTDECODER (NJD) and RETRIEVE (R). R+S, SURGEN, and R+S+T+M are three variations of our method: RETRIEVE+SWAP, RETRIEVE+SWAP+TOPIC, and RETRIEVE+SWAP+TOPIC+SMOOTHER, respectively. Overall, SURGEN performs the best across the board.

4.3 Pun Generation Results

Systems. We compare with a recent neural pun generator (Yu et al., 2018). They proposed an unsupervised approach based on generic language models to generate homographic puns.[7] Their approach takes as input two senses of a target word (e.g., *bat.n01*, *bat.n02* from WordNet synsets), and decodes from both senses jointly by taking a product of the probabilities conditioned on the two senses respectively (e.g., *bat.n01* and *bat.n02*), so that both senses are reflected in the output. To ensure that the target word appears in the middle of a sentence, they decode backward from the target word towards the beginning and then decode forward to complete the sentence. We adapted their method to generate homophonic puns by considering w^{p} and w^{a} as two input senses and decoding from the pun word. We retrained their forward / backward language models on the same BookCorpus used for our system. For comparison, we chose their best model (NEURALJOINTDECODER), which mainly captures ambiguity in puns.

In addition, we include a retrieval baseline (RETRIEVE) which simply retrieves sentences containing the pun word.

For our systems, we include the entire progression of methods described in Section 3 (RETRIEVE+SWAP, RETRIEVE+SWAP+TOPIC, and RETRIEVE+SWAP+TOPIC+SMOOTHER).

Implementation details. The key components of our systems include a retriever, a skip-gram

---

[5] Since both S_{ratio} and distinctiveness are unbounded, bounding the values gives more reliable correlation results.

[7] Sentences where the pun word and alternative word have the same written form (e.g., *bat*) but different senses.

Aspect	SurGen v.s. NJD win %	lose %	SurGen v.s. Human win %	lose %
Success	48.0	5.3	6.0	78.7
Funniness	56.7	25.3	10.7	85.3
Grammar	60.7	30.0	8.0	82.0

Table 4: Pairwise comparison between SurGen and NeuralJointDecoder (NJD), and between SurGen and human written puns. Win % (lose %) is the percentage among the human-rated 150 sentences where SurGen achieves a higher (lower) average score compared to the other method. The rest are ties.

model for topic word prediction, a type consistency checker, and a neural smoother. Given an alternative word, the retriever returned 500 candidates, among which we took the top 100 as seed sentences (Section 3.3 local surprisal). For topic words, we took the top 100 words predicted by the skip-gram model and filtered them to ensure type consistency with the deleted word (Section 3.3 global surprisal). The WordNet path similarity threshold for type consistency was set to 0.3.

The skip-gram model was trained on BookCorpus with $d_1 = 5$ and $d_2 = 10$ in Equation (5). We set the word embedding size to 300 and trained for 15 epochs using Adam (Kingma and Ba, 2014) with a learning rate of 0.0001. For the neural smoother, we trained a single-layer LSTM (512 hidden units) sequence-to-sequence model with attention on BookCorpus. The model was trained for 50 epochs using AdaGrad (Duchi et al., 2010) with a learning rate of 0.01 and a dropout rate of 0.1.

Human evaluation. We hired workers on AMT to rate outputs from all 5 systems together with expert-written puns from the SemEval pun dataset. Each worker was shown a group of sentences generated by all systems (randomly shuffled) given the same pun word and alternative word pair. Workers were asked to rate each sentence on three aspects: (1) success ("*Is the sentence a pun?*"),[8] (2) funniness ("*How funny is the sentence?*"), and (3) grammaticality ("*How grammatical is the sentence?*"). Success was rated as yes/no, and funniness and grammaticality were rated on a scale from 1 (not at all) to 5 (very). We also included a N/A choice (does not make sense) for funniness to exclude cases where the sentence are not understandable. Workers were explicitly instructed to try their best to give different scores for sentences in the same group.

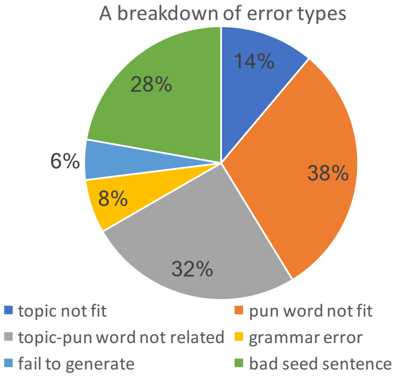

Figure 3: Error case breakdown shows that the main issues lie in finding seed sentences that accommodates both the pun word and the topic word (topic not fit + pun word not fit + bad seed sentence).

We evaluated 150 pun/alternative word pairs. Each generated sentence was rated by 5 workers and their scores were averaged. N/A ratings were excluded unless all ratings of a sentence were N/A, in which case we set its score to 0. We attracted 65, 93, 66 workers for the success, funniness, and grammaticality surveys respectively, and removed 3, 4, 4 workers because their maximum Spearman correlation with other workers was lower than 0.2. We measure inter-annotator agreement using average Spearman correlation among all workers, and the average inter-annotator Spearman correlation for success, funniness, and grammaticality are 0.57, 0.36, and 0.32, respectively.

Table 3 shows the overall results. All 3 of our systems outperform the baselines in terms of success rate and funniness. More edits (i.e. swapping, inserting topic words) made the sentence less grammatical, but also much more like puns (higher success rate). Interestingly, introducing the neural smoother did not improve grammaticality and hurt success rate slightly. Manual inspection shows that ungrammaticality is often caused by improper topic word, thus fixing its neighboring words does not truly solve the problem. For example, filling "*drum*" (related to "*lute*") in "*if that was _____ it was likely that another body would turn up soon, because someone probably wouldn't want to share the lute.*". In addition, when the neural model is given a rare topic word, it tends to rewrite it to a common phrase instead, again showing that supervised learning is against the spirit of generating novel content. For example, inserting "*gentlewoman*" to "_____ *not allow me to ...*" produces "*these people did not allow me to ...*". Overall, our

[8] They were shown the definition from Miller et al. (2017).

Method	Example	Rating
1. Pun/alternative word pair: butter – better		
NJD	He is going to come up with the butter a 'very good' approach to the world's economic crisis, the world's biggest economic climate.	1
SurGen	Well, gourmet did it, he thought, it'd butter be right.	2
Human	Why did the dairy churn? The less said, the butter...	1.5
2. Pun/alternative word pair: peace – piece		
NJD	Further, he said, at the end of the peace, it's not clear that it will be a good example.	1
SurGen	That's because negotiator got my car back to me in one peace.	1.5
Human	Life is a puzzle; look here for the missing peace.	3
3. Pun/alternative word pair: flour – flower		
NJD	Go, and if you are going on the flour.	1
SurGen	Butter want to know who these two girls are, the new members of the holy flour.	1.5
Human	Betty crocker was a flour child.	4.5
4. Pun/alternative word pair: wait – weight		
NJD	Gordon Brown, Georgia's prime minister, said he did not have to wait, but he was not sure whether he had been killed.	0
SurGen	Even from the outside, I could tell that he'd already lost some wait.	2
Human	Patience is a virtue heavy in wait.	3

Table 5: Examples of generated puns with average human ratings of funniness (1-5). 0 means that all ratings are N/A (does not make sense).

SurGen performs the best and tripled the success rate of NeuralJointDecoder with improved funniness and grammaticality scores. Nevertheless, there is still a significant gap between generated puns and expert-written puns across all aspects, indicating that pun generation remains an open challenge.

Table 4 shows the pairwise comparison results among our best model SurGen, NeuralJointDecoder, and expert-written puns. Given the outputs of two systems, we decided win/lose/tie by comparing the average scores of both outputs. We see that SurGen dominates NeuralJointDecoder with $> 50\%$ winning rate on funniness and grammaticality. On success rate, the two methods have many ties since they both have relatively low success rate. Our generated puns were rated funnier than expert-written puns around 10% of the time.

4.4 Error Analysis

In Table 5, we show example outputs of our SurGen, the NeuralJointDecoder baseline, and expert-written puns. SurGen sometimes generates creative puns that are rated even funnier than human-written puns (example 1). In contrast, NeuralJointDecoder at best generates ambiguous sentences (example 2 and 3) and sometimes the sentences are ungrammatical (example 1) or hard to understand (example 4). The examples also show the current limitation of SurGen. In example 3, it failed to realize that "*butter*" is not animate thus cannot "*want*" since our type consistency checker is very simple.

To gain further insights on the limitation of our system, we randomly sampled 50 unsuccessful generations (labeled by workers) to analyze the issues. We characterized the issues into 6 non-exclusive categories: (1) weak association between the local context and w^{a} (e.g., "*...in the form of a batty (bat)*"); (2) w^{p} does not fit in the local context, often due to different POS tags of w^{a} and w^{p} (e.g., "*vibrate with a taxed (text)*"); (3) the topic word is not related to w^{p} (e.g., "*pagan*" vs "*fabrication*"); (4) the topic word does not fit in its immediate context, often due to inconsistent types (e.g., "*slider won't go...*"), (5) grammatical errors; and (6) fail to obtain seed sentences or topic words. A breakdown of these errors is shown in Figure 3. The main issues lie in finding seed sentences that accommodate both the pun word and the topic word. There is also room for improvement in predicting pun-related topic words.

5 Discussion and Related Work

5.1 Humor Theory

Humor involves complex cognitive activities and many theories attempt to explain what might be considered humorous. Among the leading theories, the incongruity theory (Tony, 2004) is most related to our surprisal principle. The incongruity theory posits that humor is perceived at the moment of resolving the incongruity between two concepts, often involving unexpected shifts in perspectives. Ginzburg et al. (2015) applied the incongruity theory to explain laughter in dialogues. Prior work (Kao et al., 2015) on formalizing incongruity theory for puns focuses on ambiguity between two concepts and the heterogeneity nature of the ambiguity. Our surprisal principle further formalizes unexpectedness (local surprisal) and incongruity resolution (global association).

The surprisal principle is also related to studies in psycholinguistics on the relation between surprisal and human comprehension (Levy, 2013; Levy and Gibson, 2013). Our study suggests it could be a fruitful direction to formally study the relationship between human perception of surprisal and humor.

5.2 Humor generation

Early approaches to joke generation (Binsted, 1996; Ritchie, 2005) largely rely on templates for specific types of puns. For example, JAPE (Binsted, 1996) generates noun phrase puns as question-answer pairs, e.g., "*What do you call a [murderer] with [fiber]? A [cereal] [killer].*" Petrovic and Matthews (2013) fill in a joke template based on word similarity and uncommonness. Similar to our editing approach, Valitutti et al. (2013) substitutes a word with a taboo word based on form similarity and local coherence to generate adult jokes. Recently, Yu et al. (2018) generates puns from a generic neural language model by simultaneously conditioning on two meanings. Most of these approaches leverage some assumptions of joke structures, e.g., incongruity, relations between words, and word types. Our approach also relies on specific pun structures; we have proposed and operationalized a local-global surprisal principle for pun generation.

5.3 Creative text generation

Our work is also built upon generic text generation techniques, in particular recent neural generation models. Hashimoto et al. (2018) developed a retrieve-and-edit approach to improve both grammaticality and diversity of the generated text. Shen et al. (2017); Fu et al. (2018) explored adversarial training to manipulate the style of a sentence. Our neural smoother is also closely related to Li et al. (2018)'s delete-retrieve-edit approach to text style transfer.

Creative generation is more challenging as it requires both formality (e.g., grammaticality, rhythm, and rhyme) and novelty. Therefore, many works (including us) impose strong constraints on the generative process, such as Petrovic and Matthews (2013); Valitutti et al. (2013) for joke generation, Ghazvininejad et al. (2016) for poetry generation, and Yao et al. (2019) for storytelling.

6 Conclusion

In this paper, we tackled pun generation by developing and exploring a local-global surprisal principle. We show that a simple instantiation based on only a language model trained on non-humorous text is effective at detecting puns (though is not fine-grained enough to detect the degree of funniness within puns). To generate puns, we operationalize the surprisal principle with a retrieve-and-edit framework to create contrast in the amount of surprise in local and global contexts. While we improve beyond current techniques, we are still far from human-generated puns.

While we believe the local-global surprisal principle is a useful conceptual tool, the principle itself is not quite yet formalized in a robust enough way that can be be used both as a principle for evaluating sentences and can be directly optimized to generate puns. A big challenge in humor, and more generally, creative text generation, is to capture the difference between creativity (novel but well-formed material) and nonsense (ill-formed material). Language models conflate the two, so developing methods that are nuanced enough to recognize this difference is key to future progress.

Single Document Summarization as Tree Induction

Yang Liu, Ivan Titov and **Mirella Lapata**

Abstract

In this paper we conceptualize single-document extractive summarization as a tree induction problem. In contrast to previous approaches (Marcu, 1999; Yoshida et al., 2014) which have relied on linguistically motivated document representations to generate summaries, our model *induces* a multi-root dependency tree while predicting the output summary. Each root node in the tree is a summary sentence, and the subtrees attached to it are sentences whose content relates to or explains the summary sentence. We design a new iterative refinement algorithm: it induces the trees through repeatedly refining the structures predicted by previous iterations. We demonstrate experimentally on two benchmark datasets that our summarizer[1] performs competitively against state-of-the-art methods.

1 Introduction

Single-document summarization is the task of automatically generating a shorter version of a document while retaining its most important information. The task has received much attention in the natural language processing community due to its potential for various information access applications. Examples include tools which digest textual content (e.g., news, social media, reviews), answer questions, or provide recommendations.

Of the many summarization paradigms that have been identified over the years (see Mani 2001 and Nenkova and McKeown 2011 for comprehensive overviews), two have consistently attracted attention. In *abstractive* summarization, various text rewriting operations generate summaries using words or phrases that were not in the original text, while *extractive* approaches form summaries by copying and concatenating the most important spans (usually sentences) in a document. Recent approaches to (single-document) extractive summarization frame the task as a sequence labeling problem taking advantage of the success of neural network architectures (Bahdanau et al., 2015). The idea is to predict a label for each sentence specifying whether it should be included in the summary. Existing systems mostly rely on recurrent neural networks (Hochreiter and Schmidhuber, 1997) to model the document and obtain a vector representation for each sentence (Nallapati et al., 2017; Cheng and Lapata, 2016). Inter-sentential relations are captured in a sequential manner, without taking the structure of the document into account, although the latter has been shown to correlate with what readers perceive as important in a text (Marcu, 1999). Another problem in neural-based extractive models is the lack of interpretability. While capable of identifying summary sentences, these models are not able to rationalize their predictions (e.g., a sentence is in the summary because it describes important content upon which other related sentences elaborate).

The summarization literature offers examples of models which exploit the structure of the underlying document, inspired by existing theories of discourse such as Rhetorical Structure Theory (RST; Mann and Thompson 1988). Most approaches produce summaries based on tree-like document representations obtained by a parser trained on discourse annotated corpora (Carlson et al., 2003; Prasad et al., 2008). For instance, Marcu (1999) argues that a good summary can be generated by traversing the RST discourse tree structure top-down, following nucleus nodes (discourse units in RST are characterized regarding their text importance; nuclei denote central units, whereas satellites denote peripheral ones). Other work (Hirao et al., 2013; Yoshida et al., 2014) extends this idea by transforming RST trees into dependency trees and generating summaries by tree trimming. Gerani et al. (2014) summarize product reviews; their system aggregates RST trees rep-

Proceedings of NAACL-HLT 2019, pages 1745–1755
Minneapolis, Minnesota, June 2 - June 7, 2019.

1. One wily coyote traveled a bit too far from home, and its resulting adventure through Harlem had alarmed residents doing a double take and scampering to get out of its way Wednesday morning.
2. Police say frightened New Yorkers reported the coyote sighting around 9:30 a.m., and an emergency service unit was dispatched to find the animal.
3. The little troublemaker was caught and tranquilized in Trinity Cemetery on 155th street and Broadway, and then taken to the Wildlife Conservation Society at the Bronx Zoo, authorities said.
4. "The coyote is under evaluation and observation," said Mary Dixon, spokesperson for the Wildlife Conservation Society.
5. She said the Department of Environmental Conservation will either send the animal to a rescue center or put it back in the wild.
6. According to Adrian Benepe, New York City Parks Commissioner, coyotes in Manhattan are rare, but not unheard of.
7. "This is actually the third coyote that has been seen in the last 10 years," Benepe said.
8. Benepe said there is a theory the coyotes make their way to the city from suburban Westchester.
9. He said they probably walk down the Amtrak rail corridor along the Hudson River or swim down the Hudson River until they get to the city.

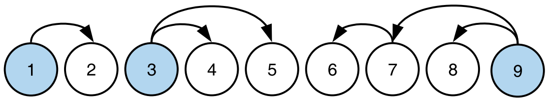

Figure 1: Dependency discourse tree for a document from the CNN/DailyMail dataset (Hermann et al., 2015). Blue nodes indicate the roots of the tree (i.e., summary sentences) and parent-child links indicate dependency relations.

resenting individual reviews into a graph, from which an abstractive summary is generated. Despite the intuitive appeal of discourse structure for the summarization task, the reliance on a parser which is both expensive to obtain (since it must be trained on labeled data) and error prone, presents a major obstacle to its widespread use.

Recognizing the merits of structure-aware representations for various NLP tasks, recent efforts have focused on learning latent structures (e.g., parse trees) while optimizing a neural network model for a down-stream task. Various methods impose structural constraints on the basic attention mechanism (Kim et al., 2017; Liu and Lapata, 2018), formulate structure learning as a reinforcement learning problem (Yogatama et al., 2017; Williams et al., 2018), or sparsify the set of possible structures (Niculae et al., 2018). Although latent structures are mostly induced for individual sentences, Liu and Lapata (2018) induce dependency-like structures for entire documents.

Drawing inspiration from this work and existing discourse-informed summarization models (Marcu, 1999; Hirao et al., 2013), we frame extractive summarization as a tree induction problem. Our model represents documents as multi-root dependency trees where each root node is a summary sentence, and the subtrees attached to it are sentences whose content is related to and covered by the summary sentence. An example of a document and its corresponding tree is shown in Figure 1; tree nodes correspond to document sentences; blue nodes represent those which should be in the summary, dependent nodes relate to or are subsumed by the parent summary sentence.

We propose a new framework that uses structured attention (Kim et al., 2017) as both the objective and attention weights for extractive summarization. Our model is trained end-to-end, it induces document-level dependency trees while predicting the output summary, and brings more interpretability in the summarization process by helping explain how document content contributes to the model's decisions. We design a new iterative structure refinement algorithm, which learns to induce document-level structures through repeatedly refining the trees predicted by previous iterations and allows the model to infer complex trees which go beyond simple parent-child relations (Liu and Lapata, 2018; Kim et al., 2017). The idea of structure refinement is conceptually related to recently proposed models for solving iterative inference problems (Marino et al., 2018; Putzky and Welling, 2017; Lee et al., 2018). It is also related to structured prediction energy networks (Belanger et al., 2017) which approach structured prediction as iterative miminization of an energy function. However, we are not aware of any previous work considering structure refinement for tree induction problems.

Our contributions in this work are three-fold: a novel conceptualization of extractive summarization as a tree induction problem; a model which capitalizes on the notion of structured attention to learn document representations based on iterative structure refinement; and large-scale evaluation studies (both automatic and human-based) which demonstrate that our approach performs competitively against state-of-the-art methods while being able to rationalize model predictions.

2 Model Description

Let d denote a document containing several sentences $[sent_1, sent_2, \cdots, sent_m]$, where $sent_i$ is the i-th sentence in the document. Extractive summarization can be defined as the task of assigning a label $y_i \in \{0, 1\}$ to each $sent_i$, indicating whether the sentence should be included in the summary. It is assumed that summary sentences represent the most important content of the document.

2.1 Baseline Model

Most extractive models frame summarization as a classification problem. Recent approaches (Zhang et al., 2018; Dong et al., 2018; Nallapati et al., 2017; Cheng and Lapata, 2016) incorporate a neural network-based encoder to build representations for sentences and apply a binary classifier over these representations to predict whether the sentences should be included in the summary. Given predicted scores r and gold labels y, the loss function can be defined as:

$$L = -\sum_{i=1}^{m} (\boldsymbol{y}_i \ln(\boldsymbol{r}_i) + (1 - \boldsymbol{y}_i) \ln(1 - \boldsymbol{r}_i)) \quad (1)$$

The encoder in extractive summarization models is usually a recurrent neural network with Long-Short Term Memory (LSTM; Hochreiter and Schmidhuber 1997) or Gated Recurrent Units (GRU; Cho et al. 2014). In this paper, our baseline encoder builds on the Transformer architecture (Vaswani et al., 2017), a recently proposed highly efficient model which has achieved state-of-the-art performance in machine translation (Vaswani et al., 2017) and question answering (Yu et al., 2018). The Transformer aims at reducing the fundamental constraint of sequential computation which underlies most architectures based on RNNs. It eliminates recurrence in favor of applying a self-attention mechanism which directly models relationships between all words in a sentence.

More formally, given a sequence of input vectors $\{\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n\}$, the Transformer is composed of a stack of N identical layers, each of which has two sub-layers:

$$\tilde{\boldsymbol{h}}^l = \mathrm{LayerNorm}(\boldsymbol{h}^{l-1} + \mathrm{MHAtt}(\boldsymbol{h}^{l-1})) \quad (2)$$

$$\boldsymbol{h}^l = \mathrm{LayerNorm}(\tilde{\boldsymbol{h}}^l + \mathrm{FFN}(\tilde{\boldsymbol{h}}^l)) \quad (3)$$

where $\boldsymbol{h}^0 = \mathrm{PosEmb}(\boldsymbol{x})$ and PosEmb is the function of adding positional embeddings to the input; the superscript l indicates layer depth; LayerNorm is the layer normalization operation proposed in Ba et al. (2016); MHAtt represents the multi-head attention mechanism introduced in Vaswani et al. (2017) which allows the model to jointly attend to information from different representation subspaces (at different positions); and FFN is a two-layer feed-forward network with ReLU as hidden activation function.

For our extractive summarization task, the baseline system is composed of a sentence-level Transformer ($\mathcal{T}_\mathrm{S}$) and a document-level Transformer ($\mathcal{T}_\mathrm{D}$), which have the same structure. For each sentence $s_i = [\boldsymbol{w}_{i1}, \boldsymbol{w}_{i2}, \cdots, \boldsymbol{w}_{in}]$ in the input document, $\mathcal{T}_\mathrm{S}$ is applied to obtain a contextual representation for each word:

$$[\boldsymbol{u}_{i1}, \boldsymbol{u}_{i2}, \cdots, \boldsymbol{u}_{in}] = \mathcal{T}_\mathrm{S}([\boldsymbol{w}_{i1}, \boldsymbol{w}_{i2}, \cdots, \boldsymbol{w}_{in}]) \quad (4)$$

And the representation of a sentence is acquired by applying weighted-pooling:

$$\boldsymbol{a}_{ij} = \boldsymbol{W}_0 \boldsymbol{u}_{ij}^T \quad (5)$$

$$\boldsymbol{s}_i = \frac{1}{n} \sum_{j=1}^{n} \boldsymbol{a}_{ij} \boldsymbol{u}_{ij} \quad (6)$$

Document-level transformer $\mathcal{T}_\mathrm{D}$ takes $\boldsymbol{s}_i$ as input and yields a contextual representation for each sentence:

$$[\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_m] = \mathcal{T}_\mathrm{D}([\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_m]) \quad (7)$$

Following previous work (Nallapati et al., 2017), we use a sigmoid function after a linear transformation to calculate the probability $\boldsymbol{r}_i$ of selecting s_i as a summary sentence:

$$\boldsymbol{r}_i = \mathrm{sigmoid}(\boldsymbol{W}_1 \boldsymbol{v}_i^T) \quad (8)$$

2.2 Structured Summarization Model

In the Transformer model sketched above, inter-sentence relations are modeled by multi-head attention based on softmax functions, which only capture shallow structural information. Our summarizer, which we call SUMO as a shorthand for **S**tructured **Sum**marization **Mo**del classifies sentences as summary-worthy or not, and simultaneously induces the structure of the source document as a multi-root tree. An overview of SUMO is illustrated in Figure 2. The model has the same sentence-level encoder $\mathcal{T}_\mathrm{S}$ as the baseline Transformer model (see the bottom box in Figure 2), but differs in two important ways: (a) it uses structured attention to model the roots (i.e., summary sentences) of the underlying tree (see the upper box in Figure 2); and (b) through iterative refinement it is able to progressively infer more complex structures from past guesses (see the second and third block in Figure 2).

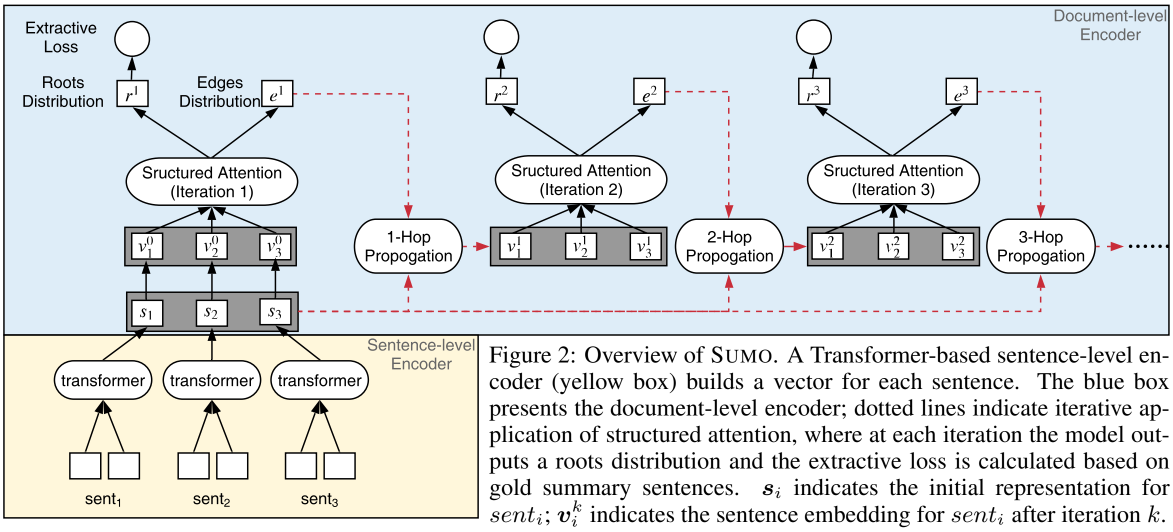

Figure 2: Overview of SUMO. A Transformer-based sentence-level encoder (yellow box) builds a vector for each sentence. The blue box presents the document-level encoder; dotted lines indicate iterative application of structured attention, where at each iteration the model outputs a roots distribution and the extractive loss is calculated based on gold summary sentences. $\boldsymbol{s}_i$ indicates the initial representation for $sent_i$; $\boldsymbol{v}_i^k$ indicates the sentence embedding for $sent_i$ after iteration k.

Structured Attention Assuming document sentences have been already encoded, SUMO first calculates the unnormalized root score $\tilde{\boldsymbol{r}}_i$ for $sent_i$ to indicate the extent to which it might be selected as root in the document tree. It also calculates the unnormalized edge score $\tilde{\boldsymbol{e}}_{ij}$ for sentence pair $\langle sent_i, sent_j \rangle$ indicating the extent to which $sent_i$ might be the head of $sent_j$ in that tree (first upper block in Figure 2). To inject structural bias, SUMO normalizes these scores as the marginal probabilities of forming edges in the document dependency tree.

We use the Tree-Matrix-Theorem (TMT; Koo et al. 2007; Tutte 1984) to calculate root marginal probability $\boldsymbol{r}_i$ and edge marginal probability $\boldsymbol{e}_{ij}$, following the procedure introduced in Liu and Lapata (2017). As illustrated in Algorithm 1, we first build the Laplacian matrix $\bar{\boldsymbol{L}}$ based on unnormalized scores and calculate marginal probabilities by matrix inverse-based operations ($\bar{\boldsymbol{L}}^{-1}$). We refer the interested reader to Koo et al. (2007) and Liu and Lapata (2017) for more details. In contrast to Liu and Lapata (2017), who compute the marginal probabilities of a single-root tree, our tree has multiple roots since in our task the summary typically contains multiple sentences. Given sentence vector $\boldsymbol{s}_i$ as input, SUMO computes:

$$\tilde{\boldsymbol{r}}_i = \boldsymbol{W}_r \boldsymbol{s}_i \tag{9}$$

$$\tilde{\boldsymbol{e}}_{ij} = \boldsymbol{s}_i \boldsymbol{W}_e \boldsymbol{s}_j^T \tag{10}$$

$$\boldsymbol{r}_i, \boldsymbol{e}_{ij} = \mathrm{TMT}(\tilde{\boldsymbol{r}}_i, \tilde{\boldsymbol{e}}_{ij}) \tag{11}$$

Iterative Structure Refinement SUMO essentially reduces summarization to a rooted-tree parsing problem. However, accurately predicting a tree in one shot is problematic. Firstly, when predicting the dependency tree, the model has solely access to labels for the roots (aka summary sentences), while tree edges are latent and learned without an explicit training signal. And as previous work (Liu and Lapata, 2017) has shown, a single application of TMT leads to shallow tree structures. Secondly, the calculation of $\tilde{\boldsymbol{r}}_i$ and $\tilde{\boldsymbol{e}}_{ij}$ would be based on first-order features alone, however, higher-order information pertaining to siblings and grandchildren has proved useful in discourse parsing (Carreras, 2007).

Algorithm 1: Calculate Tree Marginal Probabilities based on Tree-Matrix-Theorem

```
Function TMT ($\tilde{\boldsymbol{r}}_i, \tilde{\boldsymbol{e}}_{ij}$):
    $\boldsymbol{A}_{ij} = \begin{cases} 0 & \text{if } i = j \\ exp(\hat{\boldsymbol{r}}_{ij}) & \text{otherwise} \end{cases}$
    $\boldsymbol{L}_{ij} = \begin{cases} \sum_{i'=1}^{n} \boldsymbol{A}_{i'j} & \text{if } i = j \\ -\boldsymbol{A}_{ij} & \text{otherwise} \end{cases}$
    $\bar{\boldsymbol{L}}_{ij} = \begin{cases} \boldsymbol{L}_{ij} + exp(\hat{\boldsymbol{r}}_i) & i = j \\ \boldsymbol{L}_{ij} & \text{otherwise} \end{cases}$
    $\boldsymbol{e}_{ij} = (1 - \delta_{1,j}) \boldsymbol{A}_{ij} [\bar{\boldsymbol{L}}^{-1}]_{jj}$
        $- (1 - \delta_{i,1}) \boldsymbol{A}_{ij} [\bar{\boldsymbol{L}}^{-1}]_{ji}$
    $\boldsymbol{r}_i = exp(\hat{\boldsymbol{r}}_i) [\bar{\boldsymbol{L}}^{-1}]_{i1}$
    return $\boldsymbol{r}_i, \boldsymbol{e}_{ij}$
```

We address these issues with an inference algorithm which iteratively infers latent trees. In contrast to multi-layer neural network architectures like the Transformer or Recursive Neural Networks (Tai et al., 2015) where word representations are updated at every layer based on the output of previous layers, we refine only the tree structure during each iteration, word representations are not passed across multiple layers. Empirically, at early iterations, the model learns shallow and simple trees, and information propagates mostly between neighboring nodes; as the structure gets more refined, information propagates more globally allowing the model to learn higher-order features.

Algorithm 2 provides the details of our refinement procedure. SUMO takes K iterations to learn the structure of a document. For each sentence, we initialize a structural vector $\boldsymbol{v}_i^0$ with sentence vector $\boldsymbol{s}_i$. At iteration k, we use sentence embeddings from the previous iteration $\boldsymbol{v}^{k-1}$ to calculate unnormalized root $\tilde{\boldsymbol{r}}_i^k$ and edge $\tilde{\boldsymbol{e}}_{ij}^k$ scores using a linear transformation with weight $\boldsymbol{W}_r^k$ and a bilinear transformation with weight $\boldsymbol{W}_e^k$, respectively. Marginal root and edge probabilities are subsequently normalized with the TMT to obtain $\boldsymbol{r}_i^k$ and $\boldsymbol{e}_{ij}^k$ (see lines 4–6 in Algorithm 2). Then, sentence embeddings are updated with *k-Hop Propagation*. The latter takes as input the initial sentence representations $\boldsymbol{s}$ rather than sentence embeddings $\boldsymbol{v}^{k-1}$ from the previous layer. In other words, new embeddings $\boldsymbol{v}^k$ are computed from scratch relying on the structure from the previous layer. Within the *k-Hop-Propagation* function (lines 12–19), edge probabilities $\boldsymbol{e}_{ij}^k$ are used as attention weights to propagate information from a sentence to all other sentences in k hops. $\boldsymbol{p}_i^l$ and $\boldsymbol{c}_i^l$ represent parent and child vectors, respectively, while vector $\boldsymbol{z}_i^l$ is updated with contextual information at hop l. At the final iteration (lines 9 and 10), the top sentence embeddings $\boldsymbol{v}^{K-1}$ are used to calculate the final root probabilities r^K.

We define the model's loss function as the summation of the losses of all iterations:

$$L = \sum_{k=1}^{K} [y \log(r_k) + (1-y)\log(1-r_k)] \quad (12)$$

SUMO uses the root probabilities of the top layer as the scores for summary sentences.

The *k-Hop-Propagation* function resembles the computation used in Graph Convolution Networks (Kipf and Welling, 2017; Marcheggiani and Titov, 2017). GCNs have been been recently applied to latent trees (Corro and Titov, 2019), however not in combination with iterative refinement.

3 Experiments

In this section we present our experimental setup, describe the summarization datasets we used, discuss implementation details, our evaluation protocol, and analyze our results.

```
Algorithm 2: Structured Summarization Model
    Input: Document $d$

17          $\boldsymbol{z}_i^l = \tanh(\boldsymbol{W}_v^k [\boldsymbol{p}_i^{l-1}, \boldsymbol{c}_i^{l-1}, \boldsymbol{z}_i^{l-1}])$
18      end
19      return $\boldsymbol{z}^k$
```

3.1 Summarization Datasets

We evaluated SUMO on two benchmark datasets, namely the CNN/DailyMail news highlights dataset (Hermann et al., 2015) and the New York Times Annotated Corpus (NYT; Sandhaus 2008). The CNN/DailyMail dataset contains news articles and associated highlights, i.e., a few bullet points giving a brief overview of the article. We used the standard splits of Hermann et al. (2015) for training, validation, and testing (90,266/1,220/1,093 CNN documents and 196,961/12,148/10,397 DailyMail documents). We did not anonymize entities.

The NYT dataset contains 110,540 articles with abstractive summaries. Following Durrett et al. (2016), we split these into 100,834 training and 9,706 test examples, based on date of publication (test is all articles published on January 1, 2007 or later). We also followed their filtering procedure, documents with summaries that are shorter than 50 words were removed from the raw dataset. The

Table 1: Test set results on the CNN/DailyMail and NYT datasets using ROUGE F_1 (R-1 and R-2 are shorthands for unigram and bigram overlap, R-L is the longest common subsequence.

filtered test set includes 3,452 test examples out of the original 9,706. Compared to CNN/DailyMail, the NYT dataset contains longer and more elaborate summary sentences.

Both datasets contain abstractive gold summaries, which are not readily suited to training extractive summarization models. A greedy algorithm similar to Nallapati et al. (2017) was used to generate an oracle summary for each document. The algorithm explores different combinations of sentences and generates an oracle consisting of multiple sentences which maximize the ROUGE score with the gold summary. We assigned label 1 to sentences selected in the oracle summary and 0 otherwise and trained Sumo on this data.

3.2 Implementation Details

We followed the same training procedure for Sumo and various Transformer-based baselines. The vocabulary size was set to 30K. We used 300D word embeddings which were initialized randomly from $\mathcal{N}(0, 0.01)$. The sentence-level Transformer has 6 layers and the hidden size of FFN was set to 512. The number of heads in MHAtt was set to 4. Adam was used for training ($\beta_1 = 0.9$, $\beta_2 = 0.999$). We adopted the learning rate schedule from Vaswani et al. (2017) with warming-up on the first 8,000 steps. Sumo and related Transformer models produced 3-sentence summaries for each document at test time (for both CNN/DailyMail and NYT datasets).

3.3 Automatic Evaluation

We evaluated summarization quality using ROUGE F_1 (Lin, 2004). We report unigram and bigram overlap (ROUGE-1 and ROUGE-2) as a means of assessing informativeness and the longest common subsequence (ROUGE-L) as a means of assessing fluency.

Table 1 summarizes our results. We evaluated two variants of Sumo, with one and three structured-attention layers. We compared against a baseline which simply selects the first three sentences in each document (Lead-3) and several incarnations of the basic Transformer model introduced in Section 2.1. These include a Transformer without document-level self-attention and two variants with document-level self attention instantiated with one and three layers. Several state-of-the-art models are also included in Table 1, both extractive and abstractive.

Refresh (Narayan et al., 2018) is an extractive summarization system trained by globally optimizing the ROUGE metric with reinforcement learning. The system of Marcu (1999) is another extractive summarizer based on RST parsing. It uses discourse structures and RST's notion of nuclearity to score document sentences in terms of their importance and selects the most important ones as the summary. Our re-implementation of Marcu (1999) used the parser of Zhao and Huang (2017) to obtain RST trees. Durrett et al. (2016) develop a summarization system which integrates a compression model that enforces grammaticality and coherence. See et al. (2017) present an abstractive summarization system based on an encoder-decoder architecture. Celikyilmaz et al.'s (2018) system is state-of-the-art in abstractive summarization using multiple agents to represent the document as well a hierarchical attention mechanism over the agents for decoding.

As far as Sumo is concerned, we observe that it outperforms a simple Transformer model without any document attention as well as variants with document attention. Sumo with three layers of structured attention overall performs best, confirming our hypothesis that document-level structure is beneficial for summarization. The results in Table 1 also reveal that Sumo and all Transformer-based models with document attention (doc-att) outperform Lead-3 across metrics. Sumo (3-layer) is competitive or better than state-of-the-art approaches. Examples of system output are shown in Table 4.

Finally, we should point out that Sumo is superior to Marcu (1999) even though the latter employs linguistically informed document representations.

3.4 Human Evaluation

In addition to automatic evaluation, we also assessed system performance by eliciting human judgments. Our first evaluation quantified the degree to which summarization models retain key information from the document following a question-answering (QA) paradigm (Clarke and Lapata, 2010; Narayan et al., 2018). We created a set of questions based on the gold summary under the assumption that it highlights the most important document content. We then examined whether participants were able to answer these questions by reading system summaries alone without access to the article. The more questions a system can answer, the better it is at summarizing the document as a whole.

We randomly selected 20 documents from the CNN/DailyMail and NYT datasets, respectively and wrote multiple question-answer pairs for each gold summary. We created 71 questions in total varying from two to six questions per gold summary. We asked participants to read the summary and answer all associated questions as best they could without access to the original document or the gold summary. Examples of questions and their answers are given in Table 4. We adopted the same scoring mechanism used in Clarke and Lapata (2010), i.e., a correct answer was marked with a score of one, partially correct answers with a score of 0.5, and zero otherwise. Answers were elicited using Amazon's Mechanical Turk platform. Participants evaluated summaries produced by the Lead-3 baseline, our 3-layered Sumo model and multiple state-of-the-art systems. We elicited 5 responses per summary.

Model	CNN+DM Rank	CNN+DM QA	NYT Rank	NYT QA
Lead	0.07	40.1	-0.18	36.3
Narayan et al. (2018)	**0.21**	62.4	0.12	46.1
Durrett et al. (2016)	—	—	-0.11	40.1
See et al. (2017)	-0.23	36.6	-0.44	35.3
Celikyilmaz et al. (2018)	-0.64	37.5	—	—
Sumo (3-layer)	0.15	**65.3**	**0.33**	**57.2**
Gold	0.11	—	-0.16	—
Oracle	0.37	74.6	0.41	67.1

Table 2: System ranking according to human judgments on summary quality and QA-based evaluation.

Table 2 (QA column) presents the results of the QA-based evaluation. Based on the summaries generated by Sumo, participants can answer 65.3% of questions correctly on CNN/DailyMail and 57.2% on NYT. Summaries produced by Lead-3 and comparison systems fare worse, with Refresh (Narayan et al., 2018) coming close to Sumo on CNN/DailyMail but not on NYT. Overall, we observe there is room for improvement since no system comes close to the extractive oracle, indicating that improved sentence selection would bring further performance gains to extractive approaches. Between-systems differences are all statistically significant (using a one-way ANOVA with posthoc Tukey HSD tests; $p < 0.01$) with the exception of Lead-3 and See et al. (2017) in both CNN+DM and NTY, Narayan et al. (2018) and Sumo in both CNN+DM and NTY, and Lead-3 and Durrett et al. (2016) in NYT.

Our second evaluation study assessed the overall quality of the summaries by asking participants to rank them taking into account the following criteria: *Informativeness* , *Fluency*, and *Succinctness*. The study was conducted on the Amazon Mechanical Turk platform using Best-Worst Scaling (Louviere et al., 2015), a less labor-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2017). Participants were presented with a document and

	CNN+DM			NYT		
	P	H	EA	P	H	EA
Parser	24.8	8.9	—	18.7	10.6	—
Sumo (1-layer)	69.0	2.9	23.1	54.7	3.6	20.6
Sumo (3-layer)	52.7	3.7	25.3	45.1	6.2	21.6
Left Branching	—	—	21.4	—	—	21.3
Right Branching	—	—	7.3	—	—	6.7

Table 3: Descriptive statistics Projectivity(%), Height and EdgeAgreement(%) for dependency trees produced by our model and the RST discourse parser of Zhao and Huang (2017). Results are shown on the CNN/DailyMail and NYT test sets.

summaries generated from 3 out of 7 systems and were asked to decide which summary was better and which one was worse, taking into account the criteria mentioned above. We used the same 20 documents from each dataset as in our QA evaluation and elicited 5 responses per comparison.

The rating of each system was computed as the percentage of times it was chosen as best minus the times it was selected as worst. Ratings range from -1 (worst) to 1 (best). As shown in Table 2 (Rank column), participants overwhelming prefer the extractive oracle summaries followed by Sumo and Refresh (Narayan et al., 2018). Abstractive systems (Celikyilmaz et al., 2018; See et al., 2017; Durrett et al., 2016) perform relatively poorly in this evaluation; we suspect that humans are less forgiving to fluency errors and slightly incoherent summaries. Interestingly, gold summaries fare worse than the oracle and extractive systems. Albeit fluent, gold summaries naturally contain less detail compared to oracle-based ones; on virtue of being abstracts, they are written in a telegraphic style, often in conversational language while participants prefer the more lucid style of the extracts. All pairwise comparisons among systems are statistically significant (using a one-way ANOVA with post-hoc Tukey HSD tests; $p < 0.01$) except Lead-3 and See et al. (2017) in both CNN+DM and NTY, Narayan et al. (2018) and Sumo in both CNN+DM and NTY, and LEAD and Durrett et al. (2016) in NYT.

3.5 Evaluation of the Induced Structures

To gain further insight into the structures learned by Sumo, we inspected the trees it produces. Specifically, we used the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967) to extract the maximum spanning tree from the attention scores. We report various statistics on the characteristics of the induced trees across datasets in Table 3. We also examine the trees learned from different Sumo variants (with different numbers of iterations) in order to establish whether the iterative process yields better structures.

Specifically, we compared the dependency trees obtained from our model to those produced by a discourse parser (Zhao and Huang, 2017) trained on a corpus which combines annotations from the RST treebank (Carlson et al., 2003) and the Penn Treebank (Marcus et al., 1993). Unlike traditional RST discourse parsers (Feng and Hirst, 2014), which first segment a document into Elementary Discourse Units (EDUs) and then build a discourse tree with the EDUs[2] as leaves, Zhao and Huang (2017) parse a document into an RST tree along with its syntax subtrees without segmenting it into EDUs. The outputs of their parser are ideally suited for comparison with our model, since we only care about document-level structures, and ignore the subtrees within sentence boundaries. We converted the constituency RST trees obtained from the discourse parser into dependency trees using Hirao et al.'s algorithm (2013).

As can be seen in Table 3, the dependency structures induced by Sumo are simpler compared to those obtained from the discourse parser. Our trees are generally shallower, almost half of them are projective. We also calculated the percentage of head-dependency edges that are identical between learned trees and parser generated ones. Although Sumo is not exposed to any annotated trees during training, a number of edges agree with the outputs of the discourse parser. Moreover, we observe that the iterative process involving multiple structured attention layers helps generate better discourse trees. We also compare Sumo trees against a left- and right-branching baseline, where the document is trivially parsed into a left- and right-branching tree forming a chain-like structure. As shown in Table 3, Sumo outperforms these baselines (with the exception of the one-layered model on NYT). We should also point out that the edge agreement between Sumo generated trees and left/right branching trees is low (around 30% on both datasets), indicating that the trees we learn are different from a simple chain.

Table 4: Gold human authored summaries, questions based on them (answers shown in square brackets) and automatic summaries produced by the Lead-3 baseline, the abstractive system of See et al. (2017), Refresh (Narayan et al., 2018), and Sumo for a CNN and NYT (test) article.

4 Conclusions

In this paper we provide a new perspective on extractive summarization, conceptualizing it as a tree induction problem. We present Sumo, a Structured Summarization Model, which induces a multi-root dependency tree of a document, where roots are summary-worthy sentences, and subtrees attached to them are sentences which elaborate or explain the summary content. Sumo generates complex trees following an iterative refinement process which builds latent structures while using information learned in previous iterations. Experiments on two datasets, show that Sumo performs competitively against state-of-the-art methods and induces meaningful tree structures.

In the future, we would like to generalize Sumo to abstractive summarization (i.e., to learn latent structure for documents *and* sentences) and perform experiments in a weakly-supervised setting where summaries are not available but labels can be extrapolated from the article's title or topics.

Fixed That for You: Generating Contrastive Claims with Semantic Edits

Abstract

Understanding contrastive opinions is a key component of argument generation. Central to an argument is the claim, a statement that is in dispute. Generating a counter-argument then requires generating a response in contrast to the main claim of the original argument. To generate contrastive claims, we create a corpus of Reddit comment pairs self-labeled by posters using the acronym FTFY (fixed that for you). We then train neural models on these pairs to edit the original claim and produce a new claim with a different view. We demonstrate significant improvement over a sequence-to-sequence baseline in BLEU score and a human evaluation for fluency, coherence, and contrast.

1 Introduction

In the Toulmin model (1958), often used in computational argumentation research, the center of the argument is the claim, a statement that is in dispute (Govier, 2010). In recent years, there has been increased interest in argument generation (Bilu and Slonim, 2016; Hua and Wang, 2018; Le et al., 2018). Given an argument, a system that generates counter-arguments would need to 1) identify the claims to refute, 2) generate a new claim with a different view, and 3) find supporting evidence for the new claim. We focus on this second task, which requires an understanding of contrast. A system that can generate claims with different views is a step closer to understanding and generating arguments (Apothloz et al., 1993). We build on previous work in automated claim generation (Bilu et al., 2015) which examined generating opposing claims via explicit negation. However, researchers also noted that not every claim has an exact opposite. Consider a claim from Reddit:

> Get employers out of the business, **pass universal single-payer healthcare**. (1)

This is an example of a policy claim - a view on what should be done (Schiappa and Nordin, 2013).

While negation of this claim is a plausible response (e.g. asserting there should be no change by stating *Do not get employers out of the business, do not pass universal healthcare*), negation limits the diversity of responses that can lead to a productive dialogue. Instead, consider a response that provides an alternative suggestion:

> Get employers out of the business, **deregulate and allow cross-state competition**. (2)

In Example 1, the speaker believes in an increased role for government while in Example 2, the speaker believes in a decreased one. As these views are on different sides of the political spectrum, it is unlikely that a single speaker would utter both claims. In related work, de Marneffe et al. (2008) define two sentences as contradictory when they are extremely unlikely to be true simultaneously. We thus define a contrastive claim as one that is *likely to be contradictory if made by the speaker of the original claim*. Our goal, then, is to develop a method for generating contrastive claims when explicit negation is not the best option. Generating claims in this way also has the benefit of providing new content that can be used for retrieving or generating supporting evidence.

In order to make progress towards generating contrastive responses, we need large, high-quality datasets that illustrate this phenomenon. We construct a dataset of 1,083,520 contrastive comment pairs drawn from Reddit using a predictive model to filter out non-contrastive claims. Each pair contains very similar, partially aligned text but the responder has significantly modified the original post. We use this dataset to model differences in views and generate a new claim given an original comment. The similarity within these pairs

Proceedings of NAACL-HLT 2019, pages 1756–1767
Minneapolis, Minnesota, June 2 - June 7, 2019.

allows us to use them as distantly labeled contrastive word alignments. The word alignments provide semantic information about which words and phrases can be substituted *in context* in a coherent, meaningful way.

Our contributions[1] are as follows:

1. Methods and data for *contrastive claim identification* to mine comment pairs from Reddit, resulting in a large, continuously growing dataset of 1,083,520 distant-labeled examples.
2. A crowd-labeled set of 2,625 comments each paired with 5 new contrastive responses generated by additional annotators.
3. Models for *generating contrastive claims* using neural sequence models and constrained decoding.

In the following sections, we describe the task methodology and data collection and processing. Next, we present neural models for contrastive claim generation and evaluate our work and present an error analysis. We then discuss related work in contrast/contradiction, argumentation, and generation before concluding.

2 Task Definition and Motivation

Previous work in claim generation (Bilu et al., 2015) focused on explicit negation to provide opposing claims. While negation plays an important role in argumentation (Apothloz et al., 1993), researchers found that explicit negation may result in incoherent responses (Bilu et al., 2015). Furthermore, recent empirical studies have shown that arguments that provide new content (Wachsmuth et al., 2018) tend to be more effective. While new concepts can be introduced in other ways by finding semantically relevant content, we may find it desirable to explicitly model contrast in order to control the output of the model as part of a rhetorical strategy, e.g. concessions (Musi, 2018). We thus develop a model that generates a contrastive claim given an input claim.

Contrastive claims may differ in more than just viewpoint; they may also contain stylistic differences and paraphrases, among other aspects. We thus propose to model contrastive claims by controlling for context and maintaining the same text between pairs of contrastive claims except for the contrastive word or phrase. Much of the previous work in contrast and contradiction has examined the relationship between words or sentences. In order to understand when words and phrases are contrastive in argumentation, we need to examine them *in context*. For example, consider the claim *Hillary Clinton should be president.* A reasonable contrastive claim might be *Bernie Sanders should be president.* (rather than the explicit negation *Hillary Clinton should not be president.*) In this context, Hillary Clinton and Bernie Sanders are contrastive entities as they were both running for president. However, for the claim *Hillary Clinton was the most accomplished Secretary of State in recent memory.* they would be unrelated. Consider also that we could generate the claim *Hillary Clinton should be senator.* This contrastive claim is not coherent given the context. Generating a contrastive claim then requires 1) identifying the correct substitution span and 2) generating a response with semantically relevant replacements.

While some contrastive claims are not coherent, there are often multiple plausible responses, similar to tasks such as dialogue generation. For example, *Donald Trump should be president* is just as appropriate as *Bernie Sanders should be president*. We thus treat this as a dialogue generation task where the goal is to generate a plausible response given an input context.

3 Data

In order to model contrastive claims, we need datasets that reflect this phenomenon.

3.1 Collection

We obtain training data by scraping the social media site Reddit for comments containing the acronym *FTFY*.[2] FTFY is a common acronym meaning “fixed that for you.”[3] FTFY responses (hereafter FTFY) are used to respond to another comment by editing part of the “parent comment” (hereafter parent). Most commonly, FTFY is used for three categories of responses: 1) expressing a contrastive claim (e.g. the parent is ***Bernie Sanders*** *for president* and the FTFY is ***Hillary Clinton*** *should be president*) which may be sarcastic (e.g. ***Ted Cruz*** *for president* becomes ***Zodiac***

---

[3] https://reddit.zendesk.com/hc/en-us/articles/205173295-What-do-all-these-acronyms-mean

killer** for president*) 2) making a joke (e.g. *This Python library really **piques** my interest* vs. *This really ***py*ques** my interest*), and 3) correcting a typo (e.g. *This **peaks** my interest* vs. ***piques). In Section 3.2, we describe how we identify category 1 (contrastive claims) for modeling.

To obtain historical Reddit data, we mined comments from the site pushshift.io for December 2008 through October 2017. This results in 2,200,258 pairs from Reddit, where a pair consists of a parent and an FTFY. We find that many of the top occurring subreddits are ones where we would expect strong opinions (/r/politics, /r/worldnews, and /r/gaming).

3.2 Classification

To filter the data to only the type of response that we are interested in, we annotated comment pairs for contrastive claims and other types. We use our definition of contrastive claims based on contradiction, where both the parent and FTFY are a claim and they are unlikely to be beliefs held by the same speaker. A joke is a response that does not meaningfully contrast with the parent and commonly takes the form of a pun, rhyme, or oronym. A correction is a response to a typo, which may be a spelling or grammatical error. Any other pair is labeled as "other," including pairs where the parent is not a claim.

In order to identify contrastive claims, we selected a random subset of the Reddit data from prior to September 2017 and annotated 1993 comments. Annotators were native speakers of English and the Inter-Annotator Agreement using Kripendorff's alpha was 0.72. Contrast occurs in slightly more than half of the sampled cases (51.4%), with jokes (23.0%) and corrections (21.2%) comprising about one quarter each. We then train a binary classifier to predict contrastive claims, thus enabling better quality data for the generation task.

To identify the sentence in the parent that the FTFY responds to and derive features for classification, we use an edit distance metric to obtain sentence and word alignments between the parent comment and response. As the words in the parent and response are mostly in the same order and most FTFYs contain significant overlap with the parent response, it is possible to find alignments by moving a sliding window over the parent. A sample of 100 comments verifies that this approach yields exact word alignments in 75 comments and exact sentence alignments in 93.

Given these pairs of comments, we derive linguistic and structural features for training a binary classifier. For each pair of comments, we compute features for the words in the *entire comment span* and features from the *aligned phrases span* only (as identified by edit distance). From the *aligned phrases* we compute the *character edit distance* and *character Jaccard similarity* (both normalized by the number of characters) to attempt to capture jokes and typos (the similarity should be high if the FTFY is inventing an oronym or correcting a spelling error). From the *entire comment*, we use the *percentage of characters copied* as a low percentage may indicate a poor alignment and the *percentage of non-ASCII characters* as many of the jokes use emojis or upside-down text. In addition, we use features from GloVe (Pennington et al., 2014) word embeddings[4] for both the *entire comment* and *aligned phrases*. We include the *percentage of words in the embedding vocabulary* for both spans for both the parent and FTFY. The reason for this feature is to identify infrequent words which may be typos or jokes. We compute the *cosine similarity* of the average word embeddings between the parent and FTFY for both spans. Finally, we use *average word embeddings* for both spans for both parent and FTFY.

As we want to model the generation of new content, not explicit negation, we removed any pairs where the difference was only "stop words." The set of stop words includes all the default stop words in Spacy[5] combined with expletives and special tokens (we replaced all URLs and usernames). We trained a logistic regression classifier and evaluated using 4-fold cross-validation. We compare to a *character* overlap baseline where any examples with Jaccard similarity > 0.9 and edit distance < 0.15 were classified as non-contrastive. The goal of this baseline is to illustrate how much of the non-contrastive data involves simple or non-existent substitutions. Results are shown in Table 1. Our model obtains an F-score of 80.25 for an 8 point absolute improvement over the baseline.

3.3 Selection

After using the trained model to classify the remaining data, we have 1,083,797 Reddit pairs. We set aside 10,307 pairs from October 1-20, 2017 for

development and October 21-30 for test (6,773), with the remainder used for training. As we are primarily working with sentences, the mean parent length was 16.3 and FTFY length was 14.3.

The resulting test FTFYs are naturally occurring and so do not suffer from annotation artifacts. At the same time, they are noisy and may not reflect the desired phenomenon. Thus, we also conducted an experiment on Amazon Mechanical Turk[6] (AMT) to obtain additional gold references, which are further required by metrics such as BLEU (Papineni et al., 2002). We selected 2,625 pairs from the 10 most frequent categories[7] (see Table 2). These categories form a three-level hierarchy for each subreddit and we use the second-level, e.g. for /r/pokemongo the categories are "Pokémon", "Video Games", and "Gaming" so we use "Video Games." Before participating, each annotator was required to pass a qualification test - five questions to gauge their knowledge of that topic. For the movies category, one question we asked was whether for the sentence *Steven Spielberg is the greatest director of all time*, we could instead use *Stanley Kubrick* or *Paul McCartney*. If they passed this test, the annotators were then given the parent comment and "keywords" (the subreddit and three category levels) to provide additional context. We obtained *five* new FTFYs for each parent and validated them manually to remove obvious spam or trivial negation (e.g. "not" or "can't").

Category	Count	Category	Count
Video Games	1062	Basketball	116
Politics	529	Soccer	99
Football	304	Movies	88
Television	194	Hockey	60
World News	130	Baseball	55

Table 2: Comments for Mechanical Turk

4 Methods

Our goal of *generating* contrastive claims can be broken down into two primary tasks: 1) identifying the words in the original comment that should be removed or replaced and 2) generating the appropriate substitutions and any necessary context. Initially, we thus experimented with a modular approach by tagging each word in the parent and then using the model predictions to determine if we should copy, delete, or replace a segment with a new word or phrase. We tried the bi-directional LSTM-CNN-CRF model of Ma and Hovy (2016) and used our edit distance word alignments to obtain labels for copying, deleting, or replacing. However, we found this model performed slightly above random predictions, and with error propagation, the model is unlikely to produce fluent and accurate output. Instead, we use an end-to-end approach using techniques from machine translation.

4.1 Model

We use neural sequence-to-sequence encoder-decoder models (Sutskever et al., 2014) with attention for our experiments. The tokens from the parent are passed as input to a bi-directional GRU (Cho et al., 2014) to obtain a sequence of encoder hidden states h_i. Our decoder is also a GRU, which at time t generates a hidden state s_t from the previous hidden state s_{t-1} along with the input. When training, the input x_t is computed from the previous word in the gold training data if we are in "teacher forcing" mode (Williams and Zipser, 1989) and otherwise is the prediction made by the model at the previous time step. When testing, we also use the model predictions. The input word w_t may be augmented by additional features, as discussed in Section 4.2. In the baseline scenario $x_t = e(w_t)$ where e is an embedding. The hidden state s_t is then combined with a context vector h_t^*, which is a weighted combination of the encoder hidden states using an attention mechanism:

$$h_t^* = \sum_i \alpha_t^i h_i$$

To calculate α_i^t, we use the attention of Luong et al. (2015) as this encourages the model to select features in the encoder hidden state which correlate with the decoder hidden state, which we want because our input and output are similar. Our experiments on the development data verified this,

---

[6] We paid annotators the U.S. federal minimum wage and the study was approved by an IRB.

[7] Obtained from the snoopsnoo.com API

as Bahdanau attention (Bahdanau et al., 2015) performed worse. Attention is then calculated as:

$$\alpha_t^i = \frac{\exp(h_i^T s_t)}{\sum_{s'} \exp(h_{s'}^T s_t)}$$

Finally, we make a prediction of a vocabulary word w by using features from the context and decoder hidden state with a projection matrix W and output vocabulary matrix V:

$$P(w) = \text{softmax}(V \tanh(W[s_t; h_t^*] + b_w) + b_v)$$

We explored using a copy mechanism (See et al., 2017) for word prediction but found it difficult to prevent the model from copying the entire input.

4.2 Decoder Representation

Decoder Input: We evaluate two representations of the target input: as a sequence of **words** and as a sequence of **edits**. The sequence of words approach is the standard encoder-decoder setup. For the example parent *Hillary Clinton for president 2020* and FTFY *Bernie Sanders for president* we would use the FTFY without modification. Schmaltz et al. (2017) found success modeling error correction using sequence-to-sequence models by representing the target input as a sequence of edits. We apply a similar approach to our problem, generating a target sequence by following the best path in the matrix created by the edit distance algorithm. The new target sequence is the original parent interleaved with "DELETE-N tokens" that specify how many previous words to delete, followed by the newly generated content. For the same example, *Hillary Clinton for president 2020*, the modified target sequence would be *Hillary Clinton DELETE-2 Bernie Sanders for president 2020 DELETE-1*.

Counter: Kikuchi et al. (2016) found that by using an embedding for a length variable they were able to control output length via a learned mechanism. In our work, we compute a counter variable which is initially set to the number of new content words the model should generate. During decoding, the counter is decremented if a word is generated that is not in the source input (I) or in the set of stop words (S) defined in Section 3.2. The model uses an embedding $e(c_t)$ for each count, which is parameterized by a count embedding matrix. The input to the decoder state in this scenario is $x_t = e(w_t, c_t)$. At each time step, the count is computed by:

$$c_0 = |O \setminus (S \cup I)| \text{ or desired count}$$

$$c_{t+1} = \begin{cases} c_t - 1, & w_t \notin S \cup I \text{ and } c_t > 0 \\ c_t, & \text{otherwise} \end{cases}$$

where O is the set of gold output words in training.

For the parent comment *Hillary Clinton for president 2020* and FTFY *Bernie Sanders for president*, the decoder input is presented, with the time t in the first row of Table 3 and the inputs w_t and c_t in the second and third rows, respectively. At the start of decoding, the model expects to generate two new content words, which in this example it generates immediately and decrements the counter. When the counter reaches 0, it only generates stop or input words.

t	0	1	2	3	4
w_t	-	Bernie	Sanders	for	president
c_t	2	1	0	0	0

Table 3: Example of Counter

Unlike the controlled-length scenario, at test time we do not know the number of new content words to generate. However, the count for most FTFYs is between 1 and 5, inclusive, so we can exhaustively search this range during decoding. We experimented with predicting the count but found it to be inaccurate so we leave this for future work.

Subreddit Information: As the model often needs to disambiguate polysemous words, additional context can be useful. Consider the parent comment *this is a strange bug.* In a programming subreddit, a sarcastic FTFY might be *this is a strange feature.* However, in a Pokémon subreddit, an FTFY might be *this is a strange dinosaur* in an argument over whether Armaldo is a bug or a dinosaur. We thus include additional features to be passed to the encoder at each time step, in the form of an embedding g for each the three category levels obtained in Section 3.3. These embeddings are concatenated to the input word w_t at each timestep, i.e. $x_t = e(w_t, g_t^1, g_t^2, g_t^3)$.

4.3 Objective Function

We use a negative log likelihood objective function $\mathcal{L}_{NLL} = -\log \sum_{t \in 1:T} P(w_t^*)$, where w_t^* is the gold token at time t, normalized by each batch. We also include an additional loss term that uses the encoder hidden states to make a binary prediction over the input for whether a token will be copied or inserted/deleted. For the example from Section 4.2, the target for *Hillary Clinton for president 2020* would be *0 0 1 1 0*. This encourages the model to select features that indicate whether the encoder input will be copied to the output. We use a 2-layer multi-layer perceptron and a binary cross-entropy loss $\mathcal{L}_{BCE}$. The joint loss is then:

$$\mathcal{L} = \mathcal{L}_{NLL} + \lambda \mathcal{L}_{BCE}$$

4.4 Decoding

We use beam search for generation, as this method has proven effective for many neural language generation tasks. For the settings of the model that require a counter, we expand the beam by count m so that for a beam size k we calculate $k * m$ states.

Filtering: We optionally include a constrained decoding mode where we filter the output based on the counter; when $c_t > 1$ the end-of-sentence (EOS) score is set to $-\infty$ and when $c_t = 0$ the score of any word $w \in V \setminus (S \cup I)$ is set to $-\infty$. The counter c_t is decremented at every time step as in Section 4.2. In other words, when the counter is zero, we only allow the model to copy or generate stop words. When the counter is positive, we prevent the model from ending the sentence before it generates new content words and decrements the counter. The constrained decoding is possible with any combination of settings, with or without the counter embedding.

4.5 Hyper-parameters and Optimization

We used Pytorch (Paszke et al., 2017) for all experiments. We used 300-dimensional vectors for the word embedding and GRU layers. The count embedding dimension was set to 5 with $m = 5$ and $k = 10$ for decoding. The category embedding dimensions were set to 5, 10, and 25 for each of the non-subreddit categories. We also set $\lambda = 1$ for multi-task learning. We used the Adam optimizer (Kingma and Ba, 2015) with settings of $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$ and a learning rate of 10^{-3} decaying by $\gamma = 0.1$ every epoch. We used dropout (Srivastava et al., 2014) on the embeddings with a probability of 0.2 and teacher forcing with 0.5. We used a batch size of 100 with 10 epochs, selecting the best model on the development set based on perplexity. We set the minimum frequency of a word in the vocabulary to 4.

5 Results

For training, development, and testing we use the data described in Section 3.3. The test reference data consists of the Reddit FTFYs and the FTFYs generated from AMT. We evaluate our models using automated metrics and human judgments.

Automated metrics should reflect our joint goals of 1) copying necessary context and 2) making appropriate substitutions. To address point 1, we use BLEU-4 as a measure of similarity between the gold FTFY and the model output. As the FTFY may contain significant overlap with the parent, BLEU indicates how well the model copies the appropriate context. As BLEU reflects mostly span selection rather than the insertion of new content, we need alternative metrics to address point 2. However, addressing point 2 is more difficult due to the variety of possible substitutions, including named entities. For example, if the parent comment is *jaguars for the win!* and the gold FTFY is *chiefs for the win!* but the model produces *cowboys for the win!* (or any of 29 other NFL teams), most metrics would judge this response incorrectly even though it would be an acceptable response. Thus we present results using both automated metrics and human evaluation. As an approximation to address point 2, we attempt to measure when the model is making changes rather than just copying the input. To this end, we present two additional metrics - *novelty*, a measure of whether novel content (non-stop word) tokens are generated relative to the parent comment, and *partial match*, a measure of whether the novel tokens in the gold FTFY match any of the novel tokens in the generated FTFY. To provide a reference point, we find that the partial match between two different gold FTFYs (Reddit and AMT) was 11.4% and BLEU was 47.28, which shows the difficulty of automatic evaluation. The scores are lower than expected because the Reddit FTFYs are noisy due to the process in Section 3.2. This also justifies obtaining the AMT FTFYs.

Results are presented in Table 4. The baseline is a sequence-to-sequence model with attention. For other components, the counter embedding is referred to as "COUNT," the category/subreddit embeddings as "SUB," the sequence of edits as "EDIT," and the multi-task copy loss as "COPY." The models in the top half of the table use constrained decoding and those in the bottom half are unconstrained, to show the learning capabil-

			Reddit		AMT	
	Model	Novelty	BLEU-4	% Match	BLEU-4	% Match
Constrained	Baseline	79.88	18.81	4.67	40.14	10.06
	COUNT	89.69	22.61	4.72	47.55	12.55
	COUNT + SUB + COPY	**90.45**	**23.13**	**4.83**	**50.05**	**14.92**
	EDIT	64.64	16.12	3.37	35.48	7.33
	EDIT + COUNT + SUB + COPY	82.96	19.37	4.23	42.69	11.62
Unconstrained	Baseline	3.34	7.31	0.73	25.83	0.68
	COUNT	16.19	8.51	1.95	27.68	2.36
	COUNT + SUB + COPY	16.26	9.62	1.93	31.23	3.81

	EDIT + COUNT + SUB + COPY	**39.99**	32.59	**3.25**	67.56	**6.25**

Table 4: Automatic Evaluation

ities of the models. For each model we compute statistical significance with bootstrap resampling (Koehn, 2004) for the constrained or unconstrained baseline as appropriate and we find the COUNT and EDIT models to be significantly better for constrained and unconstrained decoding, respectively ($p < 0.005$).

Under constrained decoding, we see that the "COUNT + SUB + COPY" model performs the best in all metrics, although most of the performance can be attributed to the count embedding. When we allow the model to determine its own output, we find that "EDIT + COUNT" performs the best. In particular, this model does well at understanding which part of the context to select, and even does better than other unconstrained models at selecting appropriate substitutions. However, when we combine this model with constrained decoding, the improvement is smaller than for the other settings. We suspect that because the EDIT model often needs to generate a DELETE-N token before a new response, these longer-term dependencies are hard to capture with constrained decoding but easier if included in training.

We also conducted a human evaluation of the model output on the same subset of 2,625 examples described in Section 3.3. We performed an additional experiment on AMT where we asked annotators to rate responses on fluency, coherence, and contrast. **Fluency** is a measure of the quality of the grammar and syntax and the likelihood that a native English speaker would utter that statement. **Coherence** is a measure of whether the response makes sense, is semantically meaningful, and would be usable as a response to a claim. **Contrast** is a measure of how much the response contradicts the original comment. We specified that if the response is different but does not provide a contrasting view it should receive a low rating. Previous work (Bilu et al., 2015) used fluency, clarity/usability (which we combine into coherence), and opposition (where we use contrast).

Model	Fluency	Coherence	Contrast
Gold	4.34	4.26	3.01
Baseline	3.49	3.19	1.94
Constrained	3.46	3.32	2.53
Best	**3.52**	**3.46**	**2.87**

Table 5: Human Evaluation

We used a Likert scale where 5 is strongly agree and 1 is strongly disagree. We used the same data and qualification test from Section 3.3 for each category and used three annotators per example. We asked annotators to judge 4 different pairs: 3 model outputs and the gold Reddit[8] FTFYs for comparison. We include the baseline, the baseline with constrained decoding, and the best constrained model ("COUNT + SUB + COPY") according to BLEU and partial match. We verified that the annotators understood how to rate contrast by examining the distribution of responses: the annotators selected option 3 (neither) 15% of the time and preferred to select either extreme, 5 (21%) or 1 (27%). Results are presented in Table 5, showing a clear preference for the best model. Note the degradation in fluency for the constrained baseline, as the model is prevented from generating the EOS token and may repeat tokens up to the

Model: propaganda from fox news outlets

Table 6: Model Output

maximum length.

6 Qualitative Analysis

We provide three examples of the model output in Table 6 with the first and third from the News and Politics category, demonstrating how the model handles different types of input. In the first example, the contrast is between allowing markets to regulate themselves versus an increased role of government. In the second example, the contradiction is due to the choice of operating system. In the third (invalid) example, the model responds to a sarcastic claim with another right-wing news organization; this response is not a contradiction since it is plausible the original speaker would also utter this statement.

6.1 Error Analysis

We conduct an error analysis by selecting 100 responses where the model did not partially match any of the 6 gold responses and we found 6 main types of errors. One error is the model identifying an **incorrect substitution span** while the human responses all selected a different span to replace. We noticed that this occurred 5 times and may require world knowledge to understand which tokens to select. For example, in response to the claim *Hillary Clinton could have been president if not for robots*, the model generates *Donald Trump* in place of *Hillary Clinton*, whereas the gold responses generate *humans / votes / Trump’s tweets* in place of *robots*. Another type of error is when the responses are not coherent with the parent and the language model instead determines the token selection based on the **most recent context** (11 cases). For example, given the claim *bb-8 gets a girlfriend and poe still does n’t have a girlf :’)* the Reddit FTFY has *boyf* instead of *girlf* whereas the model generates ... *and poe still does n’t have a clue what i ’m talking about .* We also found examples where the model chose poorly due to unfiltered jokes or **errors in the training data** (12 in total). In 15 cases, due to the constrained decoding the model **repeated** a word until the maximum length or appended an incoherent phrase. For the most common error, the model made a substitution that **was not contrasting** as in Table 6 (19 examples). Finally, we found 38 of the samples were **valid** responses, but did not match the gold, indicating the difficulty of automatic evaluation. For example, in response to the claim *Nintendo is the only company that puts customers over profits*, the model replaces *Nintendo* with *Rockstar* (both video game companies) while the gold FTFYs had other video game companies.

7 Related Work

Understanding contrast and contradiction is key to argumentation as it requires an understanding of differing points-of-view. Recent work examined the negation of claims via explicit negation (Bilu et al., 2015). Other work investigated the detection of different points-of-view in opinionated text (Al Khatib et al., 2012; Paul et al., 2010). Wachsmuth et al. (2017; 2018) retrieved arguments for and against a particular stance using online debate forums. In non-argumentative text, researchers predicted contradictions for types such as negation, antonyms, phrasal, or structural (de Marneffe et al., 2008) or those that can be expressed with functional relations (Ritter et al., 2008). Other researchers have incorporated entailment models (Kloetzer et al., 2013) or crowdsourcing methods (Takabatake et al., 2015). Contradiction has also become a part of the natural language inference (NLI) paradigm, with datasets labeling contradiction, entailment, or neutral (Bowman et al., 2015a; Williams et al., 2018). The increase in resources with contrast and contradiction has resulted in new representations with contrastive meaning (Chen et al., 2015; Nguyen et al., 2016; Vulić, 2018; Conneau et al., 2017). Most of this work has focused on identifying contrast or contradiction while we aim to generate contrast. Furthermore, while contradiction and contrast are present in these corpora, we obtain distant-labeled alignments for contrast at the word and phrase level. Our dataset also includes contrastive concepts and entities while other corpora primarily contain antonyms and explicit negation.

Contrast also appears in the study of stance, where the opinion towards a target may vary. The SemEval 2016 Stance Detection for Twitter task (Mohammad et al., 2016) involved predicting if a tweet favors a target entity. The Interpretable Semantic Similarity task (Agirre et al., 2016) called to identify semantic relation types (including opposition) between headlines or captions. Target-specific stance prediction in debates is addressed by Hasan and Ng (2014) and Walker et al. (2012). Fact checking can be viewed as stance toward an event, resulting in research on social media (Lendvai and Reichel, 2016; Mihaylova et al., 2018), politician statements (Vlachos and Riedel, 2014), news articles (Pomerleau and Rao, 2017), and Wikipedia (Thorne et al., 2018).

In computational argumentation mining, identifying claims and other argumentative components is a well-studied task (Stab and Gurevych, 2014). Daxenberger et al. (2017) and Schulz et al. (2018) developed approaches to detect claims across across diverse claim detection datasets. Recently, a shared task was developed for argument reasoning comprehension (Habernal et al., 2018). The best system (Choi and Lee, 2018) used models pre-trained on NLI data (Bowman et al., 2015b), which contains contradictions. While this work is concerned with identification of argumentative components, we propose to generate new claims.

In the field of argument generation, Wang and Ling (2016) train neural abstractive summarizers for opinions and arguments. Additional work involved generating opinions given a product rating (Wang and Zhang, 2017). Bilu and Slonim (2016) combine topics and predicates via a template-based classifier. This work involves the generation of claims but in relation to a topic. Other researchers generated political counter-arguments supported by external evidence (Hua and Wang, 2018) and generating argumentative dialogue by maximizing mutual information (Le et al., 2018). This research considers end-to-end argument generation, which may not be coherent, whereas we focus specifically on contrastive claims.

8 Conclusion

We presented a new source of over 1 million contrastive claim pairs that can be mined from social media sites such as Reddit. We provided an analysis and models to filter noisy training data from 49% down to 25%. We created neural models for generating contrastive claims and obtained significant improvement in automated metrics and human evaluations for Reddit and AMT test data.

Our goal is to incorporate this model into an argumentative dialogue system. In addition to generating claims with a contrasting view, we can also retrieve supporting evidence for the newly-generated claims. Additionally, we plan to experiment with using our model to improve claim detection (Daxenberger et al., 2017) and stance prediction (Bar-Haim et al., 2017). Our model could be used to generate artificial data to enhance classification performance on these tasks.

To improve our model, we plan to experiment with retrieval-based approaches to handle low-frequency terms and named entities, as sequence-to-sequence models are likely to have trouble in this environment. One possibility is to incorporate external knowledge with entity linking over Wikipedia articles to find semantically-relevant substitutions.

Another way to improve the model is by introducing controllable generation. One aspect of controllability is intention; our model produces contrastive claims without understanding the view of the original claim. Category embeddings partially address this issue (some labels are "Liberal" or "Conservative"), but labels are not available for all views. Going forward, we hope to classify the viewpoint of the original claim and then generate a claim with a desired orientation. Furthermore, we hope to improve on the generation task by identifying the types of claims we encounter. For example, we may want to change the target of the claims in some claims but in others change the polarity.

We also plan to improve the dataset by improving our models for contrastive pair prediction to reduce noise. Finally, we hope that this dataset proves useful for related tasks such as textual entailment (providing examples of contradiction) and argument comprehension (providing counter-examples of arguments) or even unrelated tasks like humor or error correction.

Acknowledgments

We would like to thank the AMT annotators for their work and the anonymous reviewers for their valuable feedback. The authors also thank Alyssa Hwang for providing annotations and Smaranda Muresan, Chris Kedzie, Jessica Ouyang, and Elsbeth Turcan for their helpful comments.

Abstract

Deception often takes place during everyday conversations, yet conversational dialogues remain largely unexplored by current work on automatic deception detection. In this paper, we address the task of detecting multimodal deceptive cues during conversational dialogues. We introduce a multimodal dataset containing deceptive conversations between participants playing The Tonight Show Starring Jimmy Fallon® Box of Lies game, in which they try to guess whether an object description provided by their opponent is deceptive or not. We conduct annotations of multimodal communication behaviors, including facial and linguistic behaviors, and derive several learning features based on these annotations. Initial classification experiments show promising results, performing well above both a random and a human baseline, and reaching up to 69% accuracy in distinguishing deceptive and truthful behaviors.

1 Introduction

Deception occurs often during dialogues, but until now this setting has received little attention from the research community (Tsunomori et al., 2015). In this paper, we explore verbal, nonverbal, and conversational dialog cues between contestants playing the Box of Lies game in The Tonight Show Starring Jimmy Fallon® tv show. In the game, participants try to guess whether an object description provided by their opponent is deceptive or not. The game scenario provides a rich environment where we can explore several aspects of deceptive behavior occurring during conversations. First, it allows us to study conversational deception in the presence of multiple modalities such as verbal and non-verbal behaviors. Second, it provides observable assessments of participant's honesty, which is usually an important challenge during deception research. Third, since participants experience the pressure to win the game in front of a big audience, it presumably presents an environment with high stakes.[1]

Recent work on multimodal deception detection has already shown the importance of verbal and non-verbal behaviors during the automatic identification of deceit (Abouelenien et al., 2017a). Following this line of work, our main contribution consists of investigating whether such modalities can also be leveraged to predict deception in a conversational dialog as well as exploring whether the dialogue setting adds meaningful information to the other modalities to potentially increase the classification performance. Based on earlier work (Perez-Rosas et al., 2014; Mihalcea et al., 2013), we hypothesize that **(1)** including dialogue features in addition to other multimodal features (language and facial expressions) while training a classifier increases the prediction performance; **(2)** automatic classification of truthful and deceptive behavior is better than random guessing (50% for equal class sizes); and **(3)** automatic classification of truthful and deceptive responses is more accurate than human judgments (based on performance of participants in the dataset).

To address these hypotheses, we first generate a dataset containing verbal and non-verbal annotations of deceptive and truthful interactions between the game participants. Next, we derive linguistic, visual, and dialog cues based on our annotations for the verbal and non-verbal components of the dataset. The features are then used to conduct several learning experiments under different scenarios that attempt to distinguish between deceptive and truthful utterances either by focusing on the statements generated by one participant at a time (the game's host or the guest), or by address-

---

[1] To our knowledge, these conversations are not scripted.

Proceedings of NAACL-HLT 2019, pages 1768–1777
Minneapolis, Minnesota, June 2 - June 7, 2019.

ing them all together.

Our initial experiments show that language, as well as behavioral and dialog features, carry meaningful information. Moreover, the automatic classification of deception can be performed with an accuracy that is better than random guessing and ourperforms human judgments.

2 Related Work

To tackle the problem of reliably detecting deception, researchers have applied various forms of automated deception detection methods that rely on machine learning approaches, which are able to incorporate a variety of behavioral cues from text, audiovisual or physiological data sources (Ott et al., 2011; Fornaciari and Poesio, 2013; Mihalcea and Strapparava, 2009; Abouelenien et al., 2016).

Many studies focused on text-based classification, detecting false online reviews (Ott et al., 2013) or deceptive transcribed statements from court hearings (Fornaciari and Poesio, 2013). Other studies utilized visual cues such as facial expressions or other body movements to detect deception (Meservy et al., 2005). These methods already show success in identifying deceptive behavior using individual modalities. In addition, recent approaches, which combine multiple modalities are able to further boost classification performances (Abouelenien et al., 2017b; Perez-Rosas et al., 2015).

However, multimodal approaches have not utilized the dialogue dimension in combination with other modalities as of yet. The dialogue dimension captures the interaction between two individuals and how they react to each other. One previous study investigated such an interaction, in which the researchers examined question types and their behavioral effect on participants (Tsunomori et al., 2015). Findings of the study showed that specific questions led to more salient deceptive behavior patterns in participants. This increase in feature salience resulted in better deception detection performances.

The interaction between two individuals in deceptive conversations was also investigated by Hancock et al. (2004), who examined deception at the linguistic level. Participants, who were unaware of receiving a deceptive message, produced more words, sense terms and asked more questions as compared to when they received a truthful message. In a similar setting, in which two participants engaged in a question-response task, Levitan et al. (2018) examined linguistic, gender and native language differences. They found significant variations in these features for truthful and deceptive responses. The experimenters utilized these variations in an automated classification task and reached up to 72% accuracy.

These studies show that a focus on the linguistic level and the interaction between individuals can have a beneficial effect on detecting deceit. Other studies examined non-verbal behavior. In an experiment, Sen et al. (2018) video-recorded conversations between participants in an interrogation game and examined participant's facial expressions. The results showed that interrogators exhibited different facial expressions when they were lied to as opposed to when they were told the truth. In a different approach, Yu et al. (2015) observed head movements and facial expressions between two individuals. The authors established normalized non-verbal patterns, which enabled them to capture interactional synchrony. This allowed them to successfully discriminate between truths and lies in the experiment.

Overall, this previous research demonstrates that capturing verbal or non-verbal interactions can convey meaningful information about deceit, which can be leveraged for multimodal deception detection.

3 Dataset of Deceptive Conversations

To explore the role played by conversation dynamics in deceptive behaviors, we collected conversations where participants acted deceptively. Specifically, we opted for identifying public sources where the veracity or falsehood of conversation participants is known.

In the game show Box of Lies, which is part of the late-night talk show The Tonight Show Starring Jimmy Fallon, these labels are known. The host (Jimmy Fallon) and his guest play the game Box of Lies, where participants take turns to play the game. During the game, when is their turn, the participants pick a box (from among nine available boxes) that contains an object they have to describe to their opponent. The object is hidden from the opponent through a separation wall between the two contestants. Participants sit opposite to each other and see their upper body and face through a cut hole in the separation wall. The opponent must guess if the provided description is truthful or not. The participant with the best of three guesses wins the game.

This setup allows us to observe verbal and non-verbal behavior exhibited by the participants during the dialogue interaction. In order to better capture multimodal behavioral cues of deception throughout the conversation, we decided to conduct annotations at utterance-level. We thus built a rich multimodal dataset containing verbal and non-verbal annotations for 1049 utterances, which is used in the experiments reported in this paper. The data collection and annotation process are described below.

3.1 Data Collection

We search for publicly available Box of Lies videos on the YouTube platform.[2] We collected 25 videos that are currently available in the show video-feed. The full set consists of 2 hours and 24 minutes of video. The average length of a video is six minutes and contains around three rounds of the game (this varies depending on the score and on whether additional time was available for extra rounds). Each video features a different guest and Jimmy Fallon, resulting in 26 unique participants, with 6 of them being males and 20 females.

3.2 Annotation of Multimodal Communication Behaviors

To capture the non-verbal behavior of the participants, each video is initially segmented based on the conversation turn-taking and annotated with the help of the ELAN software (Wittenburg et al., 2006). ELAN provides a multimodal annotation platform on which audiovisual recordings are annotated in a multi-level tier structure. In our case, we defined the following structure to annotate both types of behavior: host verbal, host non-verbal, guest verbal, and guest non-verbal.

3.2.1 Non-verbal Behaviors

To annotate facial and communication behaviors, we use MUMIN, a multimodal coding scheme that is used to study gestures and facial displays in interpersonal communication with a focus on the role played by multimodal expressions for feedback, turn management, and sequencing (Allwood et al., 2005). Given the nature of the video-conversations being depicted in our dataset, which show the face and upper bodies of the participants and their interaction, we focus our annotations on facial and conversational behavior. These choices are motivated by previous research showing that different expressions for truthful and deceptive behaviors are present (DePaulo et al., 2003) in the eyes and mouth regions, as well as studies on the role of conversational involvement in deceptive interactions (Burgoon et al., 1999).

Facial behaviors. We annotate the categories for visual cues and behaviors of eyebrows, eyes, gaze, mouth-openness, mouth-lips, head, and the general face. Each of the categories takes on one of several mutually exclusive behavior values. Table 1 shows the frequencies of all facial expressions included in this set. In the table, we observe a slightly unequal representation of behavioral categories (e.g., head movements are observed more often than other facial expressions). This is mainly attributed to camera angle changes during the videos causing participant's faces to be only partly or not visible, thus restricting the behavioral coding. The annotated values reflect the most dominant observed behavior in that time segment of the video.

Two annotators coded the videos, and after the first three videos, the inter-annotator agreement was measured by calculating the Kappa score, to ensure accurate coding. If the agreement was below Kappa (weighted) = 0.45 in any category, this category was discussed to identify and reconcile differences in the coding strategy. The annotators re-coded the videos individually and compared them again. This process was repeated until the desired agreement was reached (above .40 for each category). In most cases, we repeated the process only twice, except for the "feedback receiving" and "feedback eliciting" categories which were discussed three times. Table 2 shows the final Kappa score for each category.

3.2.2 Speaker's Veracity

In the full video set, participants play 68 rounds (29 truthful and 39 deceptive). Occasionally, deceptive rounds also contain truthful statements, in which contestants describe parts of the object truthfully, but other parts deceptively, turning the overall description into a lie. For example, a contestant might say: "I have before me, a green lobster on a plate." In truth, the object is a red lob-

Figure 1: Sample screenshots of truthful and deceptive behavior from the original videoclips; left-top (truthful) : Eyebrows-raising, Eyes-open; left-bottom (truthful): Eyebrows-neutral, Eyes-open; right-top (deceptive): Eyebrows-frowning, Eyes-closing (both); right-bottom (deceptive): Eyebrows-raising, Eyes-closing (both).

ster on a plate. The description contains truthful and deceptive aspects, but it is considered to be a deceptive round since the main purpose of the statement is to deceive. This fine-grained distinction is captured during the annotation of behaviors, described below, which allows us to obtain more precise veracity labels of the behavior. In our example, the behavior associated with the description "green" is labeled as deceptive, whereas all the other behaviors are labeled as being truthful.

To enable this annotation, we further process our initial turn-by-turn segmentation to obtain spoken segments by either of the participants. We then code the veracity (i.e., truthful or deceptive) for each verbal statement of the participants. During the veracity coding, we assume that the behavior is always deceptive unless the verbal description indicates otherwise (i.e., accurate description of the object), as the general goal of each participant is to deceive their opponent. The final distribution of these annotations is 862 utterances labeled as deceptive, and 187 as truthful. Figure 1 shows examples of truthful and deceptive behaviors in the dataset.

3.3 Transcriptions

In order to include linguistic features in our analyses, we first transcribe the participants' conversations. To obtain transcriptions, we first extract the

	Kappa

General Face	0.75	0.70
Eyebrows	0.51	0.70
Eyes	0.56	0.92
Gaze	0.45	0.74
Mouth-Openness	0.64	0.47
Mouth-Lips	0.79	0.53
Head	0.60	0.55
Feedback receiving	0.47	0.72
Feedback eliciting	0.73	0.46
Average	0.61	0.64

Table 2: Inter-annotator agreement

	Truthful	Deceptive	Total
Host	749	4211	4960
Guests	748	2496	3244
Total	1497	6707	8204

Table 3: Distribution of words for all transcriptions

audio of the corresponding video clip and slice it based on the verbal annotation time-stamps. For this task, we use Pympi (Lubbers and Torreira, 2013) and Ffmpy (Developers, 2016). We transcribe the resulting audio clips using Amazon Mechanical Turk (AMT), a crowd-sourcing platform. We notice that some of the clips include brief interruptions among speakers, thus we ask the AMT workers to transcribe only the speech of the main speaker in the audio clip. After we collect all transcriptions, we proofread them to avoid mistakes such as double transcriptions and remove additional characters or descriptions (e.g. “person 1”, clapping, [pause]). The final distribution of all the words from the transcriptions is shown in Table 3. Example utterances of truthful and deceptive statements are displayed in Table 4.

4 Methodology

Gathering data from different modalities creates the need to combine them into a coherent feature set, which can be utilized by machine learning classifiers. The following subsections describe how we generate features based on our annotations for the verbal and non-verbal behavior components of the dataset. These features are then used to train and test the classifiers in our experiments.

4.1 Linguistic Features

We derive various linguistic features from the transcriptions of the participants’ speech, which include: unigrams, psycholinguistic features, part of speech features, and word embedding features.

Unigrams. These features are created with bag-of-words representations of all transcriptions from the guests and the host. The unigrams are represented using their frequencies.

Psycholinguistic Features. These features are created with the help of the Linguistic Inquiry and Word count Lexicon (Version 2015) (Pennebaker et al., 2007). They represent 80 different classes of words, which can be attributed to different psychological dimensions. The features display the frequencies of occurrences of classes, derived from the occurrences of words, attributed to each class. The lexicon has been successfully used in previous work for automatic deception detection (Ott et al., 2013; Mihalcea et al., 2013).

Part of Speech tags (PoS). These features are created by obtaining PoS-tagging of transcripts. They capture the grammatical and syntactical structure of the utterances of the transcriptions (e.g., noun, verb, adjective). Features display the distribution of these categories in percentage for each utterance.

Word Embeddings. These features are obtained using Word2Vec by creating vector representations of the words in the transcriptions. By training word representations based on other words occurring in the same context, these features capture similarities of words next to each other and in context. Together, all words are represented in a vector space in which similar words lay closer to each other as compared to dissimilar words.

4.2 Non-verbal Behavioral Features

These features are generated from the non-verbal behaviors described in Section 3.2 and represented as percentages. Specifically, the different behavioral values for a category (e.g., Head) in a verbal utterance are counted and represented as percentages. For example, a verbal utterance might last for one minute and during that time head movements might take several different values, such as *side-turn* (20 sec.), *shake* (30 sec.), and *single nod* (10 sec.). These times are transformed into percentages and the category *head* then consist of 33.33% *side-turn*, 50% *shake*, and 16.67% *single nod* during the one-minute utterance. In this manner, each facial area designates its percentage representation of behavioral values, which add up to 100%. In case a behavior cannot be fully attributed to one of the possible actions through the verbal statement, left-over percentages are assigned to

Participant	**Truthful**	**Deceptive**
Host	”In a, no. In a costume and also inside the box, a bunch of Hershey kisses.”	”Ever heard of a boy band called Backstreet Boys?”
Guest	”Ok, it is, um, a rubiks cube inside jello.”	”Okey. Its a toaster oven. Ohhh ha ha ha ha”

Table 4: Examples of utterances from the transcriptions

none, representing the lack of occurrence of a behavioral action in its category. This transformation is performed for all seven different facial areas we have annotated, including General Facial Expressions, Eyebrows, Eyes, Gaze, Mouth-Openness, Mouth-Lips, and Head.

Our non-verbal behavior feature set thus consists of all the facial expressions or head movements expressed as the percentage of times they occur during a speaker's utterance. Possible attributes for each of the seven categories can be found in Table 1.

4.3 Dialogue Features

We derive dialogue-based features by exploring verbal and non-verbal aspects of the interaction between participants that are related to deceptive behavior. The features attempt to capture deception cues the speaker's exhibited during their conversation prior to the current utterance. These features are obtained as follows:

Deception Changes. These features include the count of truthful and deceptive utterances up to the current utterance. We also aggregate the counts of deceptive and truthful utterances to represent the participation of the speaker during the conversation.

Non-verbal Changes. These features capture how facial displays differ between consequent utterances. We calculate these features by subtracting the numeric vectors representing the non-verbal behavior during the current utterance from the previous utterance.

4.4 Data Alignment

In order to attribute the corresponding non-verbal behaviors to verbal utterances for later classification tasks, each behavior receives a veracity label (truthful or deceptive) individually. The veracity label that overlaps with a behavior for more than 50% of its span, it is associated with that behavior. The overlap is determined by comparing the time stamp of the behavior and the veracity annotation, which are obtained from the ELAN files. Table 5 displays the distribution of these feature sets.

Participant	Lies	Truths	All
Guests	394	101	495
Host	468	85	553
All	862	187	1048

Table 5: Class distribution for host and guest features

5 Human Performance

In order to evaluate the automated methods and compare them to human performance, we establish a human baseline, representing how well humans guess deceptive and truthful behavior correctly. Since the game show Box of Lies is already set up in a way that participants have to guess if their opponent is lying or telling the truth, their performance serves as a baseline.

Thus, we use their assessments to obtain a confusion matrix showing their correct and incorrect guesses. We calculate their performance in terms of accuracy, which reflects the proportion of correctly categorized descriptions of all object descriptions; precision, which reflects the proportion of correctly identified descriptions in one classified category; recall, which reflects the proportion of correctly identified descriptions out of all the object descriptions truly belonging to that category; and f1-score, which reflects the weighted average of precision and recall in that category.

Human performance is shown in Table 6. Since participants tell 39 deceptive and 29 truthful descriptions in total, the distribution is slightly uneven, resulting in a baseline of 0.57 in detecting a lie. Considering this, participants and the overall accuracy is almost equal to the accuracy of random guessing. This supports earlier findings that humans are almost only as good as chance (Bond and DePaulo, 2006).

Results for each class (detecting truthful or deceptive descriptions) show that participants are better at detecting truthful descriptions. This could be based on the truth bias, which describes the phenomenon according to which people generally tend to believe others (Levine et al., 1999).

		Lie			Truth		
	Acc.	P	R	F	P	R	F
Guests	55%	0.67	0.26	0.38	0.51	0.86	0.64
Host	58%	0.17	0.17	0.17	0.72	0.72	0.72
All	56%	0.47	0.24	0.32	0.58	0.79	0.67

Table 6: Human performances in the game "Box of Lies"; Acc. = Accuracy; P = Precision; R = Recall; F = F1; Baseline (detecting a lie) = 0.57

6 Experiments

During our experiments, we use a Random Forest classifier. We perform all the classification experiments with the python package Scikit-learn (Pedregosa et al., 2011) using the standard settings for the model parameters. All classifiers are evaluated using five-fold cross-validation. During our experiments we focus on three scenarios:

(1) How well can we distinguish between truthful and deceptive utterances in the dataset? In this scenario, we explore whether the different features we propose can capture differences between truthful and deceptive behavior, regardless of the speaker. Note that in this scenario, a significant fraction of the data comes from the same speaker (host).

(2) How well can we distinguish between truthful and deceptive behaviors elicited by the guests? In this experiment, we consider the subset of deceptive and truthful utterances produced by the guests in our dataset. Again, we test our different feature sets in the prediction of truthful and deceptive behavior, but this time we focus on learning deceptive patterns from several individuals, which might exhibit different verbal and non-verbal behaviors.

(3) How well can we distinguish between truthful and deceptive behaviors exhibited by the host? In this scenario, we explore whether the availability of data by the same individual can help to improve the detection of deceptive behavior. In other words, this experiment builds personalized deception models for the host using the different sets of features representing verbal and non-verbal behavior.

For each scenario, we test classifiers with features derived from the different verbal and non-verbal modalities as well as features that represent the interaction between participants (described in Sections 4.1, 4.2 and 4.3). We test the predictive power of each feature set individually and we also build joint models that combine all feature sets. The classifiers performance is evaluated in terms of accuracy, precision, recall, and f1-score.

An important challenge during the experiments is that the nature of our dataset leads to a high unbalance between the truthful and deceptive classes, as shown in Table 5. During our experiments, the imbalance of the data is tackled by applying down-sampling to the deceptive class (Oliphant, 2006). This ensures an equal distribution of each label and results in a baseline of 0.50 in all scenarios. The results for verbal, non-verbal, dialog features, and their combination for each scenario are shown in Table 7.

Overall, our experiments show the benefit of combining multiple sources of information on this task, with accuracies well above the baseline and a noticeable accuracy improvement when using all feature sets.

7 Discussion

The different classification performances show that adding information from several modalities helps to increase the accuracy of the detection system. Not surprisingly, the linguistic modality shows the best performance among single modalities (Scenarios 1 and 2). More interestingly, the non-verbal modality is the second best indicator of deception, despite a significant amount of facial occlusions present in our dataset.[3] Furthermore, this finding is in line with other work on multi-modal deception detection also showing that gestures are a reliable indicator of deception (Perez-Rosas et al., 2015).

In addition, we generate learning curves for each modality in scenario 1 (figure 2). The curves show that when training with 50 - 60% of the data, the classifier starts to improve upon the (guessing) baseline. The ascending trend does not seem to level off, even with the entire dataset, indicating that the classifier might benefit from more data.

Our experiment on exploring the classification of deceptive behaviors from the host (scenario 3) also lead to interesting insights. First, the linguistic modality is the weakest since it obtained the lowest performance in both classes. As the difference in f-score values shows, the host does not appear to use significantly different language while telling lies or truths, at least not at the lexical and semantic level, as captured by our linguistic features. Second, his non-verbal behavior does

---

[3] Facial occlusions are mainly attributed to changes in camera angles occurring during the videos

			Lie			Truth		
Scenario	Features	Acc.	P	R	F	P	R	F
(1) General truths and lies	Linguistic	62%	0.61	0.67	0.64	0.63	0.57	0.6
	Dialog	54%	0.54	0.56	0.55	0.54	0.52	0.53

	Dialog	57%	0.58	0.52	0.55	0.56	0.61	0.59
	Non-verbal	61%	0.60	0.62	0.61	0.61	0.58	0.60
	All Features	69%	0.66	0.76	0.71	0.72	0.61	0.69
(3) Lies and truths by host	Linguistic	55%	0.55	0.60	0.57	0.56	0.51	0.53
	Dialog	58%	0.58	0.61	0.59	0.59	0.55	0.57
	Non-verbal	57%	0.56	0.62	0.59	0.58	0.52	0.55
	All Features	65%	0.67	0.61	0.64	0.64	0.69	0.67

Table 7: Automated performances for the three analyzed scenarios.The baseline for all scenarios (detecting a lie) is 50%; Acc. = Accuracy; P = Precision; R = Recall; F = F1-score

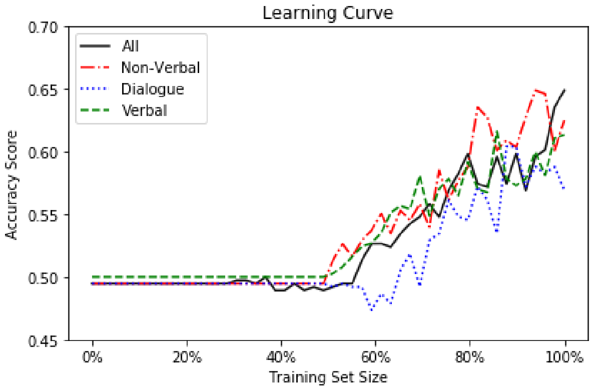

Figure 2: Learning curves (averaged 5-fold cross validation) for each modality using random forest (general truth/lie scenario)

seem to be different while telling lies and truths as we observe noticeable improvement in the models build with non-verbal cues. Third, the performance of the dialog features suggests that having evidence of previous behavior (as captured by deception changes and non-verbal behavior changes) can be useful when modeling the deceptive behavior of a single individual, further suggesting that the non-verbal component of a lie seems to be more individually shaped for each person as opposed to the linguistic component. However, the differences in performance between scenarios 1 and 2 suggest that the current features might not be enough to capture deceptive behavior by a single individual since the developed classifiers still find this task challenging.

The preliminary analyses of this new multimodal dataset show promising results by successfully classifying truthful and deceptive behaviors. Currently, the dataset provides feature sets drawn from three modalities (verbal and non-verbal, as well as dialogue) but can be further analyzed to extract additional features from other modalities such as speech. Specifically, the dialogue has the potential to add many more layers of information by systematically analyzing verbal, non-verbal, and speech patterns between the participants. These patterns can lead to detectable differences between actions and reactions within a dialogue (Tsunomori et al., 2015; Levitan et al., 2016). We consider analyzing such patterns as a future research venue to expand the analyses on our dataset.

A challenge while using this data is the current imbalance of truthful and deceptive feature sets, which can have a detrimental effect on classification performance. However, there are several other possible ways to address this issue other than down-sampling as we did during our experiments. For instance, other computational methods could be explored, such as one-class classification tasks. Such models train on a dataset from the same distribution and classify new data as being similar or different to that distribution. This way, anomalies (i.e., behavior with a feature configuration different from the training set) are detectable. Since truthful behavior is underrepresented in our dataset, the deceptive features could serve as the training set and the goal is to detect truthful behavioral patterns. Expanding on other computational tasks also tackles future applicable problems of dealing with uneven datasets, as they are often present when working with real-life datasets. The issue of an underrepresented class is prevalent in deception detection research.

Finally, the dataset could be expanded with more behavioral data, mainly by augmenting the number of truthful behaviors. Since all the contestants in our dataset are celebrities, it is likely that other videos portraying them are available.

8 Conclusion

In this paper, we showed how we can successfully build a multimodal dialog dataset for deception detection, and presented exploratory deception classification tasks. We showed how we can integrate multiple modalities and build feature sets useful for automated processing. We were able to achieve a classification performance that is better than random guessing and exceeds human performance. Furthermore, additional modalities systematically showed an improvement in classification performance. The best performance of 69% was obtained by combining multiple verbal, nonverbal, and dialogue feature sets, which represents a significant improvement over the human performance of a maximum of 58% accuracy.

The dataset introduced in this paper represents a first attempt to integrate the dialogue dimension with multiple other modalities in deception detection research. It has the potential of triggering novel research on multimodal deception data, specifically for speech and the dialogue dimension, which should be explored in the future.

All the data annotations described in this paper are available upon request.

Abstract

We present a corpus of anaphoric information (coreference) crowdsourced through a game-with-a-purpose. The corpus, containing annotations for about 108,000 markables, is one of the largest corpora for coreference for English, and one of the largest crowdsourced NLP corpora, but its main feature is the large number of judgments per markable: 20 on average, and over 2.2M in total. This characteristic makes the corpus a unique resource for the study of disagreements on anaphoric interpretation. A second distinctive feature is its rich annotation scheme, covering singletons, expletives, and split-antecedent plurals. Finally, the corpus also comes with labels inferred using a recently proposed probabilistic model of annotation for coreference. The labels are of high quality and make it possible to successfully train a state of the art coreference resolver, including training on singletons and non-referring expressions. The annotation model can also result in more than one label, or no label, being proposed for a markable, thus serving as a baseline method for automatically identifying ambiguous markables. A preliminary analysis of the results is presented.

1 Introduction

A number of datasets for anaphora resolution / coreference now exist (Poesio et al., 2016), including ONTONOTES that has been the de facto standard since the CONLL shared tasks in 2011 and 2012 (Pradhan et al., 2012), and the just introduced and very substantial PRECO corpus (Chen et al., 2018). None of these datasets however take into account the research challenging the idea that a 'gold standard' interpretation can be obtained through adjudication, in particular for anaphora (Poesio and Artstein, 2005b; Wong and Lee, 2013; Aroyo and Welty, 2015). Virtually every project devoted to large-scale annotation of discourse or semantic phenomena has reached the conclusion that genuine disagreements are widespread. This has long been known for anaphora (Poesio and Artstein, 2005b; Versley, 2008; Recasens et al., 2011) (see also the analysis of disagreements in ONTONOTES in (Pradhan et al., 2012)) and wordsenses (Passonneau et al., 2012), but more recent work has provided evidence that disagreements are frequent for virtually every aspect of language interpretation, not just in subjective tasks such as sentiment analysis (Kenyon-Dean et al., 2018), but even in the case of tasks such as part-of-speech tagging (Plank et al., 2014). In fact, researchers in the CrowdTruth project view disagreement as positive, arguing that "disagreement is signal, not noise" (Aroyo and Welty, 2015). In this paper we present what to our knowledge is the largest corpus containing alternative anaphoric judgments: 20.6 judgments per markable on average (up to 90 judgments in some cases) for about 108,000 markables. We are not aware of any comparable resource for studying disagreement and ambiguity in anaphora or indeed any other area of NLP. We present some preliminary analysis in the paper.

The corpus presented in this paper is also the largest corpus for anaphora / coreference entirely created through crowdsourcing, and one of the largest corpus of coreference information for English in terms of markables. So far, only fairly small coreference corpora have been created using crowdsourcing (Chamberlain et al.; Guha et al., 2015). The corpus presented here provides annotations for about 108,000 markables, 55% of the number of markables in ONTONOTES. Another novelty is that the corpus was created through a 'quasi' Game-With-A-Purpose (GWAP) (von Ahn, 2006; Lafourcade et al., 2015), *Phrase Detectives* (Poesio et al., 2013), and is, to our knowledge, the largest GWAP-created corpus for NLP. (So far, the success of GWAPs in other areas of science (Clery,

Proceedings of NAACL-HLT 2019, pages 1778–1789
Minneapolis, Minnesota, June 2 - June 7, 2019.

2011; Cooper et al., 2010) has not been replicated in NLP.) Finally, the corpus is notable for a richer annotation scheme than the other large coreference corpora. Singletons were marked as well as mentions participating in coreference chains (the omission of singletons being one of the main problems with ONTONOTES). Non-referring expressions were also annotated: both expletives (not annotated either in ONTONOTES or PRECO) and predicative NPs. Finally, all types of plurals were annotated, including also **split-antecedent** plurals as in *John met with Mary, and they went to dinner*, which again are not annotated either in ONTONOTES or PRECO.

Turning a crowdsourced corpus into a high-quality dataset suitable to train and evaluate NLP systems requires, however, an aggregation method appropriate to the data and capable of achieving sufficient quality, something that simple majority voting typically cannot guarantee (Dawid and Skene, 1979; Hovy et al., 2013). What made it possible to extract such a dataset from the collected judgments was the recent development of a probabilistic method for aggregating coreference annotations called MPA (Paun et al., 2018b). MPA extracts silver labels from a coreference annotation and associates them with a probability, allowing for multiple labels in cases of ambiguity. As far as we know, ours is the first use of MPA to create a large-scale dataset. We show in the paper that MPA can be used to extract from the judgments a high quality coreference dataset that can be used to develop standard coreference resolvers, as well as to investigate disagreements on anaphora.

2 Background

2.1 Datasets for Anaphora/Coreference

Since the two CONLL shared tasks (Pradhan et al., 2012), ONTONOTES has become the dominant resource for anaphora resolution research (Fernandes et al., 2014; Björkelund and Kuhn, 2014; Martschat and Strube, 2015; Clark and Manning, 2015, 2016a,b; Lee et al., 2017, 2018). ONTONOTES contains documents in three languages, Arabic (300K tokens), Chinese (950K) and English (1.6M), from several genres but predominantly news. One frequently discussed limitation of ONTONOTES is the absence of singletons (De Marneffe et al., 2015; Chen et al., 2018), which makes it harder to train models for mention detection (Poesio et al., 2018). Another limitation is that expletives are not annotated. As a consequence, downstream applications such as machine translation (Guillou and Hardmeier, 2016) that require pronoun interpretation have to adopt various workarounds. Because of these two restrictions, ONTONOTES only has 195K markables, and a low markable density (0.12 markable/token).

A number of smaller corpora provide linguistically richer information (Poesio et al., 2016). Examples include ANCORA for Spanish (Recasens and Martí, 2010), TUBA-D/Z for German (Hinrichs et al., 2005), the Prague Dependency Treebank for Czech and English (Nedoluzhko et al., 2009), and ARRAU for English (Uryupina et al., To Appear). In ARRAU, for example, singletons and expletives are annotated as well, as are split antecedent plurals, generic coreference, discourse deixis, and bridging references. The ARRAU corpus is relatively small in terms of tokens (350K), but has a higher markable density than ONTONOTES (0.29 markable/token), so it has around 100K markables, half the number of ONTONOTES. ARRAU was recently used in the CRAC 2018 shared task (Poesio et al., 2018) to evaluate a number of anaphora resolution tasks.

The recently introduced PRECO corpus (Chen et al., 2018) is the largest existing coreference corpus, consisting of 35,000 documents for a total of 12.5M tokens and 3.8M markables, half of which are singletons. However, the corpus is not intended as a general purpose dataset as only the 3000 most common English words appear in the documents (the majority - 2/3 - of the documents are from Chinese high-school English tests). The corpus's annotation scheme mainly follows the ONTONOTES guidelines, with a few important differences: singleton mentions and generic coreference are annotated, event anaphora is not, and predicative NPs are annotated as co-referring with their argument, as previously done in the MUC (Grishman and Sundheim, 1995; Chinchor, 1998) and ACE (Doddington et al., 2004) corpora.[1] As one could expect, the corpus is relatively easy for coreference systems. The Peters et al. (2018) system trained and tested on PRECO achieves an av-

---

[1] An example of predicative NP is *24 degrees* in *The temperature is 24 degrees*. As discussed by van Deemter and Kibble (2000), annotating *The temperature* and *24 degrees* as coreferent would result in nonsensical coreference chains for sentences like *The temperature was 24 degrees but it is 27 degrees now.* As a result, such markables were annotated as predicative in recent corpora. It's not clear why we find a return to the old practice in PRECO.

erage CONLL score of 81.5%, whereas the same system trained and tested on ONTONOTES only achieves a score of 70.4%.

2.2 Crowdsourcing and GWAPs for NLP

A revolution in the way language annotation tasks are carried out was achieved by **crowdsourcing** (Howe, 2008; Snow et al., 2008). Crowdsourcing comes in many forms, including **citizen science** and **microworking**. A third approach is to use a **game-with-a-purpose (GWAP)** to aggregate data from non-expert players for collective decisions similar to those from an expert (von Ahn, 2006). The game-based approach to collecting language data is initially costly, but once a game is deployed it can continue to collect data with very little financial support, especially if there is an active community. GWAPs such as *Phrase Detectives* (Poesio et al., 2013), *JeuxDesMots* (Joubert and Lafourcade, 2008) and *Zombie Lingo* (Fort et al., 2014) have been used in NLP to collect data on specific linguistic features; broader platforms such as Wordrobe (Venhuizen et al., 2013) to gamify the entire text annotation pipeline.

Crowdsourcing is the most realistic approach to collect a large number of judgments about phenomena such as anaphora. Games in particular are the one type of crowdsourcing scalable to the goal of, for example, a 100M word corpus. So far, however, only small and medium scale resources for NLP have been created via crowdsourcing. For coreference we are only aware of two, both around 50K tokens in size (Chamberlain et al.; Guha et al., 2015). The Groningen Meaning Bank being collected through the Wordrobe platform (Bos et al., 2017) includes many more documents, but so far only very few interpretations have been obtained through the games (e.g., only around 4K judgments have been collected for anaphora).

2.3 Collecting Multiple Judgments

In most of the best known efforts at creating anaphoric corpora for English and other languages substantial disagreements between the coders were observed, but none of the resulting resources contains multiple anaphoric interpretations. Systematic analyses of the disagreements among coders observed in such annotation efforts were provided for ANCORA by Recasens et al. (2011) and for TUBA-D/Z by Versley (2008). The entire ONTONOTES corpus was double annotated, finding disagreements on around 20% of the markables, i.e., around 40,000 cases. An analysis of such disagreements can be found in (Pradhan et al., 2012), but ultimately only the result of adjudication was included in the corpus. Most of the PRECO corpus was doubly annotated and the results adjudicated, but only the result of adjudication is released.

We are aware of only two corpus annotation schemes which explicitly allowed the annotation of anaphoric ambiguity: ARRAU and the Potsdam Commentary Corpus (Krasavina and Chiarcos, 2007). Most of the ARRAU corpus was single-annotated by a highly experienced annotator, who was allowed to mark a variety of cases of ambiguity (Poesio and Artstein, 2005b). It is known, however, that such explicit marking of ambiguity is difficult (Poesio and Artstein, 2005b; Recasens et al., 2012), and indeed not many cases of ambiguity were marked in this way in ARRAU.

3 Collecting the Judgments

In this Section we discuss what type of judgments were collected, and how.

3.1 A gamified approach

The gamified online platform *Phrase Detectives*[2] (Chamberlain et al., 2008; Poesio et al., 2013) was used to collect the judgments about anaphoric reference included in the corpus. *Phrase Detectives* is articulated around a number of tasks centered around the detective metaphor and uses scoring, progression and a variety of other mechanisms to make the activity enjoyable. In **annotation mode** (*Name the Culprit*), the participant provides an anaphoric judgment about a highlighted markable (the possible judgments according to the annotation scheme are discussed next). If different participants enter different interpretations for a markable then each interpretation is presented to other participants in **validation mode** (*Detectives Conference*), in which the participants have to agree or disagree with the interpretation.

One of the key differences between *Phrase Detectives* and GWAPs such as those developed by von Ahn and his lab (von Ahn, 2006) is the much greater complexity of judgments required. Yet clearly we cannot expect participants to be experts about anaphora, or to be willing to read a manual explaining the annotation scheme, so all the training still has to be done while playing the game.

---

[2] `http://www.phrasedetectives.com`

Therefore, we developed a number of mechanisms that could help in this respect: giving suggestions and tips (global, contextual and FAQ), comparing decisions with the gold standard, and showing agreement with other players in Validation Mode. When participants begin to play they are shown training texts (in which the answer is known from a gold standard) and get feedback as to whether their decisions agree with the gold standard. Once the player has completed all training tasks they are given a user rating (the percentage of correct decisions out of the total number of training tasks).

As of 17th of March 2019, 60,822 individuals have participated in *Phrase Detectives* over ten years and using different platforms, providing over 4.26 million judgments, about half of which are included in the present release.

3.2 Types of Judgments

The judgments asked to the participants to *Phrase Detectives* follow a simplified version of the ARRAU annotation scheme, which is the result of extensive tests for intercoder agreement (Uryupina et al., To Appear). The participants are asked to make two basic distinctions: whether a markable is referring or not, and if referring, whether it is **Discourse-Old** (DO), i.e., it refers to an entity already mentioned (in which case the players were asked to indicate the latest mention of that entity), or **Discourse-New** (DN), i.e., it introduces a new entity in the discourse. Anaphoric reference marked include **split antecedent** anaphora, as in *John met Mary, and they went out for drinks*, where the antecedent for *they* is the set consisting of the separately introduced *John* and *Mary*. Two types of non-referring expressions were marked: **expletives**, as in *It's five o'clock* or *There was a fireplace in the room*; and **predicative NPs**, as in *The temperature is 24 degrees*. In the case of predicative NPs, players were asked to mark the nearest mention of the entity that the predication applied to, following in this case the ONTONOTES approach instead of ARRAU's.

The key difference between this corpus and any other existing corpus for anaphora / coreference with the exception of ARRAU is that the corpus was designed to collect information about disagreement. The main difference from ARRAU is that no attempt was made to ask players to identify ambiguity, as that has proven hard or impossible to do (Poesio and Artstein, 2005b). Instead of **explicit (marking of) ambiguity**, the developers relied on **implicit ambiguity**: that genuine ambiguity would emerge if enough players supplied judgments. All the judgments produced by the players were therefore stored, without attempting to choose among them at collection.

The differences between the four corpora being compared are summarized in Table 1, modelled on a similar table in (Chen et al., 2018). In the *Phrase Detectives* corpus predication and coreference are clearly distinguished, as in ONTONOTES and ARRAU but unlike in PRECO. Singletons are considered markables. Expletives and split antecedent plurals are marked, unlike in either ONTONOTES or PRECO. Most importantly, ambiguity of anaphoric interpretation (as in the example from the TRAINS corpus (Poesio and Artstein, 2005b)) is marked, but implicitly, i.e., by asking the judgment of at least 8 players per markable, as opposed to explicitly, as attempted in ARRAU (with little success).

3.3 Markable identification

Following standard practice in anaphoric annotation and GWAPs, the markables to be annotated were not identified by the participants themselves; instead, markable identification was carried out semi-automatically. Each document would first be processed by a pipeline combining off-the-shelf tools (sentence splitting and tokenization using the OpenNLP pipeline[3] and parsing using the Berkeley Parser (Petrov and Klein, 2007)) and custom preprocessing and post-processing heuristic steps to correct the output. (See (Poesio et al., 2013) for more details about the pipeline and its performance.) Then one of the administrators would carry out a quick check of the document removing the most obvious mistakes before uploading it. After the document was uploaded, participants could report markable errors, which would then be corrected by hand.[4]

4 The corpus

4.1 Basic statistics

This second release of the *Phrase Detectives* corpus consists of a total of 542 documents contain-

---

[3] `http://opennlp.apache.org`

[4] As participants report over 10,000 errors per year, it became quickly apparent that carrying out the corrections ourselves was unfeasible. In subsequent work, we developed a gamified approach to markable identification and correction centered around the *TileAttack!* GWAP (Madge et al., 2017).

Type	**Example**	ONTONOTES	PRECO	ARRAU	Present corpus
predicative NPs	[John] is a teacher [John, a teacher]	Pred	Coref	Pred	Pred
singletons		No	Yes	Yes	Yes
expletives	It's five o'clock	No	No	Yes	Yes
split antecedent plurals	[John] met [Mary] and they ...	No	No	Yes	Yes
generic mentions	[Parents] are usually busy. Parents should get involved	Only with pronouns	Yes	Yes	Yes
event anaphora	Sales [grew] 10%. This growth is exciting	Yes	No	Yes	No
ambiguity	Hook up [the engine] to [the boxcar] and send it to Avon	No	No	Explicit	Implicit

Table 1: Comparison between the annotation schemes in ONTONOTES, PRECO, ARRAU and the present corpus

		Docs	Tokens	Markables
PD_{gold}	Gutenberg	5	7536	1947 (1392)
	Wikipedia	35	15287	3957 (1355)
	GNOME	5	989	274 (96)
	Subtotal	45	23812	6178 (2843)
$\text{PD}_{\text{silver}}$	Gutenberg	145	158739	41989 (26364)
	Wikipedia	350	218308	57678 (19444)
	Other	2	7294	2126 (1339)
	Subtotal	497	384341	101793 (47147)
All	Total	542	408153	107971 (49990)

Table 2: Summary of the contents of the current release. The numbers in parentheses indicate the total number of markables that are non-singletons.

	1	2	3	4	5	6	7
PD_{gold}	38.8	30.6	18.5	7.3	2.5	1.0	0.6
$\text{PD}_{\text{silver}}$	36.0	30.0	19.0	8.8	3.8	1.8	0.8

Table 3: Percentage of markables with X distinct interpretations

ing 408K tokens and 108K markables from two main genres: Wikipedia articles and fiction from the Gutenberg collection. This corpus is divided in two subsets. The subset we refer to as $\text{PD}_{\text{silver}}$ consists of 497 documents, for a total of 384K tokens and 101K markables, whose annotation was completed–i.e. 8 judgments per markable were collected, and 4 validations per interpretation–as of 12th of October 2018. In these documents, an aggregated ('silver') label obtained through MPA (see next Section) is also provided. 45 additional documents were also gold-annotated by two experts annotators. We refer to the subset of the corpus for which both gold and silver annotations are available as PD_{gold}, as it is intended to be used as test set.[5] The gold subset consists of a total of 23K tokens and 6K markables. The contents of the corpus are summarized in Table 2.

By comparison, the English corpus used for the CONLL 2011 and 2012 shared tasks consists of 3493 documents, for a total of 1.6M tokens and 194480 markables. In other words, although the current release of the corpus is only about 25% of the CONLL corpus in terms of tokens, it is 55.5% of its size in terms of annotated markables, i.e., actual training / testing items.

4.2 Number of Judgments

In total, 2,235,664 judgments from 1958 players are included in the current release, of which 1,358,559 annotations and 867,844 validations. On average, 20.6 judgments were collected per markable: 12.6 annotations and 8 validations. In addition, around 10K expert judgments were collected for the gold portion of the corpus from two expert annotators. This compares with 600K estimated judgments for the entire ONTONOTES corpus, about 3 per markable (total number of annotators not known), and around 10M for PRECO, also 3 per markable, from about 80 annotators.

4.3 Disagreement: a preliminary analysis

The 'raw' statistics about disagreement in the corpus are shown in Table 3. In total, only 35.7% of the markables in the corpus (38,579) were assigned only one interpretation by the participants, whereas 64.3% received more than one interpretation. This figure would seem to suggest massive ambiguity, but we are not saying that 64.3% of markables in the corpus are ambiguous. As already pointed out e.g. in (Pradhan et al., 2012),

---

[5] $\text{PD}_{\text{gold}}$is the dataset released in 2016 as *Phrase Detectives* corpus, Release 1 (Chamberlain et al.).

there are a number of reasons for disagreements among coders / players apart from ambiguity. In the case of ONTONOTES, the causes for the 20,000 observed disagreements include:

- Ambiguity proper, i.e., unclear interpretation ('Genuine Ambiguity' in (Pradhan et al., 2012)) and/or disagreement on reference (31% of the disagreements in ONTONOTES, around 7% of all markables);
- Annotator error (another 25% of the cases of disagreement in ONTONOTES);
- Various limitations of the coding scheme: unclarity in the guidelines, inability to mark certain types of coreference e.g., between generics, etc. (36.5% of the cases of disagreement in ONTONOTES).
- Interface limitations (around 7.5% of the disagreements in ONTONOTES).

Some of the disagreements due to other causes–and in particular annotation errors–can be filtered through validation, i.e., by excluding those interpretations of a markable for which the **validation score** (annotations + agreements - disagreements) falls below a threshold. For example, if only interpretations with a validation score > 0 are considered, we find that 51,075 / 107,971 markables have at least two such interpretations, i.e., 47.3% of the total, which is considerably less than the 64.3% of markables with more than one interpretation, but it's still a large number.

We will discuss a more sophisticated method for automatically identifying plausible interpretations, as well as the results of a preliminary hand-analysis of the disagreements in a few documents in our corpus, in Section 7.

5 Aggregation

5.1 Probabilistic Aggregation Methods

The data collected via *Phrase Detectives* require an aggregation method to help choose between the different interpretations provided by the players. Simple heuristics such as majority voting are known to underperform compared to probabilistic models of annotation (Whitehill et al., 2009; Raykar et al., 2010; Quoc Viet Hung et al., 2013; Sheshadri and Lease, 2013; Hovy et al., 2013; Passonneau and Carpenter, 2014; Paun et al., 2018a). The models offer a rich framework of interpretation and can employ distinct prior and likelihood structures (pooled, unpooled, and partially pooled) and a diverse set of effects (annotator ability, item difficulty, or a subtractive relationship between the two). However, most work on models of annotation assumes that the set of classes the annotators can choose from is fixed across the annotated items, which is not the case for anaphoric annotation. More specifically, in *Phrase Detectives* the participants can classify a markable as non-referring (expletive or predicative); as introducing a new discourse entity; or as discourse-old, in which case they link it to the most recent mention of its antecedent–and coreference chains are document-specific and not fixed in number (see Section 3.2 for more details on the annotation scheme). Recently, however, Paun et al. (2018b) developed a probabilistic model (MPA) able to aggregate such crowdsourced anaphoric annotations.

5.2 MPA

In MPA, the term **label** is used to refer to a specific interpretation provided by a player, and the term **class** to refer to general interpretation categories such as discourse old, discourse new, expletive, or predicative NP. Please note that under this formalism each label belongs to a class: the antecedents belong to the discourse old category, while the other possible labels (e.g., discourse new) coincide with the classes they belong to. The model assumes a preprocessing step in which the markable-level annotations are transformed into a series of binary decisions with respect to each candidate label. MPA then models these (label-level) decisions as the result of the sensitivity (the true positive rate) and specificity (the true negative rate) of the annotators which it assumes are class dependent. This latter assumption allows inferring different levels of annotator ability for each class (thus capturing, for instance, the fact that whereas most participants are generally able to recognize discourse-new mentions, they are much less good at identifying correct antecedents).

5.3 Aggregating the game data

We use the MPA model as a component in a standard mention-pair framework to extract coreference clusters: 1) link each markable with the most likely label as identified by the model, and 2) follow the link structure to build the coreference

Method	Discouse old class			Discourse new class			Predicative NPs class			Expletives class			Avg. F1	Accuracy
	P	R	F1	P	R	F1	P	R	F1	P	R	F1		
MAJVOTE	**94.5**	62.8	75.4	79.1	**99.0**	87.9	53.9	9.7	16.4	**97.2**	71.4	82.4	65.5	82.9
MPA	90.4	**87.3**	**88.8**	**94.5**	96.0	**95.3**	**64.0**	**72.4**	**68.0**	94.1	**98.0**	**96.0**	**87.0**	**92.2**

Table 4: A per class evaluation of aggregated interpretations against expert annotations.

	Method	MUC			BCUB			CEAFE			Avg. F1
		P	R	F1	P	R	F1	P	R	F1	
Singletons included	MAJVOTE	**96.0**	63.9	76.7	**95.7**	78.7	86.4	77.1	**94.9**	85.1	82.7
	MPA	91.6	**82.4**	**86.8**	94.8	**87.8**	**91.2**	**92.4**	93.8	**93.1**	**90.3**
	STANFORD	65.4	62.4	63.8	78.9	76.1	77.5	78.4	85.2	81.7	74.3
Singletons excluded	MAJVOTE	**96.1**	64.8	77.4	**93.8**	45.0	60.8	66.3	48.5	56.1	64.8
	MPA	92.2	**89.2**	**90.7**	88.1	**77.8**	**82.6**	**79.5**	**80.2**	**79.8**	**84.4**
	STANFORD	65.7	62.1	63.9	50.3	42.5	46.1	42.7	49.8	46.0	52.0

Table 5: The quality of the coreference chains for the PD$_{\text{gold}}$ subset.

chains. We next evaluate both of these components against expert annotations.

Table 4 shows a per class evaluation of the aggregated interpretations from the PD$_{\text{gold}}$ subset. The results indicate an overall better agreement with the expert annotations of MPA compared with a simple majority voting (MAJVOTE) baseline. This is because MAJVOTE makes the an implicit assumption that the annotators have equal expertise, which is not true in general even with data crowdsourced on microworking platforms, and even more so with data collected through GWAPs (Paun et al., 2018a).

After inferring the mention pairs, coreference chains can be extracted and their quality assessed using standard coreference metrics. Table 5 presents the evaluation against gold chains in PD$_{\text{gold}}$. We compare the chains produced from the mention pairs inferred by MPA and by MAJVOTE, and the chains produced by the STANFORD deterministic coreference system (Lee et al., 2011) (for which we switched off post-processing to output singleton clusters). The results indicate a far better quality of the chains produced using MPA over the alternative methods. Another interesting result is that even a simple MAJVOTE baseline based on crowdsourced annotations performed far better than the STANFORD system, underlining the advantage of crowdsourced annotations for coreference over automatically produced annotations.

6 Using the corpus for coreference resolution

Some NLP researchers may question the usefulness of the information about disagreements for coreference resolution (or other NLP tasks). In this Section, we demonstrate that even those purely interested in CONLL-style coreference resolution can use the *Phrase Detectives* corpus aggregated with MPA as a dataset. We use PD$_{\text{silver}}$ to train a coreference system able to simultaneously identify non-referring expression and build coreference chains (including singletons). As no other system of this type exists at the moment, we developed one ourselves.

6.1 Our system

The system trained and tested on the corpus is a cluster ranking system that does mention detection and corefence resolution jointly. The system uses the mention representation from the state-of-the-art (Lee et al., 2018) system, but replaces their mention-ranking model with a cluster ranking model. Our cluster ranking model forms clusters by going through the candidate mentions in their text order and adding them to the clusters, which take into consideration the relative importance of the mentions. An attention mechanism is used to assign mentions within the clusters salience scores, and the clusters are represented as the weighted sums of the mention representations. Separate classifiers are used to identify non-referring markables and singletons.

Singletons	Method	MUC			BCUB			CEAFE			Avg. F1
		P	R	F1	P	R	F1	P	R	F1	
Included	Our Model	79.3	72.5	75.7	72.1	69.3	70.7	70.5	73.2	71.8	72.7
Excluded	Our Model	79.3	**72.5**	**75.7**	58.3	52.4	**55.2**	**58.3**	**49.5**	**53.5**	**61.5**
	Our Model*	77.8	71.8	74.6	55.4	**53.7**	54.6	56.2	49.0	52.4	60.5
	Lee et al. (2018)*	**80.8**	66.1	72.7	**63.3**	45.1	52.7	56.7	44.7	50.0	58.5

Table 6: The CoNLL scores for our systems trained on PD$_{\text{silver}}$ and tested on PD$_{\text{gold}}$. * indicates the models trained on the simplified corpus.

	P	R	F1
Non-referring	55.2	54.0	54.6
Expletives	62.3	86.0	72.3
Predicative NPs	49.7	47.7	48.7

Table 7: Non-referring scores for our model

6.2 Evaluation Methodology

We randomly chose 1/20 of PD$_{\text{silver}}$ as a development set and use the rest as the training set; PD$_{\text{gold}}$ was used as test set.

To get a baseline, we compare the results of our system on a simplified version of the corpus without singletons and expletives with those obtained by the current state-of-the-art system on ONTONOTES, Lee et al. (2018) trained and tested on the same data.

6.3 Results

Table 6 shows the results of both systems on the simplified corpus. Our cluster ranking system achieved an average CONLL score of 60.5%, outperforming the Lee et al. (2018) system by 2 percentage points. Note that the Lee et al. (2018) system achieved a higher score on the CONLL data, which suggests that the present corpus is different from that dataset.

In the same Table, we also report the results obtained by training our system on the full corpus including both non-referring expressions and singletons. This version of system achieves an average CONLL score of 72.7%.[6] We will note that although this score is on system mentions, it is very close to the score (74.3%) achieved by the Stanford deterministic system evaluated with gold mentions (see Table 5 in Section 5). Also, this model trained on the full corpus including singletons achieves a gain of 1 percentage point when compared with the model trained on the simplified corpus even when evaluated in a singleton excluded setting. This indicates that the availability of the singletons is also helpful for resolving non-singleton clusters. In total, this model achieved a CONLL score on singletons excluded of 3 percentage points 3% better than our baseline.

Regarding the task of identifying non-referring mentions, our model achieved a F1 score of 54.6% (see Table 7). The scores of the system on distinct types of non-referring expressions is presented in the following two rows of Table 7. Our model achieved a higher F1 score of 72.3% on expletives, and a lower score (48.7%) on predicative NPs.

Overall, these results–the first results on system mentions for PD$_{\text{gold}}$–suggest that the silver corpus is sufficient to train a state-of-the-art system and achieve a reasonably good performance. Also, that training a model on a corpus enhanced by singletons and non-referring markables results in a better CONLL score when compared with a model trained on the simplified corpus.

7 Disagreements, revisited

In the previous Section we showed that MPA can be used to extract a silver standard out of the annotations that is suitable to train a CONLL-style coreference resolver or an extended coreference resolver also attempting identification of singletons and non-referring expressions. The key property of the corpus however is the information it provides about disagreements. The second useful contribution of MPA is that it can be used to get an assessment of the ambiguity of markables which is more refined than that discussed in Section 4.3. For each markable, MPA assigns a probability to each interpretation. Given that the model does not assume the existence of a 'gold', there are three possible cases for each markable: either only one interpretation has a probability above a

---

[6] The Extended Coreference Scorer developed for the 2018 CRAC shared task (Poesio et al., 2018) was used to evaluate coreference chains on a corpus using singletons and to assess non-referring expressions identification.

	None	One	Two	Zero or more
$\mathrm{PD}_{\mathrm{gold}}$	2.3%	93.4%	4.3%	6.6%
$\mathrm{PD}_{\mathrm{silver}}$	3.5%	94%	2.4%	5.9%

Table 8: Ambiguity in the corpus according to MPA

certain threshold–say, 0.5; or more than one interpretation is above that threshold; or none is. This assessment of ambiguity according to MPA is summarized in Table 8.

This assessment appears to suggest a similar prevalence of ambiguity in our corpus than found in ONTONOTES in the already mentioned analysis by Pradhan et al. (2012). In order to verify this, two experts hand-analyzed 2 documents in $\mathrm{PD}_{\mathrm{gold}}$ containing a total of 900 markables: *Little Red Cap (LRC)* and *Robber Bridegroom* (RG). Given that each markable has on average 20 interpretations, and that player errors are frequent (there is at least one player error for almost every markable) it wasn't possible to use the same categories as Pradhan et al. Instead, we simply attempted to assign markables to one of the categories: **Genuine ambiguity (GA)**, **Interface or Coding Scheme Problem (ICP)**, **Other (O)**. The results are summarized in Table 9. The Table has one row per document. The first column lists the total number of markables in a document; the second (Dis) the percentage of markables on which there is disagreement; the third (GA) the percentage of the *total* number of markables which are cases of genuine ambiguity; and the fourth (ICP) the percentage which are cases of Interface or Coding Scheme Problem. As we can see from the Table, 9% of the total number of markables in these documents (80 out of 865) are genuinely ambiguous, i.e., that 12.6% of the disagreements (80 out of 633) are cases of genuine ambiguity. These are only preliminary figures, and we suspect that the ultimate figures on the prevalence of ambiguity are going to be much higher, given that Recasens et al. (2012) report that 12-15% of coreference relations in their corpus are cases of quasi-coreference, and that Poesio and Artstein (2005a) report a figure of 42.6% once ambiguity on discourse deictic reference are taken into account.

We next checked the extent to which MPA can correctly predict genuine ambiguity. The results suggest that MPA is good at removing spurious ambiguity, but as a predictor of ambiguity it only has a recall of around 20% and a precision of slightly under 50%. Improving these results is one of the objectives of our current research.

	Total	Dis	GA	ICP
LRC	401	79.1%	7% (28)	7.7% (31)
RG	464	68.3%	11.2% (52)	12.9% (60)
Average		73.7%	9.1%	10.3%

Table 9: Analysis of disagreements in two corpus documents

8 Conclusions

We presented a novel resource for anaphora that, because of its annotation scheme and size, at the very least should be useful to those in the community interested in developing systems able to perform a more comprehensive form of anaphora resolution, including for instance expletive detection and split antecedent resolution. The key property of this new resource however is that it provides a large number of judgments about each anaphoric expression, thus enabling the development of systems that do not make the assumption that a 'gold standard' exists, an assumption questioned by all studies associated with the creation of the current resources for the task. The dataset is also to our knowledge the first solid evidence that the games-with-a-purpose approach can be successfully deployed to obtain substantial resources for NLP.

The corpus is freely available from the Linguistic Data Consortium and from `http://www.dali-ambiguity.org`. It is distributed in three formats: an XML format including all the judgments, suitable for analysis of disagreements and/or the development of systems taking disagreement into account; and in CONLL and CRAC18 format, with only the gold annotation or the silver label extracted, for those interested in using the corpus as an alternative resource for developing coreference systems only.

Abstract

The study of argumentation and the development of argument mining tools depends on the availability of annotated data, which is challenging to obtain in sufficient quantity and quality. We present a method that breaks down a popular but relatively complex discourse-level argument annotation scheme into a simpler, iterative procedure that can be applied even by untrained annotators. We apply this method in a crowdsourcing setup and report on the reliability of the annotations obtained. The source code for a tool implementing our annotation method, as well as the sample data we obtained (4909 gold-standard annotations across 982 documents), are freely released to the research community. These are intended to serve the needs of qualitative research into argumentation, as well as of data-driven approaches to argument mining.

1 Introduction

Empirical study of argumentation requires examples drawn from authentic, human-authored text. Likewise, the applications of computational argumentation, such as argument mining, can require significant amounts of argument-annotated data to achieve reasonable performance. However, this data can be challenging to obtain in sufficient quantity and quality, particularly for discourse-level argumentation. This is because discourse-level annotation schemes are necessarily complex with respect to discrimination and delimitation (i.e., the variety of markable elements in the text and how to define their boundaries), expressiveness (i.e., the need to tag relationships between annotated elements), and context weighting (i.e., the amount of context around markable units that needs to be considered) (Fort et al., 2012). Successfully applying such schemes typically requires expensive and laborious work by expert-trained annotators.

In this paper, we present a method that facilitates the application of one such discourse-level argument annotation scheme (Stab and Gurevych, 2014). This scheme has been widely cited and used in argumentation studies (e.g., Lippi and Torroni, 2015; Persing and Ng, 2015; Nguyen and Litman, 2015; Persing and Ng, 2016; Ghosh et al., 2016; Eger et al., 2017; Nguyen and Litman, 2018), and while it is fairly coarse-grained, it is expensive to apply to new texts. Our method breaks down the annotation process into incremental, intuitive steps, each focusing on a small portion of the overall annotation scheme. We apply this method in a crowdsourcing setup with annotators who receive no training other than a brief set of annotation guidelines, as well as in a more traditional setup with extensively trained local annotators. We find that agreement between the two groups increases sublinearly with the number of crowd annotators, achieving up to $\alpha_U = 0.52$ when using ten crowd workers. We release not only our sample data set (consisting of 4909 gold-standard argument component and argument relation annotations over 982 product reviews), but also the source code for the annotation tool itself, which will allow others to produce their own quantity- and quality-controlled annotated data sets.

Proceedings of NAACL-HLT 2019, pages 1790–1796
Minneapolis, Minnesota, June 2 - June 7, 2019.

2 Background and Previous Mork

While there exists a great diversity of argumentation theories in philosophy and logic (e.g., Toulmin, 2003; Freeman, 2011; Walton et al., 2012), they tend to agree that an argument can be decomposed into various interrelated components. Inspired by Freeman's (2011) theory of the macro-structure of argumentation, Stab and Gurevych (2014) broadly categorize these components as *claims* (the conclusions that the audience is persuaded to accept or reject), *premises* (additional information offered to support or attack a given claim), and the *major claim* (the one central claim that relates all other claims in an argument). Taken together, this can be conceptualized as a graph or tree structure, with vertices representing the *argument components* (major claims, claims, and premises) and the directed edges representing the *argument relations* (support and attack).

Stab and Gurevych (2014) annotate a collection of persuasive texts with this scheme, associating each argument component they identify with a contiguous span of text from the document. They report that the annotation process involved "several training sessions" with their annotators, including collaborative annotation of eight example documents in order to obtain a common understanding of the task. This level of effort is in line with what has been reported for other discourse-level argumentation schemes. For example, annotation studies using the Freemanesque schemes of Peldszus and Stede (2013), Li et al. (2017), Haddadan et al. (2018), and Musi et al. (2018) all required one or more lengthy training sessions guided by argumentation experts and up to six pages of written instructions.

Using existing methods to alleviate the knowledge acquisition bottleneck, such as incidental supervision (Roth, 2017), or pre-annotation (Fort and Sagot, 2010), could speed the work of annotators—possibly at the risk of introducing a training bias—but would not obviate the need for expert training. (In any case, pre-annotation has never, to our knowledge, been successfully applied to hard discourse-level tasks such as annotating argumentation structures.) The complexity of the annotation scheme also seemingly rules out the use of crowdsourcing (Howe, 2006) and gamification (von Ahn, 2006), which are geared towards microtasks that are quick and easy for humans. Though one previous study has decomposed a discourse-level scheme for use with crowdsourcing (Kawahara et al., 2014), the constraints it imposes (fixed-size annotations, maximum document length of three sentences) are too restrictive for argumentation annotation.

By contrast, the crowdsourcing approach of Sukhareva et al. (2016), while not concerned with discourse-spanning annotations, employs a few mechanisms that are relevant for our own task. Their approach, intended for the labelling of semantic verb relations, breaks down the annotation work into a series of hierarchical, atomic microtasks. Only those parts of the annotation instructions relevant to the current microtask are shown to the annotator. Furthermore, annotators are encouraged to think of connecting words ("specifically", "generally speaking", "in other words", etc.) that justify their relation annotations. As described in the following section, we adapt and extend these mechanisms for our own annotation method.

3 Annotation Method

Our approach to mitigating the knowledge acquisition problem is an iterative procedure by which annotators apply a distinct subset of the annotation scheme at each step. In this manner, complex discourse-level annotations are built up piecemeal in simple steps. The iterative annotation process is supported by an online JavaScript-based interface. Taken together, this allows the Stab and Gurevych (2014) annotation scheme to be applied even by untrained annotators in a crowdsourcing setup.

In the first step of the annotation process, annotators are presented with the complete argumentative text and asked to select the one phrase (i.e., an arbitrary sequence of words) that best represents the major claim, or else to indicate that there is no such passage.[1] In the second step, annotators are presented once again with the full argument, but with its major claim marked.[2] The annotators then select the claims—that is, all phrases that directly speak to the major claim, as well as whether those passages support or attack the major claim—or else

---

[1] If the user indicates in any step that there is no text span corresponding to the argument component type, we ask them to perform a short alternative task. This is to prevent faithless workers from taking the easy way out of the annotation task, but also to collect further annotations of interest to us.

[2] In the second and third steps, the marked annotation is not necessarily the one applied by the annotator in the previous step. In fact, as we explain below, in our study we source all annotations from a given step simultaneously, distill them into a gold standard, and mark these gold-standard annotations for the next step. With this setup, there is no need for a given annotator to participate in all three steps.

indicate that there are no such text spans. In the third step, annotators see the full argument with one of its claims marked. As with the previous step, annotators select text spans corresponding to the premises of the claim and indicate each premises's stance; they also have the option of reporting that the claim has no premises.

The annotation tool automatically enforces the restrictions that annotations must be contiguous, must begin and end on a word boundary, and cannot overlap with their siblings or ancestors. Crucially, the instructions given to annotators at each step of the process do not attempt to explain the entire annotation scheme but rather describe only the immediate annotation task in layman's terms. Furthermore, the tool attempts to make this task more intuitive for users by framing the second and third steps as a sentence completion task. An example of this is the interface for annotating claims (see Fig. 1). The full argumentative text (in this case, a product review) is shown on the left half of the screen, with the major claim marked, and we separately show a copy of the major claim on the right half of the screen. The user is instructed to extend the major claim with additional supporting or attacking information by appending a "because" or "but" clause, respectively. The user does this by pressing the "but" or "because" button below the major claim and then highlighting a sentence or phrase from the review.

4 Annotation Study

To assess the suitability of our annotation procedure, we applied it in a crowdsourcing setup. Measuring interannotator agreement for crowdsourced annotations is problematic, however, because there are typically a huge number of annotators, most of whom annotate only a tiny fraction of the data set. To gauge the reliability of our crowdsourced annotations, we instead conducted an experiment that compared them to those produced by expert-trained annotators.

For the experiment, we randomly selected 40 Amazon product reviews from the McAuley et al. (2015) data set—four from each of ten product categories. Each review was annotated for major claims by ten crowd workers; all 40 reviews were also annotated for major claims by a fixed group of three locally recruited annotators trained by argumentation experts.[3] We then converted the annotated reviews to BIO tokens (Ramshaw and Marcus, 1995) and applied the annotation aggregation/denoising tool MACE (Hovy et al., 2013) to select at most two gold-standard major-claim annotations per review, one from the crowd (crowd) and one from the trained annotators (train).[4] We then compared the crowd and train gold standards, one review at a time, using Krippendorff's (1995) α_U, a unitizing measure that considers the token-level boundaries of the text spans marked by each annotator. We repeated this process to obtain and evaluate crowd and train claim annotations on the train major claims, and then again for crowd and train premise annotations on the train claims.

Note that in the gold standards for some reviews, there may be no major claim, no claims associated with the major claim, and/or no premises associated with a given claim. In many cases this is because the annotators generally agreed that such argument components were not present in the text. However, in other cases the various annotators *did* identify such argument components, but the agreement among them was too low for MACE to output a gold-standard annotation. A quandary therefore arises when deciding how to treat reviews where *neither* the crowd nor the train gold standard contains a given type of argument component. There is no (easy) way of determining from the MACE output whether missing annotations are due to agreement or disagreement, and even if this information were available, it is not clear how it could be incorporated into the calculation of α_U. For this reason, we apply two different strategies for handling missing annotations, and provide separate α_U calculations for each. The first strategy, skip, disregards missing annotations, excluding them from the mean agreement calculation. The second strategy, agree, treats missing annotations as total agreement ($\alpha_U = 1$).[5]

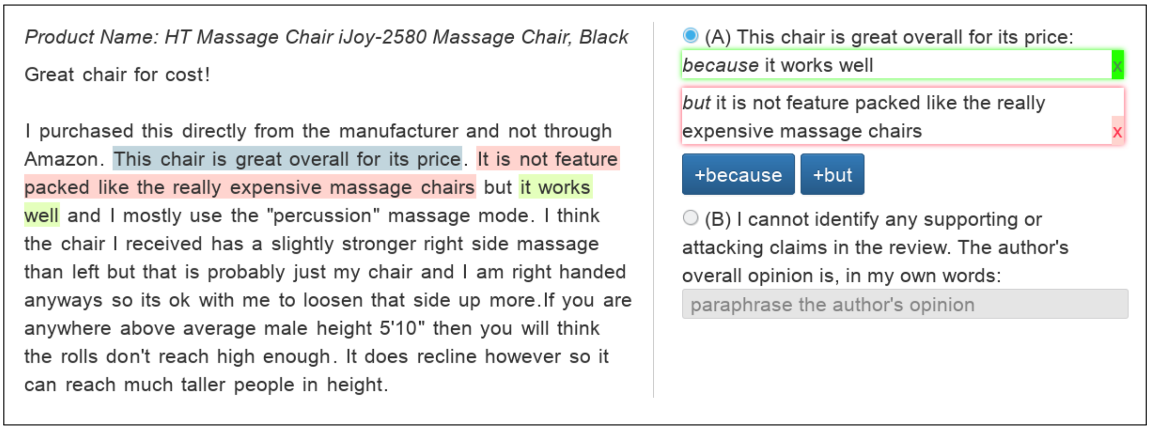
When using all ten crowdsourced annotations per review and the agree strategy, we achieved mean α_U scores of 0.4104, 0.5231, and 0.4385 for major claims, claims, and premises, respectively. With the skip strategy, the respective scores are 0.4104, 0.4845, and 0.2201. As expected, these scores

---

[3] We engaged US-based workers from Amazon Mechanical Turk at the US federal minimum wage of $7.25/hour. Our expert-trained annotators were salaried research staff whose equivalent hourly rate was three to five times higher.

[4] MACE accepts a threshold value that is used to discard instances that cannot be confidently assigned a gold label; we set this to 0.9.

[5] It is not possible to treat the missing annotations as "total disagreement" because per Krippendorff (1995), α_U has no concept of this; there is no lowest disagreement score.



Product Name: HT Massage Chair iJoy-2580 Massage Chair, Black

Great chair for cost!

I purchased this directly from the manufacturer and not through Amazon. This chair is great overall for its price. It is not feature packed like the really expensive massage chairs but it works well and I mostly use the "percussion" massage mode. I think the chair I received has a slightly stronger right side massage than left but that is probably just my chair and I am right handed anyways so its ok with me to loosen that side up more.If you are anywhere above average male height 5'10" then you will think the rolls don't reach high enough. It does recline however so it can reach much taller people in height.

● (A) This chair is great overall for its price:

because it works well

but it is not feature packed like the really expensive massage chairs

○ (B) I cannot identify any supporting or attacking claims in the review. The author's overall opinion is, in my own words:

Figure 1: Annotation interface for the second step (claim annotation)

are lower than the agreement among extensively trained annotators reported by Stab and Gurevych (2014) ($\alpha_U = 0.7726, 0.6033, 0.7594$).[6] However, they are broadly comparable to interannotator agreement scores reported in similar (and in some cases, even simpler) discourse-level argument annotation studies with expert-trained annotators, such as Aharoni et al. (2014) ($\kappa = 0.4$), Musi et al. (2018) ($\kappa = 0.296$), and Li et al. (2017) ($\alpha_U = 0.2452$).

To measure how the number of crowd annotations impacts reliability, we performed an ablation study where we iteratively removed one crowd annotation at random from each review and repeated the MACE distillation and α_U calculation. The study was repeated 100 times and the resulting α_U scores averaged. The results are shown in Fig. 2, which plots the average α_U scores for major claims, claims, and premises when using one to ten crowd annotations per review. The plots are shown as error bars, where the top of the bar is the average agree score and the bottom is the average skip score. Reliability scores start to be uniformly positive with three annotations, with agreement for major claims and premises plateauing around seven annotations. The difference between the agree and skip scores is sizable only for premises.

5 Data Set and Software

Having satisfied ourselves that our method can produce reliable annotations via crowdsourcing, we applied it to a much larger subset of McAuley et al. (2015). The raw data consists of 982 English product reviews randomly sampled from the same ten product categories used in our evaluation study. For each argument component type in a review, we sourced annotations from five crowd workers, considering this to be an acceptable trade-off between annotation quality and cost. The MACE-produced gold standard contains 4909 annotations (937 major claims, 1134 claims, 852 premises, and 1986 argument relations). Our data set is distinguished from the review corpora of García Villalba and Saint-Dizier (2012) and Wyner et al. (2012) in that it is much larger, covers a broader range of product types, and is freely released under the CC BY 4.0 licence. It is comparable in size to but broader in scope than the Chinese-language hotel review corpus of Li et al. (2017).

Our data is distributed[7] as a set of XML Metadata Interchange (XMI) files, one per review, containing stand-off argument annotations that cross-reference the original texts from McAuley et al. (2015). (Because the original review texts are not available under a free licence, we do not include them in our distribution, but we provide a script for extracting them from the original corpus and merging them into our XMIs.) Also included is the JavaScript source for our annotation tool, as well as the Java source for preprocessing the raw data and postprocessing the annotations with MACE. This code can be used to crowdsource further annotated data sets using the McAuley et al. (2015) data at the desired level of quality. It could also be adapted to work with other raw corpora and other Freemanesque annotation schemes.

6 Conclusion

We have presented a scalable, simplified, iterative method for sourcing the discourse-level argumen-

---

[6] Apart from the fact that we used untrained annotators, the difference in agreement may also be due in part to our use of online user-generated content as opposed to student essays.

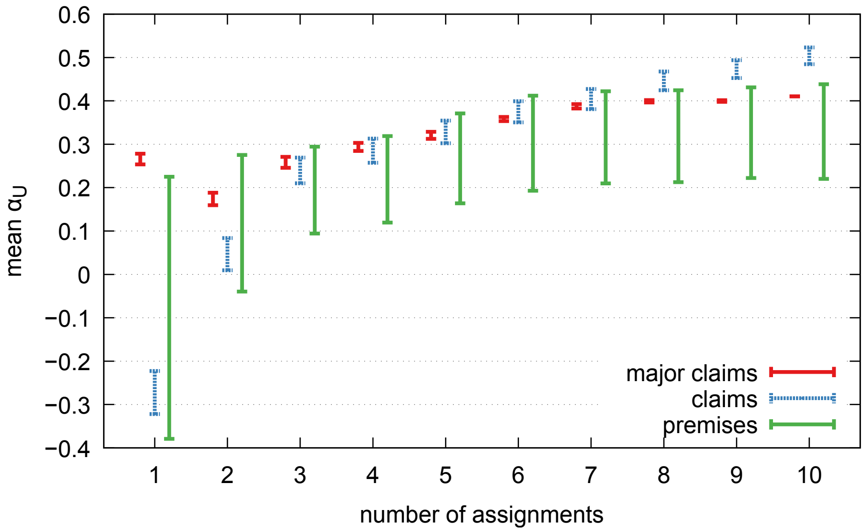

Figure 2: Results of the reliability study

tation annotations of Stab and Gurevych (2014), which may be adaptable to other annotation schemes based on Freeman's (2011) notion of argumentation. Our analysis shows that crowdsourced annotations obtained with our method yield substantial agreement with those obtained, with much greater effort, by expert-trained annotators. We have used our method to quickly and cheaply produce a large, argument-annotated data set of product reviews, which we freely release, along with the source code to our annotation interface and processing tools. Unlike with flat, context-free argument data such as that of Stab et al. (2018), training on our annotations would conceivably permit the identification not just of isolated argument components but of more complex argument structures. Our resources may also be of use for qualitative research on the linguistic features and rhetorical mechanisms of argumentative text (e.g., Peldszus and Stede, 2016).

For future work, we are investigating alternatives to MACE, which was designed for categorical annotations rather than the sequence labelling of our task. In particular, we are looking into the Bayesian method of Simpson and Gurevych (2018), which takes advantage of the sequential dependencies between BIO tags, and works more robustly with noisy, subjective data such as ours.

Abstract

Learning a shared dialog structure from a set of task-oriented dialogs is an important challenge in computational linguistics. The learned dialog structure can shed light on how to analyze human dialogs, and more importantly contribute to the design and evaluation of dialog systems. We propose to extract dialog structures using a modified VRNN model with discrete latent vectors. Different from existing HMM-based models, our model is based on variational-autoencoder (VAE). Such model is able to capture more dynamics in dialogs beyond the surface forms of the language. We find that qualitatively, our method extracts meaningful dialog structure, and quantitatively, outperforms previous models on the ability to predict unseen data. We further evaluate the model's effectiveness in a downstream task, the dialog system building task. Experiments show that, by integrating the learned dialog structure into the reward function design, the model converges faster and to a better outcome in a reinforcement learning setting.

1 Introduction

Human dialogs are like well-structured buildings, with words as the bricks, sentences as the floors, and topic transitions as the stairs connecting the whole building. Therefore, discovering dialog structure is crucial for various areas in computational linguistics, such as dialog system building (Young, 2006), discourse analysis (Grosz and Sidner, 1986), and dialog summarization (Murray et al., 2005; Liu et al., 2010). In domain specific tasks such as restaurant booking, it's common for people to follow a typical conversation flow. Current dialog systems require human experts to design the dialog structure, which is time consuming and sometimes insufficient to satisfy various customer needs. Therefore, it's of great importance to automatically discover dialog structure from existing human-human conversations and incorporate it into the dialog system design.

However, modeling human conversation is not easy for machines. Some previous work rely on human annotations to learn dialog structures in supervised learning settings (Jurafsky, 1997). But since human labeling is expensive and hard to obtain, such method is constrained by the small size of training examples, and by the limited number of application domains (Zhai and Williams, 2014). Moreover, structure annotations on human conversation can be subjective, which makes it hard to reach inter-rater agreements. Therefore, we propose an unsupervised method to infer the latent dialog structure since unsupervised methods do not require annotated dialog corpus.

Limited previous work has studied unsupervised methods to model the latent dialog structure. Most of the previous methods use the *hidden Markov model* to capture the temporal dependency within human dialogs (Chotimongkol, 2008; Ritter et al., 2010; Zhai and Williams, 2014). We propose to adopt a new type of models, the *variational recurrent neural network* (VRNN, a recurrent version of the VAE) (Chung et al., 2015), and infer the latent dialog structure with variational inference. VRNN is suitable for modeling sequential information. Compared to the simpler HMM models, VRNN also has the flexibility to model highly non-linear dynamics (Chung et al., 2015) in human dialogs.

Our basic approach assumes that the dialog structure is composed of a sequence of latent states. Each conversational exchange (a pair of user and system utterances at time t) belongs to a *latent state*, which has causal effect on the future latent states and the words the conversants produce. Because discrete latent states are more interpretable than continuous ones, we combine

Proceedings of NAACL-HLT 2019, pages 1797–1807
Minneapolis, Minnesota, June 2 - June 7, 2019.

VRNN with Gumbel-Softmax (Jang et al., 2016) to obtain discrete latent vectors to represent the latent states. A common way to represent the dialog structure both visually and numerically is to construct a transition probability table among latent states. The idea of transition table inspires us to develop two model variants to model the dependency between states indirectly and directly.

Once we obtain such a human-readable dialog structure, we can use it to facilitate many downstream tasks, such as dialog system training. The motivation is that the dialog structure contains important information on the flow of the conversation; if the automatic dialog system can mimic the behaviour in human-human dialogs, it can interact with users in a more natural and user-friendly way. Therefore, we propose to integrate the dialog structure information into the reward design of the reinforcement learning (RL). Experiments show that the model with the proposed reward functions converges faster to a better success rate.

2 Related Work

Variational Autoencoders (VAEs) (Kingma and Welling, 2013; Doersch, 2016; Kingma et al., 2014) have gained popularity in many computational linguistics tasks due to its interpretable generative model structure (Miao and Blunsom, 2016; Miao et al., 2017). Zhao et al. (2018) applied VAE to learn discrete sentence representations and achieved good results. This is similar to our work, but we focus more on modeling the dialog structure and using the learned structure to improve the dialog system training. Serban et al. (2017) presented a VHRED model which combines the VRNN and encoder-decoder structure for direct dialog response generation. While also similar, our model uses discrete latent vectors instead of continuous ones, and re-constructs the utterances to recover the latent dialog structure, instead of modeling the responses directly.

There are some previous studies on discovering latent structure of conversations (Chotimongkol, 2008; Ritter et al., 2010; Zhai and Williams, 2014). But they are all based on Hidden Markov Model (HMM). Ritter et al. (2010) extended the HMM-based method in Chotimongkol (2008) by adding additional word sources to social interaction data on Twitter. Zhai and Williams (2014) decoupled the number of topics and the number of states to allow an additional layer of information in task-oriented dialogs. Our work also focuses on task-oriented dialogs but adopts the VRNN to perform variational inference in the model. According to Chung et al. (2015), the VRNN retains the flexibility to model highly non-linear dynamics, compared to simpler Dynamic Bayesian Network models such as HMM.

Gunasekara et al. (2017) described a Quantized-Dialog Language Model (QDLM) for task-oriented dialog systems, which performs clustering on utterances and models the dialog as a sequence of clusters to predict future responses. The idea of dialog discretization is similar to our method, but we choose VAE over simple clustering to allow more context-sensitivity and to capture more dynamics in the dialog beyond surface forms of the conversation. Additionally, we propose to utilize the dialog structure information to improve the dialog system training.

Traditional reward functions in RL dialog training use delayed reward to provide feedback to the model. However, delayed reward suffers from potential slow convergence rate problem, so some studies integrated estimated per-turn immediate reward. For example, Ferreira and Lefèvre (2013) studied expert-based reward shaping in dialog management. We use the KL-divergence between the transition probabilities and the predicted probabilities as the immediate per-turn reward. Different from the expert-based reward shaping, such reward does not require any manual labels and is generalizable to different tasks.

3 Models

Fig. 1 gives an overview of the Discrete-VRNN (D-VRNN) model and the Direct-Discrete-VRNN (DD-VRNN) model. In principal, the VRNN contains a VAE at every timestep, and these VAEs are connected by a state-level RNN. The hidden state variable $\mathbf{h}_{\text{t-1}}$ in this RNN encodes the dialog context up to time t. This connection helps the VRNN to model the temporal structure of the dialog (Chung et al., 2015). The observed inputs $\mathbf{x}_t$ to the model is the constructed utterance embeddings. $\mathbf{z}_t$ is the latent vector in the VRNN at time t. Different from Chung et al. (2015), $\mathbf{z}_t$ in our model is a discrete one-hot vector of dimension N, where N is the total number of latent states.

The major difference between D-VRNN and DD-VRNN lies in the priors of $\mathbf{z}_t$. In D-VRNN, we assume that $\mathbf{z}_t$ depends on the entire dialog

(a) Discrete-VRNN (b) Direct-Discrete-VRNN

Figure 1: Discrete-VRNN (D-VRNN) and Direct-Discrete-VRNN (DD-VRNN) overview. D-VRNN and DD-VRNN use different priors to model the transition between $\mathbf{z}_{\text{t}}$, shown in red solid lines. The regeneration of $\mathbf{x}_{\text{t}}$ is in blue dotted lines. The recurrence of the state-level RNN is in gray dash-dotted lines. The inference of $\mathbf{z}_{\text{t}}$ is in black dashed lines.

context $\mathbf{h}_{\text{t-1}}$, shown in red in Fig. 1(a), which is the same as in Chung et al. (2015); while in DD-VRNN we assume that in the prior, $\mathbf{z}_t$ directly depends on $\mathbf{z}_{\text{t-1}}$ in order to model the direct transition between different latent states, shown in red in Fig. 1(b). We use $\mathbf{z}_t$ and $\mathbf{h}_{\text{t-1}}$ to regenerate the current utterances $\mathbf{x}_t$ instead of generating the next utterances $\mathbf{x}_{\text{t+1}}$, shown in blue dotted lines in Fig. 1. The idea of regeneration helps recover the dialog structure. Next, the recurrence in the RNN takes $\mathbf{h}_{\text{t-1}}$, $\mathbf{x}_t$ and $\mathbf{z}_t$ to update itself, and allows the context to be passed down as the dialog proceeds, shown in gray dash-dotted lines. Finally in the inference, we construct the posterior of $\mathbf{z}_t$ with the context $\mathbf{h}_{t-1}$ and $\mathbf{x}_t$, and infer $\mathbf{z}_t$ by sampling from the posterior, shown in black dashed lines in Fig. 1. The mathematical details of each operation are described below. $\varphi_\tau^{(\cdot)}$ are highly flexible feature extraction functions such as neural networks. $\varphi_\tau^{\mathbf{x}}$, $\varphi_\tau^{\mathbf{z}}$, $\varphi_\tau^{\text{prior}}$, $\varphi_\tau^{\text{enc}}$, $\varphi_\tau^{\text{dec}}$ are feature extraction networks for the input $\mathbf{x}$, the latent vector $\mathbf{z}$, the prior, the encoder and the decoder.

Sentence Embedding. $u_t = [\mathrm{w}_{1,\mathrm{t}}, \mathrm{w}_{2,\mathrm{t}}, \ldots \mathrm{w}_{\mathrm{n_w},t}]$ and $s_t = [\mathrm{v}_{1,t}, \mathrm{v}_{2,t}, \ldots \mathrm{v}_{\mathrm{n_v},t}]$ are the user utterance and the system utterance at time t, where $\mathrm{w}_{\mathrm{i,j}}$ and $\mathrm{v}_{\mathrm{i,j}}$ are individual words. The concatenation of utterances from both parties, $x_t = [u_t, s_t]$, is the observed variable in the VAE. We use Mikolov et al. (2013) to perform word embedding and the average of the word embedding vectors of u_t and s_t are $\overline{u_t}$ and $\overline{s_t}$. The concatenation of $\overline{u_t}$ and $\overline{s_t}$ is used as the feature extraction of $\mathbf{x}_t$, namely $\varphi_\tau^{\mathbf{x}}(\mathbf{x}_t) = [\overline{u_t}, \overline{s_t}]$. $\varphi_\tau^{\mathbf{x}}(\mathbf{x}_t)$ is the model inputs.

Prior in D-VRNN. The prior quantifies our assumption on $\mathbf{z}_t$ before we observe the data. In the D-VRNN, it's reasonable to assume that the prior of $\mathbf{z}_t$ depends on the context $\mathbf{h}_{\text{t-1}}$ and follows the distribution shown in Eq. (1), because conversation context is a critical factor that influences dialog transitions. Since $\mathbf{z}_t$ is discrete, we use softmax to obtain the distribution.

$$\mathbf{z}_t \sim \text{softmax}(\varphi_\tau^{\text{prior}}(\mathbf{h}_{t-1})) \qquad (1)$$

Prior in DD-VRNN. The dependency of $\mathbf{z}_{\text{t}}$ on the entire context $\mathbf{h}_{\text{t-1}}$ in Eq. (1) makes it difficult to disentangle the relation between $\mathbf{z}_{\text{t-1}}$ and $\mathbf{z}_{\text{t}}$. But this relation is crucial in decoding how conversations flow from one conversational exchange to the next one. So in DD-VRNN, we directly model the influence of $\mathbf{z}_{\text{t-1}}$ on $\mathbf{z}_{\text{t}}$ in the prior, shown in Eq. (2) and Fig. 1(b). To fit this prior distribution into the variational inference framework, we approximate $p(\mathbf{z}_{\text{t}}|\mathbf{x}_{<t}, \mathbf{z}_{<t})$ with $p(\mathbf{z}_{\text{t}}|\mathbf{z}_{\text{t-1}})$ in Eq. (3). Later, we show that the designed new prior has benefits under certain scenarios.

$$\mathbf{z}_t \sim \text{softmax}(\varphi_\tau^{\text{prior}}(\mathbf{z}_{\text{t-1}})) \qquad (2)$$

$$\begin{aligned} p(\mathbf{x}_{\le T}, \mathbf{z}_{\le T}) &= \prod_{t=1}^{T} p(\mathbf{x}_t|\mathbf{z}_{\le t}, \mathbf{x}_{\le t}) p(\mathbf{z}_t|\mathbf{x}_{<t}, \mathbf{z}_{<t}) \\ &\approx \prod_{t=1}^{T} p(\mathbf{x}_t|\mathbf{z}_{\le t}, \mathbf{x}_{\le t}) p(\mathbf{z}_t|\mathbf{z}_{\text{t-1}}) \end{aligned} \qquad (3)$$

Generation. $\mathbf{z}_t$ is a summarization of the current conversational exchange under the context. We use $\mathbf{z}_t$ and $\mathbf{h}_{\text{t-1}}$ to reconstruct the current utterance $\mathbf{x}_t$. This regeneration of $\mathbf{x}_t$ allows us to recover the dialog structure.

We use two RNN decoders, *dec1* and *dec2*, parameterized by γ_1 and γ_2 to generate the original u_t and s_t respectively. c_t and d_t are the hidden states of *dec1* and *dec2*. The context $\mathbf{h}_{\text{t-1}}$ and feature extraction vector $\varphi_{\tau}^{\mathbf{z}}(\mathbf{z}_t)$ are concatenated to form the initial hidden state h_0^{dec1} of *dec1*. $c_{(n_w,t)}$ is the last hidden state of *dec1*. Since v_t is the response of u_t and will be affected by u_t, we concatenate $c_{(n_w,t)}$ to d_0 to pass the information from u_t to v_t. This concatenated vector is used as h_0^{dec2} of *dec2*. This process is shown in Eq. (4) and (5).

$$\begin{aligned} c_0 &= [\mathbf{h}_{t-1}, \varphi_{\tau}^{\mathbf{z}}(\mathbf{z}_t)], \\ w_{(i,t)}, c_{(i,t)} &= f_{\gamma 1}(w_{(i-1,t)}, c_{(i-1,t)}) \end{aligned} \tag{4}$$

$$\begin{aligned} d_0 &= [\mathbf{h}_{t-1}, \varphi_{\tau}^{\mathbf{z}}(\mathbf{z}_t), c_{(n_w,t)}], \\ v_{(i,t)}, d_{(i,t)} &= f_{\gamma 2}(v_{(i-1,t)}, d_{(i-1,t)}) \end{aligned} \tag{5}$$

Recurrence. The state-level RNN updates its hidden state $\mathbf{h}_t$ with $\mathbf{h}_{\text{t-1}}$ based on the following Eq. (6). f_θ is a RNN parameterized by θ.

$$\mathbf{h}_t = f_\theta(\varphi_{\tau}^{\mathbf{z}}(\mathbf{z}_t), \varphi_{\tau}^{\mathbf{x}}(\mathbf{x}_t), \mathbf{h}_{t-1}) \tag{6}$$

Inference. We infer $\mathbf{z}_t$ from the context $\mathbf{h}_{\text{t-1}}$ and current utterances $\mathbf{x}_t$, and construct the posterior distribution of $\mathbf{z}_t$ by another softmax, shown in Eq. (7). Once we have the posterior distribution, we apply Gumbel-Softmax to take samples of $\mathbf{z}_t$. D-VRNN and DD-VRNN differ in their priors but not in their inference, because we assume the direct transitions between $\mathbf{z}_t$ in the prior instead of in the inference.

$$\mathbf{z}_t | \mathbf{x}_t \sim \text{softmax}([\varphi_{\tau}^{\text{enc}}(\mathbf{h}_{t-1}), \varphi_{\tau}^{\mathbf{x}}(\mathbf{x}_t)]) \tag{7}$$

Loss function. The objective function of VRNN is a timestep-wise variational lower bound, shown in Eq. (8) (Chung et al., 2015). To mitigate the *vanishing latent variable problem* in VAE, we incorporate bow-loss and Batch Prior Regularization (BPR) (Zhao et al., 2017, 2018) with tunable weights, λ to the final loss function, shown in Eq. (9).

$$\begin{aligned} &\mathcal{L}_{\text{VRNN}} = \mathbb{E}_{q(\mathbf{z}_{\leq T} | \mathbf{x}_{\leq T})}[\log p(\mathbf{x}_t \mid \mathbf{z}_{\leq t}, \mathbf{x}_{<t})+ \\ &\sum_{t=1}^{T} \text{-KL}(q(\mathbf{z}_t \mid \mathbf{x}_{\leq t}, \mathbf{z}_{<t}) \parallel p(\mathbf{z}_t \mid \mathbf{x}_{<t}, \mathbf{z}_{<t}))] \end{aligned} \tag{8}$$

$$\mathcal{L}_{\text{D-VRNN}} = \mathcal{L}_{\text{VRNN-BPR}} + \lambda * \mathcal{L}_{\text{bow}} \tag{9}$$

3.1 Transition Probability Calculation

A good way to represent a dialog structure both numerically and visually is to construct a transition probability table among latent states. Such transition probability can also be used to design reward function in the RL training process. We calculate transition table differently for D-VRNN and DD-VRNN due to their different priors.

D-VRNN. From Eq. (6), we know that $\mathbf{h}_t$ is a function of $\mathbf{x}_{\leq t}$ and $\mathbf{z}_{\leq t}$. Combining Eq. (1) and (6), we find that $\mathbf{z}_t$ is a function of $\mathbf{x}_{\leq t}$ and $\mathbf{z}_{<t}$. Therefore, $\mathbf{z}_{<t}$ has an indirect influence on $\mathbf{z}_t$ through $\mathbf{h}_{\text{t-1}}$. This indirect influence reinforces our assumption that the previous states $\mathbf{z}_{<t}$ impacts future state $\mathbf{z}_t$, but also makes it hard to recover a clear structure and disentangle the direct impact of $\mathbf{z}_{\text{t-1}}$ on $\mathbf{z}_t$.

In order to better visualize the dialog structure and compare with the HMM-based models, we quantify the impact of $\mathbf{z}_{\text{t-1}}$ on $\mathbf{z}_t$ by estimating a bi-gram transition probability table, where $p_{i,j} = \frac{\#(\text{state}_i, \text{state}_j)}{\#(\text{state}_i)}$. The numerator is the total number of the ordered tuples ($\text{state}_{\text{i, t-1}}$, $\text{state}_{\text{j, t}}$) and the denominator is the total number of state_i in the dataset. We choose a bi-gram transition table over a n-gram transition table with a bigger n, as the most recent context is usually the most relevant, but it should be noted that unlike the HMM models, the degree of transition in our model is not limited nor pre-determined, because $\mathbf{z}_t$ captures all the context. Depending on different applications, different n may be selected.

DD-VRNN As stated before, the dependency of $\mathbf{z}_t$ on the entire context $\mathbf{h}_{\text{t-1}}$ creates difficulty in calculating the transition table. This is our motivation to derive the prior in DD-VRNN. The outputs from the softmax in the prior (Eq. (2)) directly constitute the transition table. So rather than estimating the transition probabilities by frequency count as in D-VRNN, we can optimize the loss function of DD-VRNN and get the parameters in Eq. (2) that directly form the transition table.

3.2 NE-D-VRNN

In task-oriented dialog systems, the presence of certain named entities, such as food preference plays a crucial role in determining the phase of the dialog. To make sure the latent states capture such useful information, we assign larger weights on the named entities when calculating the loss function in Eq. (9). The weights encourage the recon-structured utterances to have more correct named entities, therefore influencing the latent state to have better representation. We refer this model as NE-D-VRNN (Named Entitiy Discrete-VRNN).

4 Datasets

We test the proposed method on the CamRest676 corpus, which was released and collected by Wen et al. (2016). The task is to help users find restaurants in Cambridge, UK. While this task is highly similar to DSTC2, we choose this dataset instead of DSTC2 because it is relatively clean and comes with good entity extraction methods. There are a total of 676 dialogs in this dataset with three information slots (*food, price range and area*) and three request table slots (*address, phone and postcode*).

We also evaluate our model on another dataset of simulated conversations, proposed in Zhao and Eskenazi (2018). The task is to help users get the weather report in a certain place at a specific time. The dialog system is controlled by a fixed structure and hand-set probabilities. Therefore, learning the dialog structure of this dataset might be easier.

We assume each latent vector in the VAE emits one conversational exchange, including one user utterance and the corresponding system response at time t, and each conversational exchange corresponds to one latent vector, following Zhai and Williams (2014).

5 Experiments

We use LSTM (Hochreiter and Schmidhuber, 1997) with 200-400 units for the RNNs, and a fully-connected network for all the $\varphi_{\tau}^{(\cdot)}$ with a dropout rate of 0.4. Additionally, we use trainable 300-dimension word embeddings initialized by Google word2vec (Mikolov et al., 2013). The maximum utterance word length is 40 and the maximum dialog length is 10. We set the λ for the bow-loss to be 0.1. 80% of the entire dataset are used for training, 10% for validation and 10% for testing. Parameters mentioned are selected based on the performance of the validation set.

The evaluation of unsupervised methods has always been a challenge. We first compare our models with a simple K-means clustering algorithm to show its context sensitivity. Then we compare our models with traditional HMM methods both qualitatively and quantitatively. Finally, we compare the three proposed model variants. The qualitative evaluation involves generating dialog structures with different models, and the quantitative evaluations involves calculating the likelihood on a held-out test set under a specific model, which measures the model's predictive power.

5.1 Comparison with K-means Clustering

We apply the model and obtain a latent state $\mathbf{z}_t$ for each conversational exchange. Since $\mathbf{z}_t$ is a discrete one-hot vector, we can group the conversational exchanges with the same latent state together. This process is similar to clustering the conversational exchanges. But we choose the VAE over simple clustering methods because the VAE introduces more flexible context-sensitive information. A straightforward clustering method like K-means usually groups sentences with similar surface forms together, unless the previous context is explicitly encoded along with the utterances. To compare the grouping result of our model with a traditional clustering method, we perform K-means clustering on the dataset and calculate the within-cluster cosine similarity between the bag-of-word vectors of the utterances and the context. This cosine similarity measures how similar the utterances are on the word token level, higher the value is, more words the utterances share in common. It turns out the average cosine similarity between the current utterance is 0.536 using the K-means and 0.357 using the D-VRNN, while the average cosine similarity between the context is 0.320 using the K-means and 0.351 using the D-VRNN. This does show that in the D-VRNN result, the context are more similar to each other, while in the K-means, the current utterances are more similar on the surface textual level,which is not ideal because the dialog system needs context information. Table 1 shows an example where the D-VRNN clustering result is different from the K-means result. The conversational exchanges to be clustered are in the last row. These two exchanges have the same surface form but different contexts. D-VRNN identifies them as different by incorporating context information, whereas K-means places them into the same cluster ignoring the context.

5.2 Comparison with HMM

HMM is similar to our model. Actually, if we remove the $\mathbf{h}_t$ layer from Fig. 1, it becomes an HMM. But it is this additional layer of $\mathbf{h}_t$ that encodes the dialog context into continuous information and is crucial in the success of our model.

From	Utterance
SYS:	Okay, you don't care *place*, do you?
USR:	That's correct.
SYS:	What date are you interested?
USR:	**Weather this morning.**
SYS:	**I believe you said this morning.**

(a) One example in State 2, "provide place and time"

From	Utterance
USR:	Weather tomorrow.
SYS:	[api_call]. your weather report is here [report]. what else can I do?
USR:	**Weather this morning.**
SYS:	**I believe you said this morning.**

(b) One example in State 3, "additional time request"

Table 1: The utterances in bold in both tables have similar surface forms but different context. They are grouped in different latent states using the Discrete-VRNN. In contrast, they are in the same cluster using the K-means.

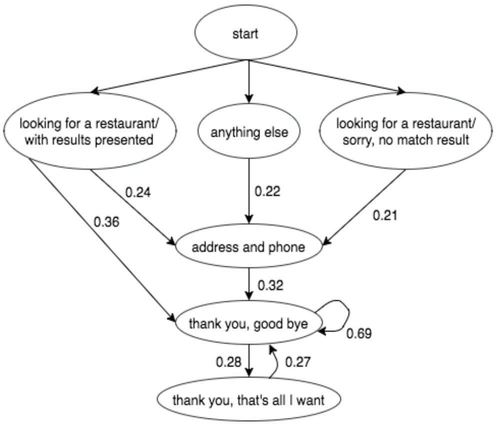

Figure 2: Dialog structure of restaurant data by D-VRNN. Transitions with $P \geq 0.2$ are visualized.

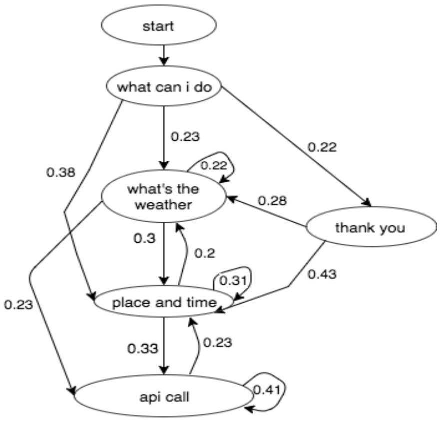

Figure 3: Dialog structure of weather data by D-VRNN. Transitions with $P \geq 0.2$ are visualized.

In Fig. 4 and 5, we compare our models quantitatively with the TM-HMM model with 10 topics and 20 topics from Zhai and Williams (2014), which performs the best on a similar task-oriented dialog dataset, the DSTC1 . The y-axis shows the negative log likelihood of reconstructing the test set under a specific model. The lower the negative log likelihood, the better the model performs. The x-axis shows different numbers of latent states N used in the models. As we can see, all of the VRNN-based models surpass the TM-HMM models by a large margin and are more invariant to the change in N on both datasets. Especially when N is small, the performance of HMM is not stable.

Qualitatively, we compare the dialog structures generated by different models. Fig. 2 and 3 show the discovered dialog structures using the D-VRNN model, and Fig. 7 in the Appendix shows the dialog structures learned by HMM. Each circle in these figures represents a latent state $\mathbf{z}_t$ with expert interpreted meanings, and the directed-arrows between the circles represent the transition probabilities between states. Human experts interpret each $\mathbf{z}_t$ consistently by going through conversational exchanges assigned to the same $\mathbf{z}_t$. For a better visualization effect, we only visualize the transitions with a probability equal or greater than 0.2 in the figures.

We observe reasonable dialog structures in Fig. 2 and 3. The D-VRNN captures the major path *looking for restaurant (anything else)* → *get restaurant address and phone* → *thank you* in the restaurant search task. It also captures *what's the weather* → *place and time* → *api call* in the weather report task. However, we do not get a dialog structure with entities separated (such as *food type I like* → *area I prefer* → *price range I want* → ...). Because users know the system's capability and tend to give as many entities as possible in a single utterance, so these entities are all mingled in one dialog exchange. But the model is able to distinguish the "presenting match result" state from the "presenting no match result" state (on the top of Fig. 2), which is important in making correct predictions. But in Fig. 7(a) generated by HMM, even if we set 10 states in the HMM, some states are still collapsed by the model because they share a similar surface form. And in Fig. 7(b) also by HMM, the dialog flow skips the "what can I do" state, and goes from the "start" directly to "providing place and time", which is not reasonable.

Another interesting phenomenon is that there are two "thank you concentrated" states in Fig. 2. This is because, users frequently say "thank you" on two occasions, 1) after the dialog system presents the restaurant information, most users will say "thank you"; 2) then the system will ask "is there anything else I can help you with", after which users typically respond with "thank you, that's all". This interesting structure is a reflection of the original rules in the dialog system. Moreover, in Fig. 3, we see 1) transitions from both directions between states "place and time" and "api call", and 2) transitions from "api call" to itself, as there are simulated speech recognition errors in the data and the system needs to confirm the entity values and update the API query.

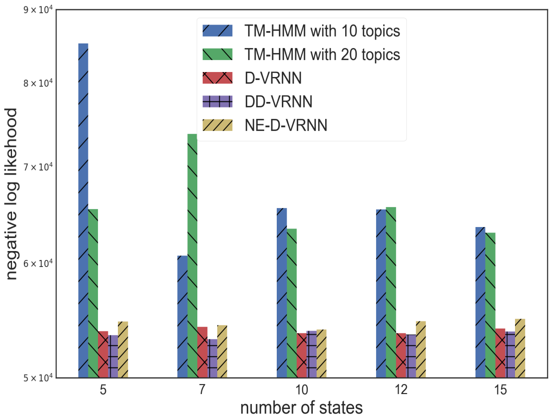

Figure 4: Negative log likelihood on restaurant data.

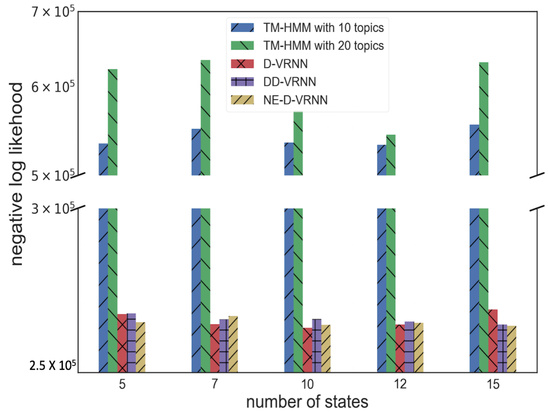

Figure 5: Negative log likelihood on weather data.

5.3 VRNN Model Variants Comparison

Even though the three proposed VRNN-based models have similar structures, they perform differently and are able to compensate each other. For example, in Fig. 8(b) in the Appendix, DD-VRNN is able to recognize a new state "not done yet, what's the weather", when users start a new query. This can complement D-VRNN's result.

Quantitatively, the three model variants also perform differently. On the restaurant test set shown in Fig. 4, DD-VRNN has the best overall performance compared with other models. Especially when the number of states N is small (e.g. 5 or 7 states), the advantage of the direct transition is more obvious. We think the reason behind is that it's easier and more accurate to model the direct transitions between a smaller set of states; as we increase N, the direct transitions between states become less and less obvious and therefore, help less on the predictive power. To our surprise, putting more weights on the named entities has a negative impact on the performance on the restaurant dataset. The underlying reason might be that the emphasis on the named entities shifts the focus of the model from abstract latent representation to a more concrete word token level. However, on the simulated weather dataset shown in Fig. 5, NE-D-VRNN performs relatively well. It might be because the weather dataset is completely simulated, which makes it easier to recognize the named entities. With a more accurate named entity recognition, NE-D-VRNN is able to help the performance. Overall, D-VRNN is the most stable one across datasets, so we will use D-VRNN in the following experiments.

6 Application on RL

The ultimate goal of such a structure discovery model is to utilize the structure to facilitate downstream tasks, such as dialog system training. Therefore, we propose to incorporate the dialog structure information into the reward function of the RL training. We believe that the transition table learned from the original dataset will guide the policy to make better decisions and converge faster by encouraging the policy to follow the real-data distribution. Similar to other RL models, we build a user simulator to perform the RL training. Please refer to the Appendix for the training details.

6.1 Reward Function Design

We use *policy gradient* method (Williams, 1992) to train the dialog policy. Traditional reward functions give a positive reward (e.g. 20) after the successful completion of the task, 0 or a negative reward to penalize a failed task and -1 at each extra turn to encourage the system to finish the task sooner rather than later (Williams et al., 2017). But this type of delayed reward functions doesn't have immediate rewards at each turn, which makes the model converge slowly. Therefore, we propose to incorporate the learned conversational exchange transition information as an immediate reward. The intuition is that in order to complete a task sooner, most users will follow a certain pattern when interacting with the system, for example, a typical flow is that users first give the entities information such as location, then ask for the restaurant information and finally, end the conversation. If we can provide the RL model with the information on what action is more likely to follow another action, the model can learn to follow real-data distributions and make better predictions. We encode the transition information through KL-divergence, a measurement of the distance between two distributions, in the reward function.

We design four types of reward functions and describe each of them in Algorithm 1 and Eq. 10 in the Appendix. The traditional delayed reward is the baseline. The second reward function, Rep-reward, uses constant penalty for repeated questions, as penalizing repetition yields better results, according to Shi and Yu (2018). The third reward function, KL-reward, incorporates the transition table information. From the RL model, we get the predicted probability p_{pred} for different actions; from the D-VRNN model, we get the transition probability p_{trans} between states and each state is translated to an action. We calculate the negation of the KL-divergence between p_{trans} and p_{pred} and use it as the immediate reward for every turn. This immediate reward links the predicted distribution with the real-data distribution by calculating the distance between them. The fourth reward function (KL+Rep) gives an additional -2 repetition penalty to the KL-reward to test the combination effect of the two types of penalties.

6.2 Result Analysis

We evaluate the RL performance by the average success rate, shown in Fig. 6. We observe that all the experimental reward functions greatly improve the performance of the baseline. We also observe that the baseline has a higher variance, which is due to the inefficient delayed rewards. Moreover, both the KL-reward and the KL-Rep reward reach a higher success rate at around 10,000 iterations than the Rep-reward and converges faster. These two reward functions also achieve a better convergent success rate after 10,000 iterations. This suggests that adding KL-divergence of p_{trans} and p_{pred} into the reward helps develop a better policy faster.

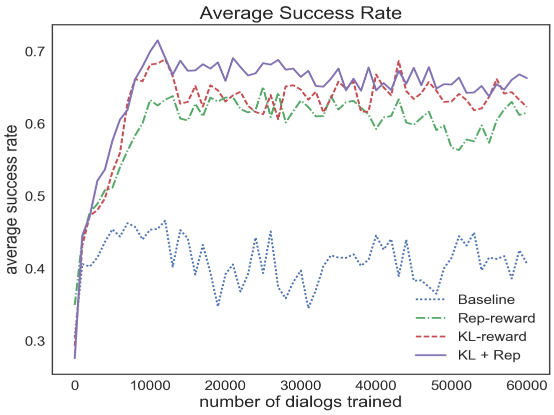

Figure 6: Average success rate of RL models with different reward functions.

The good performance comes from the transition probability p_{trans} learned by the discrete-VRNN. p_{trans} summarizes the communication pattern of most users in the real world and the KL-divergence measures the distance between the predicted distribution p_{pred} and p_{trans} from the real dataset. The RL model processes this KL-reward signal and learns to minimize the gap between p_{trans} and p_{pred}. As a result, p_{pred} will follow closer to the real data distribution, leading the model to converge faster to a better task success rate. In this way, we successfully incorporate the dialog structure information from the real data into the RL system training.

We observe that the use of KL reward improves the performance significantly in terms of both convergence rate and the final task success rate. Further, the combination of KL and repetition reward makes the model more stable and achieves a better task success rate, compared with the model with only KL-reward or Rep-reward. This indicates that the KL-reward can be combined with other type of rewards to achieve a better performance.

7 Conclusion and Future Work

A key challenge for discourse analysis and dialog system building is to extract the latent dialog structure. We adopted the VRNN with discrete latent variables to learn the latent states of each conversational exchange and the transitions between these states in an unsupervised fashion. We applied the algorithm on a restaurant search task and a simulated weather report task, and evaluated the model quantitatively and qualitatively. We also proposed a way to incorporate the learned dialog structure information into a downstream dialog system building task. We involved the dialog structure in the RL reward design, which made the model converge faster to a better task success rate.

The performance of the Discrete-VRNN model has a major impact on the performance of the policy training. We plan to further improve the dialog structure learning process. Currently, we try to capture the status of the named entities by increasing the weights on the entities, which focus on the concrete word token level. In the future, we may use more sophisticated ways to encode the entity information into the latent states.

A.2 RL Simulation Setting

The main purpose of the user simulator is to provide named entities. Therefore, it is built by sampling utterances from the real dataset according to the current status of named entities. Table 2 shows one simulated dialog in the reinforcement learning. We design seven system template actions in the simulated setting which fall under four categories, *ask for entity*, *present results*, *give restaurant information* and *closing statement*. But there are n latent states learned from the real data, and n is not necessarily equal to four. To solve this mismatch in dimensions between p_{pred} and p_{tran}, human experts further collapse similar latent states and reduce the number of latent states to four, which represents the four main categories in the actions, *ask for entity*, *present results*, *give restaurant information* and *closing statement*. For example, the two "thank you concentrated" states in Fig. 2 will be combined to the *closing statement* category. The probability of each category is the sum of the original probabilities whose actions are now under the same category.

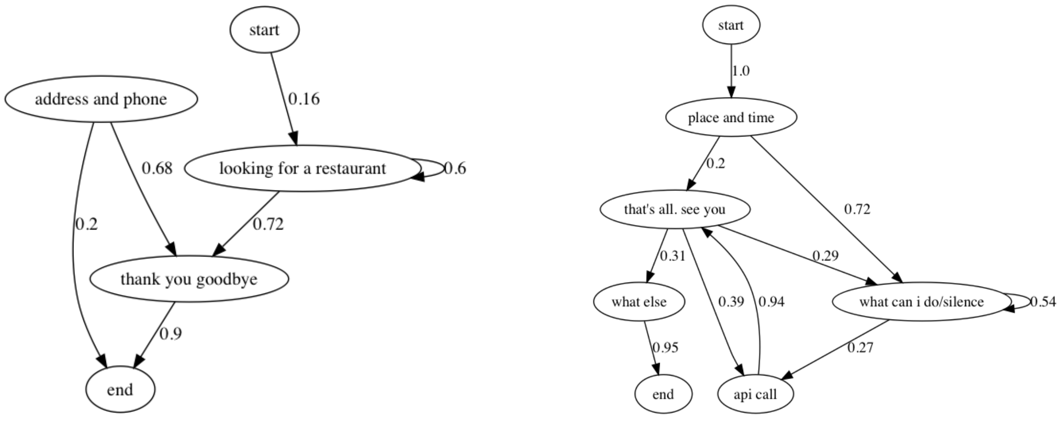
A.3 RL Training Details

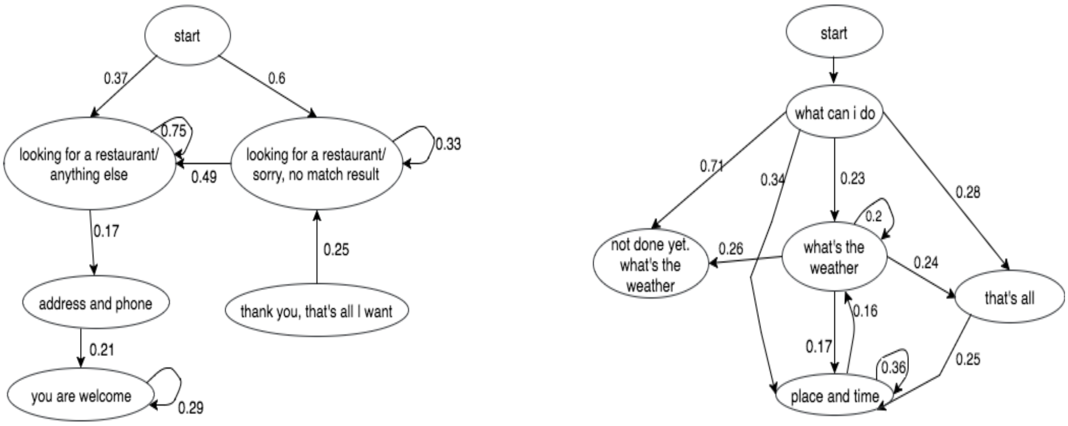
A simple action mask is used to prevent impossible actions, such as presenting results without making a query to the DB. The input to the model is a list of common contextual features, such as the presence of each entity and the last action taken. The output of the model is the system action template.



(a) HMM, restaurant data, 5 states

(b) HMM, weather data, 10 states

Figure 7: Dialog structures generated by HMM on different datasets. Transitions with $P \geq 0.2$ are visualized.



(a) DD-VRNN, restaurant data, 5 states

(b) DD-VRNN, weather data, 10 states

Figure 8: Dialog structures generated by DD-VRNN on different datasets. Transitions with $P \geq 0.2$ are visualized.

Four different reward functions are used. A discount factor of 0.9 is applied to all the experiments and the maximum number of turns is 10. An LSTM with 32 hidden units is used and the RL policy is updated after each dialog. We also apply ϵ-greedy exploration strategy (Tokic, 2010). Because the RL training can sometimes be unstable, we initialize all the model parameters using supervised learning on a simulated dataset, which consists of 500 dialogs between the user simulator and a rule-based agent simulator. The method is evaluated by freezing the policy after every 1000 updates and running 200 simulated dialogs to calculate the task success rate. We repeat the entire process 10 times and report the average success rate in Fig. 6.

Modeling Document-level Causal Structures for Event Causal Relation Identification

Lei Gao, Prafulla Kumar Choubey, Ruihong Huang
Department of Computer Science and Engineering
Texas A&M University
`(sjtuprog, prafulla.choubey, huangrh)@tamu.edu`

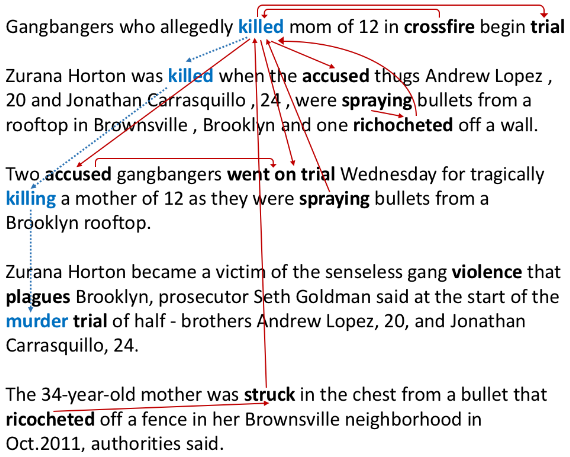
Abstract

We aim to comprehensively identify all the event causal relations in a document, both within a sentence and across sentences, which is important for reconstructing pivotal event structures. The challenges we identified are two: 1) event causal relations are sparse among all possible event pairs in a document, in addition, 2) few causal relations are explicitly stated. Both challenges are especially true for identifying causal relations between events across sentences. To address these challenges, we model rich aspects of document-level causal structures for achieving comprehensive causal relation identification. The causal structures include heavy involvements of document-level main events in causal relations as well as several types of fine-grained constraints that capture implications from certain sentential syntactic relations and discourse relations as well as interactions between event causal relations and event coreference relations. Our experimental results show that modeling the global and fine-grained aspects of causal structures using Integer Linear Programming (ILP) greatly improves the performance of causal relation identification, especially in identifying cross-sentence causal relations.

1 Introduction

Understanding causal relations between events in a document is an important step in text understanding and is beneficial to various NLP applications, such as information extraction, question answering and text summarization. Causal relations can occur between any two events in a document, both between events within a sentence and between events across sentences. In this paper, we aim to identify all the event causal relations in a document.

The main challenges for achieving comprehensive causal relation identification are that event causal relations are sparse among all the event pairs in a document and few event causal relations are explicitly stated. The challenges are especially true for identifying cross-sentence event causal relations and most of them have no clear causal indicators. To address these challenges, we model rich aspects of document-level causal structures, i.e., structural distributions of causal relations within a document, for achieving comprehensive causal relation identification in news articles.



Gangbangers who allegedly **killed** mom of 12 in **crossfire** begin **trial**

Zurana Horton was **killed** when the **accused** thugs Andrew Lopez , 20 and Jonathan Carrasquillo , 24 , were **spraying** bullets from a rooftop in Brownsville , Brooklyn and one **richocheted** off a wall.

Two **accused** gangbangers **went on trial** Wednesday for tragically **killing** a mother of 12 as they were **spraying** bullets from a Brooklyn rooftop.

Zurana Horton became a victim of the senseless gang **violence** that **plagues** Brooklyn, prosecutor Seth Goldman said at the start of the **murder** **trial** of half - brothers Andrew Lopez, 20, and Jonathan Carrasquillo, 24.

The 34-year-old mother was **struck** in the chest from a bullet that **ricocheted** off a fence in her Brownsville neighborhood in Oct.2011, authorities said.

Figure 1: An Example of Main Event Causal Structure

Our key observation for improving causal relation identification is that causal relations, especially cross-sentence causal relations, tend to involve one or two main events of a document. The main events are the focus of a story, which are usually mentioned in the title of an article and have repeated mentions throughout the document. Intuitively, causal relations in a document are often used to explain why the main events happened as well as consequences of the main events. For example, as shown in figure 1, **killing** is the main event. The events **crossfire, spraying, richocheted, struck** are its preconditions, and **accuse, trial** are its consequences. Indeed, many causal

Proceedings of NAACL-HLT 2019, pages 1808–1817
Minneapolis, Minnesota, June 2 - June 7, 2019. ©2019 Association for Computational Linguistics

relations are related to the main event.

In addition to the global causal structures related to main events of a document, we model three types of fine-grained causal structures in order to accurately identify each individual causal relation. First, specific sentential syntactic relations may evoke causal relations between event pairs. For instance, adverbial clause modifier of a verb phrase explains its consequence, condition or purpose. Second, we model implications of a discourse relation between two text units (e.g., the *contingency* discourse relation) towards causal relations between events in the two text units. Third, we model interactions between event causal relations and event coreference relations. For example, coreferent event mentions should have the same causal relations; a causal relation and an identity relation should not co-exist between any two events.

We use Integer Linear Programming (ILP) to model these rich causal structures within a document by designing constraints and modifying the objective function to encourage causal relations akin to the observed causal structures and discourage the opposite. Our experimental results on the dataset EventStoryLine (Caselli and Vossen, 2017) show that modeling the global and fine-grained aspects of causal structures within a document greatly improves the performance of causal relation identification, especially in identifying cross-sentence causal relations.

2 Related Work

In the last decade or so, both unsupervised and supervised causal relation identification approaches have been proposed including linguistic patterns, statistical measures and supervised classifiers, primarily with the goal of acquiring event causality knowledge from a text corpus. The proposed approaches mainly rely on explicit contextual patterns (Girju; Hashimoto et al., 2014) or other causality cues (Riaz and Girju, 2010; Do et al., 2011), statistical associations between events (Beamer and Girju, 2009; Hu et al., 2017; Hu and Walker, 2017; Do et al., 2011; Hashimoto et al., 2014), and lexical semantics of events (Riaz and Girju, 2013, 2014b,a; Hashimoto et al., 2014).

An increasing amount of recent works focused on recognizing event causal relations within a document, but mostly limited to identifying intra-sentence causal relations with explicit causal indicators. Mirza et al. (2014) annotated event causal relations in the TempEval-3 corpus and created CausalTimeBank. Mirza and Tonelli (2014) stated that incorporating temporal information improved the performance of a causal relation classifier. Mirza and Tonelli (2016) built both a rule-based multi-sieve approach and a feature based classifier to recognize causal relations in CausalTimeBank. However, causal relations in CausalTimeBank are few and only explicitly stated intra-sentence causal relations were annotated. In addition, Mostafazadeh et al. (2016) annotated both temporal and causal relations in 320 short stories (five sentences in each story) taken from the ROCStories Corpus and indicated strong correlations between causal relations and temporal relations.

Lately, Caselli and Vossen (2017) created a corpus called EventStoryLine, which contains 258 documents and more than 5,000 causal relations. The EventStoryLine corpus is the largest dataset for causal relation identification till now with comprehensive event causal relations annotated, both intra-sentence and cross-sentence, which presents unique challenges for causal relation identification. Caselli and Vossen (2017) showed that only 117 annotated causal relations in this dataset are indicated by explicit causal cue phrases while the others are implicit. We conduct experiments on the EventStoryLine dataset. Distinguished from most of the previous approaches that identify one causal relation each time, we model coarse-grained and fine-grained document-level event causal structures and infer all the causal relations in a document.

Integer linear programming (ILP) approaches have been applied to predict a set of temporal relations or an event timeline in a document (Do et al., 2012; Teng et al., 2016; Ning et al., 2017). ILP has been used to improve causal relation identification (Do et al., 2011), but only with fine-grained constraints considering discourse relations between two text units. Our approach innovates on modeling other aspects of document-level causal structures, especially heavy involvements of main events in causal relations, that facilitate resolving multiple causal relations.

3 The EventStoryLine Corpus

Table 1 shows the statistics of the corpus EventStoryLine v0.9[1] (Caselli and Vossen, 2017).

Item	Size
Topics	22
Documents	258
Sentences	4,316
Event Mentions	5,334
Intra-sentence causal links	1,770
Cross-sentence causal links	3,855
The Total causal links	5,625
Explicit causal links	117

Table 1: EventStoryLine v0.9

Causal relations annotated in EventStoryLine are between two event mentions. Different causal relations are annotated in EventStoryLine, called "rising_action" and "falling_action", which indicate the directions of causal relations and intuitively correspond to "precondition" and "consequence" relations. Note that in this paper, we focus on identifying all the pairs of events in a document that are causally related, but not on classifying the direction of a causal relation though; specifically, we aim to recognize if there exists a causal relation between any two events A and B in a document, but we do not further distinguish if A causes B vs. B causes A.

On average, there is 1.2 event mentions in each sentence. There are 7,805 intra-sentence and 46,521 cross-sentence event mention pairs in total in the corpus, around 22% (1,770) and 8% (3,855) of them were annotated with a causal relation respectively. Out of the annotated causal links, only 117 Caselli and Vossen (2017) causal relations are indicated by explicit causal cue phrases while the others are implicit. In our experiments, we use the gold event mentions in EventStoryLine and exclude aspectual, causative, perception and reporting event mentions[2], most of which were not annotated with any causal relation according to Caselli and Vossen (2017).

4 The Feature Based Local Pairwise Classifiers

Intra- and cross-sentence causal relations are different by nature. For instance, dependency relations between words in a sentence may be more useful for detecting intra-sentence causal relations, than when used for detecting cross-sentence causal relations. Therefore, we train two separate logistic regression classifiers, one for intra-sentence causal link detection and the other for cross-sentence causal link detection.

We consider all event mention pairs within a sentence as training instances for the intra-sentence causal relation classifier. Then we pair event mentions from two sentences with one event mention from each sentence, which are used as training instances for the cross-sentence classifier. Note that training instances for both classifiers are unbalanced, with a POS:NEG ration of around 1:3 and 1:10 for intra- and cross-sentence cases respectively. We applied the "balanced" class weight option[3] in logistic regression classifiers to deal with the class imbalance problem.

We use the same set of features for training both classifiers, but we expect the two classifiers to assign different weights to features.

4.1 The Common Feature Set

Lexical Features: We implement rich lexical features to capture event word forms and similarities between two events, event modifiers and event arguments. First, we encode word and lemma for each token in two event phrases as features. Then we created various similarity features between two events.

- Similarities Based on Event Word Form Match. Three binary features indicating whether the lowercases of two event head words, two event head lemmas and two complete event phrases are exactly the same.
- Similarities Based on Wordnet. We first identify synsets for each event head word in Wordnet. Then for each pair of synsets, with one synset for each event head word, we calculate the Wup similarity (Wu and Palmer, 1994). We create numerical features using the average, minimal and maximal Wup similarities.
- Similarities Based on Word Embeddings. We apply l2 normalization on event head word embeddings, and then we calculate the Euclidean distance and Cosine distance between

---

[1] Statistics are calculated based on latest release https://github.com/tommasoc80/EventStoryLine

[2] 639 event mentions were excluded in this way.

[3] http://scikit-learn.org/stable/modules/generated/sklearn.linear_model.LogisticRegression.html

two word embeddings and use them as features. We use Glove Vectors (Pennington et al., 2014) for word embeddings.

- Similarities Based on Event Modifiers. We run the dependency parsing tool from the Stanford CoreNLP (Manning et al., 2014) and identify event modifiers as words that have a certain dependency relation[4] with an event head word. We measure the similarity between two events using the number of common modifiers and the number of common dependency relations that connect a modifier with an event head word.
- Similarities Based on Event Arguments. We consider entities that have a direct dependency relation with an event head word as its event arguments. We use the Stanford CoreNLP to identify entities and their types. We measure the similarity between two events using the number of common event arguments and the number of common entity types.

Causal Potential Features: As inspired by the causal potential metric proposed by (Beamer and Girju, 2009), we encode features based on the point-wise mutual information (PMI) score and the relative textual order between two events. We calculate the PMI score of two event words in EventStoryLine by using co-occurrences of two events in one sentence, and we use the score as a numerical feature.

Syntactic Features: We use dependency relations on the dependency path between two events. We use the basic dependencies extracted from StanfordCoreNLP (Manning et al., 2014). For cross-sentence event pairs, we consider the dependency path from each event to the root node in its own sentence in extracting dependency relations, following Cheng and Miyao (2017). In addition, we use Part Of Speech tags of two event head words as features.

4.2 Score Replacement

We observed that the cross-sentence causal relation classifier is usually not as capable as the intra-sentence classifier, probably due to less contextual evidence to rely on. Therefore, for cross-sentence event mention pairs that can be converted to intra-sentence cases through event coreference links, we use a heuristic method to improve causal relation prediction performance and replace the predictions from the cross-sentence classifier with the predictions from the intra-sentence classifier[5], by using system predicted event coreference links. Note that two events may have more than one pair of mentions, one mention for each event, co-occur within one sentence, we will use the highest score produced by the intra-sentence classifier over all the event mention pairs.

In addition, the score replacement procedure may change prediction scores of some intra-sentence event mention pairs as well. For instance, if one event mention has a coreferent mention within the same sentence that is closer to and is more clearly in a causal relation with the other event mention according to the intra-sentence classifier, and when paired up, the new event pair has received a higher score, then we will replace the score of the original event pair with the higher score. We implemented the within-document neural network based event coreference classifier as described in (Choubey and Huang, 2017a) and used the system to obtain event coreference links.

5 Modeling Causal Structures Using ILP

Our Integer Linear Programming (ILP) system performs document level global inference for resolving all the intra-sentence and inter-sentence event causal relations in a document. Let p_{ij} denotes confidence score from the corresponding local pairwise classifier for assigning a causal relation to the event pair (i, j). Let μ refer to the set of event mentions in a document, we formulate our basic ILP objective function with equation 1.

$$\Theta_{Basic} = \max \sum_{i \in \mu} \sum_{j \in \mu} [p_{ij} x_{ij} + \neg x_{ij}(1 - p_{ij})] \quad (1)$$

We then augment the objective function with new objectives (equation 2) and add constraints to induce causal structures, including heavy involvements of main events (Θ_M and Θ_F) in causal relations throughout the document, as well as fine-grained interactions of event causal relations with discourse relations (Θ_D), and event coreference

---

[4] Specifically, we consider 'nmod', 'amod', 'advmod', 'mark', 'aux', 'auxpass', 'expl', 'cc', 'cop', 'punct' to be modifiers.

[5] Note that we only conduct the score replacement when a score produced by the intra-sentence classifier is higher than the score produced by the cross-sentence classifier, which indicates that the intra-sentence classifier is more confident.

relations(Θ_C) as well as syntactic structure constraints (Θ_S) for identifying causal relations.

$$\Theta = \Theta_{Basic} + \Theta_M + \Theta_F + \Theta_D + \Theta_C + \Theta_S \qquad (2)$$

5.1 Document Level Main Event Based Constraints

Main Event: Main events are central to the story in a document and tend to participate in multiple causal links. Similar to Choubey et al. (2018), we recognize main events based on characteristics of event coreference chains within a document. Specifically, we rank events based on the number of event mentions referring to an event, and choose the top two events as main events[6]. Then we add a new objective function (equation 3) and additional constraints to encourage causal links in event mention pairs containing a main event (equation 4) and discourage causal links in the remaining mention pairs (equation 5).

$$\begin{aligned}\Theta_M = \max \Big[&\sum_{i\in\Lambda} [k_{m_1} m_1(i) + k_{m_2} m_2(i)] \\ - &\sum_{i\in\mu-\Lambda} [k_{n_1} n_1(i) + k_{n_2} n_2(i)] \Big]\end{aligned} \qquad (3)$$

$$\begin{aligned}\forall i \in \Lambda, &\sum_{j\in\mu, d_i = d_j} x_{ij} \geq m_1(i) \\ \forall i \in \Lambda, &\sum_{j\in\mu, d_i \neq d_j} x_{ij} \geq m_2(i)\end{aligned} \qquad (4)$$

$$\begin{aligned}\forall i \in \mu - \Lambda, &\sum_{j\in\mu-\Lambda, d_i = d_j} x_{ij} \leq n_1(i) \\ \forall i \in \mu - \Lambda, &\sum_{j\in\mu-\Lambda, d_i \neq d_j} x_{ij} \leq n_2(i)\end{aligned} \qquad (5)$$

In the above equations, Λ denotes the set of main event mentions, and d_i denotes the sentence number for event i. The independent variables $m_1(i)$ and $m_2(i)$ indicate the minimum number of intra- and cross-sentence causal relations that main events participate in. By maximizing $m_1(i)$ and $m_2(i)$ in the objective function Θ_M, our model favors main events to have more causal relations. Similarly, variables $n_1(i)$ and $n_2(i)$ in equation 5 are separately defined to set upper thresholds on the maximum number of intra- and cross-sentence causal relations without a main event. Unlike $m_1(i)$ and $m_2(i)$, we aim to minimize the variables $n_1(i)$ and $n_2(i)$ to restrict non-main events from participating in causal relations. Notice that we apply the constraints separately to intra- and cross-sentence mention pairs. This is primarily because main events are likely to participate in many more cross-sentence causal relations compared to intra-sentence cases. Furthermore, we observe that a main event may trigger several consequent events which themselves are causally related. However, causal relations involving only non-main events are less likely to show transitivity. Therefore, we add the constraint 6 to ensure non-transitivity among causal relations with no main event.

$$x_{ij} + x_{jk} + x_{ik} \leq 2 + 1_{i\in\Lambda} + 1_{j\in\Lambda} + 1_{k\in\Lambda} \qquad (6)$$

Locality Constraints: Main events may not always have the largest coreference chain size, and the position of an event mention provides another strong heuristics for identifying the main event (Upadhyay and Roth, 2016). In addition, the first sentence often summarizes the central context of story and are likely to describe foreground events (Grimes, 1975) that have causal relation with multiple other events. Therefore, we add an objective function (equation 7) and additional constraints (equation 8) to encourage causal relations that contain an event from the first sentence.

$$\Theta_S = \max \sum_{i\in S} k_f b_1(i) - \sum_{i\in\mu} \sum_{j\in\mu} k_f l_{ij} \cdot |d_i - d_j| \qquad (7)$$

$$\forall i \in F, \sum_{j\in\mu} x_{ij} \geq b_1(i) \qquad (8a)$$

$$\forall < i, j > \in M, x_{ij} \leq l_{ij} + 1_{i\notin\{F\}} \wedge 1_{j\notin\{F\}} \qquad (8b)$$

where, F represents all the events in first sentence, independent variable $b_1(i)$ indicates the minimum number of causal relations that an event in F participates in, M represents the set of event mention pairs that can be mapped to the same sentence and l_{ij} is a leakage variable that allows distant event mentions in F receiving a very high confidence value p_{ij} to have a causal relation. Particularly, we encourage causal links between two event mentions that are in nearby sentences or can

---

[6] If there is a tie between two event clusters with the same number of coreferential event mentions, we use the sum of confidence scores for pairs of coreferential event mentions in a cluster to break the tie. The confidence scores were assigned by the local pairwise coreference relation classifier.

be mapped to the same sentence using coreference links[7]. By maximizing the variables $b_1(i)$ and minimizing the term $l_{ij} \cdot |d_i - d_j|$, we encourage event mentions in F complying with certain constraints to have more causal relations.

5.2 Fine-grained Causal Structure Constraints

Syntactic Relations: Specific sentential syntactic relations may evoke causal relations between event pairs. First, adverbial clause modifier of a verb phrase explains its consequence, condition or purpose; Second, nominal events mentioned as subject in the main clause presents an assertional structure that delivers foreground (Grimes, 1975) information which may have causal associations with other events; Third, non-finite verb events that share arguments and complement the main event of a sentence are likely to have causal associations with the main event.

Therefore, we add an objective function (equation 9) and additional constraints (equation 10) to encourage causal relations that contain a nominal event as subject or verb event that modifies its parent with advcl or xcomp dependency relations. Here, S represents event mentions that possess one of the above syntactic structures, independent variable $b_2(i)$ indicates the minimum number of causal relations that an event in S participates in. Note that equation 10(b) was modified from 8(b) and allows discounted optimization (with l_{ij}) for events in S that are mappable to the same or nearby sentences.

$$\Theta_S = \max \sum_{i \in S} k_s b_2(i) \tag{9}$$

$$\forall i \in S, \sum_{j \in \mu} x_{ij} \geq b_2(i) \tag{10a}$$

$$\forall < i, j > \in M, x_{ij} \leq l_{ij} + 1_{i \notin \{F,S\}} \wedge 1_{j \notin \{F,S\}} \tag{10b}$$

Discourse Relations: Note that the implications of discourse relations between two text units towards causal relations between events in the two text units have been discussed in the previous work (Do et al., 2011). In this work, we consider three types of discourse relations[8]. First, two subtypes of the *contingency* discourse relation, namely *cause* and *condition*, strongly suggest that causal links exist between events in the two discourse units. On the contrary, the *comparison* discourse relation highlights semantic independence between two discourse units, thus inhibits causal relations between events described in them. Third, all causal relations are inherently temporal. An event that causes another event must necessarily occur before or temporally overlap with the latter. Thus, clauses having one of these temporal discourse relations may also favor causal relations between events in them. We model the above three dependencies between discourse relations and causation through constraints 11 and the objective function 12.

$$\begin{aligned} &\forall r = Contingency, \sum_{i \in arg_1} \sum_{j \in arg_2} x_{ij} \geq 1 \\ &\forall r = Comparison, \sum_{i \in arg_1} \sum_{j \in arg_2} x_{ij} \leq 0 \\ &\forall r = Temporal, \sum_{i \in arg_1} \sum_{j \in arg_2} x_{ij} \geq T(r) \end{aligned} \tag{11}$$

$$\Theta_D = \max \sum_{r = Temporal} k_t T(r) \tag{12}$$

Specifically, we enforce events in clauses with the contingency discourse relation to have at least one event pair with causal relation. Similarly, we inhibit a causal relation between any event pair in clauses with the comparison discourse relation. For events in clauses with a temporal discourse relation, we aim to maximize the number of causal relations without grounding it to any hard lower bound. Here, r denotes the discourse relation between two discourse arguments, arg_1 and arg_2, and *Temporal* refers to the set of temporal discourse relations. We use the pre-trained PDTB discourse parser (Lin et al., 2014) to obtain discourse relations in a document.

Event Coreference Relations: We model interactions between event causal relations and event coreference relations by adding constraints 13 and 14 and an objective function 15.

$$\forall i \equiv j, x_{ij} \leq c_3(i, j) \tag{13}$$

$$\begin{aligned} &\forall i \equiv j, x_{ik} + \neg x_{jk} \leq 1 + c_1(i, j, k) \\ &\forall i \equiv j, \neg x_{ik} + x_{jk} \leq 1 + c_2(i, j, k) \end{aligned} \tag{14}$$

---

[7] Two event mentions are mappable if their respective coreferential event mentions co-occur in at least one sentence.

[8] We use PDTB parser (Lin et al., 2014) to identify three discourse relations.

$$\Theta_C = \max \sum_{i \in \mu} \sum_{j \in \mu} \Big[\sum_{k \in \mu} -k_c(c_1(i,j,k) \\ + c_2(i,j,k)) \Big] - (1 - k_c)(c_3(i,j)) \quad (15)$$

Here $\equiv$ represents the identity (coreference) relation. The constraint 13 ensures that causal relation and coreference relation are mutually exclusive, allowing some violations when $p_{i,j}$ is high. The constraints 14 along with the objective function 15 encourage coreferent event mentions to have a causal relation with the same other event. While this relation between causal and coreference relations is strictly true for gold standard data, we observed that these constraints make the system very sensitive to noise when using system predicted coreference links. Therefore, we added binary leakage variables $c_1(i,j,k)$, $c_2(i,j,k)$ and $c_3(i,j)$ to relax these constraints.By maximizing the negative of leakage variables, we allow our model to overcome this instability.

6 Evaluation

6.1 Experimental settings

There are 22 topics in the EventStoryLine corpus. We put them in order based on their topic IDs and use documents in the last two topics as the development set. We trained the ILP system using the rest 20 topics and tuned parameters based on the system performance on the development set. We report experimental results by conducting 5-fold cross validation on the rest 20 topics. For event causal relation identification, we report precision, recall, and F1-score.

The weighting parameters for constraints, including $k_{m_1}, k_{m_2}, k_{n_1}, k_{n_2}, k_f, k_t, k_c$ and k_s, were first pre-set to be a small number 0.1. We then conducted grid search and searched for the best value for each parameter over the range from 0.1 to 0.5 with a step size of 0.1. The best values for the parameters are $0.2, 0.1, 0.1, 0.5, 0.2, 0.1, 0.1, 0.2$ respectively.

6.2 Baseline Systems

We consider six baseline systems:

OP: a dummy model used in (Caselli and Vossen, 2017) that assigns a causal relation to every event mention pair.

Cheng and Miyao (2017): a dependency path based sequential neural network model that extensively models compositional meanings of the context between two event mentions for causal relation identification. This model was first used for identifying event temporal relations and has been shown effective in identifying both intra- and cross-sentence temporal relations.

Choubey and Huang (2017b): another dependency path based sequential neural network model that was first developed for identifying temporal relations between event mentions within a sentence. We make this model also work for cross sentence cases by merging the root nodes of two dependency trees associated with two separate sentences and extracting a dependency path connecting events across sentences.

So far, there is no well recognized effective approach for causal relation identification within a document. We applied the above two models for causal relation identification considering that causal relations are closely related with certain temporal relations and a causal event must occur before or overlap with the consequence event.

LR (Lexical): the same logistic regression classifier as our local pairwise classifier but using the lexical features only.

LR (Causal Potential): the same logistic regression classifier as our local pairwise classifier but using the causal potential features only.

LR (Full): our local pairwise classifier using the full set of features.

+ Score Replacement: our local pairwise classifier using the full set of features, with the heuristic score replacement procedure applied.

6.3 Experimental Results

The first section of table 2 shows the performance of baseline models on intra- and cross-sentence causal relation identification. The model **OP** labels each event mention pair as causal and suffers from low precisions[9], especially on identifying cross-sentence causal relations. The two dependency path based neural network model **(Cheng and Miyao, 2017; Choubey and Huang, 2017b)** do not perform effectively on identifying causal relations. The performance is especially poor on cross-sentence cases.

The model **LR (Lexical)** improved the precision of causal relation identification but suf-

---

[9] The reason it did not achieve the 100% recall is that we did not consider reporting, causative, perception or aspectual events.

Table 2: Performance of different models on causal relation identification

fers from low recall. In contrast, the model **LR (Causal Potential)** improved the recall but suffers from low precision. The model **LR (full)** with rich lexical, semantic and syntactic features achieved the best trade-off between precision and recall. **+ Score Replacement** significantly improves the recall and F1-score on identifying cross-sentence causal relations, which also slightly improves the recall of intra-sentence cases. But the precision of causal relation identification remains low, especially on cross-sentence cases.

The second section of table 2 shows the performance of our ILP model after gradually adding each type of constraints. **+Main Event Constraints** shows the performance of the ILP system with constraints encouraging causal relations involving a main event. By modeling this aspect of document-level causal structures, the precision of cross-sentence causal relation identification was clearly improved by around 6.3%. With a small loss on recall, the F1-score was improved by 4.1%. Modeling this document-level causal structure also improves both precision and recall on identifying intra-sentence causal relations, but with a relatively small margin. Compared to the local pairwise model **+ Score Replacement**, the overall F1-score improvement from using global main event constraints is statistically significant with $p<0.05$ (Dietterich, 1998). **+Locality Constraints** strengthens the effects of modeling main events and further improved the performance of both cross- and intra-sentence causal relation identification.

Next, adding sentential syntactic structure based constraints (**+Syntactic Constraints**) recovered additional intra-sentence causal relations and cross-sentence causal relations as well due to score replacement, and improved their recall by 4.4% and 2.8% respectively with little or no drop on precision. Then, after adding discourse constraints (**+Discourse Constraints**), both precision and recall on intra-sentence causal relation identification were slightly improved while the performance on cross-sentence causal relation identification remains roughly the same, this is mainly due to the fact that few cross-sentence discourse relations were identified by the discourse parser we used. Finally, after adding conference constraints (**+Coreference Constraints**), the precision of cross-sentence causal relation identification was increased by 2.9%, with a small loss on recall, the F1-score was improved by 1.8%. Unsurprisingly, the overall performance on intra-sentence causal relation identification was not affected much by coreference constraints since event coreference relations often involve events across sentences. Compared to the model considering global constraints only (the line **+ Locality Constraints**), the overall F1-score improvement from using fine-grained causal structure constraints is statistically significant with $p<0.01$.

To sum up, by modeling the global and fine-grained aspects of causal structures, the performance of both intra- and cross-sentence causal re-

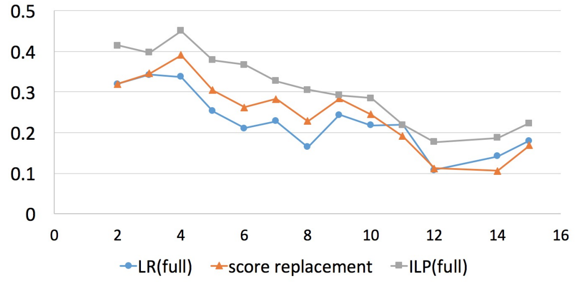

Figure 2: F1-scores on documents with different lengths. The x-axis indicates the number of sentences a document has. The y-axis indicates the macro average F1-score of causal relation identification.

lation identification was greatly improved by 3.9% and 7.5% in F1-score respectively. Compared to the local pairwise model **+ Score Replacement**, the overall F1-score improvement from using both global main event constraints and fine-grained causal structure constraints is statistically significant with $p<0.002$.

Impact of Document Lengths Figure 2 shows performance comparisons of three models on documents with different lengths. The first impression is that causal relation identification becomes harder when documents are longer. If we look into the figure, the score replacement heuristic improves the performance of causal relation identification on medium-sized documents, but not on short ($<$ 4 sentences) or long ($>$ 10 sentences) documents. This may either due to little event coreference information for use in short documents or event coreference information becoming too noisy in long documents. Compared to the mixed effects of the score replacement heuristic, the ILP system improved the performance of causal relation identification consistently in documents of any length, through modeling rich document-level causal structures.

7 Conclusions

We have presented an ILP system that collectively identifies all the causal relations within a document, both intra- and cross-sentence causal relations, by modeling the global and fine-grained aspects of causal structures. In the future, we will continue to enrich document-level causal structures, e.g., by considering segment-wise topic layouts and rhetorical discourse structures.

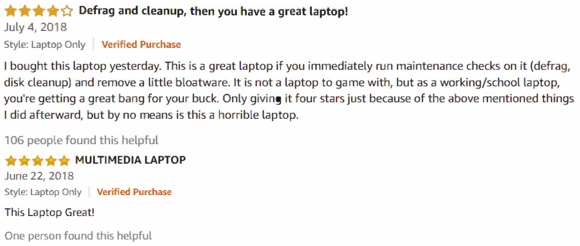
Abstract

Utilizing reviews to learn user and item representations is useful for recommender systems. Existing methods usually merge all reviews from the same user or for the same item into a long document. However, different reviews, sentences and even words usually have different informativeness for modeling users and items. In this paper, we propose a hierarchical user and item representation model with three-tier attention to learn user and item representations from reviews for recommendation. Our model contains three major components, i.e., a sentence encoder to learn sentence representations from words, a review encoder to learn review representations from sentences, and a user/item encoder to learn user/item representations from reviews. In addition, we incorporate a three-tier attention network in our model to select important words, sentences and reviews. Besides, we combine the user and item representations learned from the reviews with user and item embeddings based on IDs as the final representations to capture the latent factors of individual users and items. Extensive experiments on four benchmark datasets validate the effectiveness of our approach.

1 Introduction

Learning accurate user and item representations is very important for recommender systems (Tay et al., 2018). Many of existing recommendation methods learn user and item representations based on the ratings that users gave to items (Koren et al., 2009; Mnih and Salakhutdinov, 2008). For example, Koren et al. (2009) proposed a matrix factorization method based on SVD to learn latent representations of users and items from the rating matrix between users and items. However, since the numbers of users and items in online platforms are usually huge, and the rating matrix between users and items is usually very sparse, it is quite difficult for those rating based recommendation methods to learn accurate user and item representations (Zheng et al., 2017; Tay et al., 2018).



★★★★☆ **Defrag and cleanup, then you have a great laptop!**
July 4, 2018
Style: Laptop Only | Verified Purchase

I bought this laptop yesterday. This is a great laptop if you immediately run maintenance checks on it (defrag, disk cleanup) and remove a little bloatware. It is not a laptop to game with, but as a working/school laptop, you're getting a great bang for your buck. Only giving it four stars just because of the above mentioned things I did afterward, but by no means is this a horrible laptop.

Figure 1: Two example reviews.

Luckily, in many online platforms such as Amazon and IMDB, there are rich reviews written by the users to express their opinions on items. These reviews can provide rich information of items. For example, if sentences like “bad battery life” and “battery capacity is low” frequently appear in the reviews of a smartphone, then we can infer the performance of this item in battery life is not good. The reviews also contain rich information of users. For example, if a user frequently mentions “the price is too high” and “very expensive” in his/her reviews for different items, then we can infer this user may be sensitive to price. Thus, these reviews can help enhance the learning of user and item representations especially when ratings are sparse, which is beneficial for improving the performance of recommender systems (Zheng et al., 2017).

Utilizing reviews to learn user and item representations for recommendation has attracted increasing attentions (Zheng et al., 2017; Catherine and Cohen, 2017). For example, Zheng et al. (2017) proposed a DeepCoNN method to learn the representations of users and items from reviews using convolutional neural networks (CNN), and achieved huge improvement in recommendation performance. These methods usually concatenate the reviews from the same user or the

Proceedings of NAACL-HLT 2019, pages 1818–1826
Minneapolis, Minnesota, June 2 - June 7, 2019.

same item into a long document. However, different reviews usually have different informativeness in representing users and items. For example, in Fig. 1 the first review is much more informative than the second one. Distinguishing informative reviews from noisy ones can help learn more accurate user and item representations. In addition, different sentences in the same review may also have different informativeness. For example, in Fig. 1 the sentence “it is not a laptop to game with” contains more important information than “I bought this laptop yesterday”. Besides, different words in the same sentence may also have different importance. For example, in “this is a great laptop if you ...” the word “great” is more important than “you” in modeling this item.

In this paper, we propose a hierarchical user and item representation model with three-tier attention (*HUITA*) to learn informative user and item representations from reviews for recommendation. In our approach, the hierarchical user and item representation model contains three major components, i.e., a sentence encoder to learn sentence representations from words, a review encoder to learn review representations from sentences, and a user/item encoder to learn user/item representations from the all reviews posted by this user or for this item. In addition, we propose to incorporate a three-tier attention network into our model to select important words, sentences and reviews to learn more informative user and item representations. Besides, we combine the user and item representations learned from the reviews with the user and item embeddings based on their IDs as the final representations to capture the latent factors of each individual users and items. We conduct extensive experiments on four benchmark datasets. The results show our approach can effectively improve the performance of recommendation and outperform many baseline methods.

2 Related Work

Learning user and item representations from reviews for recommendation has attracted many attentions (McAuley and Leskovec, 2013; Ling et al., 2014; Bao et al., 2014; Zhang et al., 2014; Diao et al., 2014; He et al., 2015; Tan et al., 2016; Ren et al., 2017). Many of the existing methods focus on extracting topics from reviews to model users and items. For example, McAuley and Leskovec (2013) proposed a Hidden Factors as Topics (HFT) method to use the topic modeling technique LDA to discover the latent aspects of users and items from the reviews. Ling et al. (2014) proposed a Ratings Meet Reviews (RMR) method to enhance the representations of users and items by extracting topics from review texts and aligning the dimensions of these topics with the latent user representations obtained from the rating matrix using matrix factorization. Bao et al. (2014) proposed a TopicMF approach to jointly model user and item representations using rating scores via matrix factorization and using review texts via non-negative matrix factorization (NMF) to obtain topics. However, these methods only extract the topic information from reviews, and a large amount of important semantic information is not captured. In addition, these methods are usually based on topic models and cannot effectively model the contexts and orders of words in reviews, both of which are important for inferring user preferences and item properties.

In recent years, several deep learning based methods have been proposed to learn user and item representations from reviews for recommendation (Zhang et al., 2016; Zheng et al., 2017; Catherine and Cohen, 2017; Seo et al., 2017b,a; Chen et al., 2018; Tay et al., 2018). For example, Zheng et al. (2017) proposed a DeepCoNN method which uses CNN to learn representations of users and items from their reviews. Catherine and Cohen (2017) proposed a TransNets method to learn user and item representations from reviews using CNN and regularize these representations to be close to the representations of the review written by the target user to the target item. Seo et al. (2017b) proposed to learn user and item representations via CNN network as well as attention network over word embeddings. These methods concatenate all the reviews from the same user or for the same item into a long document, and cannot distinguish informative reviews from noisy ones. Chen et al. (2018) proposed to model the usefulness of reviews using review-level attention to enhance the learning of user and item representations. However, their method regards each review as a long sentence, and cannot distinguish informative sentences and words from less informative ones. Different from the aforementioned methods, in our approach we propose a hierarchical framework to learn user and item representations from reviews for recommendation. Our model first learns sentence representations from words, then learns review representations from their sentences, and finally learns user/item representations from their reviews. Our model also contains a three-tier attention network to jointly select important words, sentences and reviews to learn more informative user and item representations. Experiments on benchmark datasets validate the advantage of our approach over existing methods in recommendation.

3 Our Approach

In this section, we introduce our *HUITA* approach to learn user and item representations from reviews for recommendation. The architecture of our approach is shown in Fig. 2. There are three major modules in our approach. The first one is *sentence encoder* which learns representations of sentences from words. The second one is *review encoder* which learns representations of reviews from sentences. And the third one is *user/item encoder*, which learns the representations of users and items from their reviews. Next we introduce each module in detail.

3.1 Sentence Encoder

The *sentence encoder* module is used to learn representations of sentences from words. According to Fig. 2, there are three layers in this module.

The first layer is word embedding. It is used to convert a sequence of words into a sequence of low-dimensional dense vectors which contain semantic information of these words. Denote a sentence s contains M words $[w_1, w_2, ..., w_M]$. Through the word embedding layer the sentence s is transformed into a vector sequence $[\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_M]$ using a word embedding matrix $\mathbf{E} \in \mathcal{R}^{V \times D}$, where V and D represent the vocabulary size and the word embedding dimension, respectively. The word embedding matrix $\mathbf{E}$ is initialized using pretrained word embeddings, and fine-tuned during model training.

The second layer is a convolutional neural network (CNN). CNN is an effective neural architecture for capturing local information (LeCun et al., 2015). We employ a word-level CNN to capture the local contexts of words to learn their contextual representations. Denote $\mathbf{c}_i^w$ as the contextual representation of the word w_i, which is computed as follows:

$$\mathbf{c}_i^w = \mathrm{ReLU}(\mathbf{U}_w \times \mathbf{e}_{(i-K_w):(i+K_w)} + \mathbf{b}_w), \quad (1)$$

where $\mathbf{e}_{(i-K_w):(i+K_w)}$ is the concatenation of the word embedding vectors from the position $i - K_w$ to $i + K_w$. $\mathbf{U}_w \in \mathcal{R}^{N_w \times (2K_w+1)D}$ and $\mathbf{b}_w \in \mathcal{R}^{N_w}$ are the parameters of the filters in CNN network, where N_w is the number of CNN filters and $2K_w + 1$ is the window size. ReLU is the non-linear activation function (Glorot et al., 2011). The output of the CNN layer is a sequence of contextual word representations $[\mathbf{c}_1^w, \mathbf{c}_2^w, ..., \mathbf{c}_M^w]$.

The third layer is a word-level attention network. Different words in the same sentence may have different informativeness for modeling users and items. For example, in the sentence “The laptop I bought yesterday is too heavy”, the word “heavy” is more informative than the word “yesterday” in representing this laptop. Thus, we use a word-level attention network to help our model select and attend to important words based on their contextual representations to build more informative sentence representations for user and item modeling. The attention weight of the i_{th} word in the sentence s is computed as follows:

$$a_i^w = \tanh(\mathbf{v}_w \times \mathbf{c}_i^w + b_w), \quad (2)$$

$$\alpha_i^w = \frac{\exp(a_i^w)}{\sum_{j=1}^{M} \exp(a_j^w)}, \quad (3)$$

where $\mathbf{v}_w \in \mathcal{R}^{N_w}$ and $b_w \in \mathcal{R}$ are the parameters in the attention network. α_i indicates the relative importance of the i_{th} word evaluated by the attention network. The final representation of the sentence s is the summation of the contextual word representations weighted by their attention weights as follows:

$$\mathbf{s} = \sum_{i=1}^{M} \alpha_i^w \mathbf{c}_i^w. \quad (4)$$

3.2 Review Encoder

The *review encoder* module aims to build the representations of each review based on the representation of sentences in these reviews. There are two major layers in the *review encoder* module.

The first layer is a sentence-level CNN network. Neighboring sentences usually have some relatedness with each other. For example, in a laptop review “It is not a laptop to game with. But as a working laptop, you will get a great bang for your buck”, the two neighboring sentences have close relatedness and they both describe the performance of the laptop in different scenarios.

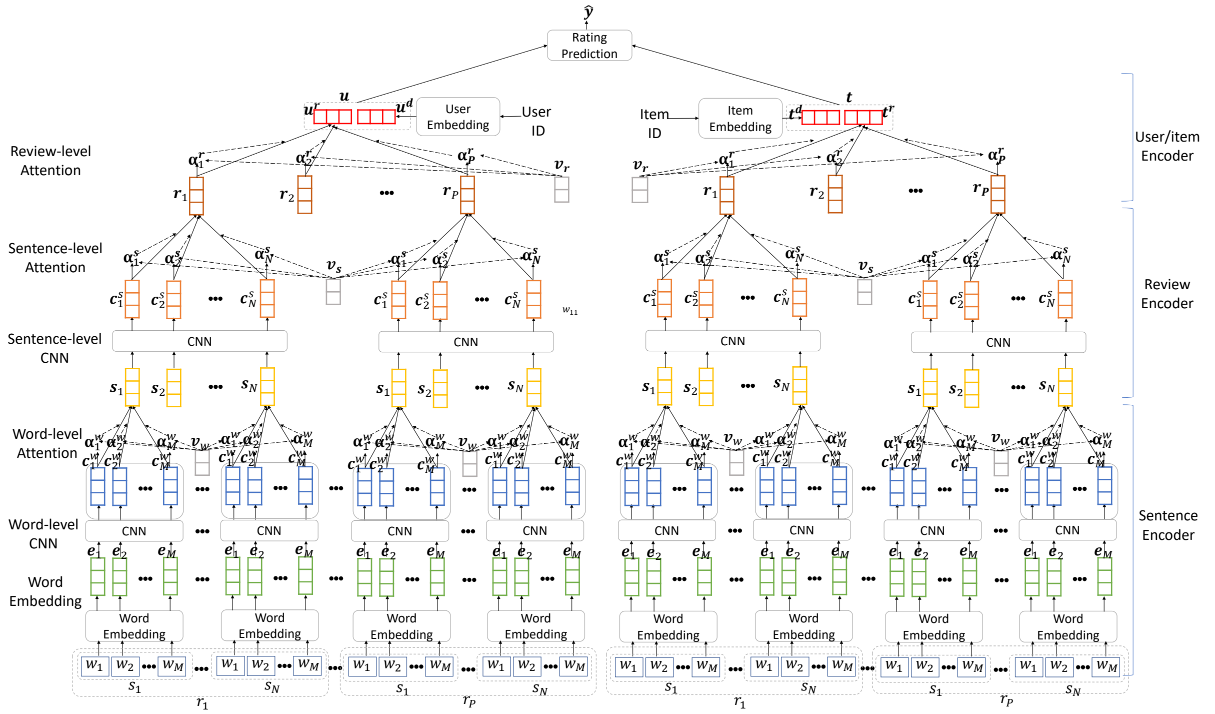

Figure 2: The framework of our *HUITA* approach for recommendation.

Thus, we employ a sentence-level CNN network to learn the contextual sentence representations by capturing the local contexts of sentences. Denote a review r contains N sentences $[s_1, s_2, ..., s_N]$. Denote the contextual representation of sentence s_i as $\mathbf{c}_i^s$, which is computed as follows:

$$\mathbf{c}_i^s = \text{ReLU}(\mathbf{U}_s \times \mathbf{s}_{(i-K_s):(i+K_s)} + \mathbf{b}_s), \quad (5)$$

where $\mathbf{U}_s \in \mathcal{R}^{N_s \times (2K_s+1)N_w}$ and $\mathbf{b}_s \in \mathcal{R}^{N_s}$ are parameters of the sentence-level CNN filters. $\mathbf{s}_{(i-K_s):(i+K_s)}$ is the concatenation of sentence representation vectors from position $i - K_s$ to $i + K_s$. N_s is the number of filters in sentence CNN network and $2K_s + 1$ is the window size.

The second layer is a sentence-level attention network. Different sentences in a review may have different informativeness for modeling users and items. For example, the sentence “it is not a laptop to game with” is more informative than the sentence “I bought this laptop yesterday” in learning the representation of this laptop. Thus, we use sentence-level attention network to help our model select and attend to important sentences to learn more informative review representations. The attention weight of sentence s_i in the review r is formulated as follows:

$$a_i^s = \tanh(\mathbf{v}_s \times \mathbf{c}_i^s + b_s), \quad (6)$$

$$\alpha_i^s = \frac{\exp(a_i^s)}{\sum_{j=1}^{N} \exp(a_j^s)}, \quad (7)$$

where $\mathbf{v}_s \in \mathcal{R}^{N_s}$ and $b_s \in \mathcal{R}$ are the parameters of the attention network. The final contextual representation of the review r is the summation of the contextual representations of sentences weighted by their attention weights, which is formulated as:

$$\mathbf{r} = \sum_{i=1}^{N} \alpha_i^s \mathbf{c}_i^s. \quad (8)$$

3.3 User/Item Encoder

The *user/item encoder* module is used to build the representations of users or items based on the representations of their reviews. Different reviews usually have different informativeness in modeling users or items. For example, in Fig. 1, the first review contains much more information of the laptop than the second review, and should has more contributions in building the representation of this laptop. Thus, we use a review-level attention network to distinguish informative reviews from less informative ones. Denote a user u has P reviews $[r_1, r_2, ..., r_P]$. Then the attention weight of the review r_i is computed as follows:

$$a_i^r = \tanh(\mathbf{v}_r \times \mathbf{r}_i + b_r), \quad (9)$$

$$\alpha_i^r = \frac{\exp(a_i^r)}{\sum_{j=1}^{P} \exp(a_j^r)}, \quad (10)$$

where $\mathbf{v}_r \in \mathcal{R}^{N_s}$ and $b_r \in \mathcal{R}$ are the parameters of the review-level attention network. The user representation learned from the reviews is the summation of the contextual representations of reviews weighted by their attention weights:

$$\mathbf{u}^r = \sum_{i=1}^{P} \alpha_i^r \mathbf{r}_i. \tag{11}$$

Although the user representation $\mathbf{u}^r$ learned from reviews contain rich information of users, there are some latent characteristics of users which are not described in their reviews but can be inferred from the rating patterns. Thus, we also represent users using the embedding of their IDs to capture the latent factors of users, which are motivated by traditional recommendation methods (Koren et al., 2009). The final representation of user u is the concatenation of the user representation $\mathbf{u}^r$ learned from reviews and the user embedding $\mathbf{u}^d$ inferred from user ID, as follows:

$$\mathbf{u} = [\mathbf{u}^r, \mathbf{u}^d]. \tag{12}$$

The representations of items can be computed in a similar way. Denote the representation of item t learned from reviews as $\mathbf{t}^r$, and the item embedding inferred from item ID as $\mathbf{t}^d$. Then the final representation of this item is as follows:

$$\mathbf{t} = [\mathbf{t}^r, \mathbf{t}^d]. \tag{13}$$

3.4 Rating Prediction

In recommender systems the recommendations are made based on the predicted ratings that a user will give to an item. In our *HUITA* approach, the rating score of a user-item pair is predicted based on the representations of users and items as follows:

$$\hat{y} = \mathrm{ReLU}(\mathbf{w}^T(\mathbf{u} \odot \mathbf{t}) + b), \tag{14}$$

where $\odot$ is item-wise dot product, $\mathbf{w}$ and b are parameters in the rating prediction layer.

In the model training stage, we optimize the model parameters to minimize the difference between gold rating and predicted ratings. We use the mean squared error as the loss function:

$$\mathcal{L} = \frac{1}{N_P} \sum_{i=1}^{N_P} (\hat{y}_i - y_i)^2, \tag{15}$$

where N_P denotes the number of user-item pairs in training data, $\hat{y}_i$ and y_i are the predicted rating score and the gold rating score respectively of the i_{th} user-item pair.

Table 1: Statistics of datasets used in our experiments.

4 Experiments

4.1 Datasets and Experimental Settings

We conducted experiments on four widely used benchmark datasets in different domains to evaluate the effectiveness of our approach. Following (Chen et al., 2018), we used three datasets from the Amazon collection[1](He and McAuley, 2016), i.e., **Toys_and_Games**, **Kindle_Store**, and **Movies_and_TV**. Another dataset is from Yelp Challenge 2017[2] (denoted as **Yelp 2017**), which is a large-scale restaurant review dataset. Following (Chen et al., 2018), we only kept the users and items which have at least 5 reviews. The detailed statistics of the four datasets are summarized in Table 1. The ratings in these datasets are in [1, 5].

In our experiments, the dimension of word embeddings was set to 300. We used the pre-trained Google embedding (Mikolov et al., 2013) to initialize the word embedding matrix. The word-level CNN has 200 filters and their window size is 3. The sentence-level CNN has 100 filters with window size of 3. We applied dropout strategy (Srivastava et al., 2014) to each layer of our model to mitigate overfitting. The dropout rate was set to 0.2. Adam (Kingma and Ba, 2014) was used as the optimization algorithm. The batch size was set to 20. We randomly selected 80% of the user-item pairs in each dataset for training, 10% for validation and 10% for test. All the hyperparameters were selected according to the validation set. We independently repeated each experiment for 5 times and reported the average performance in Root Mean Square Error (RMSE).

4.2 Performance Evaluation

We evaluate the performance of our approach by comparing it with several baseline methods. The methods to be compared include:

- *PMF*: Probabilistic Matrix Factorization, which models users and items based on

ratings via matrix factorization (Mnih and Salakhutdinov, 2008).

- *NMF*: Non-negative Matrix Factorization for recommendation based on rating scores (Lee and Seung, 2001).
- *SVD++*: The recommendation method based on rating matrix via SVD and similarities between items (Koren, 2008).
- *HFT*: Hidden Factor as Topic (HFT), a method to combine reviews with ratings via LDA (McAuley and Leskovec, 2013).
- *DeepCoNN*: Deep Cooperative Neural Networks, a neural method to jointly model users and items from their reviews via CNN (Zheng et al., 2017).
- *Attn+CNN*: Attention-based CNN, which uses both CNN and attention over word embeddings to learn user and item representation from reviews (Seo et al., 2017b).
- *NARRE*: Neural Attentional Rating Regression with Review-level Explanations, which uses attention mechanism to model the informativeness of reviews for recommendation (Chen et al., 2018).
- *HUITA*: our proposed hierarchical user and item representation approach with three-tier attention for recommendation with reviews.

In Table 2, we show a simple comparison of different methods in terms of the information considered in each method. Traditional recommendation methods such as *PMF*, *NMF* and *SVD* are solely based on rating scores, and other methods *HFT*, *DeepCoNN*, *Attn+CNN*, *NARRE* and *HUITA* can exploit both rating scores and reviews for recommendation. Among the latter methods, *HFT* is based on topic models and cannot capture the contexts and orders of words. *DeepCoNN* and *Attn+CNN* simply concatenate reviews into a long document, and cannot model the informativeness of different reviews. Although *NARRE* can model review helpfulness via attention, it simply merges all sentences in a review together, and does not model the informativeness of different sentences and words. Different from these methods, our *HUITA* approach learns user and item representations from reviews in a hierarchical manner, and uses a three-tier attention network to select and attend to important words, sentences and reviews.

The results of different methods are shown in Table 3. We have several observations from the results. First, the methods which exploit reviews (i.e., *HFT*, *DeepCoNN*, *Attn+CNN*, *NARRE* and *HUITA*) usually perform better than the methods only based on rating scores (i.e., *PMF*, *NMF* and *SVD++*). It validates reviews can provide rich information of user preferences and item properties, and is important to learn informative user and item representations and can benefit recommendation.

Methods	Toys_and_Games	Kindle_Store	Movies_and_TV	Yelp 2017
All	0.8649	0.7464	0.9631	1.1246
-word attention	0.8721	0.7610	0.9744	1.1337
-sentence attention	0.8714	0.7569	0.9715	1.1308
-review attention	0.8685	0.7523	0.9720	1.1294

Table 4: The effectiveness of different levels of attentions. The evaluation metric is RMSE.

Second, among the method which can exploit reviews, the neural network based methods (e.g., *DeepCoNN*, *Attn+CNN*, *NARRE* and *HUITA*) usually outperform the *HFT* method which is based on topic models. This is probably because in *HFT* the reviews are represented using bag-of-words features, and the contextual information and the orders of words are lost. This result validates the neural network based method can better capture the semantic information in reviews to model users and items for recommendation.

Third, the methods considering review helpfulness (i.e., *NARRE*) and word importance (i.e., *Attn+CNN*) usually outperform *DeepCoNN*. This result implies that different words and different reviews have different importance for modeling users and items from reviews. Distinguishing important reviews and words from less important ones is beneficial to learn more accurate user and item representations for recommendation.

Fourth, our approach can consistently outperform all the baseline methods compared here. This is because different from baseline methods such as *Attn+CNN* and *DeepCoNN* which merge all reviews into a long document and *NARRE* which merges all sentences into a long sentence, our *HUITA* approach learns user and item representations in a hierarchical manner. *HUITA* first learns sentence representations from words, then learns review representations from sentences, and finally learns user/item representations from reviews. Besides, our approach incorporates a three-tier attention network to jointly select and attend to important words, sentences and reviews. Thus, our approach can learn more informative user and item representations from reviews for recommendation.

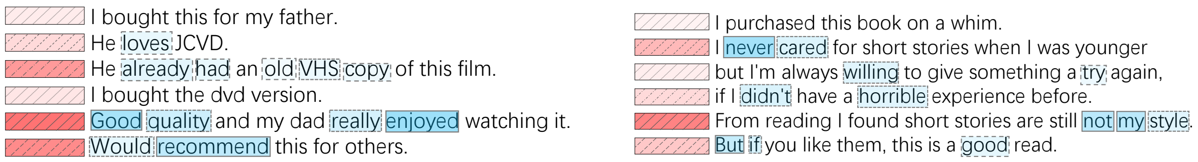
4.3 Effectiveness of Three-Tier Attention

In this section, we conducted experiments to explore the effectiveness of the three-tier attention network in our approach. We compare three variants of our model by removing one kind of attention each time to evaluate its contribution to the performance. The results are shown in Table 4.

According to Table 4, the word-level attention can effectively improve the performance of our approach. This is because different words in reviews have different importance in modeling users and items. Therefore, recognizing and highlighting the important words using the word-level attention network can help learn more informative sentence representations. In addition, the sentence-level attention is also useful. This may be because different sentences have different informativeness. For example, in a laptop review the sentence “this laptop is expensive” is more informative than “I bought this laptop yesterday” in representing this laptop. The sentence-level attention network can help to select important sentences to build review representations. Besides, the review-level attention is also useful in our *HUITA* approach. This is because different reviews have different informativeness in representing users and items. And distinguishing informative reviews from the less informative ones can help learn more accurate representations of users and items. Moreover, combining all the three levels of attentions can further improve the performance of our approach, which validates the effectiveness of our three-tier attention architecture.

4.4 Case Study

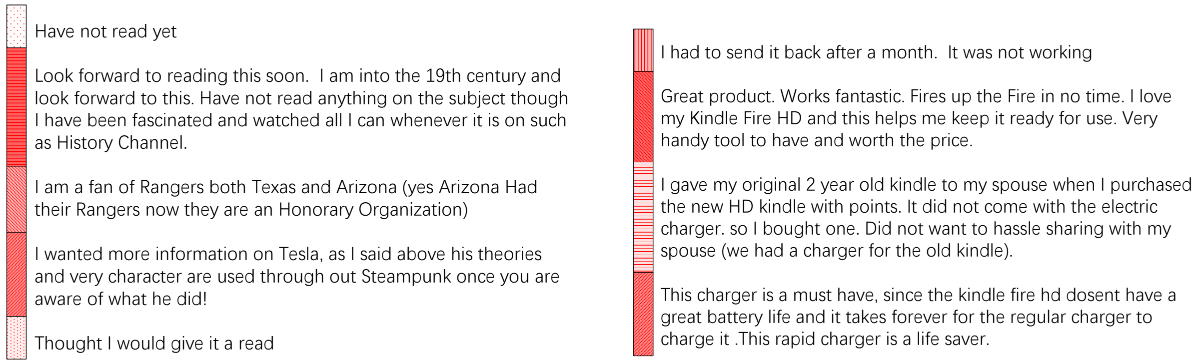
In this section, we conducted several case studies to further explore whether our approach can select informative words, sentences and reviews to learn informative user and item representations for recommendation. First, we want to explore the effectiveness of the word- and sentence-level attention networks. The visualization of the attention weights in the word- and sentence-level attention networks is shown in Fig. 3. From Fig. 3 we can see that our word-level attention network can effectively select and attend to important words. For example, in Fig. 3(a) the words “Good”, “quality” and “recommend” are assigned higher attention weights than “bought” and “dad”, since “Good”, “quality” and “recommend” can better model the properties of the film. In addition, our model can



(a) Movies_and_TV

(b) Kindle_Store

Figure 3: Visualization of attention weights in two randomly selected reviews from the Movies_and_TV and Kindle_Store datasets respectively. Red boxes to the left of the reviews represent sentence-level attention weights, and blue boxes on the individual words represent word-level attention weights. Darker color represents higher attention weights.



(a) User

(b) Item

Figure 4: Visualization of attention weights of reviews from a randomly selected user and item in the Kindle_Store dataset. Vertical bars represent review-level attention weights and darker color represents higher attention weights.

effectively select informative sentences using the sentence-level attention network. For example, in Fig. 3(b) the sentence "From reading I found short stories are still not my style" is assigned high attention weight since it is informative for representing this user and is important for recommendation, while the sentence "I purchased this book on a whim" has low attention weight since it contains limited information of users and items. Thus, these results validate that our approach is effective in selecting informative words and sentences in reviews for recommendation through the word- and sentence-level attention networks.

Second, we want to explore the effectiveness of the review-level attention in our *HUITA* approach. The visualization of the review-level attention weights is shown in Fig. 4. From Fig. 4 we can see that our approach can effectively select and attend to informative reviews. For example, the second review in Fig. 4(a) is assigned high attention weight by our approach since it reveals rich information of user preferences. However, the first review in Fig. 4(a) receives low attention weight since it contain limited information of users. Thus, these results validate the effectiveness of our approach in selecting informative reviews to learn more accurate representations of users and items from reviews for recommendation.

5 Conclusion

In this paper, we propose a hierarchical user and item representation model with three-tier attention to learn user and item representations from reviews for recommendation. In our approach, we use a sentence encoder to learn sentence representations from words, a review encoder to learn review representations from sentences, and a user/item encoder to learn user/item representations from reviews. In addition, we incorporate a three-tier attention network into our model to select and attend to informative words, sentences and reviews to learn more accurate representations of users and items. Besides, we combine the user and item representations learned from the reviews with the embeddings of user and item IDs as the final representations of users and items to capture the latent factors of individual users and items. The experiments on four benchmark datasets validate that our approach can effectively improve the performance of recommendation and consistently outperform many baseline methods.

Abstract

The prevalent way to estimate the similarity of two documents based on word embeddings is to apply the cosine similarity measure to the two centroids obtained from the embedding vectors associated with the words in each document. Motivated by an industrial application from the domain of youth marketing, where this approach produced only mediocre results, we propose an alternative way of combining the word vectors using matrix norms. The evaluation shows superior results for most of the investigated matrix norms in comparison to both the classical cosine measure and several other document similarity estimates.

1 Introduction

Estimating semantic document similarity is of utmost importance in a lot of different areas, like plagiarism detection, information retrieval, or text summarization. We will focus here on an NLP application that has been less researched, i.e., the assignment of people to the best matching target group to allow for running precise and customer-oriented marketing campaigns.

Until recently, similarity estimates were predominantly based either on deep semantic approaches or on typical information retrieval techniques like Latent Semantic Analysis. In the last couple of years, however, so-called word and sentence embeddings became state-of-the-art.

The prevalent approach to document similarity estimation based on word embeddings consists in measuring the similarity between the vector representations of the two documents derived as follows:

1. The word embeddings (often weighted by the tf-idf coefficients of the associated words (Brokos et al., 2016)) are looked up in a hashtable for all the words in the two documents to compare. These embeddings are determined beforehand on a very large corpus typically using either the skip gram or the continuous bag of words variant of the Word2Vec model (Mikolov et al., 2013).
2. The centroid over all word embeddings belonging to the same document is calculated to obtain its vector representation.

If vector representations of the two documents to compare were successfully established, a similarity estimate can be obtained by applying the cosine measure to the two vectors.

Let $x_1, \ldots, x_m$ and $y_1, \ldots, y_n$ be the word vectors of two documents. The cosine similarity value between the two document centroids C_1 und C_2 is given by:

$$\begin{aligned}&\cos(\angle(\frac{1}{m}\sum_{i=1}^{m} x_i, \frac{1}{n}\sum_{i=1}^{n} y_i))\\ =&\frac{\sum_{i=1}^{m}\sum_{j=1}^{n}\langle x_i, y_j\rangle}{mn\|C_1\|\|C_2\|}\end{aligned} \tag{1}$$

Hence, potentially small values of $\langle x_i, y_j\rangle$ can have in aggregate a considerable influence on the total similarity estimate, which makes this estimate vulnerable to noise in the data. We propose an alternative approach that is based on matrix norms and which proved to be more noise-robust by focusing primarily on high word similarities.

Finally, we conducted an evaluation where we achieved with our method superior accuracy in target group assignments than several traditional word embedding based methods.

2 Related Work

The most popular method to come up with word vectors is Word2Vec, which is based on a 3 layer neural network architecture in which the word vectors are obtained as the weights of the hidden layer. Alternatives to Word2Vec are GloVe

Proceedings of NAACL-HLT 2019, pages 1827–1836
Minneapolis, Minnesota, June 2 - June 7, 2019.

(Pennington et al., 2014), which is based on aggregated global word co-occurrence statistics and the Explicit Semantic Analysis (or shortly ESA) (Gabrilovic and Markovitch, 2009), in which each word is represented by the column vector in the tf-idf matrix over Wikipedia.

The idea of Word2Vec can be transferred to the level of sentences as well. In particular, the so-called Skip Thought Vector model (STV) (Kiros et al., 2015) derives a vector representation of the current sentence by predicting the surrounding sentences.

(Song and Roth, 2015) propose an alternative approach to applying the cosine measure to the two word vector centroids for ESA word embeddings. In particular, they establish a bipartite graph consisting of the best matching vector components by solving a linear optimization problem. The similarity estimate for the documents is then given by the global optimum of the objective function. However, this method is only useful for sparse vector representations. In case of dense vectors, (Mijangos et al., 2017) suggested to apply the Frobenius kernel to the embedding matrices, which contain the embedding vectors for all document components (usually either sentences or words) (cf. also (Hong et al., 2015)). However, crucial limitations are that the Frobenius kernel is only applicable if the number of words (sentences respectively) in the compared documents coincide and that a word from the first document is only compared with its counterpart from the second document. Thus, an optimal matching has to be established already beforehand. In contrast, the matrix norm approach as presented here applies to arbitrary embedding matrices. Since it conducts a pairwise comparison of all words contained in the two documents, there is also no need for any matching method.

Another simlarity estimate that employs the entire embedding matrix is the word mover‘s distance (Kusner et al., 2015), which is a special case of the earth mover‘s distance, a well studied transportation problem. Basically, this approach determines the minimum effort (with respect to embedding vector changes) to transform the words of one text into the words of another text. The word mover‘s distance requires a linear optimization problem to be solved. Linear optimization is usually tackled by the simplex method, which has in the worst case, which rarely occurs however, exponential runtime complexity.

Name	Definition
Frob. norm	$\|\mathbf{A}\|_F := \sqrt{\sum_{i=1}^m \sum_{j=1}^n \|\mathbf{A}_{ij}\|^2}$
2-norm	$\|\mathbf{A}\|_2 := \sqrt{\rho(\mathbf{A}^\top \mathbf{A})}$
$L_{1,1}$-norm	$\|\mathbf{A}\|_{L_{1,1}} := \sum_{i=1}^m \sum_{j=1}^n \|\mathbf{A}_{ij}\|$
1-norm	$\|\mathbf{A}\|_1 := \max_{1 \leq j \leq n} \sum_{i=1}^m \|\mathbf{A}_{ij}\|$
∞-norm	$\|\mathbf{A}\|_\infty := \max_{1 \leq i \leq m} \sum_{j=1}^n \|\mathbf{A}_{ij}\|$

Table 1: Examples of matrix norms; $\mathbf{A}$ is an $m \times n$ matrix; $\rho(\mathbf{X})$ denotes the largest absolute eigenvalue of a squared matrix $\mathbf{X}$.

A drawback of conventional similarity estimates as described above is that slightly related word pairs can have in aggregate a considerable influence on their values, i.e., these estimates are sensitive to noise in the data. In contrast, several of our matrix norm based similarity estimates focus primarily on strongly related word pairs and are therefore less vulnerable to noise.

3 Similarity Measure / Matrix Norm

Before going more into detail, we want to review some concepts that are crucial for the remainder of this paper. According to (Belanche and Orozco, 2011), a similarity measure on some set $\mathbf{X}$ is an upper bounded, exhaustive and total function $s : X \times X \to I \subset \mathbb{R}$ with $|I| > 1$ (therefore I is upper bounded and $\sup I$ exists). Additionally, it should fulfill the properties of reflexivity (the supremum is reached if an item is compared to itself) and symmetry. We call such a measure normalized if the supremum equals 1 (Attig and Perner, 2011). Note that an asymmetric similarity measure can easily be converted into a symmetric by taking the geometric or arithmetic mean of the asymmetric measure applied twice to the same arguments in switched order.

A norm is a function $f : V \to \mathbb{R}$ over some vector space V that is absolutely homogeneous, positive definite and fulfills the triangle inequality. It is called matrix norm if its domain is a set of matrices and if it is sub-multiplicative, i.e., $\|\mathbf{AB}\| \leq \|\mathbf{A}\| \cdot \|\mathbf{B}\|$. Several popular matrix norms are given in Table 1. Note that the Frobenius norm can also be represented by $\|\mathbf{A}\|_F = \sqrt{\mathrm{tr}(\mathbf{A}\mathbf{A}^\top)}$.

4 Document Similarity Measure based on Matrix Norms

For an arbitrary document t we define the embeddings matrix $E(t)$ as follows: $E(t)_{ij}$ is the i-th component of the normalized embeddings vector belonging to the j-th word of the document t. Let t, u be two arbitrary documents, then the entry (i, j) of a product $E(t)^\top E(u)$ specifies the result of the cosine measure estimating the semantic similarity between word i of document t and word j of document u. The value of a matrix norm $\|E(t)^\top E(u)\|$ is then a measure for the similarity of the two documents. Since the vector components obtained by Word2Vec can be negative, the cosine measure between two word vectors can also assume negative values (rather rarely in practice though). Negative cosine values indicate negatively correlated words and should be handled akin to the uncorrelated case. Because a matrix norm usually treats negative and positive matrix entries alike, we replace all negative values in the matrix by zeros. Finally, since our measure should be restricted to values from zero to one, we have to normalize it.

Formally, we define our similarity measure $sn(t, u)$ as follows :

$$\frac{\|K(E(t)^\top E(u))\|}{\sqrt{\|K(E(t)^\top E(t))\| \cdot \|K(E(u)^\top E(u))\|}}$$

where $E(t)$ is the embeddings matrix belonging to document t, where all embedding column vectors are normalized. $K(\mathbf{M})$ is the matrix, where all negative entries are replaced by zero, i.e. $K(\mathbf{M})_{ij} = \max\{0, \mathbf{M}_{ij}\}$.

Proposition 1. *If the cosine similarity values between all embedding vectors of words occurring in any of the documents are non-negative, i.e., if* $K(E(t)^\top E(u)) = E(t)^\top E(u)$ *for all document pairs* (t, u), *then* sn *is a normalized similarity measure for the 2-norm, the Frobenius norm and the* $L_{1,1}$*-norm.*

Proof. We give the proof for the 2-norm here and for the other two norms in the appendix.

Symmetry At first, we focus on the symmetry condition.

Let $\mathbf{A} := E(t)$, $\mathbf{B} := E(u)$, where t and u are arbitrary documents. Symmetry directly follows, if we can show that

$$\|\mathbf{Z}\| = \|\mathbf{Z}^\top\|$$

for arbitrary matrices $\mathbf{Z}$, since with this property we have

$$\begin{aligned} sn(t,u) =& \frac{\|\mathbf{A}^\top\mathbf{B}\|}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\| \cdot \|\mathbf{B}^\top\mathbf{B}\|}} \\ =& \frac{\|(\mathbf{B}^\top\mathbf{A})^\top\|}{\sqrt{\|\mathbf{B}^\top\mathbf{B}\| \cdot \|\mathbf{A}^\top\mathbf{A}\|}} \\ =& \frac{\|\mathbf{B}^\top\mathbf{A}\|}{\sqrt{\|\mathbf{B}^\top\mathbf{B}\| \cdot \|\mathbf{A}^\top\mathbf{A}\|}} = sn(u,t) \end{aligned} \tag{2}$$

Let $\mathbf{M}$ and $\mathbf{N}$ be arbitrary matrices such that $\mathbf{MN}$ and $\mathbf{NM}$ are both defined and quadratic, then (see (Chatelin, 1993))

$$\rho(\mathbf{MN}) = \rho(\mathbf{NM}) \tag{3}$$

where $\rho(\mathbf{X})$ denotes the largest absolute eigenvalue of a squared matrix $\mathbf{X}$.

Using identity 3 one can easily infer that:

$$\|\mathbf{Z}\|_2 = \sqrt{\rho(\mathbf{Z}^\top\mathbf{Z})} = \sqrt{\rho(\mathbf{Z}\mathbf{Z}^\top)} = \|\mathbf{Z}^\top\|_2 \tag{4}$$

□

Boundedness

Proof. The following property needs to be verified:

$$\frac{\|\mathbf{A}^\top\mathbf{B}\|_2}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_2 \cdot \|\mathbf{B}^\top\mathbf{B}\|_2}} \leq 1 \tag{5}$$

In the proof, we exploit the fact that for every positive-semidefinite matrix $\mathbf{X}$, the following equation holds

$$\rho(\mathbf{X}^2) = \rho(\mathbf{X})^2 \tag{6}$$

We observe that for the denominator

$$\begin{aligned} & \|\mathbf{A}^\top\mathbf{A}\|_2 \cdot \|\mathbf{B}^\top\mathbf{B}\|_2 \\ =& \sqrt{\rho((\mathbf{A}^\top\mathbf{A})^\top\mathbf{A}^\top\mathbf{A})}\sqrt{\rho((\mathbf{B}^\top\mathbf{B})^\top\mathbf{B}^\top\mathbf{B})} \\ =& \sqrt{\rho((\mathbf{A}^\top\mathbf{A})^\top(\mathbf{A}^\top\mathbf{A})^\top)}\sqrt{\rho((\mathbf{B}^\top\mathbf{B})^\top(\mathbf{B}^\top\mathbf{B})^\top)} \\ =& \sqrt{\rho([(\mathbf{A}^\top\mathbf{A})^\top]^2)}\sqrt{\rho([(\mathbf{B}^\top\mathbf{B})^\top]^2)} \\ \overset{(6)}{=}& \sqrt{\rho((\mathbf{A}^\top\mathbf{A})^\top)^2}\sqrt{\rho((\mathbf{B}^\top\mathbf{B})^\top)^2} \\ =& \rho((\mathbf{A}^\top\mathbf{A})^\top)\rho((\mathbf{B}^\top\mathbf{B})^\top) \\ \overset{(4)}{=}& \|\mathbf{A}\|_2^2 \cdot \|\mathbf{B}\|_2^2 \end{aligned} \tag{7}$$

Putting things together we finally obtain

$$\begin{aligned} \frac{\|\mathbf{A}^\top\mathbf{B}\|_2}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_2\|\mathbf{B}^\top\mathbf{B}\|_2}} & \overset{\text{sub-mult.}}{\leq} \frac{\|\mathbf{A}^\top\|_2 \cdot \|\mathbf{B}\|_2}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_2\|\mathbf{B}^\top\mathbf{B}\|_2}} \\ & \overset{(4)}{=} \frac{\|\mathbf{A}\|_2 \cdot \|\mathbf{B}\|_2}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_2\|\mathbf{B}^\top\mathbf{B}\|_2}} \\ & \overset{(7)}{=} \frac{\|\mathbf{A}\|_2 \cdot \|\mathbf{B}\|_2}{\sqrt{\|\mathbf{A}\|_2^2 \cdot \|\mathbf{B}\|_2^2}} = 1 \end{aligned} \tag{8}$$

□

However, proposition 1 is not sufficient in all cases, since negative cosine similarity values can occur in practice. Therefore, we also prove a stronger claim stated in the following proposition.

Proposition 2. *If the cosine measure values between embedding vectors belonging to words of the same document are all non-negative, then* sn *is a normalized similarity measure for the Frobenius and the* $L_{1,1}$*-norm.*

Proof. The proof of symmetry and reflexivity is analogous to proposition 1. So we only prove boundedness of sn. Since the cosine measure for two embedding vectors emb belonging to words of the same document cannot be negative, we have $\langle emb(w_i), emb(w_k)\rangle \geq 0$ for i,k with $1 \leq i \leq k \leq |t|$ and therefore $K(E(t)^\top E(t)) = E(t)^\top E(t)$. We furthermore have $\|K(E(t)^\top E(u))\| \leq \|E(t)^\top E(u)\|$ for the Frobenius and $L_{1,1}$-norm, since replacing a zero entry with another value can never decrease the value of the norm. Thus,

$$\begin{aligned} &\frac{\|K(E(t)^\top E(u))\|}{\sqrt{\|K(E(t)^\top E(t))\| \cdot \|K(E(u)^\top E(u))\|}} \leq \\ &\frac{\|E(t)^\top E(u)\|}{\sqrt{\|E(t)^\top E(t)\| \cdot \|E(u)^\top E(u)\|}} \leq 1. \end{aligned} \tag{9}$$

The last inequality follows from proposition 1. ☐

However, the proposed normalization factor $\sqrt{\|K(E(t)^\top E(t))\| \cdot \|K(E(u)^\top E(u))\|}$ is not eligible for all types of matrix norms, which is an immediate consequence of the following proposition.

Proposition 3. *There exist no mean value function* $mean : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$ *such that*

$$\begin{aligned} sn_1 :=& \frac{\|K(E(t_0)^\top E(u_0))\|_1}{m} \\ m :=& mean(\|K(E(t_0)^\top E(t_0))\|_1, \\ & \|K(E(u_0)^\top E(u_0))\|_1) \end{aligned} \tag{10}$$

is bounded by one. Hence, sn_1 *cannot be a normalized similarity measure.*

Proof. We give a counter-example for the maximum mean, for which we show that sn_1 exceeds the value of 1:

$$E(t_0) = \begin{bmatrix} 0.1644 & 0.5025 \\ 0 & 0.5025 \\ 0.9864 & 0.7035 \end{bmatrix}$$

Corpus	# Words
German Wikipedia	651 880 623
Frankfurter Rundschau	34 325 073
News journal *20 Minutes*	8 629 955

Table 2: Corpus sizes measured by number of words.

$$E(u_0) = \begin{bmatrix} 0.1204 & 0.9759 & 0.2722 \\ 0.2408 & 0.0976 & 0.9526 \\ 0.9631 & 0.1952 & 0.1361 \end{bmatrix}$$

Since the maximum mean $mean_{max}(a, b) = \max\{a, b\}$ is greater or equal to all other means (including the geometric mean), we have that:

$$\begin{aligned} &\frac{\|K(E(t_0)^\top E(u_0))\|_1}{mean(\|K(E(t_0)^\top E(t_0))\|_1, \|K(E(u_0)^\top E(u_0))\|_1)} \\ &\geq \frac{\|K(E(t_0)^\top E(u_0))\|_1}{\max\{\|K(E(t_0)^\top E(t_0))\|_1, \|K(E(u_0)^\top E(u_0))\|_1\}} \\ &= 1.0284 > 1 \end{aligned} \tag{11}$$

for arbitrary type of means $mean$. ☐

Note that the matrices used in the counter-example can be extended to any number of embedding dimensions by adding additional zeros.

A further issue is, whether the similarity measure is invariant to word permutations. Actually, this is the case for our matrix norm similarity estimates, which is stated in the following proposition.

Proposition 4. *The obtained similarity estimate for all of the considered matrix norms is independent of the word sequence of the input texts.*

This property is quite beneficial in our scenario since one of the texts to compare constitutes of an unordered key word list (see more details in the next section).

Proof. We focus in this proof on the 2-norm, for which this property is not directly obvious like for the other regarded norms. For simplicity, we first concentrate on the special case that all cosine values between word embeddings are non-negative. This proof can easily be extended to the general case, too. In particular, we show that the similarity estimate does not change, if two columns of the first matrix are exchanged, which can be expressed by postmultiplying this matrix with a permutation matrix $\mathbf{P}$. By employing symmetry and induction this proof can be applied to arbitrary sequence permutations and to the second argument matrix as well. With this, the similarity estimate is given as:

$$\begin{aligned} sn_2(t,u) =& \|((\mathbf{AP})^\top \mathbf{B})\|_2 \\ =& \sqrt{\rho(((\mathbf{AP})^\top \mathbf{B})^\top ((\mathbf{AP})^\top \mathbf{B}))} \\ =& \sqrt{\rho(\mathbf{B}^\top \mathbf{APP}^\top \mathbf{A}^\top \mathbf{B})} \\ & (\mathbf{P} \text{ is an orthogonal matrix}) \\ =& \sqrt{\rho(\mathbf{B}^\top \mathbf{AIA}^\top \mathbf{B})} \\ =& \sqrt{\rho(\mathbf{A}^\top \mathbf{B})^\top (\mathbf{A}^\top \mathbf{B})} \\ =& \|\mathbf{A}^\top \mathbf{B}\|_2 \end{aligned} \tag{12}$$

By exploiting that $K(\mathbf{MP}) = K(\mathbf{M})\mathbf{P}$ for arbitary matrices $\mathbf{M}$, this proof can be generalized to negative cosine measure values as well. □

The question remains, how the similarity measure value induced by matrix norms performs in comparison to the usual centroid method. Let us first focus on L_{11} and the Frobenius norm. Actually, both are special cases of a norm that raises the absolute values of the matrix components to a certain power e. If this exponent e becomes large, then:

$$\begin{aligned} & sn_{L_{e,1}}(t,u) \\ =& \frac{\|E(u)^\top E(t)\|_{L_{e,1}}}{\sqrt{\|E(t)^\top E(t)\|_{L_{e,1}} \cdot \|E(u)^\top E(u)\|_{L_{e,1}}}} \\ \approx& \frac{(\#p)^{1/e}}{\sqrt{\left\|\begin{bmatrix} 1 & 0 & \dots \\ & \ddots & \\ 0 & \dots & 1 \end{bmatrix}\right\|_{L_{e,1}} \cdot \left\|\begin{bmatrix} 1 & 0 & \dots \\ & \ddots & \\ 0 & \dots & 1 \end{bmatrix}\right\|_{L_{e,1}}}} \\ & (\text{mainly the diagonal elements of the} \\ & \text{matrices in the denominator assume } 1) \\ \approx& \left(\frac{\#p}{\sqrt{nm}}\right)^{1/e} \end{aligned} \tag{13}$$

where $\#p$ denotes the number of perfect matches (similarity value of 1.0) between words of the two documents and n (m) is the number of words in text t (u). Thus, with an increasing exponent, $sn_{L_{e,1}}$ tends to focus on very good matches and disregards the others. This property is quite beneficial in our scenario, where often only one or two words of the contest answers (cf. next section) indicate the right target group.

General statements about the 2-norm based similarity measure are difficult, but we can draw some conclusions, if we restrict to the case, where $\mathbf{A}^\top \mathbf{B}$ is a square diagonal matrix. Hereby, one word of the first text is very similar to exactly one word of the second text and very dissimilar to all remaining words. The similarity estimate is then given by the largest eigenvalue (also called the spectral radius) of $\mathbf{A}^\top \mathbf{B}$, which equals the largest cosine measure value. Thus, the 2-norm based similarity estimate is able to filter out noise (low word similarity values) akin to the Frobenius norm.

Let us now take a look at the similarity measure sn_1, which is induced by the 1-norm. sn_1 assumes high values, if there is one word of the second document that matches very well with all words of the first document. All other less matching words of the second document do not contribute to the assumed similarity estimate at all.

5 Application to Targeted Marketing

Market segmentation is one of the key tasks of a marketer. Usually, it is accomplished by clustering over demographic variables, geographic variables, psychographic variables and behaviors (Lynn, 2011). In this paper, we will describe an alternative approach based on unsupervised natural language processing. In particular, our business partner operates a commercial youth platform for the Swiss market, where registered members get access to third-party offers such as discounts and special events like concerts or castings. Actually, several hundred online contests per year are launched over this platform sponsored by other firms, an increasing number of them require the members to write short free-text snippets, e.g. to elaborate on a perfect holiday at a destination of their choice in case of a contest sponsored by a travel agency. Based on the results of a broad survey, the platform provider's marketers assume five different target groups (called *milieus*) being present among the platform members: *progressive postmodern youth* (people primarily interested in culture and arts), *young performers* (people striving for a high salary with a strong affinity to luxury goods), *freestyle action sportsmen*, *hedonists* (rather poorly educated people who enjoy partying and disco music) and *conservative youth* (traditional people with a strong concern for security). A sixth milieu called *special groups* comprises all those who cannot be assigned to one of the upper five milieus. For each milieu (with the exception of *special groups*) a keyword list was manually created to describe its main characteristics.

Table 4: Minimum and maximum average inter-annotator agreements (Cohen's kappa) / average inter-annotator agreement values for our automated matching method, FN=Frobenius norm.

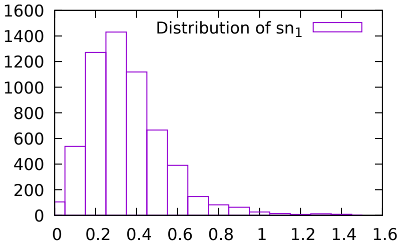

Figure 1: Distribution of sn_1 determined on contest 1.

For triggering marketing campaigns, an algorithm shall be developed that automatically assigns each contest answer to the most likely target group: we propose the youth milieu as best match for a contest answer, for which the estimated semantic similarity between the associated keyword list and user answer is maximal. In case the highest similarity estimate falls below the 10 percent quantile for the distribution of highest estimates, the special groups milieu is selected. Since the keyword list typically consists of nouns (in the German language capitalized) and the user contest answers might contain a lot of adjectives and verbs as well, which do not match very well to nouns in the Word2Vec vector representation, we actually conduct two comparisons for our Word2Vec based measures, one with the unchanged user contest answers and one by capitalizing every word beforehand. The final similarity estimate is then given as the maximum value of both individual estimates.

6 Evaluation

For evaluation, we selected three online contests (language: German), where people elaborated on their favorite travel destination for an example, speculated about potential experiences with a pair of fancy sneakers (contest 2) and explained why they emotionally prefer a certain product out of four available candidates. We experimented with different keyword list sizes but obtained the best results with rather few and therefore precise keywords. In particular, we used the following number of keywords for the individual milieus:

- Action Sportsman: 3
- Young Performer: 4
- Hedonist: 7
- Conservative Youth: 4
- Progressive Postmodern Youth: 6

In order to provide a gold standard, three professional marketers from different youth marketing companies annotated independently the best matching youth milieus for every contest answer. We determined for each annotator individually his/her average inter-annotator agreement with the others (Cohen's kappa). The minimum and maximum of these average agreement values are given in Table 4. Since for contest 2 and contest 3, some of the annotators annotated only the first 50 entries (last 50 entries respectively), we specified min/max average kappa values for both parts. We further compared the youth milieus proposed by our unsupervised matching algorithm with the majority votes over the human experts' answers (see Table 3)[1]. Moreover, we computed its average inter-annotator agreement with the human annotators (see again Table 4), quasi treating the predictions like additional annotations.

The Word2Vec word embeddings were trained on the German Wikipedia (dump originating from 20 February 2017) merged with a Frankfurter Rundschau newspaper Corpus and 34 249 articles of the news journal *20 minutes*[2], where the latter is targeted to the Swiss market and freely available at various Swiss train stations (see Table 2 for a comparison of corpus sizes). By employing articles from *20 minutes*, we want to ensure the reliability of word vectors for certain Switzerland specific expressions like *Velo* or *Glace*, which are underrepresented in the German Wikipedia and the Frankfurter Rundschau corpus. ESA is usually trained on Wikipedia, since the authors of the original ESA paper suggest that the articles of the training corpus should represent disjoint concepts, which is only guaranteed for encyclopedias. However, Stein and Anerka (Gottron et al., 2011) challenged this hypothesis and demonstrated that promising results can be obtained by applying ESA on other types of corpora like the popular Reuters newspaper corpus as well. Unfortunately, the implementation we use (Wikiprep-ESA[3]) expects its training data to be a Wikipedia Dump. Furthermore, Wikiprep-ESA only indexes words that are connected by hyperlinks, which are usually lacking in ordinary newspaper articles. So we could train Wikiprep-ESA on Wikipedia only but additionally have developed a version of ESA that can be applied on arbitrary corpora (in the following referred to as ESA2) and which was trained on the full corpus (Wikipedia+Frankfurter Rundschau+20 minutes). The STVs were also trained on the same corpus as our matrix norms based estimates and Word2Vec embedding centroids. The actual document similarity estimation is accomplished by the usual centroid approach (we did not evaluate matrix norms here). An issue we were faced with is that STVs are not bag of word models but actually take the sequence of the words into account and therefore the obtained similarity estimate between milieu keyword list and contest answer would be dependent on the keyword ordering. However, this order could have arbitrarily been chosen by the marketers and might be completely random. A possible solution is to compare the contest answers with all possible permutation of keywords and determine the maximum value over all those comparisons. However, such an approach would be infeasible already for medium keyword list sizes. Therefore, we use a beam search approach instead, which extends the keyword list iteratively and keeps only the n-best performing permutations.

Method	Accuracy
ESA	0.672
STV	0.716
W2VC	0.726
sn_2	0.731
$sn_{L_{1,1}}$	0.741
sn_F	0.781

Table 5: Accuracy value otbained for matching a sentence of the first to the associated sentence of the second translation.

Finally, to verify the general applicability of our approach, we conducted a second experiment, where a novel from Edgar Allen Poe (The purloined letter) was independently translated by two translators into German. We aim to match a sentence from the first translation to the associated sentence of the second by looking for the assignment with the highest semantic relatedness disregarding the sentence order. The obtained accuracy values based on the first 200 sentences of both translations are given in Table 5. To guarantee an 1:1 sentence mapping, periods were partly replaced by semicolons.

7 Discussion

The evaluation showed that the inter-annotator agreement values vary strongly for contest 2 part 2 (minimum average annotator agreement according to Cohen's kappa of 0.03 while the maximum is 0.149, see Table 4). On this contest part, our matrix norm-based matching (2-norm and Frobenius-norm) obtains a considerably higher average agreement than one of the annotators. Regarding baseline systems, the most relevant comparison is naturally the one with Word2Vec cen-

---

[1] Note that the geometric mean of the 1- and ∞-norm as specified in Table 3 is not a matrix norm itself, since it lacks submultipicativity.

(a) W2VC vs $sn_{L_{11}}$ (b) W2VC vs sn_2 (c) W2VC vs sn_F

Figure 2: Scatter plots of cosine between centroids of Word2Vec embeddings (W2VC) vs sn.

troids, since it employs the same type of data. Hereby we reached higher accuracy values for the best performing matrix norms on two of the three contests including the largest contest 1. Note that the elimination of negative values from the embedding matrix product proved to be important. If we omit this step, the obtained accuracy of sn_f for instance will drop by around 0.023 determined over all three contests (column: *all*).

It is quite striking that, although sn_1 lacks two properties of a normalized similarity measure (boundedness by 1 and symmetry), it reaches quite good results on contest 1. As you can see in Figure 1, which shows the distribution of sn_1 in contest 1, the value of 1 is indeed exceeded several times (the maximum value is 1.5), but this occurs rather rarely in our experiment. Actually, 99% of its values fall into the interval [0,1]. Thus, the non-boundedness is much less a problem in practice than the theoretical results indicate.

Finally, we determined the scatter plots (see Figure 2) showing cosine of Word2Vec embeddings (W2VC) vs several matrix norm based similarity estimates. These scatter plots exhibits that the score distributions of sn_f and sn_2 are quite similar and their values often exceed the cosine measure value due to the fact that a few very strong word matches can already result in a high similarity estimate. The scatter plot for sn_{L11} reveals that this measure is much closer to W2VC than the other two matrix norm based similarity estimates.

Note that a downside of our approach in relation to the usual Word2Vec centroids method is the increased runtime, since it requires the pairwise comparison of all words contained in the input documents. In our scenario with rather short text snippets and keyword lists, this was not much of an issue. However, for large documents, such a comprehensive comparison could become soon infeasible. One possible solution for this performance issue is to apply our proposed estimates to sentence embeddings instead of word embeddings, which on the one hand would reduce the dimensionality of the embedding matrices and on the other hand would take word order into account.

8 Conclusion

We proposed a novel similarity measure to compare word embeddings from different documents, which makes use of matrix norms. This measure was evaluated on the task to assign users to the best matching marketing target groups. We obtained superior results compared to the usual centroid / cosine measure similarity estimation for most of the investigated matrix norm especially for the largest contest 1. Furthermore, we proved elementary properties for our proposed similarity measure regarding its well-definedness and its performance in comparison to the usual centroid-based approach.

Acknowledgement

Hereby we thank the Jaywalker GmbH as well as the Jaywalker Digital AG for their support regarding this publication and especially for annotating the contest data with the best-fitting youth milieus.

A Proof of Proposition 1

In this section we give the proof of proposition 1 for Frobenius and $L_{1,1}$-norm.

Reflexivity is trivially fulfilled for Frobenius, 2- and $L_{1,1}$-norm. Therefore, we only prove that the induced similarity measures are symmetric and upper-bounded by 1.

Let $\mathbf{A} := E(t)$, $\mathbf{B} := E(u)$, where t and u are arbitrary documents.

A.1 Frobenius norm

Symmetry The trace of a matrix is known to be invariant under cyclic permutations. With this property, the symmetry of sn_F can easily be deduced.

Boundedness

Proof. We need to show that:

$$\frac{\|\mathbf{A}^\top\mathbf{B}\|_F}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_F \cdot \|\mathbf{B}^\top\mathbf{B}\|_F}} \leq 1 \tag{14}$$

For that we leverage the Cauchy-Schwarz inequality that states that for an inner product space $\mathcal{H}$ we have

$$|\langle x, y\rangle| \leq \sqrt{\langle x, x\rangle \cdot \langle y, y\rangle} \tag{15}$$

for all $x, y \in \mathcal{H}$, where equality holds if, and only if, x is a scalar multiple of y. In particular, the function $f(\mathbf{Y}, \mathbf{X}) = \mathrm{tr}(\mathbf{Y}^\top\mathbf{X})$ is such an inner product.

Let $\mathbf{X} = \mathbf{A}\mathbf{A}^\top$ and $\mathbf{Y} = \mathbf{B}\mathbf{B}^\top$ such that $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{m\times m}$. Then we can infer

$$\begin{aligned}\mathrm{tr}(\mathbf{B}\mathbf{B}^\top\mathbf{A}\mathbf{A}^\top) &= \mathrm{tr}((\mathbf{B}\mathbf{B}^\top)^\top\mathbf{A}\mathbf{A}^\top)\\ &= \mathrm{tr}(\mathbf{Y}^\top\mathbf{X})\\ &\overset{(15)}{\leq} \sqrt{\mathrm{tr}(\mathbf{X}^\top\mathbf{X}) \cdot \mathrm{tr}(\mathbf{Y}^\top\mathbf{X})}\\ &= \sqrt{\mathrm{tr}((\mathbf{A}\mathbf{A}^\top)^\top\mathbf{A}\mathbf{A}^\top) \cdot \mathrm{tr}((\mathbf{B}\mathbf{B}^\top)^\top\mathbf{B}\mathbf{B}^\top)}\\ &= \sqrt{\mathrm{tr}(\mathbf{A}\mathbf{A}^\top\mathbf{A}\mathbf{A}^\top) \cdot \mathrm{tr}(\mathbf{B}\mathbf{B}^\top\mathbf{B}\mathbf{B}^\top)}\end{aligned} \tag{16}$$

Next, we observe that for the numerator

$$\begin{aligned}\|\mathbf{A}^\top\mathbf{B}\|_F &= \sqrt{\mathrm{tr}(\mathbf{A}^\top\mathbf{B}(\mathbf{A}^\top\mathbf{B})^\top)}\\ &= \sqrt{\mathrm{tr}(\mathbf{A}^\top\mathbf{B}\mathbf{B}^\top\mathbf{A})}\\ &= \sqrt{\mathrm{tr}(\mathbf{B}\mathbf{B}^\top\mathbf{A}\mathbf{A}^\top)}\\ &\overset{(16)}{\leq} \sqrt[4]{\mathrm{tr}(\mathbf{A}\mathbf{A}^\top\mathbf{A}\mathbf{A}^\top) \cdot \mathrm{tr}(\mathbf{B}\mathbf{B}^\top\mathbf{B}\mathbf{B}^\top)}\\ &= \sqrt[4]{\mathrm{tr}(\mathbf{A}^\top\mathbf{A}^\top\mathbf{A}\top\mathbf{A}) \cdot \mathrm{tr}(\mathbf{B}\top\mathbf{B}\mathbf{B}^\top\mathbf{B})}\\ &= \sqrt{\|\mathbf{A}^\top\mathbf{A}\|_F \cdot \|\mathbf{B}^\top\mathbf{B}\|_F}\end{aligned} \tag{17}$$

Hence, we finally obtain

$$\begin{aligned}\frac{\|\mathbf{A}^\top\mathbf{B}\|_F}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_F\cdot\|\mathbf{B}^\top\mathbf{B}\|_F}} &\overset{(17)}{\leq} \frac{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_F\cdot\|\mathbf{B}^\top\mathbf{B}\|_F}}{\sqrt{\|\mathbf{A}^\top\mathbf{A}\|_F\cdot\|\mathbf{B}^\top\mathbf{B}\|_F}}\\ &= 1.\end{aligned}$$

□

A.2 $L_{1,1}$-norm

Proof for symmetry. For the $L_{1,1}$-norm, we have that

$$\begin{aligned}&\|A\|_{L_{1,1}} = \sum_{i=1}^{m}\sum_{j=1}^{n}|A_{ij}| = \sum_{j=1}^{n}\sum_{i=1}^{m}|A^\top_{ji}|\\ &=\|A^\top\|_{L_{1,1}}\end{aligned} \tag{18}$$

□

The boundedness follows directly from the Cauchy-Schwarz inequality, since the induced similarity estimate $sn_{L_{1,1}}$ is an inner product.

Glocal: Incorporating Global Information in Local Convolution for Keyphrase Extraction

Abstract

Graph Convolutional Networks (GCNs) are a class of spectral clustering techniques that leverage localized convolution filters to perform supervised classification directly on graphical structures. While such methods model nodes' local pairwise importance, they lack the capability to model global importance relative to other nodes of the graph. This causes such models to miss critical information in tasks where global ranking is a key component for the task, such as in keyphrase extraction. We address this shortcoming by allowing the proper incorporation of global information into the GCN family of models through the use of scaled node weights. In the context of keyphrase extraction, incorporating global random walk scores obtained from TextRank boosts performance significantly. With our proposed method, we achieve state-of-the-art results, bettering a strong baseline by an absolute 2% increase in F_1 score.

1 Introduction

Learning directly on a graphical structure is a crucial requirement in many domains. These graphs represent information in many forms, ranging from interconnected user groups to contextually linked documents to a central document by shared vocabulary. Learning on graphs has been studied extensively in the form of spectral clustering (Ng et al., 2002). The potential of learning directly on graphs has realized in semi-supervised settings where labels for only a few of the nodes are available. Some prior work formulates such setup as propagating the label information using some form of graph-based regularization (Kipf and Welling, 2016). Recently proposed works have updated such methods to be end-to-end learnable in the deep learning style by employing gradient descent on nodes within a fixed neighborhood, approximating spectral clustering's means of approximating the graph's eigenvectors (Bronstein et al., 2017) by aggregating neighborhood features. Recent advancements in normalizing the gradient range further improve the efficiency of such solutions (Kipf and Welling, 2016). However, these techniques can only exploit local features within the neighborhood of individual nodes. For some tasks, such simplified local feature aggregation may be sufficient, but insufficient for tasks that need global relative importance information.

One such important graph-based task is keyphrase extraction. In this task, individual words or phrases serve as graph nodes, and edges represent some form of co-occurrence. Keyphrase extraction has been extensively studied, in both supervised (classification) and unsupervised (ranking) modes. Depending on the length of the text and the final application of the task, solutions can be sample-based classification, pairwise ranking or sequential labeling. For example, Kim et al.(2010) explore the case of extracting top keyphrases from complete documents for downstream indexing, while Augenstein et al.(2017) connects its usage for knowledge base generation, aiming to extract all plausible keyphrases within a short excerpt. Treating a full-text scenario is arguably more challenging than the treatment of an excerpt scenario, as it requires the understanding of the much larger scale of text and extracting its most salient aspects.

Traditional supervised models employ a host of hand-engineered features — $tf.idf$, candidate length, POS tags, sectional information, frequency, among others (Kim et al., 2013; Hasan and Ng, 2010) — trained with a wide range of classifiers. As they typically model the task as a binary classification task (*i.e.*, $keyphrase, \neg keyphrase$), they suffer severely from class imbalance as keyphrases are the excep-

Proceedings of NAACL-HLT 2019, pages 1837–1846
Minneapolis, Minnesota, June 2 - June 7, 2019.

tion among most plausible candidates.

Unsupervised methods use co-occurrence as a signal for the labels. Under the hypothesis that keyphrase saliency is strongly correlated with repetition, graphical methods for unsupervised keyphrase extraction employ centrality measures and random walk techniques to rank prospective keyphrases (Mihalcea and Tarau, 2004). This hypothesis is widely exploited, with proposed extensions further enriching the graph by incorporating topic, section and/or position information (Florescu and Caragea, 2017b,a; Jiang et al., 2018), among other forms of side information.

With these in mind, we make two important observations about the existing keyphrase extraction techniques:

- In the supervised setting, word importance is captured in metrics and engineered features, as is local random walk scores. However, the structure of the graph formed by the text is not exploited.
- In the unsupervised setting, most techniques do not tightly incorporate the rich semantic features common in the supervised setting. Furthermore, random walk scores are used as-is, without the capability of being fine-tuned by downstream supervision.

From this dichotomy, we see there is a gap to close in merging the advantages of both. We propose a Glocal (global–local portmanteau) technique which incorporates both components directly over the word–graph. Specifically, we contribute a neural model that elegantly incorporates the random walk scores, while incorporating parameters to fit keyphrase labels. To the best of our knowledge, our model is the only supervised full-text keyphrase extraction model that operates directly on the word–graph.

2 Related Work

Our work draws motivation from the introduction of random walks to NLP. In this regard, TextRank (Mihalcea and Tarau, 2004), is a central representative work that serves as a basis for many text extraction modeling techniques used in entity extraction and extractive summarization (we use random walk and TextRank interchangeably in this paper). The success of the application of such random walks in text extraction is based on the hypothesis that the important nodes aggregate more mass and are thereby representative of the graph as a whole. Importantly, TextRank can be viewed as a **ranking** model, as it induces a ranking of graph nodes via its centrality calculation. However, as noted, supervised techniques for properly incorporating this information natively within the model, in our opinion, has yet to be explored.

Recently, neural models have been developed to work on graphs. These models port the ideas of spectral clustering into the deep learning modality, allowing direct computation on graphs. Methods such as Graph Convolution Network (or GCN) can then be applied to many different task scenarios which natively feature graphical structures such as citation and community graphs, which are common in the database, information retrieval, and digital library domains (Kipf and Welling, 2016; Hamilton et al., 2017). They enrich the graph by aggregating features with information gathered from the neighborhood of the node to be classified. Enhancements to the model introduce much sophisticated local information aggregation between the node pairs as in Graph Attention Networks (GAT) Veličković et al.. However, we note that such prior methods fall inherently into the **classification** paradigm, and hence focus on only local aggregation; i.e., to pull in the most significant feature from its neighbors.

In the context of keyphrase extraction, Zhang et al. (2017) is a recent work that learns directly on the graph. Their method, MIKE, determines the weight of edges and nodes in a supervised manner, rather than just utilizing co-occurrence statistics. Their work features 5 orthogonal features, one of which is topic distribution. They consider the prominence of the tokens per topic as the surrogate for ranking, utilized for model training, by minimizing the difference in predicted and gold-standard rank between iterations. MIKE can be employed only when topic information is available, but unfortunately, does not generalize to the more common case where only gold-standard keyphrases are available for training.

In Augenstein et al.(2017) benchmarking, state-of-the-art rich semantic embeddings deep learning and handcrafted feature–based statistical sequential labeling models used LSTM (Ammar et al., 2017) and CRF (Prasad and Kan, 2017) models respectively. Meng et al.(2017) uses an encoder–decoder model with a copy mechanism for keyphrase extraction (as a special case of

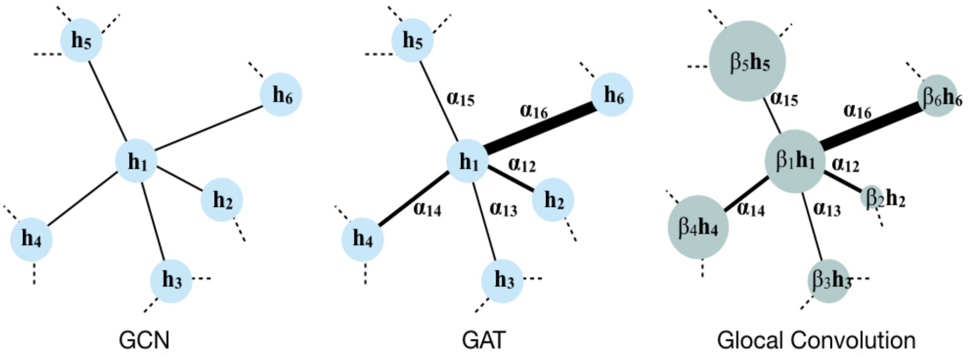

Figure 1: Graph Convolution Model Architectures. Illustrations of the Graph Convolution Network (GCN, left), Graph Attention Network (GAT, center) and our proposed Glocal technique (right), centered on node h_1 within its $1-$hop neighborhood. TextRank on the complete graph is used to compute parameter β_i. GAT parameterizes the edge weights based on gradients (α_i, also represented by the differing edge widths). Our Glocal technique adds the TextRank score (represented by different scaling of nodes), which is not derived from the gradient.

generation). This state-of-the-art technique exploits a complementary idea of sequential semantic modeling focused on generating keyphrases rather than merely extracting them. However, their model does not address the common scenario of keyphrase extraction from long documents but only for short excerpts (namely, the abstract). This assumption reduces the complexity of the problem for sequential models that can effectively encode short text spans but may be ineffective on full-text. We suspect this is a current limitation of the encoder–decoder based models, which necessarily reduces the entire textual sequence into a single vector during the encoding stage – making it susceptible to the vanishing gradient and representation underfitting on large text. Further advances using the encoder–decoder framework such as (Chen et al., 2018) further explore the sequential modeling architectures by improving the attention mechanism with traditional features like title guidance. Note that many forms of such structural information — such as sectional information and citation graph co-occurrence — can enhance basic models, however without loss of generality, in this work we consider only text-based features for all the models.

3 Method

Our proposed model exploits the strength of both supervised and unsupervised modalities by combining two baseline models. Our Glocal model has two components:

- For learning directly over the graph (classification), we use the recently proposed GCN as our baseline model.
- For incorporating global importance (ranking), we use TextRank as our baseline model.

We will first introduce the preliminaries: *e.g.*, Graph Convolution Network (GCN), followed by the modifications that result in the Graph Attention Network (GAT). We then explain how we modify the local convolution operation, to incorporate global importance scores.

3.1 The Graph Convolution Network (GCN)

Graph $G = (V, A)$, where V is a a finite set of vertices such that $|V| = n$ and $A \in R^{n\times n}$ is an undirected weighted adjacency matrix representing all edges, assume $x : V \to R^n$ maps each node to x_i, which is a n-dimensional feature vector. Spectral filtering on a signal x is then represented as (Defferrard et al., 2016):

$$y = g_\theta(L)x = Ug_\theta(\Lambda)U^T x, \qquad (1)$$

where $L = I_n - D^{-1/2}AD^{-1/2}$ and where I_n is the identity matrix and $D_{ii} = \sum_j A_{ij}$. Further, parameterization and simplification of the filter by (Hammond et al., 2011) results in:

$$g_\theta(\Lambda) \approx \sum_{k=0}^{K-1} \theta_k T_k(\tilde{\Lambda}), \qquad (2)$$

where the Chebyshev polynomial $T_k(x)$ is computed recursively. Note that Eqn. 2 is K-localized; *i.e.* it depends only on nodes that are at a maximum of K hops away from the target node.

A linear model can approximate this (Kipf and Welling, 2016) resulting in the simplified form:

$$y \approx \theta_0' x + \theta_1' \left(L - I_N\right) x = \theta_0' x - \theta_1' D^{-\frac{1}{2}} A D^{-\frac{1}{2}} x \,, \tag{3}$$

with two free, tunable parameters θ_0' and θ_1'. Constraining $\theta = \theta_0' = -\theta_1'$ further simplifies the approximation to a single-parameter form:

$$y \approx \theta \left(I_N + D^{-\frac{1}{2}} A D^{-\frac{1}{2}}\right) x \,. \tag{4}$$

Note $I_N + D^{-\frac{1}{2}} A D^{-\frac{1}{2}}$ has eigenvalues in the range $[0, 2]$, so a re-normalization trick was proposed previously $I_N + D^{-\frac{1}{2}} A D^{-\frac{1}{2}} \rightarrow \tilde{D}^{-\frac{1}{2}} \tilde{A} \tilde{D}^{-\frac{1}{2}}$, with $\tilde{A} = A + I_N$ and $\tilde{D}_{ii} = \sum_j \tilde{A}_{ij}$ to keep gradients stable. This formulation (GCN) supports the following layer-wise propagation rule:

$$H^{(l+1)} = \sigma\left(\tilde{D}^{-\frac{1}{2}} \tilde{A} \tilde{D}^{-\frac{1}{2}} H^{(l)} W^{(l)}\right) \,. \tag{5}$$

Here, $\tilde{A} = A + I_N$ is the adjacency matrix of the undirected graph G with added self-connections and $W^{(l)}$ is the layer-specific set of weight parameters. σ denotes an activation function; in the GCN model, ReLU is preferred. $H^{(l)}$ is the matrix of activation in the l^{th} layer; $H^{(0)} = X$.

3.2 The Graph Attention Network (GAT)

Unfortunately, the expressive power represented by $\tilde{A}$ is also its biggest limitation: as such, the model only incorporates features from the neighborhood as weighted by the connecting edge normalized to unit sum (*cf.* Fig. 1, left). To address this, the Graph Attention Network model (Veličković et al., 2018) incorporates learnable scaling for each edge. This introduces a local function $attn : R^{F'} \times R^{F'} \rightarrow R$,

$$a_{ij} = attn(W\vec{h}_i, W\vec{h}_j), \tag{6}$$

that computes a score (attention) per node pair (or *edge*, inclusive of self-loops). Here, the $attn$ operator is a single feed-forward layer employing Leaky ReLU activation. This attention is normalized in GAT as:

$$\alpha_{ij} = \frac{\exp\left(a_{ij}\right)}{\sum_{k \in \mathcal{N}_i} \exp\left(a_{ik}\right)}, \tag{7}$$

to smooth the gradients. In contrast to GCN, GAT replaces the $\tilde{A}$ with a learned $\tilde{A}'$ where each entry α_{ij} is a normalized score computed on each node pair by the gradient (Fig. 1, center). The normalized attention coefficients are used to compute a linear combination of the features in a node neighborhood $\mathcal{N}$, yielding the equivalent layer-wise propagation rule:

$$\vec{h}_i^{(l+1)} = \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha_{ij} W \vec{h}_j^{(l)}\right). \tag{8}$$

In terms of Eqn. 5, the fixed weights in the adjacency are replaced with learned weights or equivalently hard neighborhood is replaced by soft neighborhood. Since all edge weights are parameterized, a number ($= T$) of multiple random initializations learn different representations, resulting in a number of different scalings for multiple linear combinations. A final result is achieved by either concatenating or averaging the multiple representations as formulated in Eqns. 9 and 10, respectively.

$$\vec{h}_i^{(l+1)} = \Big\Vert_{t=1}^{T} \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha_{ij}^t \mathbf{W}^t \vec{h}_j^{(l)}\right) \tag{9}$$

$$\vec{h}_i^{(l+1)} = \sigma\left(\frac{1}{T} \sum_{t=1}^{T} \sum_{j \in \mathcal{N}_i} \alpha_{ij}^t \mathbf{W}^t \vec{t}_j^{(l)}\right) \tag{10}$$

3.3 Glocal: GAT with Random Walk Scores

In both GCN and GAT, a model with K layers incorporates the feature for a node up to its K hop neighbors. Though GAT improves upon GCN by assigning different importance to nodes via learned weights as compared to the static edge weight in GCN, it is still a local computation. The attention factor, *i.e.* the scaling coefficients α_{ij}, are the function of pairwise feature interaction within the local neighborhood and do not account for node centrality nor the global graph structure. We fix this with our Glocal model.

Consider the random walk based score generated for the graph G such that:

$$\beta_j = TextRank(i). \tag{11}$$

We introduce this parameter β_j to the GAT model. Considering this as the global importance component to the node, we obtain two alternative formulations that encode the node importance as either an additive or a multiplicative form:

$$\vec{h}_i^{(l+1)} = \sigma\left(\sum_{j\in\mathcal{N}_i} \alpha_{ij}\mathbf{W}\vec{h}_j^{(l)} + \sum_{j\in\mathcal{N}_i} \beta_j\mathbf{W}'\vec{h}_j^{(l)}\right) \qquad (12)$$

$$\vec{h}_i^{(l+1)} = \sigma\left(\sum_{j\in\mathcal{N}_i} \beta_j\alpha_{ij}\mathbf{W}\vec{h}_j^{(l)}\right) \qquad (13)$$

From Eqns. 12 and 13, we see two scaling factors α and β, which either reinforce or diminish the other's effect (Fig. 1, right). Unlike α, β is neither calculated locally nor normalized. Not normalizing β is an essential component for having both classification and ranking ability. With normalization, even in a neighborhood with minimal TextRank scores, we will get an aggregation of features with unit sum weights. While without normalization it would perform almost no feature aggregation from such nodes.

In our experiments, we use the formulation of Eqn. 13, as a multiplicative formulation easily enables multi-head attention (achieved by multiplying $\tilde{A}$ with B such that $B_{ii} = \beta_i$). Note that this modeling applies to GCN as well: the second component of the Eqn. 13 actually closely resembles the GCN formulation for our proposed model.

4 Experiments

Dataset	Total	Training	Testing
Schutz (2008)	1,323	1,058*	265*
Krapivin (2009)	2,304	1844*	460*
SemEval (2010)	1,095	708	387

Table 1: Number of documents in our keyphrase extraction datasets. '*' denotes that the dataset does not have an official split; results are based on random splits.

We investigate keyphrase extraction, using the most commonly reported full-text datasets, as shown in Table 1. We divide the training data in 80 : 20 fraction for train and validation splits. Our complete pipeline comprises the following steps:

1. Feature Processing. First we perform TextRank on the complete text of each document, retaining only tokens that are nouns and adjectives, filtering out other words (equivalent to simplex noun phrases). We use the gensim library (Řehůřek and Sojka, 2010) to perform TextRank and compute the scores. This process helps in two ways – first, it gives us the node importance value for each keyphrase, needed by Glocal; second, it helps to manage the graph size and lessen the label skew on the minority positive label by removing extraneous tokens. For documents larger than a max size (1200 tokens) we drop the extra least scored tokens. We find that the tokens that have a TextRank score in bottom 50% possess only 16% of partial or full keyphrases in the validation dataset. Hence dropping them from the processing does not affect the recall much. The nodes of the graph are single tokens and not complete phrases, therefore all the tokens of multi-token keyphrases are marked as $keyphrase$ during learning ion the graph. For the node/keyphrase representations, we map our vocabulary to GloVe embeddings using the $2.2M$ vocabulary sized, 300 dimension vector variant (Pennington et al., 2014). For reference, we observe GloVe covers about 90% of the words overall 3 datasets. We then extract various textual features for the candidate keyphrases, including their position of the first occurrence, $tf.idf$ and n-gram count. These features are appended to the word embedding to obtain a final feature vector representing each node. Rather than discard them, we choose to append the n-gram features to retain rich lexical signals obtained from the tokens.

2. Learning. The second step is to train the model with the formulated graphs. We use a 2-layer network with 128 units with ReLU activations for hidden layers, followed by a simple 2-way softmax classification layer ($keyphrase$, $\neg keyphrase$). We further employ 8 attention heads at all layers. We follow Glorot initialization (Glorot and Bengio, 2010) for all setting initial parameters weights, use a dropout of 0.5, and employ a $L2$ regularization of 0.001. We train with Adam optimizer on cross-entropy loss and initial learning rate of 0.01 for 200 epochs using an early stopping strategy with patience set to 20 epochs. In both evaluation and training, as gold standard keyphrases have multiple tokens, we use each token of the gold keyphrase as the true label for each token.

3. Post-processing. This step reconstructs the multi-token keyphrase from the probability scores as generated by the Glocal model. This formation step then requires a re-ranking (calculating $R(p)$) of the resultant phrase as:

$$R(p) = len(p) * \sum_{w_i \epsilon p} r(w_i) \qquad (14)$$

Table 2: Main comparative system evaluations on keyphrase extraction. All figures are $F_1@K$. † uses only abstract, rest all models are trained on full-text, * shows significant improvement over strongest baseline CopyRNN.

The initial rank of each candidate token is in this case equal to the probability of the $keyphrase$, i.e., $\forall w_i \in p$, $r(w_i) = p_{keyphrase}(w_i)$. We also constrain the process such that the actual word sequence must appear in the original text.

An important note that we strictly do not normalize the β_i scores; the re-ranking process and the preservation of raw scores work in tandem. Topologically, such graphs generated from textual data often have a few dense neighborhoods and many sparse ones, resulting in significant raw score differences that can benefit from scaling down the feature appropriately. If normalization is done in each neighborhood (as done for α_i), it will scale up individual nodes in a sparse neighborhood and suppress nodes in a dense neighborhood, the reverse of the intended operation.

5 Results

We compare our Glocal model's results against other models on the core task of keyphrase extraction. We select baselines which represent the related state-of-the-art under particular learning paradigms: unstructured retrieval-based ($tf.idf$), unsupervised graph-based (TextRank), supervised sequence learning (RNN and derivatives) and supervised structured models (GCN and derivatives). The marked performance differences help us to ablate and understand the gain brought about by the supervision directly on the graph over unsupervised graph-based techniques, as well as that brought by incorporation of the random walk-based score into the supervised model. We also report TextRank and $tf.idf$ baselines to measure ablative effects, as they contribute to Glocal.

For the sake of comparison, we restrict our comparison to modeling approaches, deciding to keep the feature inventory constant; *i.e.* textual and statistical features. Closely related work discussed earlier — such as MIKE (Zhang et al., 2017) — are not directly comparable, since such works may use many other orthogonal features. Similarly, many supervised techniques use additional features. The best reported SemEval-2010 systems show very close performance to our proposed model, but they take advantages of other sources of side information, such as Wikipedia term acquisition, logical section information, bagging, and ensembles; hence, they are not directly comparable (reported in (Kim et al., 2010)). We argue that our main contribution is in the capacity of modeling; other features utilized in prior work can enhance Glocal's performance and suitable incorporation is future work. In a similar vein, PositionRank (Florescu and Caragea, 2017b) enhances the random walk itself which can again act as a replacement for the TextRank in our model and is thus not strictly a comparable method.

We argued earlier that the recently proposed supervised encoder–decoder based CopyRNN (Meng et al., 2017) deep learning models trained using word embedding do not scale well to the full-text setup. In their work, they only report results for extracting (and generating) keyphrases from abstracts. For direct comparison, we have retrained these models in the full-text scenario to validate our claim that these models have difficulty with scaling. Further, we still compare with the abstract-only trained model for CopyRNN to benchmark both approaches.

The results are reported in F_1@K where $F_1 = 2 * precision * recall/(precision + recall)$ and K is the number of keyphrases generated by the model. Table 2 shows that our Glocal model outperforms both GCN and GAT; and that no other text-only based model shows comparable performance. In the full-text scenario, sequential neural models fare comparably to TextRank, Text example from SemEval: Edge Indexing in a Grid for Highly Dynamic Virtual Environments. Newly emerging game-based application systems such as Second Life provide 3D virtual environments where multiple users interact with each other in real-time. Figure 2: Examples from the SemEval and Schutz datasets. Full matches are bolded; partial matches, italicized. Output from SemEval dataset are stemmed before evaluation

but the recent graphical deep learning models represented by GCN and GAT outperforms it easily. Further, notice that TextRank alone performs weakly in comparison to GAT, but does synergize well with the base GAT in our Glocal system yielding state-of-the-art performance over all three datasets. These results are consistent microscopically as well. Fig. 2 gives two illustrations of keyphrases generated by TextRank, GAT, and Glocal, which show the ability of Glocal to pull out a larger ratio of exact keyphrase matches.

We drill down on SemEval dataset for a closer look, as in Table 3, which has the highest positive label ratio at 14.8 keyphrases per document on average. Keyphrases in SemEval are further classified as either author- or reader-annotated. Despite the task being difficult (15% of the reader- and 19% of the author-assigned keyphrases are not in the text) Glocal's performance edge holds out well, and the results are consistent on both forms of assigned keyphrases.

We experiment with adding the neighborhood normalization for β_j which resulted in a significant decrease in performance of the Glocal model. To further explore this issue of whether normalization thus formed classification model has any benefit over GCN and GAT, we experiment with the Cora and Citeseer scientific document classification tasks (as reported in (Kipf and Welling, 2016) and (Veličković et al., 2018)) which assigns a document into one of six or seven topical categories. We find that the incorporation of global random walk information does not influence topical categorization much (with a minor gain in the case of Cora dataset), and hence Glocal's performance is almost identical to the less expressive GAT model in terms of classification.

Model	Author	Reader
KP-Miner	17.1%	21.5%
Maui	16.2%	16.1%
TextRank	14.5%	15.1%
GAT	25.5%	26.0%
Glocal	**32.2%**	**34.5%**

Table 3: Summary of the fine-grained F_1@15 on SemEval. We compare with other state-of-the-art SemEval systems using text-only feature-based models.

6 Discussion

We now discuss three aspects of the model with respect to the task of keyphrase extraction.

1. Feature versus Scaling. TextRank scores are used in supervised classifiers, traditionally incorporated as a feature. How well would just incorporating TextRank as an additional feature to GAT work? While it does help to improve performance, it does not incorporate the ranking component element in the model; *i.e.* even nodes with very low centrality can positively contribute to its neighbors' scores. Glocal's tight integration is beneficial as it allows further gradient optimization, rather than just simply adding a new feature dimension. Our experiment with adding TextRank as an additional feature show $\approx 2\%$ performance gain for GCN and $< 0.5\%$ performance gain for GAT on average as compared to Glocal showing gain of 5% on average. The behavior is consistent with that of the classification model as in the absence of β_j, the GAT model is inherently a classification model.

As an example (*cf.* Fig. 1, right), consider a neighboring Node h_5 to the prospective keyphrase represented by Node h_1. Node h_5 has a low similarity with the target (low α_{15}), but if a prominent node in the graph will be accorded a higher β_5. In this way, such a node channels more to its neighbor, exerting comparatively steeper gradients to less essential nodes, hence giving a larger chance for Node h_1 to be considered a keyphrase. However, without Glocal's scaling mechanism, such modeling is not captured and essentially unlearnable. We further elaborate on this point next, which shows how our scaling is equivalent to known embedding aggregation techniques (in contrast to adding an extra feature dimension).

2. TextRank Averaged Node Embedding. Kipf and Welling argue that GCN is analogous with node embedding approach with the Weisfeiler-Lehman algorithm for graph isomorphism. Namely, for every node i in V, and scalar feature h_i, the algorithm repeats for k steps or until convergence:

$$\vec{h}_i \leftarrow hash\left(\sum_{j\in\mathcal{N}_i} \vec{h}_j\right). \tag{15}$$

In case $\vec{h}_j$ is a scalar this as well represents the TextRank.

Comparing with layer-wise propagation rules for GAT, GCN, and Glocal, we find a common structure among the methods for incorporating features. Eqn. 16b (representative of GAT) converts a constant aggregation of Eqn. 16a (representing GCN) to be a locally learnable parametric scaling. Eqn. 16c (Glocal) further factorizes the scaling with one locally learnable parametric and one global random walk score. In short, our means of generating node representations (*i.e.*, the post-training embedding) weights the representations for each node/candidate keyphrase by its random walk score. Such a procedure generates stable representations, similar to $tf.idf$ weighted word embeddings used for sentence representation. Such techniques have shown better performance as compared against complex aggregators (like LSTMs) on tasks with insufficient data to train end-to-end models.

$$\vec{h}_i^{(l+1)} \leftarrow \sigma\left(\sum_{j\in\mathcal{N}_i} c_{ij}\vec{h}_j^{(l)}\mathbf{W}\right), \tag{16a}$$

$$\vec{h}_i^{(l+1)} \leftarrow \sigma\left(\sum_{j\in\mathcal{N}_i} \alpha_{ij}\vec{h}_j^{(l)}\mathbf{W}\right), \tag{16b}$$

$$\vec{h}_i^{(l+1)} \leftarrow \sigma\left(\sum_{j\in\mathcal{N}_i} \beta j\alpha_{ij}\vec{h}_j^{(l)}\mathbf{W}\right). \tag{16c}$$

3. Generating Longer Keyphrases. The re-ranking trick for promoting the generation of longer keyphrases – discussed earlier and in the final step of our pipeline – is fielded in many systems (Zhang et al., 2017). This is a difficult requirement to incorporate directly into the model, relegating such techniques to post-processing by default. A nice offshoot effect of our model is that it implicitly favors generating longer keyphrases, due to the inherent nature of the graph convolution operator in aggregating neighboring nodes' features. This, compounded with a high random walk score for the prospective keyphrase node, results in a higher fraction of features propagating from such nodes being included to its neighboring nodes. In turn, this favors dense local keyphrase neighborhoods of highly weighted keyphrases, making the re-ranking step easier.

7 Conclusion

We have presented Glocal, a global plus local graph convolution model for incorporating the global importance of the node within the local convolution operation for supervised learning on graphs. We argue both theoretical and validate empirically that such a model has benefits in strengthening the graph node ranking component, particularly helpful in tasks such as keyphrase extraction. On our detailed experiments on keyphrase extraction on 3 real-world full-text datasets, our model achieves better performance than traditional, graph-based unsupervised graph-based ranking models and bests sequential supervised classifiers as well. The specific component of incorporating global importance further improve the performance by up to 8.0% absolute F_1 on different evaluation criteria on full-text setup as compared to GAT and up to 2% absolute gain as compared to CopyRNN.

Abstract

The structured output framework provides a helpful tool for learning to rank problems. In this paper, we propose a structured output approach which regards rankings as latent variables. Our approach addresses the complex optimization of Mean Average Precision (MAP) ranking metric. We provide an inference procedure to find the max-violating ranking based on the decomposition of the corresponding loss. The results of our experiments on WikiQA and TREC13 datasets show that our reranking based on structured prediction is a promising research direction.

1 Introduction

The current state-of-the-art learning approaches for answer sentence reranking in question answering (QA) are mostly based on learning pairwise ranking signals or simple binary classification (relevant versus irrelevant labels). Intuitively, global information over a rank should improve the ranker accuracy. Thus, there have been promising attempts to learn global ranking functions which encompass the signals of all the candidates for a given query (Chapelle et al., 2007; Weston and Blitzer, 2012; Le et al., 2018). These works employ the structured output learning framework to represent a ranking as a structured object, with respect to which it is possible to directly optimize a ranking measure.

Direct optimization of the target ranking measures is affordable when they are factorizable, e.g., the structural SVM of Chapelle et al. (2007) makes use of the factorization properties of the Normalized Discounted Cumulative Gain (NDCG) ranking score. In contrast, MAP is rather complex making its treatment harder. Yue et al. (2007) could still find an exact solution to the hinge-loss relaxation of Average Precision (AP) for the structural SVM approach. It is found for the particular case of a combined feature mapping of inputs and structured outputs. Such a mapping accounts for respective orderings of the pairs of candidate items, where one item is relevant and the other is not, without explicitly encoding the order of all the items in the rank. Encoding such order (Chapelle et al., 2007; Weston and Blitzer, 2012), i.e., adding yet more complexity to the structural feature space, might lead to intractability of the previous exact max-violating inference with respect to MAP. Furthermore, the feature representation of the gold standard rankings, which could be many for a given candidate list of items, is not unique anymore.

In this work, we study the effect of using structured ranking representations (Chapelle et al., 2007) within the large-margin structured prediction framework versus direct MAP optimization on the most representative task of QA, i.e., passage reranking. To make two ends meet, we have to tackle the above two issues, i.e., i) intractability of the max-violating inference with respect to MAP, and ii) multiplicity of the ground truths.

Regarding the latter, it should be noted that different rankings can correspond to optimal performance, thus, Chapelle et al. (2007) select one among all possible correct rankings at random to build the ground truth for training. Weston and Blitzer (2012) bypass the necessity of comparison to a complete ranking during training and sample the candidate pairs. In this work, we show how this issue can be seamlessly circumvent using the latent structured prediction formulation.

For optimizing MAP, we derive a strict decomposition of the loss corresponding to AP and propose an approximate method for inference of the max-violating constraint with respect to it. More

specifically, we provide two structured output approaches optimizing the MAP metric based on Latent Structured Perceptron (LSP) (Sun et al., 2009; Fernandes et al., 2014) and Latent Structural SVM (LSSVM) (Yu and Joachims, 2009) algorithms.

We compare LSP and LSSVM using our MAP optimization strategy on WikiQA (Yang et al., 2015) and TREC13 (Wang et al., 2007) datasets against an SVM classifier and SVM^{map} – the structural approach of Yue et al. (2007). All the models use state-of-the-art traditional feature vectors for the task. Our experiments on WikiQA dataset show a large improvement of our structural approaches over the SVM baseline, i.e., more than 7 absolute points in MAP, MRR and Precision@1.

However, we acknowledge the fact that neural models can produce better representations, which can lead to a superior performance. Thus, to collocate our results in a more general setting, we also carried out experiments using the embeddings of questions and passages, produced by an accurate Convolutional Neural Network (CNN) for passage reranking. In this setting, the structured output models approach the state of the art, confirming the positive impact of our models, which may also be used to train neural networks.

2 Related work

The work related to our approach can be divided in two research areas: (i) structured prediction for reranking problems and (ii) passage reranking in question answering systems.

Structured prediction Seminal work on large-margin structured prediction is by Tsochantaridis et al. (2004), which enables the optimization of multivariate loss functions, exploiting structural dependencies within complex output variables. Chapelle et al. (2007) devise an approach based on the structural SVM, which enables direct optimization of the NDCG ranking measure. Le et al. (2018) facilitate the optimization of a range of ranking measures, within a unified structured output formulation. However, they do not provide any solution for MAP. Weston and Blitzer (2012) optimize a retrieval AUC loss, which decomposes into pairwise decision variables.

The approach most similar to ours is SVM^{map} by Yue et al. (2007), who provide a structural solution for optimizing MAP. They find exactly the max-violating ranking structure with respect to AP within the structural hinge loss formulation. This is done for the case when a ranking is represented by aggregating pairwise outputs between all the relevant and all the irrelevant items in the rank. Our approach is an alternative to this technique, providing an approximate max-violating inference with respect to AP for a more general case of the ranking represenation.

Passage Reranking Most representative *pre-neural networks* work for answer selection/passage reranking is from Wang et al. (2007), who used quasi-synchronous grammar to model relations between a question and a candidate answer with syntactic transformations. Heilman and Smith (2010) and Wang and Manning (2010) applied Tree Edit Distance (TED) to learn the match between question and passage. Yao et al. (2013) applied linear chain CRFs with features derived from TED. Yih et al. (2013) used lexical semantics to build a word-alignment model.

Most recently, Deep Neural Networks (DNNs) have shown to be more competitive. DNN can learn relational patterns between a question (Q) and its passage (P) in a variety of ways, e.g., (i) by using a Q-to-P transformation matrix and simple Q-to-P similarity features (Yu et al., 2014; Severyn and Moschitti, 2015), (ii) by relying on RNN and LSTM architectures (Wang and Nyberg, 2015; Shen et al., 2017), (iii) by employing attention components (Yin et al., 2016; Shen et al., 2017; Wang et al., 2016a), (iv) by decomposing input into similarity and dissimilarity matches (Wang et al., 2016b) or (v) by comparing-aggregating matching results (Wang and Jiang, 2017; Bian et al., 2017).

Since our baselines, SVM and SVM^{map}, as well as our proposed models, LSP and LSSVM, do not apply such transformations, they may perform lower than the state of the art. Thus, we will use the embedding vectors generated by a CNN to show that they can achieve the state-of-the-art accuracy.

3 Structured prediction for ranking

In this section, we provide the task formulation with an introduction of structured prediction algorithms.

3.1 Task formulation

We have training examples of the form $\{(\mathbf{x}_i, y_i)\}$, where $\mathbf{x}_i = (q_i, D_i)$, q_i is a query, $D_i = \{d_i^j\}_{j=1}^{N_i}$ is a list of candidate items corresponding to q_i and

N_i is the number of candidates. $y_i = \{y_i^j : y_i^j \in \{0,1\}\}_{j=1}^{N_i}$ is a vector of gold item labels, label y_i^j corresponding to item d_i^j, taking value of 1 for relevant (good or positive) items and 0 – for irrelevant (bad or negative). The task is to learn to predict, for each example $\mathbf{x}_i$, a ranking of its items $r(\mathbf{x}_i) = r(q_i, D_i)$, such that the relevant items, d_i^j with gold labels $y_i^j = 1$, are always at top positions in $r(q_i, D_i)$. Finally, $r(\mathbf{x}_i) = \{r^j\}_{j=1}^{N_i}$ is a permutation of D_i. In the following, we omit the example index i for simplification of the notation.

3.2 Structured prediction

Generally, structured output approaches aim at linking structured input and output patterns. More formally, in a linear case, such algorithms learn a scoring function $f : X \times Y \to \mathbb{R}$, $f(\mathbf{x}, \mathbf{y}) = \mathbf{w} \cdot \Psi(\mathbf{x}, \mathbf{y})$, where $\Psi(\mathbf{x}, \mathbf{y})$ is a combined feature mapping of input variables X and output variables Y. The predicted structure is derived as $\hat{\mathbf{y}} = \underset{\mathbf{y} \in Y}{\operatorname{argmax}} f(\mathbf{x}, \mathbf{y})$. Online structured prediction approaches, e.g., the structured perceptron by Collins (2002), are based on gradient descent updates of the model on the current predicted structure $\hat{\mathbf{y}}$ against the correct structure $\mathbf{y}^* : \mathbf{w} \leftarrow \mathbf{w} + \Psi(\mathbf{x}, \mathbf{y}^*) - \Psi(\mathbf{x}, \hat{\mathbf{y}})$. The large-margin perceptron variants augment the inference with the structural loss (Fernandes and Brefeld, 2011): $\hat{\mathbf{y}} = \underset{\mathbf{y} \in Y}{\operatorname{argmax}} f(\mathbf{x}, \mathbf{y}) + \Delta(\mathbf{y}^*, \mathbf{y})$. When exhaustive search over Y is impossible, the problem can still be solved if the loss Δ and the scoring function $f(\mathbf{x}, \mathbf{y})$ are decomposable over the subparts of the structure $\mathbf{y}$ and there exists an efficient procedure for finding the argmax using such a decomposition.

3.3 Structured prediction for ranking

The structured prediction framework for ranking (Chapelle et al., 2007; Le et al., 2018) considers a joint feature representation of an input example $\mathbf{x}$ together with an output ranking r: $\Psi(\mathbf{x}, r) = \Psi(q, D, r)$, which factorizes over the individual feature representations of items with respect to the query, weighted relatively to the item positions j in the rank:

$$\Psi(\mathbf{x}, r) = \Psi(q, D, r) = \sum_{j=1}^{N} v_j \psi(q, r^j). \quad (1)$$

The typically used weighting schema, v, implies non-increasing weights associated with the positions j: $v_1 \geq v_2 \geq ... \geq v_N \geq 0$, where the importance decreases gradually from the top to the bottom of the ranking. Inferring a ranking corresponding to a linear model $\mathbf{w}$, i.e., finding

$$\underset{r \in R(\mathbf{x})}{\operatorname{argmax}} \mathbf{w} \cdot \Psi(\mathbf{x}, r) \quad (2)$$

among all possible rankings, $R(\mathbf{x}) = R(q, D)$, simply reduces to ordering the items by scores $\mathbf{w} \cdot \psi(q, d)$, since v_j are fixed.

As the correct ranking r^* for an example $\mathbf{x}$ is often not unique, Chapelle et al. (2007) select one of the correct rankings at random as a gold label during training. This evidently biases the training towards such ground truths.

3.4 Latent structured prediction

The above problem can be alleviated using a latent structured prediction framework. We describe now the general idea of latent variables, and after that we introduce our approach, in which, we implement this idea for ranking tasks.

Latent variables $\mathbf{h}$ are auxiliary structures which are not fully observed in the training data (Yu and Joachims, 2009). The training examples are extended with $\mathbf{h}$ – $(\mathbf{x}, \mathbf{y}, \mathbf{h})$, and the learning is shifted to the space H of latent output structures $\mathbf{h}$. Normally, each $\mathbf{h}$ corresponds to one $\mathbf{y}$, while the opposite is not the case. The problem of multiplicity of the ground truths $\mathbf{h}$ is overcome by finding the best $\mathbf{h}$ explaining the gold $\mathbf{y}^*$:

$$\mathbf{h}^* = \underset{\mathbf{h} \in H(\mathbf{x}, \mathbf{y}^*)}{\operatorname{argmax}} \mathbf{w} \cdot \Psi(\mathbf{x}, \mathbf{h}), \quad (3)$$

using the current model weights $\mathbf{w}$ at each iteration of the training, and $\mathbf{h}^*$ used as gold labels.

4 Our learning approach

In the following, we describe the two classical steps in structured prediction, i.e., learning and inference. Regarding inference, we show our new approximation of MAP.

4.1 Learning

We deal with a non fully observed case as the ground truth ranking labels r we intend to learn are not given in the input data. The case suits perfectly the latent structural formulation (Sec. 3.4), where r can be regarded as latent variables $\mathbf{h}$. Consider the following latent structural large-margin objective (Yu and Joachims, 2009), in terms of the structured ranking variables:

$$\min_{\mathbf{w}} [\frac{1}{2}||\mathbf{w}||^2 + C\sum_{i=1}^{n} \max_{r\in R(\mathbf{x}_i)} [\Delta(y_i,r) + \mathbf{w}\cdot\Psi(\mathbf{x}_i,r)] - C\sum_{i=1}^{n} \max_{r\in R(\mathbf{x}_i,y_i)} \mathbf{w}\cdot\Psi(\mathbf{x}_i,r)], \tag{4}$$

in which the upper bound on the training loss Δ involves (i) finding the max-violating ranking structure, $\hat{r}_i$, over the set $R(\mathbf{x}_i)$ of all possible rankings for the example $\mathbf{x}_i$, under the first max, and (ii) the current ground truth ranking structure, r_i^*, over the set $R(\mathbf{x}_i, y_i)$ of all rankings that comply with the gold label y_i, under the second max.

We adapt the loss-augmented LSP algorithm (Fernandes and Brefeld, 2011) for ranking. LSP is essentially a gradient descent operated on the objective in Eq. 4 with a gradient taken with respect to the example variable. The pseudocode of our adaptation of the algorithm is shown in Alg. 1.

Iterating over the training examples $(\mathbf{x}_i, y_i)$, the algorithm, for each example, first finds the max-violating $\hat{r}_i$ with respect to a ranking loss $\Delta(y_i, r)$, over the set $R(\mathbf{x}_i)$ for the example $\mathbf{x}_i$ (Line 5). Δ can represent any arbitrary ranking loss. In this work, we instantiate Δ with the loss corresponding to the MAP ranking metric. Sec. 4.2 describes the procedure we use here for the max-violating inference with respect to it.

If the max-violating ranking $\hat{r}_i$ is erroneous (Line 6), the algorithm updates the model $\mathbf{w}$. In Line 7, the current ground truth ranking structure – the best correct r_i^* corresponding to the current model weights $\mathbf{w}_t$ – is found. The search here is restricted to the set $R(\mathbf{x}_i, y_i)$ of all correct rankings of the example $\mathbf{x}_i$, i.e., those at which good items take top positions and bad – bottom positions. Thus, the operation is reduced to simple ordering of the good and bad items (separately) by weights, and putting the former to the top, and the latter – to the bottom of the resulting ranking. This step corresponds exactly to imputing latent variables, described by Eq. 3, in the general latent formulation. In Line 8, we update the weights $\mathbf{w}$ using the structural feature representations (defined by Eq. 1) of the two ranking outputs, the current ground truth r_i^* and the max-violating $\hat{r}_i$.

Algorithm 1 Latent Structured Perceptron for Ranking

```
1: Input: $X = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$, $\mathbf{w}$, $C^1$, $T$
2: $\mathbf{w}_0 \leftarrow \mathbf{w}; t \leftarrow 0$
3: repeat
4:     for $i = 1, ..., n$ do
5:         $\hat{r}_i \leftarrow \operatorname{argmax}_{r\in R(\mathbf{x}_i)} \mathbf{w}_t \cdot \Psi(\mathbf{x}_i, r) + C \times \Delta(y_i, r)$
6:         if $\Delta(y_i, \hat{r}_i) > 0$ then
7:             $r_i^* \leftarrow \operatorname{argmax}_{r\in R(\mathbf{x}_i, y_i)} \mathbf{w}_t \cdot \Psi(\mathbf{x}_i, r)$
8:             $\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t + \Psi(\mathbf{x}_i, r_i^*) - \Psi(\mathbf{x}_i, \hat{r}_i)$
9:         end if
10:        $t \leftarrow t + 1$
11:    end for
12: until $t < nT$
13: $\mathbf{w} \leftarrow \frac{1}{t}\sum_{i=1}^{t} \mathbf{w}_i$
    return w
```

Likewise, we adapt the Latent Structural SVM (LSSVM) algorithm (Yu and Joachims, 2009) for ranking. We employ also LSSVM in our experiments for its generalization guarantees. The only minor difference from the LSP adaptation is that, in the LSSVM adaptation, we consider only the top items in the joint feature representation in Eq. 1, i.e., $\Psi(\mathbf{x}, r) = \sum_{j=1}^{P} v_j \psi(q, r^j)$, where P is the number of good/positive items in the candidate list D of the example $\mathbf{x}$. This is relevant only at the training phase and only for the updates of the model; for the max-violating inference, still all the items at all N positions participate. By doing so, we help LSSVM to keep the balance between positive and negative items. The test phase inference (respective to Eq. 2), for both LSP and LSSVM, consists only in ordering of all the items by their weight with respect to the model.

Weston and Blitzer (2012) adopt the same structural feature representation of Eq. 1 for ranking, however, in the latent embedding space. They do online SGD updates in correspondence to the positive-negative item pairs, and not on the whole rank, which relates to the way we proceed with LSSVM. In their case, this is due to the impossibility of the global inference (their model is also augmented with the structural component describing item-item interactions) and the scale of the task (they do ranking for recommendation domain). However, they perform a cascade-like inference of the rank which is scattered over the iterations.

---

[1] C here is a loss scaling parameter.

4.2 Max-violating inference

Our target is to optimize the MAP ranking metric. Thus, in training, we intend to minimize the following loss on structural examples which is the inverse of the average precision (AP): $\Delta_{ap}(y, r) = 1 - AP(y, r)$. AP is a global measure, non-decomposable in a strict sense over the position variables, so that to enable iterative exact inference. Here, we propose a method for approximate inference with respect to Δ_{ap}, which is efficient and enables exact local search.

Let us denote by $P = |\{d|y(d) = 1\}|$ the number of good/positive items in the candidate list D, and by $I_j^+ = I_{[y(r^j)=1]}$ and $I_j^- = I_{[y(r^j)\neq 1]}$ the indicator functions that the item at position j in r is good and not good (positive and negative), respectively. Then,

$$AP(y, r) = \frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+\sum_{k=1}^{j}I_k^+.$$

We can have a strict decomposition of Δ_{ap} over the negative items. We rewrite the AP formula as follows:

$$AP(y, r) = \frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+(\sum_{k=1}^{j-1}I_k^+ + I_j^+) =$$
$$\frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+(\sum_{k=1}^{j-1}I_k^+ + 1).$$

Here, I_j^+ inside the parentheses becomes 1 in the right-hand side because $I_j^+ * I_j^+ = I_j^+$. Then,

$$\Delta_{ap}(y, r) = 1 - \frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+(\sum_{k=1}^{j-1}I_k^+ + 1) =$$
$$\frac{1}{P}(P - \sum_{j=1}^{N}\frac{1}{j}I_j^+(\sum_{k=1}^{j-1}I_k^+ + 1)) =$$
$$\frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+(j - 1 - \sum_{k=1}^{j-1}I_k^+) =$$
$$\frac{1}{P}\sum_{j=1}^{N}\frac{1}{j}I_j^+\sum_{k=1}^{j-1}(1 - I_k^+) = \frac{1}{P}\sum_{j=1}^{N}\frac{I_j^+}{j}\sum_{k=1}^{j-1}I_k^- =$$
$$\frac{1}{P}\sum_{j=1}^{N-1}I_j^-\sum_{k=j+1}^{N}\frac{I_k^+}{k}. \tag{5}$$

According to the last line of Eq. 5, Δ_{ap} decomposes into a sum of quantities $l_j(y, r) = \frac{1}{P}\sum_{k=j+1}^{N}\frac{I_k^+}{k}$ over all positions j with negative items (those activating I_j^-) except for the last position N.

Note that $I_j^- l_j(y, r)$ gives the loss at position j considering the correct items below position j in the ranking. Therefore, we can use it for a bottom-up (max-violating) inference procedure, which first finds the best candidate item to be put at the lowest position of the rank and proceeds filling the positions in the ascending order. Specifically, we start with the last Nth position of the rank and put there the minimum weighted item:

$$\hat{r}^N = \underset{d\in D}{\operatorname{argmin}}\ v_N\mathbf{w}\cdot\psi(q, d). \tag{6}$$

According to the decomposition in Eq. 5, loss is always 0 at position N. At each of the following steps j, $\hat{r}^{N-j} =$

$$= \underset{d\in D\setminus\{\hat{r}^{N-k}\}_{k=0}^{j-1}}{\operatorname{argmin}} v_{N-j}\mathbf{w}\cdot\psi(q, d) + I_{N-j}^- l_{N-j}(y, \hat{r}). \tag{7}$$

Note that the loss part, $I_{N-j}^- l_{N-j}(y, \hat{r})$, in the above formula will be invariant for all the negative items remained in the candidate list, as well as it is for all the positive ones (equal to 0). Thus, $\hat{r}^{N-j}$ is essentially the argmin taken over only two candidate items from $D\setminus\{\hat{r}^{N-k}\}_{k=0}^{j-1}$: one is the positive item with the minimal weight $\mathbf{w}\cdot\psi(q, d)$, and the other, respectively, is the minimal weighted negative one. It is sufficient then to sort independently the positive and the negative items, in the beginning of the whole procedure, in the increasing order of their weights $\mathbf{w}\cdot\psi(q, d)$. Argmin's in equations 6 and 7 are then to be taken over the first items of the two sorted lists, which have not been selected at previous steps. This goes in line with the observation of Yue et al. (2007), that the max-violating ranking output $\hat{r}$ is an interleaving of such two sorted lists, which turns true also for our choice of the structural joint feature representation $\Psi(\mathbf{x}, r)$ in Eq. 1. However, the exact algorithm for max-violating inference of Yue et al. (2007) cannot be applied in our case, since our Ψ, due to distinctive contributions of items at different rank positions scaled with v_j weights, does not satisfy its conditions for an arbitrary choice of v_j.

Since, in our loss decomposition, the position-wise components are not independent of the decisions for the other positions, using a greedy procedure does not find a global optimum, but finds a local optimum with respect to the loss exactly. Namely, an item chosen at each step is optimal with respect to the partial rank constructed at the previous steps of the inference procedure.

Regarding the running time complexity of our greedy inference procedure, it is bounded by the complexity of the sort operation, $\mathcal{O}(N \log N)$, for the candidate lists of size N. In comparison, the worst case complexity of the exact inference in SVM^{map} by Yue et al. (2007) is $\mathcal{O}(N^2)$. In several cases, as shown by our experiments, doing inexact inference produces also higher MAP values compared to SVM^{map}.

5 Experiments

In our experiments, we compare the proposed structural ranking approach with the classification and structural baselines.

5.1 Setup

The setup reports on data, large margin models, CNN and measures we use in our experiments.

WikiQA We use only examples with at least one correct and at least one incorrect answer candidate (Yang et al., 2015) both for training and evaluation. This corresponds to 857 examples for training from train set, 237 – for testing from test, and 122 – for validation from development (dev.) set.

TREC13 We apply the same evaluation strategy as above on TREC13 dataset (Wang et al., 2007), however, for training, we limit to 10 the number of answer candidates for each question. This gives us 970 training examples, 65 examples for validation, and 68 test examples.

5.1.1 Large margin methods

We implement our structural ranking approach described in Sec. 3.3 using both LSP and LSSVM[2] algorithms, denoting the resulting models LSP-AP and LSSVM-AP, respectively.

We compare the models to an SVM baseline using the same feature set for the pairs, (q, d_i), and a polynomial kernel. We consider also a couple of structural baselines: (i) the standard LSP model (Sun et al., 2009), without loss-augmented inference, which we use in order to explore the impact of optimizing the target evaluation measure. This model still follows Alg. 1, however, the difference is that instead of finding the max-violating $\hat{r}_i$ in Line 5, it finds the following max-scoring:

$$\hat{r}_i \leftarrow \underset{r \in R(\mathbf{x}_i)}{\operatorname{argmax}}\, \mathbf{w}_t \cdot \Psi(\mathbf{x}_i, r).$$

And another structural baseline is (ii) SVM^{map} [3] (Yue et al., 2007) – a structural SVM approach affording exact max-violating inference with respect to AP.

Features In our study, we use two feature settings: (i) simple textual similarity features – the setting by Barrón-Cedeño et al. (2016), i.e., *cosine similarity* over the text pair, *the similarity based on the PTK score*, *longest common substring/subsequence measure*, *Jaccard similarity*, *word containment measure*, *greedy string tiling*, *ESA similarity* based on Explicit Semantic Analysis (ESA), and (ii) powerful features coming from the embeddings trained with the state-of-the-art neural networks (Tymoshenko et al., 2017).

Parametrization We use the following weighting schema for the ranking structures: $v_j = \frac{1}{j}$, in LSP, LSP-AP, and LSSVM-AP. LSP-AP requires specifying a loss scaling parameter C. In LSSVM and SVM^{map}, C is the standard trade-off between regularization and training error. In all the three models, we select C on dev. set from the values $\{1, 10, 100, 1000, 2000, 5000\}$. The max number of epochs, T, is set to 100, for both LSP and LSP-AP. We apply weight averaging in the LSP models. We derive the best number, T_{best}, with respect to the MAP score on dev. set. The baseline SVM is trained with polynomial kernels of degree 3.

Cross-validation On TREC13, which has a very small test set we apply cross-validation. On WikiQA, we obtain results on the official test set as well as applying cross-validation. We employ disjoint cross-validation as in Tymoshenko et al. (2017). For each approach, we train 5 models on the training set following the traditional 5-fold cross-validation strategy. We split dev. and test sets in 5 subsets each, and use ith dev. subset to tune the parameters of the models trained on the ith fold, and ith test subset – to test them. We report the results averaged over 5 test subsets.

5.1.2 Convolutional Neural Networks

We borrowed the CNN embeddings of questions and answer passages produced by the neural model for passage reranking of Tymoshenko et al. (2017); Severyn and Moschitti (2015)[4].

Table 1: Experimental results on WikiQA.

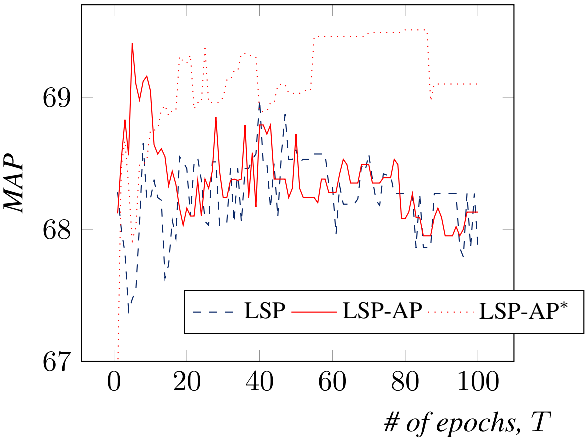

Figure 1: LSP curves on dev. set over the training epochs.

The neural model by Tymoshenko et al. (2017) includes (i) two sentence encoders that map input questions q_i and answer passages d_i^j into fixed size m-dimensional vectors $\phi(q_i)$ and $\phi(d_i^j)$ using a convolutional operation followed by a max pooling layer, and (ii) a feed forward neural network that computes the similarity between the two sentences in the input. The sentence vectors of a question and a passage, $\phi(q_i)$ and $\phi(d_i^j)$, are concatenated together and given in input, at stage (ii), to a standard NN architechture, constituted by a nonlinear hidden layer and a sigmoid output layer, which optimizes binary cross-entropy loss.

Note that we use exactly the concatenated question-passage sentence vectors (CNN embeddings) from stage (i) of the above model as features in SVM and the structured output models: $\psi(q, d) = [\phi(q), \phi(d)]$.

Evaluation metrics We report Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and Prec@1 (P@1).

5.2 Comparative analysis on WikiQA dataset

We first report the results using standard similarity features in all of our models. Then, we show the outcome of our models when fed with embeddings produced by the CNN.

5.2.1 Results with textual similarity features

In Tab. 1, we provide the results of our latent structural approaches optimizing MAP in comparison to SVM, LSP, and SVM^{map} models on WikiQA dataset. LSSVM-AP and LSP-AP are better than the SVM classifier baseline by roughly 8 and 10 points, respectively, in terms of MAP metric on the test set. It should be noted that SVM uses kernels, while LSSVM and LSP are simple linear models. Moreover, for SVM, we also had to limit the number of candidates to 10 for each query to make the positive/negative example rate more balanced.

The baseline LSP model (without augmented loss optimization) performs surprisingly well in this setting. It lacks only 0.15 of a MAP point on test set as compared to the highest scoring LSP-AP model. However, as LSP does not optimize the ranking measure directly, it may result unstable. We verified this hypothesis by exploring the performance of the two LSP models (with our loss and without) on dev. set, plotting the learning curves over the training epochs, T. Fig. 1 shows that the LSP-AP curve is distinctly superior to that of LSP only in the beginning of training, before epoch 17. We further verify this issue in cross-validation experiments in Sec. 5.2.3.

LSSVM-AP outperforms the structural baseline SVM^{map}. The latter targets direct optimization of MAP, and it clearly outperforms the SVM classifier. However, it is worse than the standard perceptron model, LSP, which does not optimize MAP. This suggests a higher appropriateness of the structural feature representation for rankings in Eq. 1. Indeed, it encodes the real positioning of items within a ranking (using positional weights v_i), compared to that used by SVM^{map}, agnostic to it and considering only pairwise relevant/irrelevant relative placements among

---

Reimers and Gurevych (2017); Crane (2018). Thus, we rely on the model that is easily replicable and achieves competitive results.

the items.

Finally, in the last lines of Dev. and Test subparts of Tab. 1, we report the results of the models denoted with *. In these model variants, we perform exact search for the max-violating ranking $\hat{r}$ with respect to Δ_{AP} over the structural hypothesis space $R(\mathbf{x})$, e.g., in Line 5 of Alg. 1, instead of our approximate inference procedure in Sec. 4.2.

In the current setting, exhaustive search over all possible rankings is reduced to an inference procedure, which inspects all interleavings of the two sorted lists, of positive and negative items, as pointed out in Sec. 4.2. In addition to the sorting complexity, this operation needs to traverse through a subset R' of ranking structures r, $R' \subset R(\mathbf{x})$, where $|R'|$ is estimated by the binomial coefficient $\binom{N}{N-P}$, which, for fixed P, grows polynomially as $\mathcal{O}(N^P)$. Recall that N is a total number of items in the candidate list D, among which P items are positive. In the context of WikiQA dataset, this is affordable, since the candidate lists D_i of the training examples are relatively short.

This way, LSSVM-AP* adds around 1.3 of a MAP point to its result using our approximate inference. LSP-AP*'s best number of epochs on dev., T_{best}, gives a nearly identical result on the test set in terms of MAP. However, its scores are lower compared to those of LSP-AP.

Fig. 1 illustrates a clear advantage of the direct optimization of AP using exact inference, which results in the best curve on dev. for LSP-AP*, stabilizing to its highest values on the interval between epochs 55 and 85. Still such a level of accuracy is nearly reachable by LSP-AP, although actually achieved at a very narrow interval (see the spike around epoch 5), while LSP's curve lies almost always lower. In future, we would like to study the impact of the loss approximation onto the convergence speed of the structural algorithms.

The LSP models in the current setting do not reveal a clear correlation between dev. and test results in Tab. 1, which might (i) signal of insufficient generalization power of LSP, and (ii) suggest that the effect of direct loss optimization can be reached by carefully selecting the epoch's number parameter, T, in the considered feature space. The test set results of LSSVM in terms of MAP instead conform appropriately to the optimized loss function (using approximate versus exact inference) in the large-margin objective in Eq. 4. This should be due to a better generalization capability of the SVM solver.

Table 2: Models on WikiQA trained on CNN embeddings.

5.2.2 Results using neural network embeddings

In these experiments, we used the CNN embeddings, described in Sec. 5.1.2, as features in all of the models. This setting allows us to examine the performance of the models in a more complex and richer feature space, at the level of the state-of-the-art performance. It can also be seen as a coarse way to "neuralize" the structural ranking approaches.

The results of all the models are shown in Tab. 2. As before, we note the relative inconsistency of the performance of the LSP models between dev. and test sets. The non-loss-augmented structured perceptron, LSP, is the weakest of the models on dev. set, while on test it is better than LSP-AP by around 1 point in terms of MAP. It only slightly outperforms now the baseline SVM, which benefited greatly from using the embeddings. Recall, however, that the baseline SVM is trained with kernels. LSP-AP*, reaching considerably higher scores than the rest of the models, including CNN, on dev., is better than LSP by no more than 0.5 of a MAP point.

LSSVM is in general more robust and consistent as with similarity features. Although SVM^{map} outperforms it on dev., LSSVM-AP is better on test in each of the three metrics. LSSVM-AP* with exact inference further improves the results of LSSVM-AP. It outperforms SVM^{map} by more than 1 point in terms of MAP.

It should be noted that the embeddings that we use were trained in a classification setting, thus, giving an additional advantage to the classification models, e.g., the relative improvement of the baseline SVM when passing to embeddings is the highest among the models. Nonetheless, LSSVM approaches closest of all to CNN, with the variant of the model with exact search showing P@1 superior to that of CNN. This suggests that the structural ranking approaches are of decent capacity, and that the optimal solution lies in regions feasible to the structural linear model, considering also the high results of LSP-AP* on dev. set. This is despite the fact that, in contrast to CNN, which trains on the whole training set, we omit examples with only negative and only positive candidates (Sec. 5.1). Exploiting the information from such examples (subject to additional enhancement of our approach, as it would currently perform a zero update on them in Line 8 of Alg. 1 due to equal max-violated and ground truth rankings) might advance the performance. Thus, good features make our models competitive with the state of the art.

5.2.3 Cross-validation experiments

In Tab. 3, we repeat the main experiments in the cross-validation setting, using the similarity features. On average, LSSVM-AP outperforms SVM^{map} in terms of MAP and MRR, as in the standard setting, however, having relatively higher variance across the folds. The LSP models sustain their superiority using the similarity features also in cross-validation, with LSP-AP scoring the best across the models and with the least variance.

5.3 Experiments on TREC13 dataset

The results of our cross-validation experiments on TREC13 are depicted in Tab. 4. LSP-AP slightly improves over the baseline models in terms of MAP. The baseline LSP this time deviates the least over the folds and reaches better P@1 among all the models. LSSVM-AP instead underperforms in this experiment, which might be for the reason of shortage of the data for validation.

It is also true that in this work, by fixing the weighting schema v, we limited our study to one particular case of a structural ranking representation. However, finding an appropriate structural feature space, e.g., to the extent enabled by tuning the positional weights v_j for the particular application, can be potentially beneficial.

Table 4: Cross-validation results on TREC13.

6 Conclusions

In this paper, we proposed new structured prediction algorithms for ranking problems. In particular, we designed (i) a new loss function that leads to the direct optimization of MAP; and (ii) two new algorithms, based on LSP and LSSVM solvers, to optimize it. The comparative results on the benchmarks for passage reranking, WikiQA and TREC13, demonstrate an improvement of LSP-AP over the standard SVM classifier, which is particularly large in the case of WikiQA. LSP without any loss augmentation can achieve good performance, as well, subject to accurate tuning of the epoch number parameter. In the same setting, LSSVM-AP is comparable to SVM^{map} baseline.

Finally, we used CNN embeddings as more expressive features in our models. We found that (i) linear models can benefit from them; (ii) LSSVM-AP is more robust than the LSP models to the use of a complex representation; and (iii) traditional max margin methods may not be on par with neural networks on tasks, such as WikiQA, however providing them with right features (embeddings) can make them approach the performance of neural models. This suggests an interesting research line on using our structural models and loss function optimizing MAP in neural models.

Acknowledgments

We would like to thank the anonymous reviewers for their competent and useful suggestions. Many thanks to Kateryna Tymoshenko and Daniele Bonadiman for kindly providing us with the CNN embeddings for our experiments.

Combining Distant and Direct Supervision for Neural Relation Extraction

Iz Beltagy **Kyle Lo** **Waleed Ammar**
Allen Institute for Artificial Intelligence, Seattle, WA, USA
{beltagy,kylel,waleeda}@allenai.org

Abstract

In relation extraction with distant supervision, noisy labels make it difficult to train quality models. Previous neural models addressed this problem using an attention mechanism that attends to sentences that are likely to express the relations. We improve such models by combining the distant supervision data with an additional directly-supervised data, which we use as supervision for the attention weights. We find that joint training on both types of supervision leads to a better model because it improves the model's ability to identify noisy sentences. In addition, we find that sigmoidal attention weights with max pooling achieves better performance over the commonly used weighted average attention in this setup. Our proposed method[1] achieves a new state-of-the-art result on the widely used FB-NYT dataset.

1 Introduction

Early work in relation extraction from text used directly supervised methods, e.g., Bunescu and Mooney (2005), which motivated the development of relatively small datasets with sentence-level annotations such as ACE 2004/2005, BioInfer and SemEval 2010 Task 8. Recognizing the difficulty of annotating text with relations, especially when the number of relation types of interest is large, others (Mintz et al., 2009; Craven and Kumlien, 1999) introduced the distant supervision approach of relation extraction, where a knowledge base (KB) and a text corpus are used to automatically generate a large dataset of labeled *bags of sentences* (a set of sentences that might express the relation) which are then used to train a relation classifier. The large number of labeled instances produced with distant supervision make it a practical alternative to manual annotations.

However, distant supervision implicitly assumes that all the KB facts are mentioned in the text (at least one of the sentences in each bag expresses the relation) and that all relevant facts are in the KB (use entities that are not related in the KB as negative examples). These two assumptions are generally not true, which introduces many noisy examples in the training set. Although many methods have been proposed to deal with such noisy training data (e.g., Hoffmann et al., 2011; Surdeanu et al., 2012; Roth et al., 2013; Fan et al., 2014; Zeng et al., 2015; Jiang et al., 2016; Liu et al., 2017), a rather obvious approach has been understudied: combine distant supervision data with additional direct supervision. Intuitively, directly supervising the model can improve its performance by helping it identify which of the input sentences for a given pair of entities are more likely to express a relation.

A straightforward way to combine distant and direct supervision is to concatenate instances from both datasets into one large dataset. We show in Section 4.2 that this approach doesn't help the model. Pershina et al. (2014) also observed similar results; instead, they train a graphical model on the distantly supervised instances while using the directly labeled instances to supervise a subcomponent of the model. We discuss prior work in more detail in Section 5.

In our paper, we demonstrate a similar approach with neural networks. Specifically, our neural model attends over sentences to distinguish between sentences that are likely to express some relation between the entities and sentences that do not. We use the additional direct supervision to supervise these attention weights. We train this model jointly on both types of supervision in a multitask learning setup. In addition, we experimentally find that sigmoidal attention weights with max pooling achieves better perfor-

The left side shows one sentence in the labeled data and how it is used to provide direct supervision for the sentence encoder. The right side shows snippets of the text corpus and the knowledge base, which are then combined to construct one training instance for the model, with a bag of three input sentences and two active relations: 'founder_of' and 'ceo_of'.

mance in this model setup than the commonly used weighted average attention.

The contributions of this paper are as follows:

- We propose an effective neural network model for improving distant supervision by combining it with a directly supervised data in the form of sentence-level annotations. The model is trained jointly on both types of supervision in a multitask learning setup, where the direct supervision data is employed as supervision for attention weights.
- We show experimentally that our model setup benefits from sigmoidal attention weights with max pooling over the commonly used softmax-based weighted averaging attention.
- Our best model achieves a new state-of-the-art result on the FB-NYT dataset, previously used by Lin et al. (2016); Vashishth et al. (2018). Specifically, combining both forms of supervision achieves a 4.4% relative AUC increase than our baseline without the additional supervision.

The following section defines the notation we use, describes the problem and provides an overview of our approach.

2 Overview

Our goal is to predict which relation types are expressed between a pair of entities (e_1, e_2), given all sentences in which both entities are mentioned in a large collection of unlabeled documents.

Following previous work on distant supervision, we use known tuples (e_1, r, e_2) in a knowledge base $\mathcal{K}$ to automatically annotate sentences where both entities are mentioned with the relation type r. In particular, we group all sentences s with one or more mentions of an entity pair (e_1, e_2) into a bag of sentences B_{e_1,e_2}, then automatically annotate this bag with the set of relation types $L^{\text{distant}} = \{r \in \mathcal{R} : (e_1, r, e_2) \in \mathcal{K}\}$, where $\mathcal{R}$ is the set of relations we are interested in. We use 'positive instances' to refer to cases where $|L| > 0$, and 'negative instances' when $|L| = 0$.

In this paper, we leverage an existing dataset of direct supervision for relations. Each direct supervision instance consists of a token sequence s containing mentions of an entity pair (e_1, e_2) and one relation type (or 'no relation'). We do not require that the entities or relation types in the direct supervision annotations align with those in the KB. Furthermore, we replace the relation label associated with each sentence with a binary indicator of 1 if the sentence expresses one of the relationships of interest and 0 otherwise.

Figure 1 illustrates how we modify neural architectures commonly used in distant supervision, e.g., Lin et al. (2016); Liu et al. (2017) to effectively incorporate direct supervision. The model consists of two components: 1) A **sentence encoder** (displayed in blue) reads a sequence of tokens and their relative distances from e_1 and e_2, and outputs a vector s representing the sentence encoding, as well as $P(e_1 \sim e_2 \mid \mathrm{s})$ representing the probability that the two entities are related given this sentence. 2) The **bag encoder** (displayed in green) reads the encoding of each sentence in the bag for the pair (e_1, e_2) and predicts $P(r = 1 \mid e_1, e_2), \forall r \in \mathcal{R}$.

We combine both types of supervision in

a multi-task learning setup by minimizing the weighted sum of the cross entropy losses for $P(e_1 \sim e_2 \mid \mathbf{s})$ and $P(r = 1 \mid e_1, e_2)$. By sharing the parameters of sentence encoders used to compute either loss, the sentence encoders become less susceptible to the noisy bag labels. The bag encoder also benefits from the direct supervision by using the supervised distribution $P(e_1 \sim e_2 \mid \mathbf{s})$ to decide the weight of each sentence in the bag.

3 Model

The model predicts a set of relation types $L^{\text{pred}} \subset \mathcal{R}$ given a pair of entities e_1, e_2 and a bag of sentences B_{e_1,e_2}. In this section, we first describe the sentence encoder part of the model (Figure 2, bottom), then describe the bag encoder (Figure 2, top), then we explain how the two types of supervision are jointly used for training the model end-to-end.

3.1 Sentence Encoder Architecture

Given a sequence of words $w_1, \ldots, w_{|s|}$ in a sentence s, a sentence encoder translates this sequence into a fixed length vector $\mathbf{s}$.

Input Representation. The input representation is illustrated graphically with a table at the bottom of Figure 2. We map word token i in the sentence w_i to a pre-trained word embedding vector $\mathbf{w}_i$.[2] Another crucial input signal is the position of entity mentions in each sentence $s \in B_{e_1,e_2}$. Following Zeng et al. (2014), we map the distance between each word in the sentence and the entity mentions[3] to a small vector of learned parameters, namely $\mathbf{d}_i^{e1}$ and $\mathbf{d}_i^{e2}$.

We find that adding a dropout layer with a small probability ($p = 0.1$) before the sentence encoder reduces overfitting and improves the results. To summarize, the input layer for a sentence s is a sequence of vectors:

$$\mathbf{v}_i = [\mathbf{w}_i; \mathbf{d}_i^{e1}; \mathbf{d}_i^{e2}], \text{ for } i \in 1, \ldots, |s|$$

Word Composition. Word composition is illustrated with the block `CNN` in the bottom part of Figure 2, which represents a convolutional neural network (CNN) with multiple filter sizes. The outputs of the max pool operations for different filter sizes are concatenated then projected into a smaller vector using one feed forward linear layer.

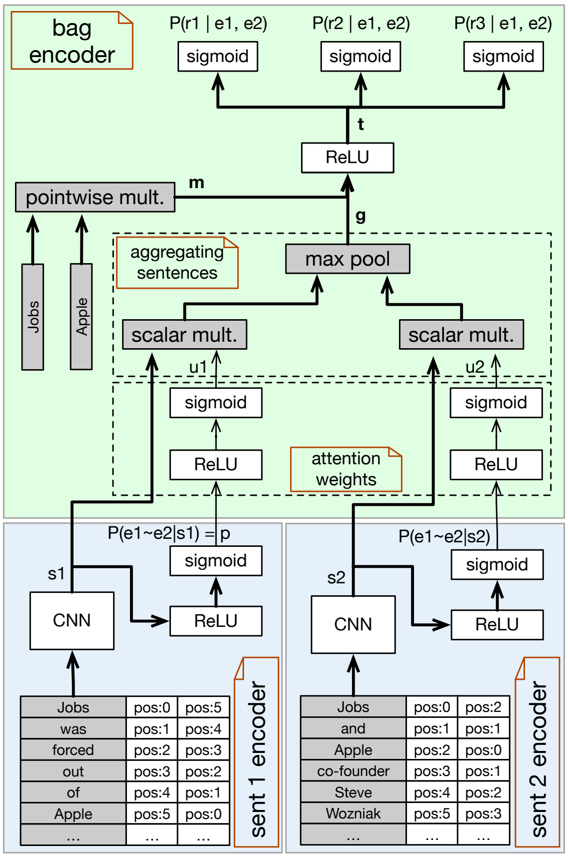

Figure 2: Blue box is the sentence encoder, it maps a sentence to a fixed length vector (`CNN` output) and the probability it expresses a relation between e_1 and e_2 (`sigmoid` output). Green box is the bag encoder, it takes encoded sentences and their weights and produces a fixed length vector (`max pool` output), concatenates it with entity embeddings (`pointwise mult.` output) then outputs a probability for each relation type r. White boxes contain parameters that the model learns while gray boxes do not have learnable parameters. Directly supervised annotations provide supervision for $P(e_1 \sim e_2 \mid \mathbf{s})$. Distantly supervised annotations provide supervision for $P(r = 1 \mid e_1, e_2)$.

Sentence encoding $\mathbf{s}$ is computed as follows:

$$\mathbf{c}_x = \text{CNN}_x(\mathbf{v}_1, \ldots, \mathbf{v}_{|s|}), \text{for } x \in \{2, 3, 4, 5\}$$

$$\mathbf{s} = \mathbf{W}_1 \left[\mathbf{c}_2; \mathbf{c}_3; \mathbf{c}_4; \mathbf{c}_5\right] + \mathbf{b}_1,$$

where CNN_x is a standard convolutional neural network with filter size x, $\mathbf{W}_1$ and $\mathbf{b}_1$ are model parameters and $\mathbf{s}$ is the sentence encoding.

We feed the sentence encoding s into a ReLU layer followed by a sigmoid layer with output size 1, representing $P(e_1 \sim e_2 \mid \mathbf{s})$, as illustrated in Figure 2 (bottom):

$$P(e_1 \sim e_2 \mid \mathbf{s}) = \qquad (1)$$
$$p = \sigma(\mathbf{W}_3 \text{ReLU}(\mathbf{W}_2 \mathbf{s} + \mathbf{b}_2) + \mathbf{b}_3),$$

---

[2] Following Lin et al. (2016), we do not update the word embeddings while training the model.

[3] If an entity is mentioned more than once in the sentence, we use the distance from the word to the closest entity mention. Distances greater than 30 are mapped to the embedding for distance = 30.

where σ is the sigmoid function and $\mathbf{W}_2, \mathbf{b}_2, \mathbf{W}_3, \mathbf{b}_3$ are model parameters.

3.2 Bag Encoder Architecture

Given a bag B_{e_1,e_2} of $n \geq 1$ sentences, we compute their encodings $\mathbf{s}_1, \ldots, \mathbf{s}_n$ as described earlier and feed them into the bag encoder, which combines the information in all of the sentence encodings and predicts the probability $P(r = 1 \mid e_1, e_2), \forall r \in \mathcal{R}$. The bag encoder also incorporates the signal $p = P(e_1 \sim e_2 \mid \mathbf{s})$ from Equation 1 as an estimate of the degree to which sentence s expresses "some" relation between e_1 and e_2.

Attention. To aggregate the sentence encodings $\mathbf{s}_1, \ldots, \mathbf{s}_n$ into a fixed length vector that captures the important features in the bag, we use attention. Attention has two steps: (1) computing weights for the sentences and (2) aggregating the weighted sentences. Weights can be uniform, or computed using a sigmoid or softmax. Weighted sentences can be aggregated using average pooling or max pooling. Prior work (Jiang et al., 2016; Lin et al., 2016; Ji and Smith, 2017) have explored some of these combinations but not all of them. In the ablation experiments, we try all combinations and we find that the (sigmoid, max pooling) attention gives the best result. We discuss the intuition behind this in Section 4.2. For the rest of this section, we will explain the architecture of our network assuming a (sigmoid, max pooling) attention.

Given the encoding $\mathbf{s}_j$ and an unnormalized weight u_j for each sentence $s_j \in B_{e_1,e_2}$, the bag encoding $\mathbf{g}$ is a vector with the same dimensionality as $\mathbf{s}_j$. With (sigmoid, max pooling) attention, each sentence vector is multiplied by the corresponding weight, then we do a "dimension-wise" max pooling (taking the maximum of each dimension across all sentences, not the other way around). The k-th element of the bag encoding $\mathbf{g}$ is computed as:

$$\mathbf{g}_j[k] = \max_{j \in 1,\ldots,n}\{\mathbf{s}_j[k] \times \sigma(u_j)\}.$$

As shown in Figure 2, we do not directly use the p from Equation 1 as attention weights. Instead, we found it useful to feed it into more non-linearities. The unnormalized attention weight for s_j is computed as:

$$u_j = \mathbf{W}_7 \, \mathrm{ReLU}(\mathbf{W}_6 \, p + \mathbf{b}_6) + \mathbf{b}_7.$$

Entity Embeddings. Following Ji et al. (2017), we use entity embeddings to improve our model of relations in the distant supervision setting, although our formulation is closer to that of Yang et al. (2015) who used point-wise multiplication of entity embeddings: $\mathbf{m} = \mathbf{e}_1 \odot \mathbf{e}_2$, where $\odot$ is point-wise multiplication, and $\mathbf{e}_1$ and $\mathbf{e}_2$ are the embeddings of e_1 and e_2, respectively. In order to improve the coverage of entity embeddings, we use pretrained GloVe vectors (Pennington et al., 2014) (same embeddings used in the input layer). For entities with multiple words, like "Steve Jobs", the vector for the entity is the average of the GloVe vectors of its individual words. If the entity is expressed differently across sentences, we average the vectors of the different mentions. As discussed in Section 4.2, this leads to big improvement in the results, and we believe there is still big room for improvement from having better representation for entities. We feed the output $\mathbf{m}$ as additional input to the last block of our model.

Output Layer. The final step is to use the bag encoding $\mathbf{g}$ and the entity pair encoding $\mathbf{m}$ to predict a set of relations L^{pred} which is a standard multilabel classification problem. We concatenate $\mathbf{g}$ and $\mathbf{m}$ and feed them into a feedforward layer with ReLU non-linearity, followed by a sigmoid layer with an output size of $|\mathcal{R}|$:

$$\mathbf{t} = \mathrm{ReLU}(\mathbf{W}_4[\mathbf{g}; \mathbf{m}] + \mathbf{b}_4)$$
$$P(\mathbf{r} = 1 \mid e_1, e_2) = \sigma(\mathbf{W}_5\mathbf{t} + \mathbf{b}_5),$$

where $\mathbf{r}$ is a vector of Bernoulli variables each of which corresponds to one of the relations in $\mathcal{R}$. This is the final output of the model.

3.3 Model Training

To train the model on the distant supervision data, we use binary cross-entropy loss between the model predictions and the labels obtained with distant supervision, i.e.,

$$\mathrm{DistSupLoss} = \sum_{B_{e_1,e_2}} - \log P(\mathbf{r} = \mathbf{r}^{\text{distant}} \mid e_1, e_2)$$

where $\mathbf{r}^{\text{distant}}[k] = 1$ indicates that the tuple (e_1, r_k, e_2) is in the knowledge base.

In addition to the distant supervision, we want to improve the results by incorporating an additional direct supervision. A straightforward way to combine them is to create singleton bags for direct supervision labels, and add the bags to those obtained with distant supervision. However, results in Section 4.2 show that this approach does not improve the results. Instead, a better use of the direct supervision is to improve the model's ability to predict the potential usefulness of a sentence. According to our analysis of baseline models, distinguishing between positive and negative examples is the real bottleneck in the task. Therefore, we use the direct supervision data to supervise $P(e_1 \sim e_2 \mid \mathbf{s})$. This supervision serves two purposes: it improves our encoding of each sentence, and improves the weights used by the attention to decide which sentences should contribute more to the bag encoding. It also has the side benefit of not requiring the same set of relation types as that of the distant supervision data, because we only care about if there exists *some relevant relation* or not between the entities.

We minimize log loss of gold labels in the direct supervision data $\mathcal{D}$ according to the model described in Equation 1:

$$\text{DirectSupLoss} = \sum_{s, l^{\text{gold}} \in \mathcal{D}} - \log P(l = l^{\text{gold}} \mid \mathbf{s})$$

where $\mathcal{D}$ is all the direct supervision data and all distantly-supervised *negative* examples.[4]

We jointly train the model on both types of supervision. The model loss is a weighted sum of the direct supervision and distant supervision losses,

$$\text{loss} = \frac{1}{\lambda + 1}\text{DistSupLoss} + \frac{\lambda}{\lambda + 1}\text{DirectSupLoss} \tag{2}$$

where λ is a parameter that controls the contribution of each loss, tuned on a validation set.

4 Experiments

4.1 Data and Setup

This section discusses datasets, metrics, configurations and the models we are comparing with.

Distant Supervision Dataset (DistSup). The FB-NYT dataset[5] introduced in Riedel et al. (2010) was generated by aligning Freebase facts with New York Times articles. The dataset has 52 relations with the most common being "location", "nationality", "capital", "place_lived" and "neighborhood_of". They used the articles of *2005* and *2006* for training, and *2007* for testing. Recent prior work (Lin et al., 2016; Liu et al., 2017; Huang and Wang, 2017) changed the original dataset. They used all articles for training except those from *2007*, which they left for testing as in Riedel et al. (2010). We use the modified dataset which was made available by Lin et al. (2016).[6] The table below shows the dataset size.

	Train	Test
Positive bags	16,625	1,950
Negative bags	236,811	94,917
Sentences	472,963	172,448

Direct Supervision Dataset (DirectSup). Our direct supervision dataset was made available by Angeli et al. (2014) and it was collected in an active learning framework. The dataset consists of sentences annotated with entities and their relations. It has 22,766 positive examples for 41 relation types in addition to 11,049 negative examples. To use this dataset as supervision for $P(e_1 \sim e_2 \mid \mathbf{s})$, we replace the relation types of positive examples with 1s and label negative examples with 0s.

Metrics. Prior work used precision-recall (PR) curves to show results on the FB-NYT dataset. In this multilabel classification setting, the PR curve is constructed using the model predictions on all entity pairs in the test set for all relation types sorted by the confidence scores from highest to lowest. Different thresholds correspond to different points on the PR curve. We use the area under the PR curve (AUC) for early stopping and hyperparameter tuning. Following previous work on this dataset, we only keep points on the PR curve with recall below 0.4, focusing on the high-precision low-recall part of the PR curve. As a result, the largest possible value for AUC is 0.4.

Configurations. The FB-NYT dataset does not have a validation set for hyperparameter tuning and early stopping. Liu et al. (2017) use the test set for validation, Lin et al. (2016) use 3-fold cross validation, and Vashishth et al. (2018) split the training set into 80% training and 20% testing. In our experiments, we use 90% of the training set for training and keep the other 10% for validation. The main hyperparameter we tune is lambda (section 4.3).

The pre-trained word embeddings we use are 300-dimensional GloVe vectors, trained on 42B tokens. Since we do not update word embeddings while training the model, we define our vocabulary as any word which appears in the training, validation or test sets with frequency greater than two. When a word with a hyphen (e.g., 'five-star') is not

---

[4] We note that the distantly supervised negative examples may still be noisy. However, given that relations tend to be sparse, the signal to noise is high.

[5] `http://iesl.cs.umass.edu/riedel/ecml/`

[6] `https://github.com/thunlp/NRE`

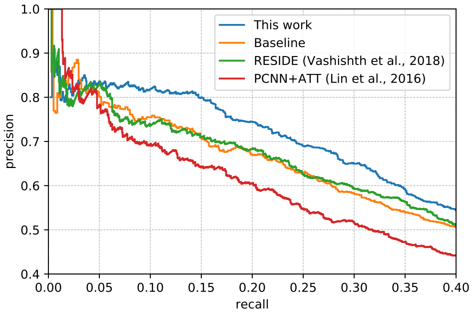
in the GloVe vocabulary, we average the embeddings of its subcomponents. Otherwise, all OOV words are assigned the same random vector (normal with mean 0 and standard deviation 0.05).

Our model is implemented using PyTorch and AllenNLP (Gardner et al., 2017) and trained on machines with P100 GPUs. Each run takes five hours on average. We train for a maximum of 50 epoch, and use early stopping with patience = 3. Each dataset is split into minibatches of size 32 and randomly shuffled before every epoch. We use the Adam optimizer with its default PyTorch parameters. We run every configuration with three random seeds and report the PR curve for the run with the best validation AUC. In the controlled experiments, we report the mean and standard deviation of the AUC across runs.

Compared Models. Our best model (Section 3) is trained on the DistSup and DirectSup datasets in our multitask setup and it uses (sigmoid, max pooling) attention. **Baseline** is the same model described in Section 3 but trained only on the DistSup dataset and uses the more common (softmax, average pooling) attention. This baseline is our implementation of the **PCNN+ATT** model (Lin et al., 2016) with two main differences; they use piecewise convolutional neural networks (PCNNs Pennington et al., 2014) instead of CNNs, and we add entity embeddings before the output layer.[7] We also compare our results to the state of the art model **RESIDE** (Vashishth et al., 2018), which uses graph convolution over dependency parse trees, OpenIE extractions and entity type constraints.

4.2 Main Results

Figure 3 summarizes the main results of our experiments. First, we note that "our baseline" outperforms PCNN+ATT (Lin et al., 2016) despite using the same training data (DistSup) and the same form of attention (softmax, average pooling), which confirms that we are building on a strong baseline. The improved results in our baseline are due to using CNNs instead of PCNNs, and using entity embeddings.



Model	AUC
PCNN+ATT (Lin et al., 2016)	0.247
RESIDE (Vashishth et al., 2018)	0.271
Our baseline	$0.272_{\pm 0.005}$
This work	$\mathbf{0.283}_{\pm 0.007}$

Figure 3: Precision-recall curves and their AUC comparing our model with the baseline and existing models. Baseline is trained on DistSup and uses (softmax, average pooling) attention. Our best model is trained using multitask learning on DistSup and DirectSup and uses (sigmoid, max pooling) attention. Results of Lin et al. (2016) and Vashishth et al. (2018) are copied from their papers.

pooling type	supervision signal	attention weight computation		
		uniform	softmax	sigmoid
average pooling	DistSup	$0.244_{\pm 0.008}$	$0.272_{\pm 0.005}$	$0.258_{\pm 0.020}$
	DistSup + DirectSup	$0.224_{\pm 0.009}$	$0.272_{\pm 0.009}$	$0.256_{\pm 0.009}$
	MultiTask (our model)	$0.220_{\pm 0.012}$	$0.262_{\pm 0.014}$	$0.258_{\pm 0.015}$
max pooling	DistSup	$0.277_{\pm 0.009}$	$0.278_{\pm 0.001}$	$0.274_{\pm 0.004}$
	DistSup + DirectSup	$0.269_{\pm 0.003}$	$0.269_{\pm 0.005}$	$0.277_{\pm 0.012}$
	MultiTask (our model)	$0.266_{\pm 0.007}$	$0.280_{\pm 0.004}$	$0.283_{\pm 0.007}$

Table 1: Controlled experiments for a) how the supervised data is used in the model, b) which function is used to compute attention weights, c) how sentence embeddings are aggregated

A new state-of-the-art. Adding DirectSup in our multitask learning setup and using (sigmoid, max pooling) attention gives us the best result, outperforming our baseline that doesn't use either by 4.4% relative AUC increase, and achieves a new state-of-the-art result outperforming (Vashishth et al., 2018).

We note that the improved results reported here conflate additional supervision and model improvements. Next, we report the results of controlled experiments to tease apart the contributions of different components.

Table 1 summarizes results of our controlled experiments showing the impact of how the training data is used, and the impact of different configurations of the attention (computing weights and aggregating vectors). The model can be trained

---

[7] Contrary to the results in Pennington et al. (2014), we found CNNs to give better results than PCNNs in our experiments. Lin et al. (2016) also compute unnormalized attention weights as $o_j = \mathbf{s}_j \times \mathbf{A} \times \mathbf{q}$ where $\mathbf{s}_j$ is the sentence encoding, $\mathbf{A}$ is a diagonal matrix and $\mathbf{q}$ is the query vector. In our experiments, we found that implementing it as a feedforward layer with output size $= 1$ works better. All our results use the feedforward implementation.

on DistSup only, DistSup + DirectSup together as one dataset with DirectSup expressed as singleton bags, or DistSup + DirectSup in our multitask setup. Attention weights can be uniform, or computed using softmax or sigmoid.[8] Sentence vectors are aggregated by weighting them then averaging (average pooling) or weighting them then taking the max of each dimension (max pooling). (Uniform weights, average pooling) and (softmax, average pooling) were used by Lin et al. (2016), (sigmoid, average pooling) was proposed by Ji and Smith (2017) but for a different task, and (uniform weights, max pooling) is used by Jiang et al. (2016). To the best of our knowledge, (softmax, max pooling) and (sigmoid, max pooling) have not been explored before.

Pooling type. Results in Table 1 show that aggregating sentence vectors using max pooling generally works better than average pooling. This is because max pooling might be better at picking out useful features (dimensions) from each sentence.

Supervision signal. The second dimension of comparison is the use of the supervision signal used to train the model. The table shows that training on DistSup + DirectSup, where the DirectSup dataset is simply used as additional bags, can hurt the performance. We hypothesize that this is because the DirectSup data change the distribution of relation types in the training set from the test set. However, using DirectSup as supervision for the attention weights in our multitask learning setup leads to considerable improvements (1% and 3% relative AUC increase using softmax and sigmoid respectively) because it leads to better attention weights and improves the model's ability to filter noisy sentences.

Attention weight computation. Finally, comparing uniform weights, softmax and sigmoid. We found the result to depend on the available level of supervision. With DistSup only, the results of all three are comparable with softmax being slightly better. However, when we have good attention weights (as provided by the multitask learning), softmax and sigmoid work better than uniform weights where sigmoid gives the best result with 6% relative AUC increase. Sigmoid works better than softmax, because softmax assumes that exactly one sentence is correct by forcing the probabilities to sum to 1. This assumption is not correct for this task, because zero or many sentences could potentially be relevant. On the other hand, sigmoidal attention weights does not make this assumption, which gives rise to more informative attention weights in cases where all sentences are not useful, or when multiple ones are. This makes the sigmoidal attention weights a better modeling for the problem (assuming reliable attention weights).

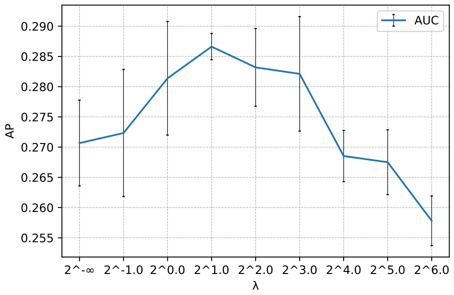


Figure 4: AUC at different λ. X-axis is in log-scale.

4.3 Selecting Lambda.

Although we did not spend much time tuning hyperparameters, we made sure to carefully tune λ (Equation 2) which balances the contribution of the two losses of the multitask learning. Early experiments showed that DirectSupLoss is typically smaller than DistSupLoss, so we experimented with $\lambda \in \{0, 0.5, 1, 2, 4, 8, 16, 32, 64\}$. Figure 4 shows AUC results for different values of λ, where each point is the average of three runs. It is clear that picking the right value for λ has a big impact on the final result.

4.4 Qualitative Analysis.

An example of a positive bag is shown in Table 2. Our best model (Multitask, sigmoid, max pooling) assigns the most weight to the first sentence while the baseline (DistSup, softmax, average pooling) assigns the most weight to the last sentence (which is less informative for the relation between the two entities). Also, the baseline does not use the other two sentences because their weights are dominated by the last one.

5 Related Work

Distant Supervision. The term 'distant supervision' was coined by Mintz et al. (2009) who used relation instances in a KB to identify sentences in

---

[8] We also tried normalizing sigmoid weights as suggested in (Rei and Søgaard, 2018), but this did not work better than regular sigmoid or softmax.

Baseline	This work	Sentences
0.00	0.029	You can line up along the route to cheer for the 32,000 riders, whose 42-mile trip will start in battery park and end with a festival at **Fort Wadsworth** on **Staten Island** .
0.00	0.026	Gateway is a home to the nation's oldest continuing operating lighthouse, Sandy Hook lighthouse, built in 1764; Floyd Bennett field in Brooklyn, which was the city's first municipal airfield; **Fort Wadsworth** on **Staten Island**, which predates the revolutionary war.
0.99	0.027	home energy smart fair, gateway national recreation area, **Fort Wadsworth** visitor center, bay street and school road, **Staten Island**.

Table 2: Weights assigned to sentences by our baseline and our best model. The baseline incorrectly predicts "no_relation", while our best model correctly predicts "neighbourhood_of" for this bag.

a text corpus where two related entities are mentioned, then developed a classifier to predict the relation. Researchers have since extended this approach further (e.g., Takamatsu et al., 2012; Min et al., 2013; Riedel et al., 2013; Koch et al., 2014).

A key source of noise in distant supervision is that sentences may mention two related entities without expressing the relation between them. Hoffmann et al. (2011) used multi-instance learning to address this problem by developing a graphical model for each entity pair which includes a latent variable for each sentence to explicitly indicate the relation expressed by that sentence, if any. Our model can be viewed as an extension of Hoffmann et al. (2011) where the sentence-bound latent variables can also be directly supervised in some of the training examples.

Neural Models for Distant Supervision. More recently, neural models have been effectively used to model textual relations (e.g., Hashimoto et al., 2013; Zeng et al., 2014; Nguyen and Grishman, 2015). Focusing on distantly supervised models, Zeng et al. (2015) proposed a neural implementation of multi-instance learning to leverage multiple sentences which mention an entity pair in distantly supervised relation extraction. However, their model picks only one sentence to represent an entity pair, which wastes the information in the neglected sentences. Jiang et al. (2016) addresses this limitation by max pooling the vector encodings of all input sentences for a given entity pair. Lin et al. (2016) independently proposed to use attention to address the same limitation, and Du et al. (2018) improved by using multilevel self-attention. To account for the noise in distant supervision labels, Liu et al. (2017); Luo et al. (2017); Wang et al. (2018) suggested different ways of using "soft labels" that do not necessarily agree with the distant supervision labels. Ye et al. (2017) proposed a method for leveraging dependencies between different relations in a pairwise ranking framework, while Han et al. (2018) arranged the relation types in a hierarchy aiming for better generalization for relations that do not have enough training data. To improve using additional resources, Vashishth et al. (2018) used graph convolution over dependency parse, OpenIE extractions and entity type constraints, and Liu et al. (2018) used parse trees to prune irrelevant information from the sentences.

Combining Direct and Distant Supervision. Despite the substantial amount of work on both directly and distantly supervised relation extraction, the question of how to combine both signals has not received the same attention. Pershina et al. (2014) trained MIML-RE from (Surdeanu et al., 2012) on both types of supervision by locking the latent variables on the sentences to the supervised labels. Angeli et al. (2014) and Liu et al. (2016) presented active learning models that select sentences to annotate and incorporate in the same manner. Pershina et al. (2014) and Liu et al. (2016) also tried simple baseline of including the labeled sentences as singleton bags. Pershina et al. (2014) did not find this beneficial, which agrees with our results in Section 4.2, while Liu et al. (2016) found the addition of singleton bags to work well.

Our work is addressing the same problem, but combining both signals in a state-of-the-art neural network model, and we do not require the two datasets to have the same set of relation types.

6 Conclusion

We improve neural network models for relation extraction by combining distant and direct supervision data. Our network uses attention to attend to relevant sentences, and we use the direct supervision to improve attention weights, thus improving the model's ability to find sentences that are likely to express a relation. We also found that sigmoidal attention weights with max pooling achieves better performance than the commonly used weighted average attention. Our model combining both forms of supervision achieves a new state-of-the-art result on the FB-NYT dataset with a 4.4% relative AUC increase than our baseline without the additional supervision.

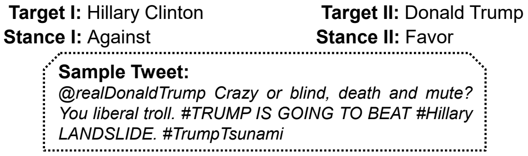
Abstract

Stance detection in twitter aims at mining user stances expressed in a tweet towards a single or multiple target entities. To tackle this problem, most of the prior studies have been explored the traditional deep learning models, e.g., LSTM and GRU. However, in compared to these traditional approaches, recently proposed densely connected Bi-LSTM and nested LSTMs architectures effectively address the vanishing-gradient and overfitting problems as well as dealing with long-term dependencies. In this paper, we propose a neural ensemble model that adopts the strengths of these two LSTM variants to learn better long-term dependencies, where each module coupled with an attention mechanism that amplifies the contribution of important elements in the final representation. We also employ a multi-kernel convolution on top of them to extract the higher-level tweet representations. Results of extensive experiments on single and multi-target stance detection datasets show that our proposed method achieves substantial improvement over the current state-of-the-art deep learning based methods.

1 Introduction

Tweet stance detection is the task of automatically determining the stance of a tweet whether the tweet is in favor of, against, or none towards a target (Mohammad et al., 2017). We can consider it as a sub-domain of sentiment analysis. However, the goal of sentiment analysis is to classify the polarity of a tweet sentiment based on its contents, whereas identification of stance is dependent on the specific target. For example, Figure 1 depicts the stance of a tweet towards different targets.



Target I: Hillary Clinton
Stance I: Against

Target II: Donald Trump
Stance II: Favor

Sample Tweet:
@realDonaldTrump Crazy or blind, death and mute? You liberal troll. #TRUMP IS GOING TO BEAT #Hillary LANDSLIDE. #TrumpTsunami

Figure 1: Example of target-specific stance detection.

Stance detection in twitter poses unique challenges to the research community since tweets are short and informal user-generated text, which usually tend not to follow the grammatical rules. Moreover, tweets contain plenty of idiosyncratic abbreviations as well as other twitter specific syntaxes such as #hashtags and emoticons. To address the challenges of stance detection in twitter, Mohammad et al. (2016) presented a tweet stance detection task that focused on a single target in SemEval-2016. Top performing systems in this task proposed several deep learning based approaches by using CNN (Wei et al., 2016), RNN (Zarrella and Marsh, 2016), and so on.

Later, (Du et al., 2017) utilized the target-augmented embeddings in an attention based neural network, whereas (Zhou et al., 2017) proposed an attention mechanism at the semantic level in the bidirectional GRU-CNN structure to perform target-specific stance detection on tweets. More recently, (Dey et al., 2018) proposed a two-phase LSTM based model with attention and (Wei et al., 2018b) proposed an end-to-end neural memory model via target and tweet interactions.

By considering the dependency of related targets, Sobhani et al. (2017) introduced a multi-target stance detection (MTSD) task and proposed an attentive encoder-decoder network to capture the dependencies among stance labels regarding multiple targets. Later, (Wei et al., 2018a) proposed a dynamic memory-augmented network that utilized a shared external memory to capture and store multi-targets stance indicative clues.

However, most of the related work of tweet stance detection explored the traditional deep learning models in their methods. In this paper,

Proceedings of NAACL-HLT 2019, pages 1868–1873
Minneapolis, Minnesota, June 2 - June 7, 2019.

we propose a neural ensemble method that combines the attention based state-of-the-art densely connected Bi-LSTM and nested LSTMs models with the multi-kernel convolution in a unified architecture. Experimental results on both the single and multi-target benchmark stance detection datasets demonstrate the efficacy of our method over the state-of-the-art deep learning based methods discussed above.

The rest of the paper is structured as follows: In **Section 2**, we introduce our proposed stance detection framework. **Section 3** includes experiments and evaluations as well as the comparisons with the state-of-the-arts to show the effectiveness of our proposed method. Some concluded remarks and future directions of our work are described in **Section 4**.

2 Proposed Stance Detection Framework

In this section, we describe the details of our proposed neural ensemble model (PNEM) for twitter stance detection. Figure 2 depicts an overview of our proposed framework.

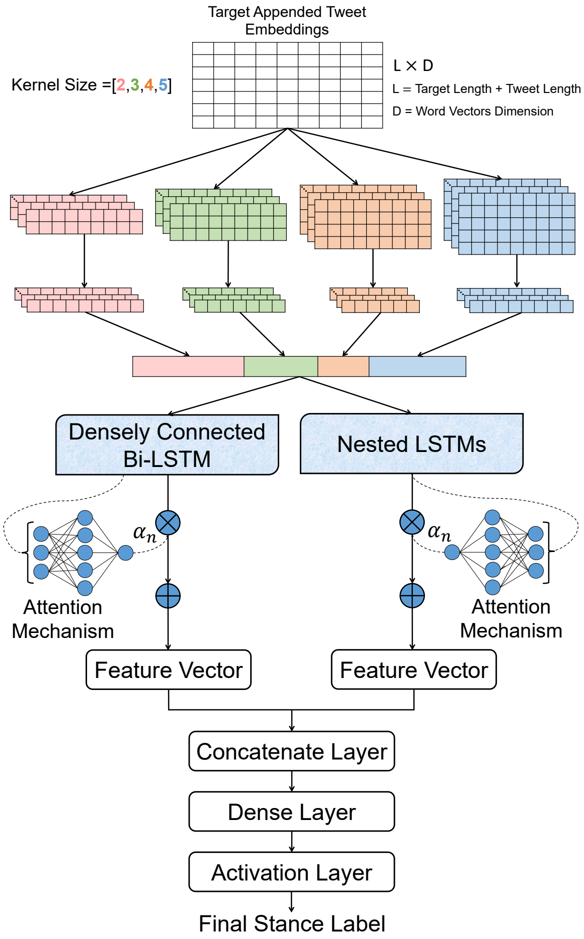


Figure 2: Proposed stance detection framework.

At first, we utilize the multi-kernel convolution filters to extract higher-level feature sequences from the target appended tweet embeddings. These feature sequences are fed into the attention based densely connected Bi-LSTM and nested LSTMs to learn long-term dependencies. Final representations of these modules are concatenated and pass to the stance prediction module to determine the stance label. Next, we describe each component elaborately.

Embedding Layer: Prior works already established the significance of target information for stance detection. To integrate the target information, we generate a unified word vector matrix by concatenating the vector representations of the target and tweet. The dimensionality of the matrix will be $L \times D$, where length L is the sum of the target length and tweet length, and D denotes the word-vector dimension. We utilize a pre-trained word embedding model for obtaining the vector representation of words.

Multi-Kernel Convolution: In our multi-kernel convolution, we adopt the idea proposed by (Kim, 2014) to extract the higher-level features. The input of this module is the target appended tweet matrix generated in the embedding layer. We then perform the convolution on it by using a filter. We apply multiple convolutions based on four different kernel sizes, i.e., the size of the convolution filters: 2, 3, 4, and 5. After performing convolutions, each filter generates the corresponding feature maps and a max pooling function is then applied to generate a univariate feature vector. Finally, the feature vectors generated from each kernel are concatenated to form a single high-level feature vector.

Densely Connected Bi-LSTM: With the emerging trend of deep learning, LSTM based models are the most popular for sequential tasks. Recently, the densely connected structure of LSTM models gets attention among the researchers (Li et al., 2018; Wu et al., 2017) that enable the effective connection from lower to upper layers features without any loss of information on lower-layer features thus alleviate the vanishing-gradient and overfitting problems effectively.

In our proposed framework, we utilize the densely connected Bi-LSTM (Ding et al., 2018) (DC-Bi-LSTM) model. A DC-Bi-LSTM model consists of multiple Bi-LSTM layers, where representation of each layer is estimated by concatenating its hidden states and all the preceding layers' hidden states. Hence, for the first Bi-LSTM layer, the input is a higher-level features sequences generated from multi-kernel convolution (MKC) and the output is $\{h^1 = h_1^1, h_2^1, ..., h_s^1\}$. For the second Bi-LSTM layer, the input is the concatenation of higher-level feature sequences from MKC and the output from first Bi-LSTM layer to generate the corresponding output. Rest of the layers are processed accordingly. We can define the above process as follows:

$$
\begin{aligned}
&h_t^l = [\overrightarrow{h_t^l}; \overleftarrow{h_t^l}], h_t^0 = \text{MKC feature sequence},\\
&\overrightarrow{h_t^l} = \text{lstm}(\overrightarrow{h_{t-1}^l}, M_t^{l-1}),\\
&\overleftarrow{h_t^l} = \text{lstm}(\overleftarrow{h_{t+1}^l}, M_t^{l-1}),\\
&M_t^{l-1} = [h_t^0; h_t^1; ...; h_t^{l-1}].
\end{aligned}
$$

Therefore, from a L layer DC-Bi-LSTM model, the output is $\{h^L = h_1^L, h_2^L, ..., h_s^L\}$.

Nested LSTMs: The nested LSTMs (NLSTMs) architecture (Moniz and Krueger, 2017) creates a temporal hierarchy of memories that achieved significant improvement over the single-layer or stacked LSTM architectures to learn longer-term dependencies.

In NLSTMs, the LSTM memory cells have access to their inner memory, where they can selectively read and write relevant long-term information. While the value of the outer memory cell in the LSTM is estimated as $c_t^{outer} = f_t \odot c_{t-1} + i_t \odot g_t$, memory cells of the NLSTMs use the concatenation $(f_t \odot c_{t-1}, i_t \odot g_t)$ as input to an inner LSTM (or NLSTM) memory cell, and set $c_t^{outer} = h_t^{inner}$. Therefore, in compared to the LSTM and stacked LSTM, the inner memories of NLSTMs operate on longer time-scales and effectively capture the context information from the input texts.

Feed-Forward Attention: Recently, the attention mechanism has been introduced in the neural network models for effectively modeling the long-term dependencies by enabling the model to learn what to attend based on the input text (Vaswani et al., 2017). In order to amplify the contribution of important elements in the final representation of both the DC-Bi-LSTM and NLSTMs module, we employ a feed-forward attention mechanism (Raffel and Ellis, 2015) to aggregate all the hidden states according to their relative importance weight.

Stance Prediction and Model Training: We concatenate the final tweet representation from the attention based DC-Bi-LSTM and NLSTMs module and pass it to a fully connected softmax layer for stance detection. We consider cross-entropy as the loss function and train the model by minimizing the error, which is defined as:

$$
E(x^{(i)}, y^{(i)}) = \sum_{j=1}^{k} 1\{y^{(i)} = j\} \log(y_j^{\sim(i)})
$$

where $x^{(i)}$ is the training sample with its true label $y^{(i)}$. $y_j^{\sim(i)}$ is the estimated probability in $[0, 1]$ for each label j. $1\{condition\}$ is an indicator which is 1 if true and 0 otherwise. We use the stochastic gradient descent (SGD) to learn the model parameter and adopt the Adam optimizer (Kingma and Ba, 2014).

3 Experiments and Evaluations

3.1 Model Configuration

In the following, we describe the set of parameters that we have used in our proposed neural ensemble model (PNEM) during experiments. We used the 300-dimensional fastText embedding model pre-trained on Wikipedia with skip-gram (Bojanowski et al., 2017) to initialize the word embeddings in the embedding layer. For the multi-kernel convolution, we employed 4 kernel sizes (2,3,4,5), and the number of filters was set to 600. In our model, DC-Bi-LSTM module contains 5 layers and NLSTMs module contains 2 layers. We trained all models for max 45 epochs with a batch size of 32 and an initial learning rate 0.001 by Adam optimizer. $L2$ regularization with a factor of 0.01 was applied to the weights in the softmax layer. In this paper, we reported the results based on these settings. Unless otherwise stated, default settings were used for the other parameters.

To preprocess the data, we removed the stop words based on NLTK's standard stoplist, special characters removal, and performed hashtag segmentation according to (Baziotis et al., 2017).

3.2 Single Target Stance Detection

Dataset and Setup: To validate the effectiveness of our proposed method for the single target stance detection, we made use of a widely popular benchmark twitter dataset used in the SemEval-2016 Task 6-A (Mohammad et al., 2016). The training set consists of 2914 tweets and the test set consists of 1249 tweets relevant to 5 targets. Each tweet was annotated as *Favor*, *Against* or *None* towards the specific target.

Following the SemEval-2016 Task 6-A benchmark, we employed the macro-average of F1-score for the *Favor* and *Against* stance classes as the evaluation measure. To estimate it, we used the evaluation script provided by the organizer.

Results and Analysis: We divided the whole dataset across targets and trained the model accordingly. We used 5% of the training samples as the validation set. The summarized experimental results of our proposed neural ensemble model (PNEM) on single target stance detection are presented in Table 1.

At first, we report the results based on the baseline, which is the combination of CNN and LSTM (Zhou et al., 2015) and obtained competitive performances on several text classification tasks. Next, we report the results of our proposed PNEM model. It showed that our PNEM method outperformed the baseline by a large margin. In order to estimate the effect of each component of our model, we performed the component ablation study on our proposed model. In this regard, we removed one component each time and repeated the experiment. From the results, it can be observed that when removing target embedding, multi-kernel convolution (MKC), attention mechanism (ATT), NLSTMs with corresponding attention (NLSTMs+ATT), and DC-Bi-LSTM with corresponding attention (DC-Bi-LSTM+ATT), the results decreased by 0.99%, 4.98%, 1.68%, 4.14%, and 1.11%, respectively. Thus deduced the importance of each of the component in our model.

Method	F_{favor}	$F_{against}$	F_{avg}
CNN+LSTM	59.36	74.93	67.15
PNEM	**66.56**	**77.66**	**72.11**
– Target Embedding	64.87	77.36	71.12
– MKC	60.49	73.78	67.13
– ATT	63.94	76.92	70.43
– (NLSTMs+ATT)	61.51	74.43	67.97
– (DC-Bi-LSTM+ATT)	64.47	77.52	71.00

Table 1: Comparative performance with different experimental settings for single target stance detection. The best results are highlighted in boldface.

Moreover, the comparative performance of our proposed model, PNEM with the state-of-the-art methods are presented in Table 2. It showed that our model gained 3.13% and 4.29% improvement while compared with the SemEval-2016 baseline (SVM-ngrams) and the best performing system MITRE, respectively. Furthermore, in comparison with the related deep learning based methods, PNEM achieved at least 1.07% and at best 3.44% improvement. Overall, our proposed PNEM method greatly surpassed the previous works. The results show that attentive neural ensemble model could benefit stance detection.

3.3 Multi-Target Stance Detection

Dataset and Setup: In order to assess our method for the multi-target stance detection, we made use of a benchmark twitter dataset (Sobhani et al., 2017), where each tweet is annotated with two stance labels towards two targets of a pair. The tweets in this dataset are related to the 2016 US election. Overall, the dataset contains 4455 tweets for the three target-pairs including Hillary Clinton - Bernie Sanders, Hillary Clinton - Donald Trump, and Ted Cruz - Donald Trump. The train, development, and test set contains 3119, 446, and 890 tweets, respectively.

As the evaluation measure, we used a similar kind of approach reported in the dataset paper (Sobhani et al., 2017). Following this, the F_{avg} of each target is estimated according to the SemEval-2016 Task-A benchmark (Mohammad et al., 2016). Then, the F_{avg} of the two targets of a target-pair is averaged to estimate the average score of a target-pair. Finally, the average scores of all the target-pairs are averaged to estimate the overall score.

Results and Analysis: We divided the whole dataset based on each target-pairs. The dataset is then separated into two parts for each target in the target-pair. We trained and evaluated the model for each target in the target-pair and combined the results to estimate the overall performance.

We used a similar kind of baseline (CNN+LSTM) for comparison that we used in the single target stance detection as well as compared with the state-of-the-art deep learning based methods. The comparative results of our proposed PNEM model on multi-target stance dataset are presented in Table 3. It showed that our method surpassed the baseline by a large margin and gained 3.91% and 1.99% improvement over the state-of-the-art methods Seq2Seq and DMAN, respectively.

Method	Overall			Target				
	F_{favor}	$F_{against}$	F_{avg}	Atheism	Climate Change	Feminist Movement	Hillary Clinton	Legal. of Abortion
PNEM	**66.56**	**77.66**	**72.11**	67.73	44.27	**66.76**	60.28	64.23
SemEval-2016 Baseline and Related Deep Learning based Methods								
SVM-ngrams	62.98	74.98	68.98	65.19	42.35	57.46	58.63	66.42
MITRE	59.32	76.33	67.82	61.47	41.63	62.09	57.67	57.28

TAN	-	-	68.79	59.33	53.59	55.77	65.38	63.72

Table 2: (Single target) Comparative performance of our model against the SemEval-2016 official baseline (SVM-ngrams) (Mohammad et al., 2016) and related deep learning based methods including MITRE (SemEval-2016 best performing system) (Zarrella and Marsh, 2016), n-grams+embeddings (Mohammad et al., 2017), TGMN-CR (Wei et al., 2018b), T-PAN (Dey et al., 2018), AS-biGRU-CNN (Zhou et al., 2017), and TAN (Du et al., 2017). The best results are highlighted in boldface.

Method	Overall	Target-Pair		
		Clinton Sanders	Clinton Trump	Cruz Trump
CNN+LSTM	46.03	43.02	47.35	47.71
Seq2Seq	54.81	54.72	56.60	53.12
DMAN	56.73	56.25	**60.30**	53.64
PNEM	**58.72**	**57.74**	60.05	**58.36**

Table 3: (Multi-target) Comparative performance of our model against the baseline (CNN+LSTM) and state-of-the-art deep learning based methods including Seq2Seq (Sobhani et al., 2017) and DMAN (Wei et al., 2018a). The best results are highlighted in boldface.

4 Conclusion

In this paper, we proposed an attention based neural ensemble model for the target-specific tweet stance detection. The main contribution of our unified model is to learn the contextual information effectively which in turns improved the stance detection performance and outperformed the state-of-the-art deep learning based methods for both the single and multi-target stance detection benchmark datasets.

In the future, we have a plan to leverage external knowledge and generalize our model for target-independent stance detection in the same domain.

Abstract

We propose a new automatic evaluation metric for machine translation. Our proposed metric is obtained by adjusting the Earth Mover's Distance (EMD) to the evaluation task. The EMD measure is used to obtain the distance between two probability distributions consisting of some signatures having a feature and a weight. We use word embeddings, sentence-level $tf \cdot idf$, and cosine similarity between two word embeddings, respectively, as the features, weight, and the distance between two features. Results show that our proposed metric can evaluate machine translation based on word meaning. Moreover, for distance, cosine similarity and word position information are used to address word-order differences. We designate this metric as **W**ord **E**mbedding-based automatic MT evaluation using **W**ord **P**osition **I**nformation (WE_WPI). A meta-evaluation using WMT16 metrics shared task set indicates that our WE_WPI achieves the highest correlation with human judgment among several representative metrics.

1 Introduction

Recent advances in neural machine translation (NMT) (Sutskever et al., 2014; Luong et al., 2015) are remarkable. Results based on human evaluation have demonstrated that NMT outperforms statistical machine translations significantly (Chiang, 2005; Tufiş and Ceauşu, 2009). The NMT achieved especially high performance in terms of fluency. However, it tends to generate more omission errors than statistical machine translations generate. Unfortunately, it is difficult for automatic evaluation metrics to evaluate outputs with omission errors because those errors are not included as non-match words between the translation and reference. For such cases, the word embedding-based automatic MT evaluation metric, which is based on word position information, is effective.

Various automatic evaluation metrics have been proposed for machine translation, but none is sufficient for NMT. Actually, BLEU (Papineni et al., 2002) is the representative metric based on n-gram matching. Unfortunately, because it is a surface-level metric, it is difficult to address word meaning during evaluation for MT outputs. The word-embedding-based distance measure for document (Kusner et al., 2016) and the word-alignment-based automatic evaluation metric using word embedding (Matsuo et al., 2017) are effective to address word meanings. Nevertheless, they can only ineffectively accommodate word order differences between the translation and reference.

Given those circumstances, a new metric with word embedding-based automatic MT evaluation metric using word position information is proposed in which the evaluation score is obtained by adjusting the Earth Mover's Distance (EMD) (Rubner et al., 1998, 2000) to the evaluation task. The EMD measure represents the distance between two probability distributions. Moreover, the EMD distance is obtained based on a signature consisting of the feature and the weight, and the distance between two features. The feature, weight, and distance must therefore be defined to adjust EMD to the evaluation task.

Proceedings of NAACL-HLT 2019, pages 1874–1883
Minneapolis, Minnesota, June 2 - June 7, 2019.

In our proposed metric, the word embeddings and the sentence-level $tf \cdot idf$ respectively denote the feature and the weight. Consequently, our proposed metric can produce an evaluation based on the word meaning. Moreover, our proposed metric uses word position information in the distance between two word embeddings. The distance is obtained using cosine similarity and the difference of word position between the translation and reference. Results demonstrate that our proposed metric can evaluate translations also considering word order differences. We designate this new metric as **W**ord **E**mbedding-based automatic MT evaluation using **W**ord **P**osition **I**nformation (WE_WPI).

The experimentally obtained results based on the WMT16 metrics shared task (Bojar et al., 2016) demonstrated that our WE_WPI achieves the highest correlation with human judgment among several metrics: BLEU, METEOR (Banerjee and Lavie, 2005), IMPACT (Echizen-ya and Araki, 2007), and RIBES (Isozaki et al., 2010). Moreover, the correlation of WE_WPI is better than that of WE_WPI without word position information (WE). Results therefore confirmed the effectiveness of WE_WPI using word position information.

2 Related Work

Kusner et al. (2016) proposed the Word Mover's Distance (WMD) as a distance measure using word embedding and word alignment. This measure obtains the distance between two documents adjusting EMD to a document. However, it cannot accommodate differences of word order between the translation and reference. Matsuo et al. (2017) also proposed a word-alignment-based automatic evaluation metric using word embeddings for segment-level evaluation. As described in that paper, Maximum Alignment Similarity (MAS) was found to have higher correlation with human evaluation than BLEU for European-to-English, which has similar grammar structures. For Japanese-to-English, which has different grammar structures, Average Alignment Similarity (AAS) showed better correlation with human evaluation than other metrics. However, neither MAS nor AAS uses word position information. Therefore, neither can sufficiently accommodate word order differences. Actually, WE_WPI uses not only the word alignment but also word position information.

One system, DREEM (Chen and Guo, 2015), learns distributed word representations from a neural network model and from distributed sentence representations computed with a recursive autoencoder. Moreover, it uses a penalty based on translation and reference lengths. By contrast, the WE_WPI system specifically examines the difference between the word positions of the translation and reference, not the difference of lengths between the translation and reference. Therefore, it can sufficiently accommodate word order differences. Moreover, it can evaluate the translation efficiently using word embeddings of target languages without requiring large amounts of data or learning time. Our WE_WPI requires no learning of bilingual knowledge or a relation between translation and reference. It needs only a model of word embeddings in advance to apply EMD to the automatic MT evaluation task.

In a non-trained evaluation metric, MEANT 2.0 (Lo, 2017; Bojar et al., 2017) uses a distributional word vector model to evaluate lexical semantic similarity and shallow semantic parses to evaluate structural semantic similarity between the translation and reference. It is a new version of MEANT (Lo and Wu, 2011), which is a non-ensemble and untrained metric. Moreover, MEANT 2.0 - nosrl is a subversion of MEANT 2.0 to evaluate the translation for any output language by removing the dependence on semantic parsers for semantic role labeling (SRL). In that case, phrasal similarity is calculated using n-gram lexical similarities. However, MEANT 2.0 series do not specifically examine the position of each word in the translation and reference. Results show that it is difficult to deal sufficiently with language pairs for which the grammar differs. In WE_WPI, the evaluation score is calculated using the relative difference between the positions of each word in the translation and reference. Therefore, WE_WPI can evaluate translations dealing with word order in languages pairs for which the grammar differs.

3 Word Embedding-Based Automatic Evaluation Metric with Word Position Information (WE_WPI)

3.1 The Earth Mover's Distance (EMD)

3.1.1 Definitions

As described herein, we propose WE_WPI as the automatic MT evaluation metric obtained by adjusting the **E**arth **M**over's **D**istance (EMD) to the

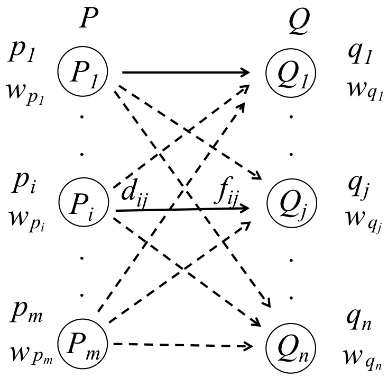

Figure 1: Outline of EMD.

automatic MT evaluation task. First, we describe EMD. Figure 1 depicts an outline of EMD.

In Figure 1, two probability distributions are presented respectively as P and Q. The P and Q consist of some P_i and Q_j, which are the respective signatures. Each signature consists of a feature (*i.e.*, p_i in P_i and q_j in Q_j) and a weight (*i.e.*, w_{p_i} in P_i and w_{q_j} in Q_j). Therefore, two probability distributions P and Q are defined respectively as $P = \{(p_1, w_{p_1})...(p_m, w_{p_m})\}$ and $Q = \{(q_1, w_{q_1})...(q_n, w_{q_n})\}$. Moreover, d_{ij} represents the distance between two features p_i and q_j.

The goal of EMD is to obtain total flow $F = [f_{ij}]$ that minimizes the overall cost from the perspective of a transportation problem. In that case, the overall cost is defined as Eq. (1).

$$WORK(P, Q, F) = \sum_{i=1}^{m} \sum_{j=1}^{n} d_{ij} f_{ij} \tag{1}$$

Moreover, four constraints are defined for f_{ij}, which is the transportation amount in the transportation problem, to find minimum F as the following Eqs. (2)–(5):

$$f_{ij} \geq 0 \quad 1 \leq i \leq m, \quad 1 \leq j \leq n \tag{2}$$

$$\sum_{j=1}^{n} f_{ij} \leq w_{p_i} \quad 1 \leq i \leq m \tag{3}$$

$$\sum_{i=1}^{m} f_{ij} \leq w_{q_j} \quad 1 \leq j \leq n \tag{4}$$

$$\sum_{i=1}^{m} \sum_{j=1}^{n} f_{ij} = min\left(\sum_{i=1}^{m} w_{p_i}, \sum_{j=1}^{n} w_{q_j}\right) \tag{5}$$

Constraint (2) shows that each amount of weight f_{ij} is transported only in the direction from signature P_i to signature Q_j to be nonnegative. In Constraint (3), the amount of weight which is supplied from P_i (*i.e.*, $\sum_{j=1}^{n} f_{ij}$) does not exceed w_{p_i}, which is the weight of P_i. Moreover, in Constraint (4), the amount of weight which Q_j receives (*i.e.*, $\sum_{i=1}^{m} f_{ij}$) does not exceed w_{q_j}, which is the weight of Q_j. Finally, the total amount of weight is equal to the weight of the lighter distribution in Constraint (5). In Eqs. (1)–(5), m shows the number of signatures in P; n shows the number of signatures in Q.

The EMD is defined as shown below.

$$EMD(P, Q) = \frac{min(WORK(P, Q, F))}{\sum_{i=1}^{m} \sum_{j=1}^{n} f_{ij}} \tag{6}$$

In Eq. (6), the $min(WORK(P, Q, F))$ is normalized by the minimum amount of work of Eq. (5).

3.1.2 Computing EMD

P_1		P_2		P_3		P_4	
p_1	w_{p_1}	p_2	w_{p_2}	p_3	w_{p_3}	p_4	w_{p_4}
(1,5)	0.6	(5,5)	0.6	(1,1)	0.6	(5,1)	0.6

Table 1: Examples of signatures of P.

Q_1		Q_2		Q_3	
q_1	w_{q_1}	q_2	w_{q_2}	q_3	w_{q_3}
(2,3)	0.8	(4,3)	0.8	(3,2)	0.8

Table 2: Examples of signatures of Q.

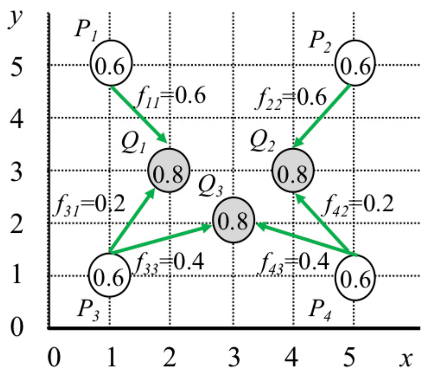

Figure 2: Example of EMD calculation.

We describe the computation of EMD using two probability distributions P and Q in two-dimensional surface. Tables 1 and 2 respectively present the examples of P and Q signatures.

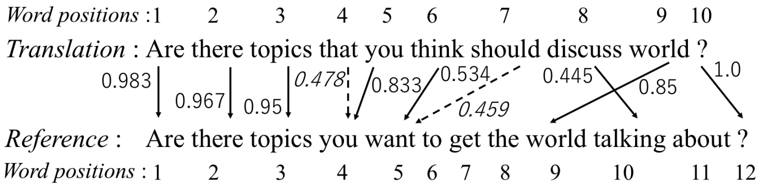

Figure 3: Example of word alignment by WE_WPI.

In Tables 1 and 2, all features p_i and q_j correspond to the coordinate (x, y) of two-dimensional surface.

Figure 2 depicts an example of an EMD calculation based on the signatures in Tables 1 and 2. In Figure 2, the green arrow indicates the amount of weight f_{ij}. All f_{ij} are transported only in the direction from P_i to Q_j according to Constraint (2). In each signature P_i, $\sum_{j=1}^{n} f_{ij}$ does not exceed w_{p_i} by Constraint (3). For example, in P_3, $\sum_{j=1}^{3} f_{3j}$ is 0.6 (=0.2+0.0+0.4). It does not exceed 0.6, which is the weight of P_3. Moreover, in each signature Q_j, $\sum_{i=1}^{m} f_{ij}$ does not exceed w_{q_j} according to Constraint (4). For example, in Q_1, $\sum_{i=1}^{4} f_{i1}$ is 0.8 (=0.6+0.0+0.2+0.0). It does not exceed 0.8, which corresponds to the weight of Q_1. The total amount of weight by $\sum_{i=1}^{m}\sum_{j=1}^{n} f_{ij}$ is 2.4. It is equal to 2.4 by $\sum_{i=1}^{m} w_{p_i}$ or 2.4 by $\sum_{j=1}^{n} w_{q_j}$. Therefore, this example of Figure 2 conforms to Constraint (5).

Moreover, the distance between two features is necessary to obtain EMD. When the Euclidean distance is used as the calculation of distance in this example, 2.236 (=$\sqrt{1^2 + 2^2}$) is obtained as d_{11}, d_{22}, d_{31}, d_{33}, d_{42}, and d_{43}, and other distances are 3.606 (=$\sqrt{2^2 + 3^2}$) in Figure 2. As a result, 5.366 (=2.236 × (0.6+0.6+0.2+0.4+0.2+0.4)) is obtained as the value of EMD by two probability distributions P and Q in Tables 1 and 2.

We obtain WE_WPI adjusting EMD to the automatic MT evaluation task. Details of application of EMD to WE_WPI are presented in 3.2.2.

3.2 New Automatic MT Evaluation Metric: WE_WPI

3.2.1 Word Alignment using Position Information

For the application of EMD to automatic MT evaluation, we use word alignment results. Word alignment is done using cosine similarity based on word embeddings and the relative difference between the word positions in the translation and reference. In that case, WE_WPI obtains $align\_score$ using Eqs. (7) and (8) presented below.

$$\begin{aligned} &align\_score \\ &= cos\_sim(t_i, r_j) \times (1.0 - pos\_inf(T_i, R_j)) \quad (7) \end{aligned}$$

$$pos\_inf(T_i, R_j) = \left| \frac{pos(T_i)}{m} - \frac{pos(R_j)}{n} \right| \quad (8)$$

In Eq. (7), t_i and r_j respectively represent the word embeddings of word T_i in the translation and word R_j in the reference. The $cos\_sim(t_i, r_j)$ denotes the cosine similarity between t_i and r_j. Moreover, $pos\_inf(T_i, R_j)$ represents the relative difference between the position of word T_i in the translation and the position of word R_j in the reference. It is defined as Eq. (8). In Eq. (8), $pos(T_i)$ and $pos(R_j)$ respectively denote the positions of word T_i in the translation and word R_j in the reference. Actually, m and n respectively denote the word numbers in the translation and reference. The $pos\_inf(T_i, R_j)$ becomes larger as the relative difference between $pos(T_i)$ and $pos(R_j)$ becomes larger . Therefore, $(1.0 - pos\_inf(T_i, R_j))$ is used as the negative weight for $cos\_sim(t_i, r_j)$. The ranges of $cos\_sim(t_i, r_j)$ and $pos\_inf(T_i, R_j)$ are both 0.0-1.0. Figure 3 depicts an example of word alignment using Eqs. (7) and (8).

The WE_WPI calculates $align\_score$ between a word in the translation and all words in reference. Based on those results, the word with the highest $align\_score$ in the reference is selected as the corresponding word to the word in the translation. In Figure 3, the $align\_score$ between "that" in the translation and "you" in the reference is the highest (*i.e.*, 0.478) among the $align\_score$ between "that" in the translation and all words in the reference. However, it is lower than the $align\_score$ 0.833 between "you" in the translation and "you" in the reference. Therefore, the word which corresponds to "that" in the translation cannot be obtained in the reference. Similarly, the word which

		reference											
		Are	there	topics	you	want	to	get	the	world	talking	about	?
trans-lation	Are	**0.017**	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0

	think	1.0	1.0	1.0	1.0	**0.456**	1.0	1.0	1.0	1.0	1.0	1.0	1.0
	should	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
	discuss	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	**0.555**	1.0	1.0
	world	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	**0.139**	1.0	1.0	1.0
	?	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	**0.0**

Table 3: Distance matrix incorporating translation and reference.

corresponds to "should" in the translation cannot be obtained in the reference.

In contrast, "discuss" in the translation corresponds to "talking" in the reference using $pos\_inf(T_i, R_j)$ of Eq. (8) although "discuss" in the translation corresponds to "topics" in the reference when $(1.0 - pos\_inf(T_i, R_j))$ is not used in Eq. (7) (*i.e.*, $align\_score = cos\_sim(t_i, r_j)$). The 0.477, which is the cos_sim between "discuss" in the translation and "topics" in the reference, is greater than 0.460, which is the cos_sim between "discuss" in the translation and "talking" in the reference. Here, $pos\_inf(T_i, R_j)$ between "discuss" in the translation and "talking" in the reference is 0.033 ($\left|\frac{8}{10} - \frac{10}{12}\right|$). That between "discuss" in the translation and "topics" in the reference is 0.550 ($\left|\frac{8}{10} - \frac{3}{12}\right|$). Consequently, the $align\_score$ of "discuss" in the translation and "talking" in the reference is 0.445 ($0.460 \times (1.0 - 0.033)$). That of "discuss" in the translation and "topics" in the reference is 0.215 ($0.477 \times (1.0 - 0.550)$) using Eq. (7). The WE_WPI can select "talking" in the reference as the corresponding word for "discuss" in the translation using $pos\_inf(T_i, R_j)$. The use of $pos\_inf(T_i, R_j)$ is effective for the correct word alignment.

3.2.2 Adjustment of EMD to the Automatic MT Evaluation Metric

We obtain WE_WPI as new automatic MT evaluation metrics by adjusting EMD to the automatic MT evaluation task. In WE_WPI, the variables P and Q in Figure 1 respectively correspond to a translation T and reference R. Moreover, the features (*i.e.*, p_i and q_j in Figure 1), the weight (*i.e.*, w_{p_i} and w_{q_j} in Figure 1), and distance (*i.e.*, d_{ij} in Figure 1) are required as parameters to adjust EMD to the automatic MT evaluation task. As described herein, we use the word embeddings as features and the sentence-level $tf \cdot idf$ as the weight. The weight definition is presented in Eq. (9) below.

$$w = tf \times \left(\log \frac{N}{df} + 1.0\right) \tag{9}$$

In Eq. (9), tf denotes the appearance frequency of a word in a translation or reference. In addition, df represents the number of sentences in which the word appears in all translations or references. In addition, N is the total number of translations or references. Actually, WE_WPI distinguishes the function word and the content word using Eq. (9). Furthermore, w_{t_i} of the word in the translation and w_{r_i} of the word in the reference by Eq. (9) are normalized respectively using the following Eqs. (10) and (11).

$$\tilde{w}_{t_i} = \frac{w_{t_i}}{\sum_{i=1}^{m} w_{t_i}} \tag{10}$$

$$\tilde{w}_{r_j} = \frac{w_{r_j}}{\sum_{j=1}^{n} w_{r_j}} \tag{11}$$

The dependence of w in Eq. (9) by difference of dataset can be kept to the minimum by normalizing Eqs. (10) and (11). Moreover, we define distance d_{ij}, which is ascertained from the result of the word alignment described in 3.2.1. The d_{ij} is obtained using the following Eq. (12):

$$d_{ij} = \begin{cases} 1.0 - cos\_sim(t_i, r_j) \\ \qquad\qquad \times \mathrm{e}^{-pos\_inf(T_i, R_j)} \\ \qquad \text{if } T_i \text{ corresponds to } R_j \\ 1.0 \quad \text{if } T_i \text{ does not correspond to } R_j \end{cases} \tag{12}$$

In Eq. (12), $1.0 - cos\_sim(t_i, r_j) \times \mathrm{e}^{-pos\_inf(T_i, R_j)}$ is used as d_{ij} when word T_i in the translation corresponds to word R_j in the reference by the word alignment result. The $pos\_inf(T_i, R_j)$ is obtained by Eq. (8). Here, t_i and r_j respectively correspond to the word embeddings of the words in the translation and reference. The $\mathrm{e}^{-pos\_inf(T_i, R_j)}$ represents the penalty

to $cos\_sim(t_i, r_j)$ because it becomes smaller as $pos\_inf(T_i, R_j)$ becomes larger. As a result, d_{ij} becomes large when the relative difference between the position of word T_i in the translation and the position of word R_j in the reference (*i.e.*, $pos\_inf(T_i, R_j)$) is large. The d_{ij} by Eq. (12) is 1.0 when word T_i does not correspond to word R_j. Finally, the range of d_{ij} becomes 0.0-1.0.

Moreover, the WE_WPI generates the distance matrix using d_{ij} in Eq. (12). Table 3 presents the distance matrix between the translation "Are there topics that you think should discuss world?" and the reference "Are there topics you want to get the world talking about?" in Figure 3. In Table 3, the bold typeface represents the distance between the two aligned words. The distance matrix using Eq. (12) is effective because it is not influenced by the words which are not aligned between the translation and reference.

The WE_WPI obtains the evaluation score by word embedding, sentence-level $tf \cdot idf$, and the distance matrix based on Eq. (12). The evaluation score of WE_WPI is obtained as Eq. (13).

$$WE\_WPI(T, R) = 1.0 - \frac{min(WORK(T, R, F))}{\sum_{i=1}^{m} \sum_{j=1}^{n} f_{ij}} \tag{13}$$

In that equation, the range of $\frac{min(WORK(T,R,F))}{\sum_{i=1}^{m} \sum_{j=1}^{n} f_{ij}}$ becomes 0.0-1.0 using the weights normalized by Eqs. (10) and (11). Near 0.0, the distance between T and R is small. However, in the automatic MT evaluation metrics, the score is close to 1.0 when the evaluation for the translation is generally high. Therefore, we obtain WE_WPI by taking the value of $\frac{min(WORK(T,R,F))}{\sum_{i=1}^{m} \sum_{j=1}^{n} f_{ij}}$ from 1.0. As a result, in between the translation "Are there topics that you think should discuss world?" and the reference "Are there topics you want to get the world talking about?", 0.608 is obtained as the score using Eq. (13).

The WE_WPI can evaluate the translation based on the meanings of words using word embedding. Moreover, it can deal with the word order using the relative difference between the positions of words in the translation and the reference.

4 Experiments

4.1 Experiment Data and Procedure

We conducted evaluation experiments to confirm the effectiveness of WE_WPI. The "newstest2016" set, which is the main test set in WMT16 metrics shared task (Bojar et al., 2016), was used. The script is available at `http://www.statmt.org/wmt16/results.html`.

Table 7: Segment-level metric results for out-of-English language pairs with the absolute values of correlation coefficients reported for all metrics: absolute correlation of segment-level metric scores with human assessment variants, where τ are official results computed similarly to Kendall's τ and over standard WMT relative ranking (RR) human assessments; r are Pearson correlation coefficients of metric scores with direct assessment (DA) of absolute translation adequacy.

Therefore, we can readily obtain the correlation coefficient between the metrics and human judgments in WMT16 metrics shared task. The WMT16 metrics task includes English paired with Czech, German, Finnish, Romanian, Russian, and Turkish. For all translations, references and scores by human judgment in these language pairs are obtained from the url described above.

For these experiments, we used different automatic MT evaluation metrics for comparison with our WE_WPI: BLEU, METEOR, IMPACT, RIBES, and WE. Here, IMPACT and RIBES, which are surface-based metrics, are effective for language pairs with greatly different word order, such as English and Japanese. In addition, WE is an automatic MT evaluation metric that does not perform word alignment. It uses only $d_{ij} = 1.0 - cos\_sim(t_i, r_j)$ as the d_{ij} of Eq. (12) in the WE_WPI. In both WE and WE_WPI, the word vectors for seven languages (*i.e.*, English, Czech, German, Finnish, Romanian, Russian, and Turkish) were obtained using fastText (Grave et al., 2018).

4.2 Experiment Results and Discussion

Tables 4 and 5 respectively present the correlation coefficient of to-English and out-of-English at the system level. Tables 6 and 7 respectively present the correlation coefficients of to-English and out-of-English at the segment level.

In Tables 4–7, RR represents the correlation based on the relative ranking by human judgment to 5 translations at a time. The bold typeface shows the highest correlation coefficient among all correlation coefficients of metrics. Moreover, the coefficients of MEANT 2.0 described in (Lo, 2017) are added to Tables 4–6. Here, WE_WPI achieves the highest correlation with human judgment in Table 5, DA in Table 6, and Table 7. Especially, the correlation coefficients of WE_WPI are high with language pairs for which the grammar differs (*i.e.*, English-to-German (en-de), German-to-English (de-en),

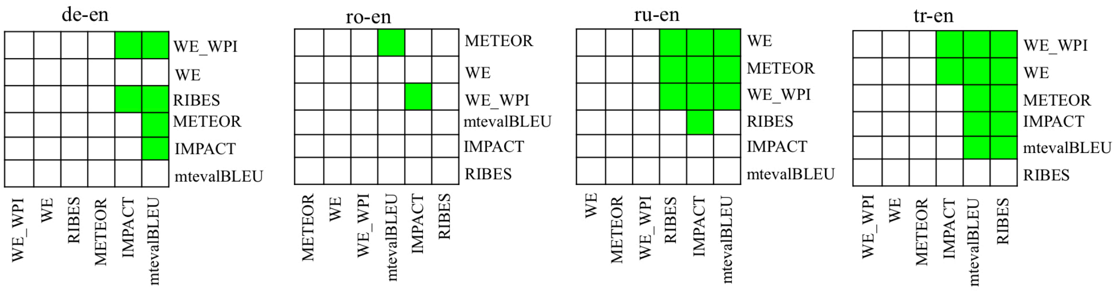

Figure 4: To-English system-level metric significance test of results for human assessment variants, where DA denotes the direct assessment of translation adequacy. Green cells show a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column according to the Williams test.

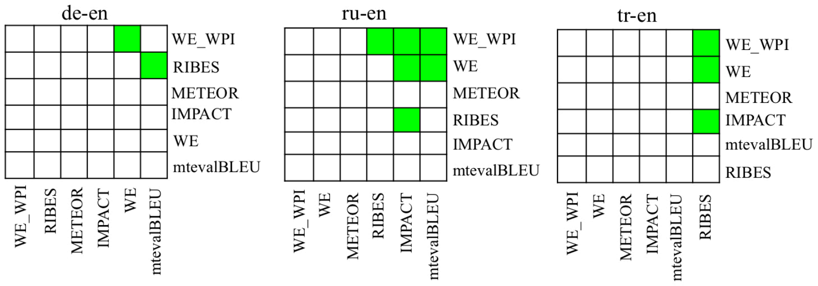

Figure 5: To-English system-level metric significance test of results for human assessment variants, where RR denotes the standard WMT relative ranking for the translation task system only. Green cells show a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column according to the Williams test.

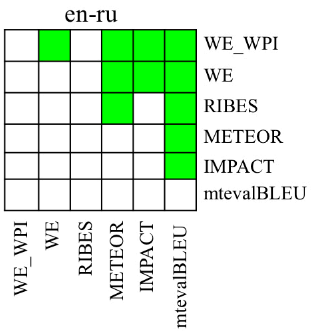

Figure 6: English-to-Russian system-level metric significance test of results for human assessment variants, where DA denotes direct assessment of translation adequacy. Green cells show a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column according to the Williams test.

English-to-Turkish (en-tr), and Turkish-to-English (tr-en)). Therefore, the WE_WPI is effective with such language pairs because it uses word position information.

Moreover, we investigated the significance of WE_WPI results and those of other metrics except those of MEANT 2.0 and MEANT 2.0 - nosrl. As described herein, Williams significance test (Williams, 1959) was used to assess differences in dependent correlations. Figures 4–9 present significance test results for every competing pair of metrics, including those of our WE_WPI. However, the language pairs for which significant differences could not be obtained in any competing pair of metrics are excluded from Figures 4–9 (*i.e.*, cs-en and fi-en in Figure 4, cs-en, fi-en and ro-en in Figure 5, en-cs in Figure 7).

In Figures 4–9, green cells signify that the metric shows significant difference from other metrics with 95% or greater confidence. Results demonstrated that our WE_WPI yielded significantly different results among metrics. Particularly, WE_WPI was found to have significantly better results than those of WE at the segment level, as shown in Figures 8 and 9. This particular result demonstrates that the word position information in WE_WPI is effective for segment-level evaluation.

Moreover, WE_WPI does not need much time to calculate the scores described in 3.2.2. However, it takes time to calculate $tf \cdot idf$ of words and to change the surface-level words to the word vectors. It is efficient to calculate $tf \cdot idf$ of all words in the translations and references, and to extract the word vectors, which correspond to the words in the translations and references, from the fastText models in advance.

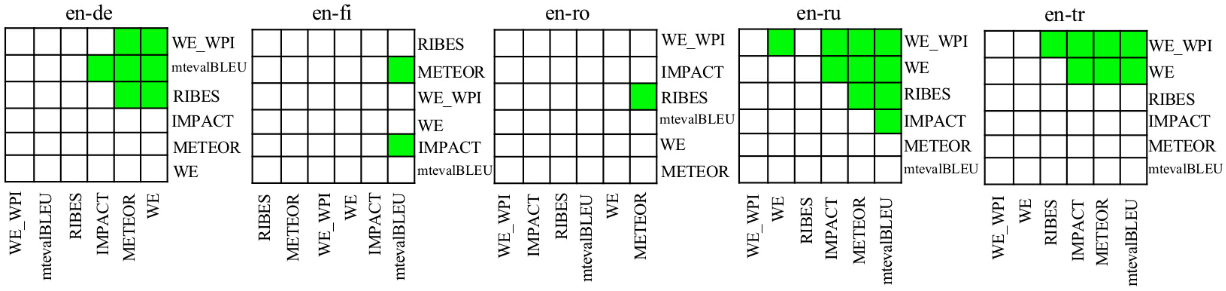

Figure 7: Out-of-English system-level metric significance test of results for human assessment variants, where RR denotes the standard WMT relative ranking for translation task system only. Green cells show a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column according to the Williams test.

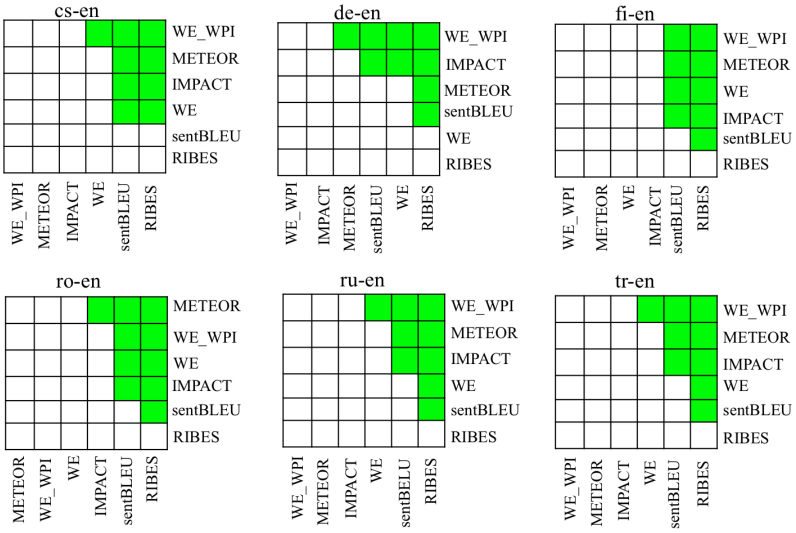

Figure 8: To-English segment-level metric significance test of results for human assessment variants, where DA denotes direct assessment of translation adequacy. Green cells show marked benefits obtained with the metric in a given row over the metric in a given column according to the Williams test.

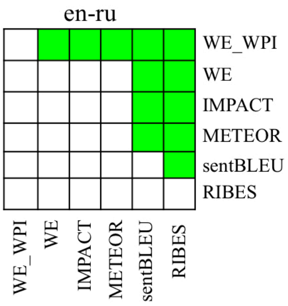

Figure 9: English-to-Russian segment-level metric significance test of results for human assessment variants, where DA denotes direct assessment of translation adequacy: green cells show marked benefits obtained with the metric in a given row over the metric in a given column according to the Williams test.

5 Conclusion

As described herein, we proposed WE_WPI as a new automatic MT evaluation metric. It produces an evaluation based on the meanings of words using word embedding. Moreover, it can accommodate word-order differences. Evaluation experiments demonstrated that our WE_WPI obtains the highest correlation with human judgments among several representative metrics in language pairs for which the grammar differs, and demonstrated that it is significantly better than other metrics at segment-level evaluation.

Our future work will improve WE_WPI to obtain high-quality evaluation scores in combination with other metrics. We will conduct evaluation experiments using various data. Moreover, we will use WE_WPI to improve NMT quality. For instance, WE_WPI can be used easily in Minimum Risk Training (MRT) (Shen et al., 2016), which minimizes the expected loss on the training data.

Abstract

Beam search optimization (Wiseman and Rush, 2016) resolves many issues in neural machine translation. However, this method lacks principled stopping criteria and does not learn how to stop during training, and the model naturally prefers *longer* hypotheses during the testing time in practice since they use the raw score instead of the probability-based score. We propose a novel ranking method which enables an optimal beam search stopping criteria. We further introduce a structured prediction loss function which penalizes suboptimal finished candidates produced by beam search during training. Experiments of neural machine translation on both synthetic data and real languages (German→English and Chinese→English) demonstrate our proposed methods lead to better length and BLEU score.

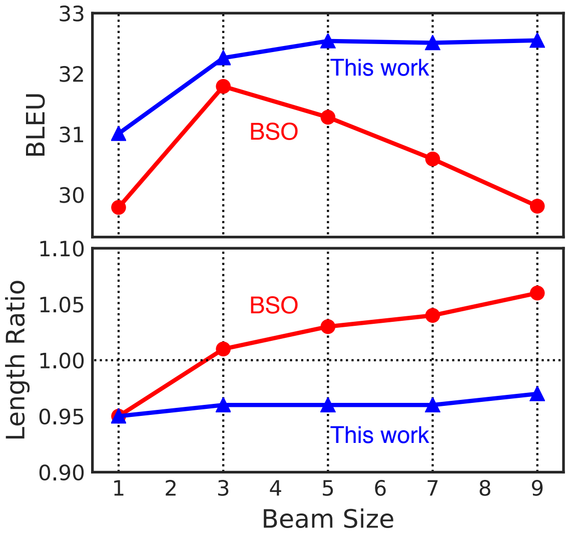

Figure 1: The BLEU score of BSO decreases after beam size 3 as results of increasing length ratio[1] in German→English translation. Our model gets higher BLEU with larger beam.

1 Introduction

Sequence-to-sequence (seq2seq) models based on RNNs (Sutskever et al., 2014; Bahdanau et al., 2014), CNNs (Gehring et al., 2017) and self-attention (Vaswani et al., 2017) have achieved great successes in Neural Machine Translation (NMT). The above family of models encode the source sentence and predict the next word in an autoregressive fashion at each decoding time step. The classical "cross-entropy" training objective of seq2seq models is to maximize the likelihood of each word in the translation reference given the source sentence and all previous words in that reference. This word-level loss ensures efficient and scalable training of seq2seq models.

However, this word-level training objective suffers from a few crucial limitations, namely the *label bias*, the *exposure bias*, and the *loss-evaluation mismatch* (Lafferty et al., 2001; Bengio et al., 2015a; Venkatraman et al., 2015). In addition, more importantly, at decoding time, *beam search* is universally adopted to improve the search quality, while training is fundamentally local and greedy. Several researchers have proposed different approaches to alleviate above problems, such as reinforcement learning-based methods (Ranzato et al., 2016; Rennie et al., 2017; Zheng et al., 2018b), training with alternative references (Shen et al., 2016; Zheng et al., 2018a). Recently, Wiseman and Rush (2016) attempt to address these issues with a structured training method, Beam Search Optimization (BSO). While BSO outperforms other proposed methods on German-to-English translation, it also brings a different set of problems as partially discussed in (Ma, 2018) which we present with details below.

---

[*] Equal contribution

[1] There are two types of "length ratios" in this paper: (a) target to reference ratio ($|\mathbf{y}|/|\mathbf{y}^*|$), which is used in BLEU, and (b) target to source ratio ($|\mathbf{y}|/|\mathbf{x}|$). By default, the term "length ratio" in this paper refers to the former.

Proceedings of NAACL-HLT 2019, pages 1884–1889
Minneapolis, Minnesota, June 2 - June 7, 2019.

BSO relies on unnormalized raw scores instead of locally-normalized probabilities to get rid of the label bias problem. However, since the raw score can be either positive or negative, the optimal stopping criteria (Huang et al., 2017) no longer holds, e.g., one extra decoding step would increase the entire unfinished hypothesis's model score when we have positive word score. This leads to two consequences: we do not know when to stop the beam search and it could return overlength translations (Fig. 1) or underlength translations (Fig. 3) in practice. As shown in Fig. 1, the BLEU score of BSO drops significantly when beam size gets larger as a result of overlong translations (as evidenced by length ratios larger than 1). Furthermore, BSO performs poorly (shown in Section 4) on hard translation pairs, e.g., Chinese→English (Zh→En) translation, when the target / source ratio is more diverse (Table 1).

To overcome the above issues, we propose to use the sigmoid function instead of the raw score at each time step to rank candidates. In this way, the model still has probability properties to hold optimal stopping criteria without label bias effects. Moreover, we also encourage the model to generate the hypothesis which is more similar to gold reference in length. Compared with length reward-based methods (Huang et al., 2017; Yang et al., 2018), our model does not need to tune the predicted length and per-word reward. Experiments on both synthetic and real language translations (De→En and Zh→En) demonstrate significant improvements in BLEU score over strong baselines and other methods.

2 Preliminaries: NMT and BSO

Here we briefly review the conventional NMT and BSO (Wiseman and Rush, 2016) to set up the notations. For simplicity, we choose to use RNN-based model but our methods can be easily applied to other designs of seq2seq model as well.

Regardless of the particular design of different seq2seq models, generally speaking, the decoder always has the following form:

$$p(\mathbf{y} \mid \mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} p(y_t \mid \mathbf{x},\, \mathbf{y}_{<t}) \qquad (1)$$

where $\mathbf{x} \in R^{N \times D}$ represents the D-dimension hidden states from encoder with N words and $\mathbf{y}_{<t}$ denotes the gold prefix $(y_1, ..., y_{(t-1)})$ before t. The conventional NMT model is locally trained to maximize the above probability.

Instead of maximizing each gold word's probability, BSO tries to promote the non-probabilistic scores of gold sequence within a certain beam size b. BSO removes the softmax layer and directly uses the raw score after hidden-to-vocabulary layer, and the non-probabilistic scoring function $f_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t})$ represents the score of word y_t given gold prefix $\mathbf{y}_{<t}$ and $\mathbf{x}$. Similarly, $f_{\mathbf{x}}(\hat{y}_t^b \mid \hat{\mathbf{y}}_{<t}^b)$ is the b^{th} sequence with beam size b at time step t. Then, we have the following loss function to penalize the b^{th} candidate and promote gold sequence:

$$\mathbb{L} = \sum_{t=1}^{|\mathbf{y}|} \Delta(\hat{\mathbf{y}}_{\leq t}^b)(1 + f_{\mathbf{x}}(\hat{y}_t^b \mid \hat{\mathbf{y}}_{<t}^b) - f_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t}))^+ \qquad (2)$$

where $\Delta(\hat{\mathbf{y}}_{\leq t}^b)$ is defined as $(1-\text{BLEU}(\hat{\mathbf{y}}_{\leq t}^b, \mathbf{y}_{\leq t}))$ which scales the loss according to BLEU score between gold and b^{th} hypothesis in the beam. The notation $(\cdot)^+$ represents a max function between any value and 0, i.e., $z^+ = max(0, z)$.

When Eq. 1 equals to 0 at time step t, then the gold sequence's score is higher than the last hypothesis in the beam by 1, and a positive number otherwise. Finally, at the end of beam search ($t = |\mathbf{y}|$), BSO requires the score of $\mathbf{y}$ exceed the score of the highest incorrect hypothesis by 1.

Note that the above non-probabilistic score function $f_{\mathbf{x}}(\cdot)$ is not bounded as probabilistic score in conventional NMT. In practice, when we have positive word score, then the unfinished candidates always get higher model scores with one extra decoding step and the optimal stopping criteria [2] (Huang et al., 2017) is no longer hold. BSO implements a similar "shrinking beam" strategy which duplicates top unfinished candidate to replace finished hypotheses and terminates the beam search when there are only `</eos>` in the beam. Non-probabilistic score function works well in parsing and Statical MT where we know when to stop beam search. However, in the NMT scenario, without optimal stopping criteria, we don't know when to stop beam search.

3 Learning to Stop

We propose two major improvements to BSO.

3.1 Sigmoid Scoring Function

As mentioned in Section 2, BSO relies on raw score function to eliminate label bias effects.

---

[2] Beam search stops when the score of the top unfinished hypothesis is lower than any finished hypothesis, or the `</eos>` is the highest score candidate in the beam.

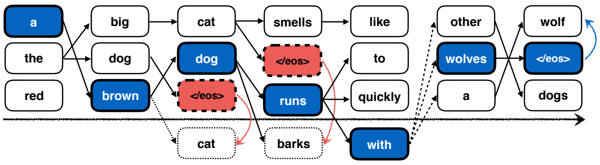

Figure 2: Training illustration with beam size $b = 3$ and gold reference "a brown dog runs with the wolves". The gold reference is highlighted in blue solid boxes. We penalize the under-length translation (short) hypotheses by expelling out the early `</eos>` out of beam (red dashed boxes). The beam search restarts with gold when gold falls off the beam (at step 5).

However, without using locally-normalized score does not mean that we should stop using the probabilistic value function. Similar with multi-label classification in (Ma et al., 2017), instead of using locally normalized softmax-based score and non-probabilistic raw scores, we propose to use another form of probabilistic scoring function, sigmoid function, which is defined as follows:

$$g_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t}) = (1 + e^{w \cdot f_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t})})^{-1} \tag{3}$$

where w is a trainable scalar parameter which shifts the return value of $f_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t})$ into a non-saturated value region of sigmoid function. Eq. 3 measures the probability of each word independently which is different from locally-normalized softmax function. Similar to the scenario in multi-label classification, $g_{\mathbf{x}}(y_t \mid \mathbf{y}_{<t})$ only promotes the words which are preferred by gold reference and does not degrade other words. Eq. 3 enables the model to keep the probability nature of scoring function without introducing label bias effects. After the model regain probability-based scoring function, the optimal stopping criteria can be used in testing time decoding.

3.2 Early Stopping Penalties

Similar to Eq. 1, testing time decoder multiplies the new word's probabilistic score with prefix's score when there is a new word appends to an unfinished hypothesis. Though the new word's probabilistic score is upper bounded by 1, in practice, the score usually far less than one. As described in (Huang et al., 2017; Yang et al., 2018), decoder always prefers short sentence when we use the probabilistic score function.

To overcome the above so-called "*beam search curse*", we propose to penalize early-stopped hypothesis within the beam during training. The procedure during training is illustrated in Fig. 2.

Data	Split	$\overline{\lvert x\rvert}$	$\sigma(\lvert x\rvert)$	$\overline{(\frac{\lvert y\rvert}{\lvert x\rvert})}$	$\sigma(\frac{\lvert y\rvert}{\lvert x\rvert})$	# sents

Table 1: Dataset statistics of source sentence length and the ratio between target and source sentences. σ is standard deviation. *shows statistics of cleaned test set.

Different from BSO, to penalize the underlength finished translation hypotheses, we include additional violations when there is an `</eos>` within the beam before the gold reference finishes and we force the score of that `</eos>` lower than the $b+1$ candidate by a margin. This underlength translation violation is formally defined as follows:

$$\begin{aligned} \mathbb{L}^{\mathrm{s}} &= \sum_{t=1}^{|\mathbf{y}|} \sum_{j=1}^{b} \mathbb{1}(\hat{y}_t^j = \texttt{</eos>}) \cdot Q(\hat{y}_t^j, \hat{y}_t^{b+1}) \ , \\ Q(\hat{y}_t^j, \hat{y}_t^{b+1}) &= (1 + f_{\mathbf{x}}(\hat{y}_t^j \mid \hat{\mathbf{y}}_{<t}^j) - f_{\mathbf{x}}(\hat{y}_t^{b+1} \mid \hat{\mathbf{y}}_{<t}^{b+1}))^+ \end{aligned} \tag{4}$$

where notation $\mathbb{1}$ is identification function which only equals to 1 when i^{th} candidate in beam $\hat{y}_t^j$ is `</eos>`, e.g. in Fig. 2. We only have non-zero loss when the model score of underlength translation candidates are greater than the $b+1$ candidate by a margin. In this way, we penalize all the short hypotheses during training time. Note that during both training and testing time, the decoder stops beam search when it satisfies the optimal stopping criteria (Huang et al., 2017). Therefore, we do not need to penalize the overlength translations since we have already promoted the gold reference to the top of the beam at time step $|y|$ during training.

4 Experiments

We showcase the performance comparisons over three different datasets. We implement seq2seq model, BSO and our proposed model based on PyTorch-based OpenNMT (Klein et al., 2017). We use a two-layer bidirectional LSTM as the encoder and a two layer LSTM as the decoder. We train Seq2seq model for 20 epochs to minimize perplexity on the training dataset, with a batch size of 64, word embedding size of 512, the learning rate of 0.1, learning rate decay of 0.5 and dropout rate of 0.2. Following Wiseman and Rush (2016), we then train BSO and our model based on the previous Seq2seq model with the learning rate of

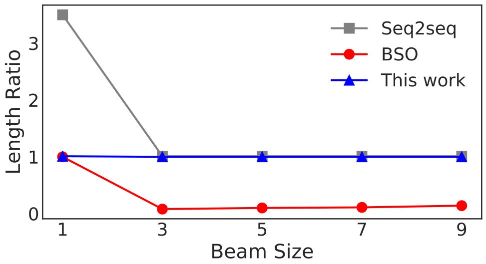

Figure 3: Length ratio on synthetic test dataset.

0.01 and learning rate decay of 0.75, batch size of 40. Note that our pretrained model is softmax-based, and we only replace the softmax layer with the sigmoid layer for later training for simplicity. The performance will have another boost when our pretrained model is sigmoid-based. We use Adagrad (Duchi et al., 2011) as the optimizer.

In Zh→En task, we employ BPE (Sennrich et al., 2015) which reduces the source and target language vocabulary sizes to 18k and 10k. Following BSO, we set the decoding beam size smaller than the training beam size by 1.

4.1 Synthetic Task

Table 1 shows the statistics of source sentence length and the ratio between target and source sentences. The synthetic dataset is a simple translation task which generates target sentences from this grammar: $\{a \to x, b \to x\ x, c \to x\ x\ x, d \to x\ x\ x\ x, e \to x\ x\ x\ x\ x\}$. For example:

1. source sentence $[b\ c\ a]$ will generate the target sentence $[x\ x\ x\ x\ x\ x]$ (2 x from b, 3 x from c and 1 x from a).
2. source sentence $[a, b, c, d, e]$ will be translated into $[x\ x\ x\ x\ x\ x\ x\ x\ x\ x\ x\ x\ x\ x\ x]$ in target side (1 x from a, 2 x from b, 3 x from c, 4 x from d and 5 x from e).

This dataset is designed to evaluate the length prediction ability of different models. Fig. 3 shows the length ratio of different models on the test set. Only our model can predict target sentence length correctly with all beam sizes which shows a better ability to learn target length.

4.2 De→En Translation

The De→En dataset is previously used in BSO and MIXER (Ranzato et al., 2016), which is from IWSLT 2014 machine translation evaluation campaign (Cettolo et al., 2014) [3].

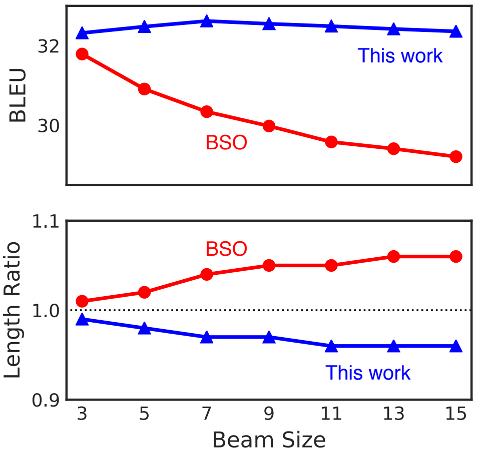

Figure 4: BLEU and length ratio of models with training beam size $b = 6$ and decode with different beam size on De→En dataset.

Table 2 shows the BLEU score and length ratio of different models on dev-set. Similar to seq2seq, our proposed model achieves better BLEU score with larger beam size and outperforms the best BSO $b = 4$ model with 0.76 BLEU. The ablation study in Table 3 shows that the model produces shorter sentence without scale augment (term $\Delta(\hat{y}^b_{\le t})$ in Eq. 2) and early stopping loss. The model also performs worse when replacing softmax to sigmoid because of the label bias problem. Fig. 4 shows BLEU score and length ratio of BSO and our models trained with beam size $b = 6$ with different decoding beam size. Compared with BSO, whose BLEU score degrades dramatically when increasing beam size, our model performs much more stable. Moreover, BSO achieves much better BLEU score with decoding beam $b = 3$ while trained with $b = 6$ because of a better

length ratio, this is inconsistent with their claim that decoding beam size should smaller than training beam size by 1.

Table 4 shows better accuracy of our proposed model than not only published test results of BSO (Wiseman and Rush, 2016), DAD (Bengio et al., 2015b) and MIXER (Ranzato et al., 2016), but also our implemented seq2seq and BSO model.

Model	BLEU	Len.
Seq2Seq†	34.19	0.95
w/ Len. reward†	34.60	0.99
BSO†	31.78	1.04
This work	35.40	0.99

Table 6: BLEU and length ratio of models on Zh→En test set. †indicates our own implementation.

We also perform experiments on NIST Zh→En translation dataset. We use the NIST 06 and 08 dataset with 4 references as the validation and test set respectively. Table 1 shows that the characteristic of Zh→En translation is very different from De→En in source length and variance in target/source length ratio.

We compare our model with seq2seq, BSO and seq2seq with length reward (Huang et al., 2017) which involves hyper-parameter to solve neural model's tendency for shorter hypotheses (our proposed method does not require tuning of hyper-parameter). Fig. 5 shows that BSO prefers overlength hypotheses in short source sentences and underlength hypotheses when the source sentences are long. This phenomenon degrades the BLEU score in dev-set from Table 5. Our proposed model comparatively achieves better length ratio on almost all source sentence length in dev-set.

5 Future Works and Conclusions

Our proposed methods are general techniques which also can be applied to the Transformer (Vaswani et al., 2017). As part of our future works, we plan to adapt our techniques to the Transformer to further evaluate our model's performance.

There are some scenarios that decoding time beam search is not applicable, such as the simultaneous translation system proposed by Ma et al. (2018) which does not allow for adjusting the committed words, the training time beam search still will be helpful to the greedy decoding performance. We plan to further investigate the performance of testing time greedy decoding with beam search optimization during training.

We propose two modifications to BSO to provide better scoring function and under-translation penalties, which improves the accuracy in De-En and Zh-En by 0.8 and 3.7 in BLEU respectively.

Abstract

Recent research has discovered that a shared bilingual word embedding space can be induced by projecting monolingual word embedding spaces from two languages using a self-learning paradigm without any bilingual supervision. However, it has also been shown that for distant language pairs such fully unsupervised self-learning methods are unstable and often get stuck in poor local optima due to reduced isomorphism between starting monolingual spaces. In this work, we propose a new robust framework for learning unsupervised multilingual word embeddings that mitigates the instability issues. We learn a shared multilingual embedding space for a variable number of languages by incrementally adding new languages one by one to the current multilingual space. Through the gradual language addition our method can leverage the interdependencies between the new language and all other languages in the current multilingual hub/space. We find that it is beneficial to project more distant languages later in the iterative process. Our fully unsupervised multilingual embedding spaces yield results that are on par with the state-of-the-art methods in the bilingual lexicon induction (BLI) task, and simultaneously obtain state-of-the-art scores on two downstream tasks: multilingual document classification and multilingual dependency parsing, outperforming even supervised baselines. This finding also accentuates the need to establish evaluation protocols for cross-lingual word embeddings beyond the omnipresent intrinsic BLI task in future work.

1 Introduction

The ubiquitous use and success of word embeddings in monolingual tasks inspired further research on inducing cross-lingual word embeddings for two or more languages in the same vector space. Embeddings of translations and words with similar meaning are geometrically close in the *shared cross-lingual vector space*. This property makes them effective features for cross-lingual NLP tasks such as cross-lingual document classification (Klementiev et al., 2012), cross-lingual information retrieval (Vulić and Moens, 2015), bilingual lexicon induction (Mikolov et al., 2013b; Gouws et al., 2015; Heyman et al., 2017), and (unsupervised) machine translation (Artetxe et al., 2017b; Lample et al., 2018; Artetxe et al., 2018c).

Most prior work has focused on methods for constructing *bilingual* word embeddings (BWEs), yielding word representations for exactly two languages. For problems such as multilingual document classification, however, it is highly-desirable to represent words in a *multilingual* space. A favourable property is that it enables fitting a single classifier on the union of training datasets in many languages, which results in 1) knowledge transfer across languages that may lead to better classification performance, and 2) a setup that is easier to maintain as it is no longer required to train many different monolingual or bilingual classifiers.

Multilingual word embedding (MWE) methods typically generalize existing BWE methods by mapping multiple source language spaces to the space of one target language (Ammar et al., 2016), which is used as a pivot/hub language. This approach may lead to suboptimal solutions as it does not account for interdependencies between the source languages. Most BWE and MWE methods rely on *cross-lingual supervision* to some extent: e.g., bilingual lexicons (Mikolov et al., 2013a), parallel corpora (Gouws et al., 2015), or subject-aligned document pairs (Vulić and Moens, 2016). In such paradigms, modeling dependencies between all languages is impractical as it requires supervision for all language pair combinations.

Recent research has shown that BWEs can also be learned *without* cross-lingual supervision and can even outperform supervised BWE variants

Proceedings of NAACL-HLT 2019, pages 1890–1902
Minneapolis, Minnesota, June 2 - June 7, 2019.

on bilingual lexicon induction benchmarks (Conneau et al., 2018; Artetxe et al., 2018a). Chen and Cardie (2018) took a first step towards learning multilingual spaces without supervision while incorporating dependencies between all languages but their approach extends the work of Conneau et al. (2018), which has known limitations concerning optimization stability with distant language pairs (Søgaard et al., 2018). In this work, we investigate robust methods to induce MWEs without any cross-lingual supervision. The robustness of our approach is illustrated in good performance for distant languages such as Finnish and Bulgarian. This paper makes the following contributions.

First, based on a reformulation of the BWE method of Artetxe et al. (2018a), we propose two novel methods for inducing MWEs: 1) the single hub space model (SHS) uses the classical idea of mapping source languages to a single hub language; 2) the incremental hub space model (IHS) incorporates dependencies between all languages by incrementally expanding the multilingual space by one language in each step. IHS results in mappings that are more robust and coherent across languages. Both SHS and IHS only require monolingual data.

Second, we evaluate our method on benchmarks for bilingual lexicon induction (BLI), multilingual document classification, and dependency parsing. We find that the IHS method is competitive with state-of-the-art BWE methods on the bilingual lexicon induction benchmarks, while yielding the highest scores on the multilingual document classification and dependency parsing benchmarks.

Third, unlike the majority of prior work (Conneau et al., 2018; Artetxe et al., 2018a; Chen and Cardie, 2018, *inter alia*), we do not limit our evaluation to the intrinsic BLI task only. Consequently, we investigate if embedding reweighting, a recently proposed best practice for BWEs, is useful for extrinsic tasks such as document classification and dependency parsing in multilingual settings.

2 Related Work

Cross-lingual word embeddings have received a lot of attention in recent years. Most methods construct a space shared between two languages using cross-lingual supervision in the form of bilingual lexicons (Mikolov et al., 2013a; Artetxe et al., 2016; Smith et al., 2017), parallel corpora (Klementiev et al., 2012; Faruqui and Dyer, 2014; Gouws et al., 2015; Luong et al., 2015) or subject-aligned document pairs (Vulić and Moens, 2016). See Ruder et al. (2018) for a full overview of BWE model typology in relation to the required supervision.

To enable knowledge transfer across an arbitrary number of languages, multilingual methods have been introduced. Huang et al. (2015), propose decomposing a matrix with multilingual co-occurrence counts weighted by probabilistic dictionaries. Ammar et al. (2016) compare this method to three other MWE models: MultiCluster, MultiCCA, and MultiSkip. MultiCluster uses bilingual dictionaries to cluster translations and then train the monolingual Skip-gram model (SG) (Mikolov et al., 2013a) on a union of monolingual corpora where they replace words with their cluster id such that words in the same cluster get the same representation. MultiCCA is the multilingual extension of the method of Faruqui and Dyer (2014): Using canonical correlation analysis (CCA) and dictionaries with English as the target language, monolingual embeddings are projected to the English vector space. MultiSkip is a straightforward extension of the BiSkip method (Luong et al., 2015) which generalizes the monolingual SG objective to account for word alignments in parallel corpora. Similarly, Duong et al. (2017), extend CBOW to multiple languages. All these methods learn multilingual embeddings using bilingual dictionaries of parallel corpora: This limits their applicability for many languages.

More recently, Conneau et al. (2018); Artetxe et al. (2018a) showed that BWEs can be effectively induced without any cross-lingual supervision. The approaches are based on the assumption that monolingual embedding spaces are approximately isomorphic.[1] Improving on earlier attempts (Cao et al., 2016; Zhang et al., 2017), Conneau et al. (2018) propose a two-step framework to map two monolingual spaces to the shared space. First, they use an adversarial objective to get an initial bilingual space in which the discriminator can no longer distinguish to which language a given word embedding belongs. They then fine-tune the initial solution. An important limitation is that the adversarial objective is prone to converge to degenerate solutions. Furthermore, Søgaard et al. (2018) empirically prove that the method typically fails for distant language pairs such as English-Finnish.

In parallel, Artetxe et al. (2018a) proposed an-

---

[1] One of the necessary conditions for this assumption to hold is that the monolingual corpora on which the embeddings are trained are comparable (Søgaard et al., 2018).

other framework with the same goal. Expanding on their earlier work (Artetxe et al., 2017a, 2018b), they use an unsupervised heuristic to obtain a noisy initial seed lexicon which is used to obtain an initial bilingual space. This solution is iteratively improved similar to Artetxe et al. (2017a) and Conneau et al. (2018) while using value dropping regularization to escape early convergence to local minima. Their method is the starting point for this work, and it is discussed in detail in §3.

The two unsupervised approaches are limited to finding mappings between a pair of languages. To the best of our knowledge, Chen and Cardie (2018) is the only unsupervised method that constructs a multilingual embedding space. Their method extends the adversarial pre-training and iterative refinement steps of Conneau et al. (2018) to the multilingual setting. Their work does not investigate the limitations of Conneau et al. (2018)'s method: Less stable optimization and difficulties with mapping spaces with reduced isomorphism. Furthermore, their generalization turns the iterative refinement into a non-convex optimization problem. In contrast, our multilingual methods proposed in this work are applicable to distant language pairs and decompose every iteration in the refinement step in multiple convex optimization problems, making them very robust and widely applicable.

3 Unsupervised Bilingual Embeddings

We now summarize mapping-based approaches to learning BWEs, which serve as the backbone of our multilingual approach. These methods rely on a *mapping procedure*, that is, a way to transform two monolingual spaces such that translations and similar words obtain similar representations. Supervised approaches take translations from readily available seed training dictionaries. Unsupervised approaches construct a seed lexicon from scratch, and use an iterative procedure to refine the seed lexicon and the mapped bilingual space.

Mapping Procedure. Various mapping procedures have been proposed in the literature (Mikolov et al., 2013b; Dinu et al., 2015; Lazaridou et al., 2015; Vulić and Korhonen, 2016). These methods can be seen as variants of a a single framework (Artetxe et al., 2018b), summarized here.

At its core, each mapping procedure learns the orthogonal transformations $\boldsymbol{W}_x$ and $\boldsymbol{W}_z$ for the monolingual embedding spaces $\boldsymbol{X}$ and $\boldsymbol{Z}$ that minimize the distance between embeddings of translations in the mapped spaces $\boldsymbol{X}\boldsymbol{W}_x$ and $\boldsymbol{Z}\boldsymbol{W}_z$. The orthogonality constraint ensures that the transformations preserve the monolingual constellation of embeddings. Formally, let $\boldsymbol{D}$ be a matrix representing a bilingual dictionary s.t. $D_{ij} = 1$ if the i^{th} source word is translated by the j^{th} target word and $D_{ij} = 0$ otherwise, then $\boldsymbol{W}_x$ and $\boldsymbol{W}_z$ are found by solving the following optimization problem:

$$\begin{aligned} &\underset{\boldsymbol{W}_x,\boldsymbol{W}_z}{\arg\max} \sum_i \sum_j D_{ij} (\boldsymbol{X}_{i,:}\boldsymbol{W}_x) \cdot (\boldsymbol{Z}_{j,:}\boldsymbol{W}_z) \\ &= \underset{\boldsymbol{W}_x,\boldsymbol{W}_z}{\arg\max}\ tr(\boldsymbol{X}\boldsymbol{W}_x(\boldsymbol{D}\boldsymbol{Z}\boldsymbol{W}_z)^\intercal) \qquad (1) \\ &\text{subject to } \boldsymbol{W}_x\boldsymbol{W}_x^\intercal = \boldsymbol{I}\,, \boldsymbol{W}_z\boldsymbol{W}_z^\intercal = \boldsymbol{I} \end{aligned}$$

where $tr(\cdot)$ denotes the trace operator.

Eq. (1) has a closed-form solution based on the singular vectors of $\boldsymbol{X}^\intercal\boldsymbol{D}\boldsymbol{Z}$: $\boldsymbol{W}_x = \boldsymbol{U}, \boldsymbol{W}_z = \boldsymbol{V}$ with $\boldsymbol{U}\boldsymbol{S}\boldsymbol{V}^\intercal = \text{SVD}(\boldsymbol{X}^\intercal\boldsymbol{D}\boldsymbol{Z})$. In addition to the transformation, there are several optional pre-processing (S1-S2) and post-processing (S3-S5) steps:

S1. *Normalization*: apply length normalization (normalizing $\boldsymbol{X}$ and $\boldsymbol{Z}$ such that all embeddings have a unit Euclidean norm), or mean centering, or a combination of both;

S2. *Whitening*: apply ZCA whitening (Bell and Sejnowski, 1997) on $\boldsymbol{X}$ and $\boldsymbol{Z}$ which transforms the monolingual embedding matrices such that each dimension/component has unit variance and such that the dimensions are uncorrelated (see Eq. (2) later). The intuition is that it is easier to align the vector spaces along directions of high variance;

S3. *Re-weighting* the components according to the singular value matrix $\boldsymbol{S}$ of $\boldsymbol{X}^\intercal\boldsymbol{D}\boldsymbol{Z}$: This is an attempt to further align the embeddings in the multilingual space as each singular value measures how well a dimension in the multilingual space correlates across languages for the given dictionary;

S4. *De-whitening*, the inverse transformation of S2: After the mapping, it was shown as important to restore the variance information in case whitening was applied (Artetxe et al., 2018c);

S5. *Dimensionality reduction* truncates the embedding vectors such that only components with the highest singular values are kept.

Refinement Procedure. The refinement aims at iteratively improving the seed dictionary and the bilingual space with Expectation Maximization (Dempster et al., 1977). In each iteration, the mapping procedure is executed using the dictionary from the previous iteration to obtain a new bilingual space, and then a new dictionary is induced using nearest neighbor retrieval in the *cross-lingual similarity matrix* $\boldsymbol{M}$. This is repeated until the (unsupervised) training objective $\sum_i \sum_j D_{ij}\big((\boldsymbol{X}_{i,:}\boldsymbol{W}_x) \cdot (\boldsymbol{Z}_{j,:}\boldsymbol{W}_z)\big)$ stops increasing.

The matrix $\boldsymbol{M}$ is calculated using cross-domain similarity local scaling (CSLS; Conneau et al. (2018)), an extended variant of cosine similarity that avoids the hubness problem (Radovanović et al., 2010; Dinu et al., 2015).[2] In particular, the element m_{ij} at row i and column j of $\boldsymbol{M}$ corresponds to the CSLS value between the cross-lingual vectors $\boldsymbol{x}_i^{CL}$ and $\boldsymbol{z}_j^{CL}$ of the i^{th} source word and the j^{th} target word respectively: $m_{ij} = \text{CSLS}(\boldsymbol{x}_i^{CL}, \boldsymbol{z}_j^{CL})$; $\text{CSLS}(\boldsymbol{x}, \boldsymbol{z}) = 2cos(\boldsymbol{x}, \boldsymbol{z}) - r_{Zk}(\boldsymbol{x}) - r_{Xk}(\boldsymbol{z})$. $r_{Xk}(\boldsymbol{x})$ and $r_{Zk}(\boldsymbol{z})$ calculate the average cosine similarity of a vector with its k nearest neighbors (measured by cosine) in the mapped spaces of $\boldsymbol{X}$, $\boldsymbol{Z}$, respectively. It is also beneficial to jointly infer dictionaries source-to-target and target-to-source (Artetxe et al., 2018a).[3] The mapping is then learned from the concatenation of these two dictionaries.[4]

To avoid suboptimal local minima, Artetxe et al. (2018a) propose to randomly drop values from the matrix $\boldsymbol{M}$ with probability $1 - p$ (further *value dropping*). The value of p is exponentially increased as training progresses. p is initialized to a small value (e.g., 0.1). Whenever the objective stops improving for $N_{patience}$ refinement steps, p is multiplied with a given factor (e.g., 2) until $p \geq 1$ after which all values in $\boldsymbol{M}$ are kept. Value dropping was shown to be crucial when constructing bilingual spaces between distant language pairs. We later analyze its impact on the proposed multilingual methods.

Inducing a Seed Lexicon. Artetxe et al. (2018a) obtain a seed lexicon based on the assumption that for a translation pair w_i^X, w_j^Z, the monolingual similarity vectors, $\sqrt{\boldsymbol{X}_i\boldsymbol{X}^\top}$ and $\sqrt{\boldsymbol{Z}_j\boldsymbol{Z}^\top}$ of translations i, j are (approximately) equal up to a permutation.[5] Therefore, seed translations for a source word i are generated by finding the nearest neighbor based on similarity of monolingual similarities. This heuristic yields a very noisy seed lexicon, but it was proven to contain a sufficiently strong bilingual signal to bootstrap the refinement procedure. The seed lexicon is inferred symmetrically (i.e., by concatenating respective source-to-target and target-to-source seed lexicons) and the vocabularies are truncated to the C_{seed} most frequent words.

4 Unsupervised Multilingual Embeddings: Methodology

We now present two models for learning unsupervised multilingual word embedding spaces: the single hub space model (SHS) and the incremental hub space model (IHS). The methods generalize the bilingual framework described in §3, and rely on (a subset of) preprocessing and postprocessing steps S1-S5 in the multilingual setting.

Single Hub Space (SHS). The SHS model defines one language as the hub language L_0 and projects the embedding spaces $\boldsymbol{Z}_1, ..., \boldsymbol{Z}_N$ of all other languages $L_1, ..., L_N$ (further *secondary languages*) to the hub space $\boldsymbol{X}$. Hence, we reduce the construction of a multilingual space of N languages to the alignment of $N - 1$ vector spaces. Learning these projections is similar to the bilingual case: We use the unsupervised iterative refinement procedure and seed lexicon heuristic from §3. However, we require the orthogonal mapping to be asymmetric: The hub language space should either remain unchanged or it should be transformed with the same operation for each of the $N - 1$ language pairs. We therefore derive an asymmetric version of the mapping framework from §3 that yields the exact same solution as the original.

Let $\boldsymbol{X}$ be the embedding matrix of the, $\boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_N$ the embedding matrices of the secondary languages, and $\boldsymbol{D}^{k,l}$ the dictionary between languages L_k and L_l. We induce a multilingual space $\boldsymbol{X}^m$, $\boldsymbol{Z}_1^m$, ... , $\boldsymbol{Z}_N^m$ in three main steps. First, the embeddings of each language are preprocessed by normalizing and whitening the embeddings, as described by Eqs. (2)-(6). Normalization consists of subsequently performing length normalization, mean

---

[2] Hubness is the phenomenon observed in a high-dimensional vector space where there are vectors, called hubs, which are the nearest neighbors to many vectors in the space.

[3] Note that $\boldsymbol{z}_j^{CL}$ being the nearest neighbor of $\boldsymbol{x}_i^{CL}$ does not imply that the inverse is also true.

[4] Due to the large search space, limiting the search space by truncating both vocabularies and their corresponding embedding matrices to the $C_{refinement}$ most frequent words results in better solutions and speeds up computation.

[5] The square root in the formulas is empirically motivated.

centering, and then again length normalization.

$$\text{ZCAwhiten}(\boldsymbol{W}) = \boldsymbol{W}(\boldsymbol{W}^\intercal \boldsymbol{W})^{-0.5} \quad (2)$$

$$\boldsymbol{X}^{'} = \text{normalize}(\boldsymbol{X}) \quad (3)$$

$$\boldsymbol{X}^{''} = \text{ZCAwhiten}(\boldsymbol{X}^{'}) \quad (4)$$

$$\boldsymbol{Z}_l^{'} = \text{normalize}(\boldsymbol{Z}_l) \quad (5)$$

$$\boldsymbol{Z}_l^{''} = \text{ZCAwhiten}(\boldsymbol{Z}_l^{'}) \quad (6)$$

After preprocessing, we rotate each secondary language L_l to a bilingual space between the hub language space and its own embedding space, as described by Eqs. (7)-(10). The calculations are analogous to the bilingual mapping procedure: the left and right singular vectors $\boldsymbol{U}_l$ and $\boldsymbol{V}_l$ of $\boldsymbol{X}^{''} \boldsymbol{D}^{k,l} \boldsymbol{Z}_l^{''\intercal}$ are the rotation matrices that project the preprocessed matrices $\boldsymbol{X}^{''}$ and $\boldsymbol{Z}_l^{''}$ to their bilingual space; this is formulated in Eqs. (7)-(8). The bilingual projection of $\boldsymbol{Z}_l^{''}$ can be reweighted by multiplying it with a given power q of the singular values matrix $\boldsymbol{S}_l$ of $\boldsymbol{X}^{''\intercal} \boldsymbol{D}^{0,l} \boldsymbol{Z}_l^{''}$, Eq. (9). Intuitively, the reweighting operation makes the dimensions that correlate better across languages more important. Next, we restore the variance information of $\boldsymbol{Z}_l^{'}$ by performing a dewhitening operation: we project back to the monolingual space, multiply with the inverse of the whitening matrix, and then project back to the bilingual space (Eq. (10)).[6]

$$\boldsymbol{U}_l \boldsymbol{S}_l \boldsymbol{V}_l^\intercal = \text{SVD}(\boldsymbol{X}^{''\intercal} \boldsymbol{D}^{0,l} \boldsymbol{Z}_l^{''}) \quad (7)$$

$$\boldsymbol{Z}_{l,bi(l)} = \boldsymbol{Z}_l^{''} \boldsymbol{V}_l \quad (8)$$

$$\boldsymbol{Z}_{l,bi(l)}^{'} = \boldsymbol{Z}_{l,bi(l)} \boldsymbol{S}_l^q \quad (9)$$

$$\boldsymbol{Z}_{l,bi(l)}^{''} = \boldsymbol{Z}_{l,bi(l)}^{'} \boldsymbol{V}_l^\intercal (\boldsymbol{Z}_l^{'\intercal} \boldsymbol{Z}_l^{'})^{0.5} \boldsymbol{V}_l \quad (10)$$

Finally, we project $\boldsymbol{Z}_{l,bi(l)}^{''}$ to the space of the hub language in Eq. (11)). The multilingual space for the hub language is simply the monolingual embedding space after preprocessing, see Eq. (12).

$$\boldsymbol{Z}_l^m = \boldsymbol{Z}_{l,bi(l)}^{''} \boldsymbol{U}_l^\intercal \quad (11)$$

$$\boldsymbol{X}^m = \boldsymbol{X}^{'} \quad (12)$$

For the bilingual case this formulation is equivalent to the symmetric mapping introduced in §3: one can easily verify that the dot products between the mapped spaces simplify to the same formula.

Incremental Hub Space (IHS). SHS enables language interactions only indirectly through the hub language. Ideally, a multilingual method should incorporate interdependencies between all languages. We hypothesize that, especially when mapping a language distant to the hub language, it is beneficial to incorporate the structural similarities with all other languages as a regularization mechanism to find a more robust mapping.

We therefore propose the incremental hub space (IHS) model. It incrementally expands the multilingual space $\boldsymbol{X}^m$ and takes into account all languages in the current multilingual space when adding a new language. First, we define a language order and initialize the space to the preprocessed embedding space of language L_0. Next, following the order, we gradually add new languages to the space: in each iteration we rotate the preprocessed embedding space $\boldsymbol{Z}_l^{''}$ of language l to the multilingual space by minimizing the dot product between embeddings of the translations between language l and all the languages in the multilingual space. The recipe to calculate the cross-lingual embedding $\boldsymbol{Z}_l^m$ is similar to the SHS model: the preprocessing and postprocessing steps are the same, but the projection matrices are calculated with Eq. (14) instead of Eq. (7) and conform with the new objective from Eq. (13). After convergence, $\boldsymbol{Z}_l^m$ is added to the multilingual space $\boldsymbol{X}^m$: $\boldsymbol{X}_l^m = \boldsymbol{Z}_l^m$.

$$\underset{\boldsymbol{W}_{xl}, \boldsymbol{W}_{zl}}{\arg\max} \sum_{k=0}^{l-1} tr(\boldsymbol{X}_k^m \boldsymbol{W}_{xl} (\boldsymbol{D}^{k,l} \boldsymbol{Z}_l^{''} \boldsymbol{W}_{zl})^\intercal) \quad (13)$$

$$\text{subject to } \boldsymbol{W}_{xl} \boldsymbol{W}_{xl}^\intercal = \boldsymbol{I}, \boldsymbol{W}_{zl} \boldsymbol{W}_{zl}^\intercal = \boldsymbol{I}$$

$$\boldsymbol{U}_l \boldsymbol{S}_l \boldsymbol{V}_l^\intercal = \text{SVD}(\boldsymbol{C}) \quad (14)$$

$$\boldsymbol{C} = (\boldsymbol{X}_0^m)^\intercal \boldsymbol{D}^{0,l} \boldsymbol{Z}_l^{''} || \ldots ||(\boldsymbol{X}_{l-1}^m)^\intercal \boldsymbol{D}^{l-1,l} \boldsymbol{Z}_l^{''}$$

where $||$ denotes concatenation along the row axis

In supervised settings this approach would be impractical as it requires bilingual dictionaries $\boldsymbol{D}^{k,l}$ for all language pairs k, l, and not only with the hub language. However, within an unsupervised framework this constraint is lifted.

5 Experimental Setup

Tasks and Datasets. The induced embeddings are evaluated in three tasks: bilingual lexicon induction (BLI), multilingual dependency parsing, and multilingual document classification. BLI is currently the most widely used method to evaluate bilingual embedding spaces. Although BLI performance is not the primary goal of our multilingual

---

[6] Note that the projection matrices that map from the bilingual to the monolingual spaces are given by the inverses of $\boldsymbol{U}_l$ and $\boldsymbol{V}_l$. Since the matrices are orthogonal their inverses are equal to their transposes.

embedding spaces, it provides a fast means to address the following questions: **1)** Is the incremental construction of multilingual embedding spaces indeed an effective regularization method? Is it still necessary to perform value dropping in this case?[7]; **2)** Is the reweighting of embedding spaces also beneficial for BLI in multilingual settings?; **3)** Does multilingual training improve bilingual lexicon induction performance? How do our multilingual models compare to each other and to the state-of-the-art unsupervised BLI methods?

We report *Precision@1 (P@1)* BLI performance on two standard BLI datasets. 1) DINUARTETXE is the extended version of Dinu et al. (2015)'s dataset, used by Artetxe et al. (2018a).[8] It consists of bilingual dictionaries for English-German, English-Italian, English-Spanish and English-Finnish. Monolingual embeddings are provided, based on the CBOW model trained on the WaCKy corpora for English, Italian and German (Baroni et al., 2009), the monolingual WMT Common Crawl corpus for Finnish, and the WMT News Crawl for Spanish (Bojar et al., 2015). The test dictionary sizes are between 1.869 and 1,993 word pairs for each language pair. As our methods are unsupervised, we do not use the provided training dictionaries. 2) EURMUSEWIKI is the dataset compiled from dictionaries for all combinations of the following European languages: English, German, Spanish, French, Italian, and Portuguese. The test set sizes range between 1,513 and 3,660 word pairs. We rely on publicly available monolingual fastText embeddings (Bojanowski et al., 2016).[9] All monolingual word embeddings are 300-dimensional and represent the 200k most frequent words as in prior work (Dinu et al., 2015; Conneau et al., 2018).

Multilingual dependency parsing and multilingual document classification tasks assess the embeddings w.r.t. their actual goal: enabling transfer learning across multiple languages. The word embeddings are used as feature vectors for classifiers in the respective downstream tasks. We address the following research questions: **4)** Is reweighting of embedding spaces also beneficial in downstream tasks?; **5)** How do our methods compare against supervised multilingual embedding models?

We rely on the evaluation platform of Ammar et al. (2016) for the downstream tasks[10]: the users submit their multilingual embeddings and obtain the final scores, which ensures that the classifiers we use are identical to the ones used in prior work (Ammar et al., 2016; Duong et al., 2017).

REUTERSMLDC is a multilingual document classification dataset covering seven languages: English, German, French, Italian, Spanish, Danish, and Swedish. The final performance is reported as the average accuracy across all languages. The respective training and test set consist of 7,000 and 13,058 documents. The dataset is well balanced in the number of documents per language.[11] The architecture of the document classifier is the average perceptron used by Klementiev et al. (2012).

MLPARSING is a multilingual dependency parsing dataset sampled from the Universal Dependencies 1.1 corpus (Agić et al., 2015)[12]. It contains 12 languages: English, German, French, Spanish, Italian, Bulgarian, Czech, Danish, Swedish, Greek, Finnish, and Hungarian. The respective training and test set contain 6,748 and 1,200 sentences. The test set contains 100 sentences for each language, while for the training set the number of sentences for a language ranges between 98 and 6,694. The parser used is the stack-LSTM parser by Dyer et al. (2015). The parser is not allowed to use any part-of-speech and morphology features, and keeps the input word embeddings fixed to isolate the effect of the evaluated embeddings on the parsing performance (Ammar et al., 2016). The reported scores are UAS scores averaged across languages.

For comparison with related work, we train 512-dimensional monolingual embeddings on the text collections used by Ammar et al. (2016) and Duong et al. (2017). The monolingual embeddings are again trained using fastText.

Training Setup. In all experiments, we set the following hyper-parameters to values that were used in prior research (Conneau et al., 2018; Artetxe et al., 2018a). When constructing the seed lexicon the 4,000 most frequent words of each language are considered ($C_{seed} = 4,000$), and during the refinement step the 20,000 most frequent words

---

[7] Value dropping significantly slows down training time and leads to non-deterministic outcomes. However, it has been shown to be crucial in the bilingual setting to obtain good results when mapping distant language pairs in previous work (Artetxe et al., 2018a).

Model	Drop	EN-DE	EN-IT	EN-ES	EN-FI	Avg
SHS	no	48.00	45.93	36.53	0.14	32.65
SHS	yes	47.51	45.60	36.33	31.92	**40.34**
IHS	no	47.93	45.93	36.07	31.04	**40.24**
IHS	yes	47.45	45.48	36.43	30.97	40.08

Table 1: Comparison of *P@1* scores for SHS and IHS models with and without value dropping (*Drop*) on the DINUARTETXE BLI dataset.

of each language are used ($C_{refinement} = 20,000$). When using value dropping, the keep probability p is initialized is 0.1, $N_{patience}$ is set to 50, and the stochastic multiplier is set to 2. Dictionaries are constructed symmetrically: from hub language(s) to the secondary language and from the secondary language to the hub language(s): during refinement each dictionary consists of $2 \times 20,000$ translation pairs. We use CSLS with $k = 10$ nearest neighbors following the setup of Conneau et al. (2018).

6 Results and Discussion

Experiment 1: Value Dropping. In the first experiment, we investigate if the expensive value dropping procedure is a necessary condition for mapping between distant language pairs in our multilingual framework. Table 1 provides results on the DINUARTETXE dataset for SHS and IHS models. For IHS we process the languages in the following order: English, German, Italian, Spanish, Finnish. When using value dropping we report the average and best results across five runs.

We observe that value dropping is crucial for SHS to succeed for English-Finnish. However, it is not necessary for IHS. This supports our hypothesis that mapping a language to a multilingual hub space serves a type of regularization that can substitute value dropping. As validated later, it is still important to avoid adding distant languages early with the incremental IHS procedure.[13,14]

Experiment 2: Comparative BLI Performance and Reweighting. In this experiment, we test if reweighting embedding spaces is beneficial for BLI in our multilingual setup, and also compare our methods against state-of-the-art BLI methods. Table 2 and Table 3 show the results for SHS and IHS with reweighting coefficients q of 0, 0.5 and 1 on DINUARTETXE and EURMUSEWIKI, respectively. We also include the state-of-the-art results of Artetxe et al. (2018a) and Chen and Cardie (2018) for reference. The EURMUSEWIKI benchmark evaluates BLI performance on all language pair combinations of its six languages and does this in both directions (EN-DE, DE-EN, EN-ES, ... IT-PT, PT-IT) yielding 28 $P@1$ scores per model. For clarity, we report the average $P@1$ scores per language as well as the global $P@1$ average. Following Experiment 1, all results for SHS are obtained using value dropping (again averaged across 5 different runs), while we do not use it with IHS. The SHS hub language is English, and the language orders for IHS are EN, DE, IT, ES, FI for DINUARTETXE, and EN, DE, ES, FR, IT, PT for EURMUSEWIKI.

The scores reveal that reweighting the embedding spaces is indeed still beneficial for BLI when mapping to a multilingual space. Both SHS and IHS obtain best results with the reweighting coefficient $q = 0.5$. When comparing SHS and IHS, we see that for language pairs involving English (the SHS hub language) SHS obtains slightly better results, but for the other language pairs IHS outperforms SHS slightly. This is no surprise as IHS by design incorporates dependencies between all languages when learning the projection matrices, though it is striking that mapping to a single hub language is still a strong BLI baseline. For both datasets IHS obtains BLI performance on par with the state-of-the-art: on DINUARTETXE, SHS and IHS ($q = 0.5$) obtain scores similar to (Artetxe et al., 2018a); on EURMUSEWIKI IHS ($q = 0.5$) slightly outperforms Chen and Cardie (2018) for all languages except Spanish. Although optimizing BLI performance is not the main goal of this work, these results verify the soundness of our methods.

Experiment 3: Language Order. Next, we investigate 1) the influence of the hub language choice for SHS, and 2) the impact of the language order for IHS. We run both SHS and IHS with reweighting 0.5 on DINUARTETXE. SHS is with value dropping (results are again averaged over 5 runs), and for IHS we do not use value dropping.

We find that the SHS model is sensitive to the hub language: the best average scores are obtained when using English (41.6%) or German (41.0%).

---

[13] For instance, when using IHS with a language order that starts with English and Finnish, value dropping still prevents bad performance for Finnish. However, this is not a problem in practice as the language order can be easily predetermined according to various language similarity heuristics.

[14] We further validated the robustness of our approach on other distant language pairs but moved this experiment to the appendix due to space constraints.

Model	q	EN-DE	EN-IT	EN-ES	EN-FI	All
Artetxe	2×0.5	48.13	**48.19**	37.33	**32.63**	**41.57**
SHS	0	47.51	45.60	36.33	31.92	40.34
IHS	0	47.93	45.93	36.07	31.04	40.24
SHS	0.5	**48.69**	47.67	37.51	32.40	**41.57**
IHS	0.5	48.60	47.73	37.53	31.74	41.40
SHS	1	47.77	47.91	37.00	31.82	41.13
IHS	1	48.00	**48.00**	**37.93**	31.46	41.35
IHS order	0.5	48.60	47.81	**38.24**	**33.22**	**41.96**

Table 2: BLI $P@1$ scores on DinuArtetxe: SHS and IHS are evaluated for different values of the reweighting parameter q. The state-of-the-art results (Artetxe et al., 2018a) are added as a reference. The result with the highest average score obtained when trying different language orders is in the bottom row.

Model	q	EN	DE	ES	FR	IT	PT	All
UME		79.57	70.46	**82.88**	82.01	80.69	80.13	79.29
SHS	0	80.04	68.24	80.95	80.10	78.71	77.96	77.67
IHS	0	79.61	69.52	82.35	81.26	80.00	79.02	78.63
SHS	0.5	**80.34**	70.16	82.15	81.65	80.31	79.78	79.07
IHS	0.5	79.91	**70.77**	82.68	**82.08**	**81.08**	**80.47**	**79.50**
SHS	1	79.61	69.59	81.53	81.10	79.74	79.47	78.51
IHS	1	79.05	69.99	81.63	81.23	80.13	79.68	78.62

Table 3: BLI $P@1$ scores on EurMuseWiki averaged per language: SHS and IHS are tested for different values of the reweighting parameter q. The results of Chen and Cardie (2018) (UME) are added as a reference.

With Italian, the average score drops to 40.4%, mainly due to worse performance on English and German. With Spanish, the average score further drops to 31.6%, as Spanish and Finnish completely fail to align even when using value dropping. With Finnish, EN-ES alignment becomes unstable, while $P@1$ for EN-DE and EN-IT drops 5.5% and 3.7% compared to the case with English as the hub. These results indicate that the hub language has to be chosen carefully to avoid instability issues.

For IHS, we evaluate all 120 order permutations on DinuArtetxe. The best performing order (EN-DE-ES-FI-IT) achieves an average accuracy of 41.96%, see the last row in Table 2. The full results, not reported due to space constraints[15] confirm our hypothesis that distant languages (Finnish) should be mapped at the end: when using Finnish as one of the first two languages performance drops significantly. EN-FI scores drop below 1% and the results for all other language pairs are also suboptimal.

Experiment 4: Downstream Tasks. In this experiment, we investigate the effect of reweighting input word embeddings on downstream model performance, and compare SHS and IHS to several supervised methods that use cross-lingual supervision. Table 4 reports the results for SHS and IHS with q set to 0 and 0.5 on the ReutersMLDC and MLParsing benchmarks,[16] along with the results from related work. For SHS the hub language is English and for IHS the language order is English, German, Spanish, Italian, French, Bulgarian, Czech, Danish, Finnish, Greek, Hungarian, and Swedish. We again use SHS with value dropping and IHS without it. The results in Table 4 are comparable: all methods were trained on the same text corpora (i.e., the collections of Ammar et al. (2016)), but our methods do not use parallel corpora nor bilingual dictionaries.

Model	q	Parsing	MLDC
Invariance (Huang et al., 2015)		59.80	91.10
MultiSkip (Luong et al., 2015)		57.70	90.40
MultiCluster (Ammar et al., 2016)		61.00	92.10
MultiCCA (Ammar et al., 2016)		58.70	92.10
(Duong et al., 2017)		61.20	90.80
SHS	0	63.48	92.59
IHS	0	**65.77**	**92.72**
SHS	0.5	62.23	92.63
IHS	0.5	63.42	92.56

Table 4: Results on the MLParsing (dependency parsing) and ReutersMLDC (document classification) benchmarks: SHS and IHS are compared with and without reweighting and we show the state-of-the-art results of supervised embedding mapping methods as a reference. The results for Invariance, MultiSkip, MultiCluster, MultiCCA are from (Ammar et al., 2016).

A first interesting result is that, contrary to the BLI task, reweighting the embeddings is not beneficial for multilingual dependency parsing and document classification. This can be explained by the fact that the reweighted embedding spaces are no longer isomorphic to the original monolingual embedding spaces, hence important patterns in the embedding space could be distorted. Further, we notice that both SHS and IHS improve over the best reported results on the ReutersMLDC and MLParsing benchmarks. This result is surprising given that all the reported baselines require supervision to induce the multilingual embedding spaces. Further, we again find that the best results are obtained with IHS, most notably for dependency parsing for which the difference in UAS scores between

---

[15] The full results can be found in Appendix A.2.

[16] Since the languages covered in MLParsing is a superset of the languages in ReutersMLDC, we use the same multilingual embedding space for both tasks.

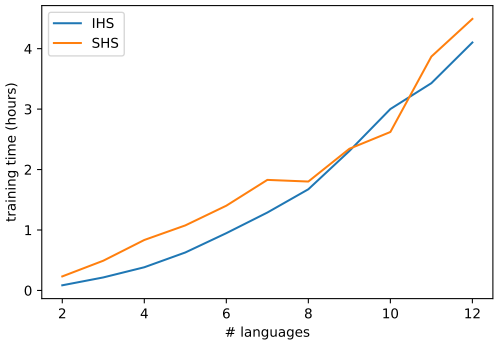

Figure 1: Training times for SHS and IHS for an increasing number of languages.

the best IHS and SHS models is 2.29%.

Experiment 5: Time Complexity. In this experiment, we study how training time of SHS and IHS behaves as a function of the number of languages that are mapped. The singular value decompositions are more expensive for IHS as the matrices grow linearly with the number of languages (see Eq. (14)) whereas for SHS they are constant. On the other hand, IHS does not require the use of value dropping. Figure 1 plots training time for IHS and SHS conditioned on the number of languages. The estimates are based on training on a single Nvidia Titan Xp GPU. We find that SHS with value dropping and IHS without value dropping have similar training times, IHS being a bit more efficient when mapping 7 languages or less. Mapping 12 languages takes approximately four hours for both methods.

7 Conclusion

We proposed two novel methods for learning multilingual word embeddings (MWEs) without any cross-lingual supervision. The better-performing incremental hub space model (IHS) is the first unsupervised MWE method that combines three desirable properties: 1) It incorporates interdependencies between all targeted languages; 2) It works for distant language pairs; and 3) It is both deterministic and robust, that is, it does not produce degenerate solutions. Our evaluation on standard benchmarks has proven that the IHS method induces multilingual word embeddings that are competitive with the state of the art in bilingual lexicon induction. Moreover, we have shown that IHS outperforms even supervised models on downstream tasks of multilingual dependency parsing and document classification, and this anomaly requires further investigation in future work. Furthermore, we looked at the influence of reweighting the dimensions of the embedding spaces according to their cross-correlations with the hub language space(s) and found that, while it improves performance for the BLI task, it is harmful to downstream cross-lingual transfer tasks. These empirical observations stress the requirement to include comprehensive evaluation protocols for cross-lingual word embedding models in future research.

Acknowledgments

We thank the reviewers for their insightful comments. IV would like to thank Goran Glavaš and Anders Søgaard for interesting discussions, and the ERC Consolidator Grant LEXICAL (no 648909) for the support. GH, BV and MFM would like to thank Stijn Jaques, Evelyn Reynders and Evelien Verbaenen for the fruitful collaboration and Flanders Innovation & Entrepreneurship (VLAIO) for funding TELLMI within the ITEA 3 project PAPUD.

A Appendices

A.1 Experiment with Distant Language Pairs

In this section, we report an additional bilingual lexicon induction experiment that further supports our claim that the IHS model is still applicable when mapping languages with different characteristics, we performed an additional bilingual lexicon induction experiment on the following language pairs: Dutch-Turkish, Spanish-Hungarian, and Finnish-Bulgarian. We induced multilingual spaces with the IHS model and the model of Chen and Cardie (2018) using the publicly available monolingual embeddings trained with fastText. IHS is run with reweighting ($q = 0.5$), without value dropping, and with the following language order Dutch, Spanish, Bulgarian, Finnish, Hungarian, Turkish. The model of Chen and Cardie (2018)[17] is run with Dutch as the target language and with the recommended hyper-parameters. For evaluation, we obtained dictionaries for each language pair using Panlex (Kamholz et al., 2014).

The results are reported in Table 5. We find average BLI accuracy scores of 28.24% (IHS) and 28.20% (Chen and Cardie, 2018). The fact that both models are robust to distant languages without using value dropping further supports our hypothesis that mapping multiple languages simultaneously is an effective regularization mechanism.

A.2 Results Experiment 3

In this section, we report all the results of Experiment 3 of the paper. In Table 6 we report the results for the SHS model with different hub languages and in Table 7 we report the performance for IHS

Abstract

We introduce a curriculum learning approach to adapt generic neural machine translation models to a specific domain. Samples are grouped by their similarities to the domain of interest and each group is fed to the training algorithm with a particular schedule. This approach is simple to implement on top of any neural framework or architecture, and consistently outperforms both unadapted and adapted baselines in experiments with two distinct domains and two language pairs.

1 Introduction

Neural machine translation (NMT) performance often drops when training and test domains do not match and when in-domain training data is scarce (Koehn and Knowles, 2017). Tailoring the NMT system to each domain could improve performance, but unfortunately high-quality parallel data does not exist for all domains. Domain adaptation techniques address this problem by exploiting diverse data sources to improve in-domain translation, including *general domain* data that does not match the domain of interest, and *unlabeled domain* data whose domain is unknown (e.g. webcrawl like Paracrawl).

One approach to exploit unlabeled-domain bitext is to apply *data selection* techniques (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013) to find bitext that are similar to in-domain data. This selected data can additionally be combined with in-domain bitext and trained in a continued training framework, as shown in Figure 1. Continued training or fine-tuning (Luong et al., 2015; Freitag and Al-Onaizan, 2016; Chu et al., 2017) is an adaptation technique where a model is first trained on the large general domain data, then used as initialization of a new model which is further trained on in-domain bitext. In our framework, the selected samples are concatenated with in-domain data, then used for continued training. This effectively increases the in-domain training size with "pseudo" in-domain samples, and is helpful in continued training (Koehn et al., 2018).

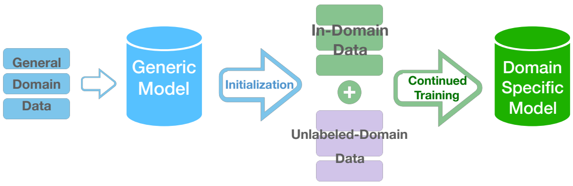

Figure 1: Workflow of our domain adaptation system.

A challenge with employing data selection in continued training is that there exists no clear-cut way to define whether a sample is sufficiently similar to in-domain data to be included. In practice, one has to define a threshold based on similarity scores, and even so the continued training algorithm may be faced with samples of diverse similarities. We introduce a new domain adaptation technique that addresses this challenge.

Inspired by curriculum learning (Bengio et al., 2009), we use the similarity scores given by data selection to rearrange the order of training samples, such that *more similar examples are seen earlier and more frequently during training*. To the best of our knowledge, this is the first work applying curriculum learning to domain adaptation.

We demonstrate the effectiveness of our approach on TED Talks and patent abstracts for German-English and Russian-English pairs, using two distinct data selection methods, Moore-Lewis method (Moore and Lewis, 2010) and cynical data selection (Axelrod, 2017). Results show that our approach consistently outperforms standard continued training, with up to 3.22 BLEU improvement. Our S^4 error analysis (Irvine et al., 2013) reveal that this approach reduces a reasonable number of SENSE and SCORE errors.

2 Curriculum Learning for Adaptation

Weinshall and Cohen (2018) provide guidelines for curriculum learning: “A practical curriculum learning method should address two main questions: how to rank the training examples, and how to modify the sampling procedure based on this ranking.” For domain adaptation we choose to estimate the difficulty of a training sample based on its distance to the in-domain data, which can be quantified by existing data selection methods (Section 2.1). For the sampling procedure, we adopt a probabilistic curriculum training (CL) strategy that takes advantage of the spirit of curriculum learning in a nondeterministic fashion without discarding the good practice of original standard training policy, like bucketing and mini-batching.

2.1 Domain Similarity Scoring

We adopt similarity metrics from prior work on data selection to score examples for curriculum learning. Let I be an in-domain corpus, and N be a unlabeled-domain data set. Data selection models rank sentences in N according to a domain similarity measure with respect to I, and choose top n samples from N by a cut-off threshold for further training purpose. We examine two data selection methods, Moore-Lewis method (Moore and Lewis, 2010) and cynical data selection (Axelrod, 2017).

Moore-Lewis Method Each sentence s in N is assigned a *cross-entropy difference score*,

$$H_I(s) - H_N(s), \qquad (1)$$

where $H_I(s)$ is the per-word cross-entropy of s according to a language model trained on I, and $H_N(s)$ is the per-word cross-entropy of s according to a language model trained on a random sample of N with roughly the same size as I. A lower cross-entropy difference indicates that s is more like the in-domain data and less like the unlabeled-domain data.

Cynical Data Selection Iteratively select sentence s from N to construct a training corpus that would approximately model I. At each iteration, each sentence is scored by the expected cross-entropy change from adding it to the already selected subset of N. The selected sentence is the one which most decreases H_n, the cross-entropy between previously selected n-sentence corpus and I.

2.2 Curriculum Learning Training Strategy

We identify two general types of curriculum learning strategy. The *deterministic* curriculum (c.f. Kocmi and Bojar (2017)) trains on a fixed order of samples based on their scores (e.g. “easy-to-hard” or “more similar to less”). While simple to motivate, this may not always perform well because neural methods benefit from randomization in the minibatches and multiple epochs. In contrast, the *probabilistic* curriculum (Bengio et al., 2009) works by dividing the training procedure into distinct phases. Each phase creates a random sample from the entire pool of data, but earlier phases sample the “easier” or “more similar” sentence with higher probability.. Since each phase can be viewed as creating a new training dataset, all the well-tested tricks of the trade for neural network optimization can be employed.

In this paper, we use the same probabilistic curriculum strategy and code base[1] as Zhang et al. (2018). The main difference here is the application to domain adaptation. The proposed strategy is summarized as follows:

- Sentences are first ranked by similarity scores and then distributed evenly into shards, such that each shard contains samples with similar similarity criteria values.
- The training process is segmented into consecutive *phases*, where only a subset of shards are available for training.
- During the first phase, only the easiest shard is presented. When moving to the next phase, the training set will be increased by adding the second easiest shard into it, and so on. Easy shards are those that are more similar to the in-domain data, as quantified by either Moore-Lewis or Cynical Data Selection.
- The presentation order of samples is not deterministic. (1) Shards within one curriculum phase are shuffled, so they are not necessarily visited by the order of similarity level during this phase. (2) Samples within one shard are bucketed by length and batches are drawn randomly from buckets.

3 Experiments and Results

We evaluate on four domain adaptation tasks. The code base is provided to ensure reproducibility.[2]

3.1 Data and Setup

General Domain Data We have two general domain datasets, Russian-English (ru) and German-English (de). Both are a concatenation of OpenSubtitles2018 (Lison and Tiedemann, 2016) and WMT 2017 (Bojar et al., 2017), which contains data from several domains, e.g. parliamentary proceedings (Europarl, UN Parallel Corpus), political/economic news (news commentary, Rapid corpus), and web-crawled parallel corpus (Common Crawl, Yandex, Wikipedia titles). We performed sentence length filtering (up to 80 words) after tokenization, ending up with 28 million sentence pairs for German and 51 million sentence pairs for Russian.

In-domain Data We evaluate our proposed methods on two distinct domains per language pair:

- TED talks: data-split from Duh (2018).
- Patents: from the World International Property Organization COPPA-V2 dataset (Junczys-Dowmunt et al., 2016).

We randomly sample 15k parallel sentences from the original corpora as our in-domain bitext.[3] We also have around 2k sentences of development and test data for TED and 3k for patent.

Unlabeled-domain Data For additional unlabeled-domain data, we use web-crawled bitext from the Paracrawl project.[4] We filter the data using the Zipporah cleaning tool (Xu and Koehn, 2017), with a threshold score of 1. After filtering, we have around 13.6 million Paracrawl sentences available for German-English and 3.7 million Paracrawl sentences available for Russian-English. Using different data selection methods, we include up to the 4096k and 2048k sentence-pairs for our German and Russian experiments, respectively.

Data Preprocessing All datasets are tokenized using the Moses (Koehn et al., 2007) tokenizer. We learn byte pair encoding (BPE) segmentation models (Sennrich et al., 2016) from general domain data. The BPE models are trained separately for each language, and the number of BPE symbols is set to 30k. We then apply the BPE models to in-domain and Paracrawl data, so that the parameters of the generic model can be applied as an initialization for continued training. Once we have a converged generic NMT model, which is very expensive to train, we can adapt it to different domains, without building up a new vocabulary and retraining the model.

NMT Setup Our NMT models are developed in Sockeye[5] (Hieber et al., 2017). The generic model and continued training model are trained with the same hyperparameters. We use the seq2seq attention architecture (Bahdanau et al., 2015) with 2 LSTM layers for both encoder and decoder, and 512 hidden nodes in each layer. The word embedding size is also set to 512. Our models apply Adam (Kingma and Ba, 2014) as the optimizer, with an initial learning rate 0.0003. The learning rate is multiplied by 0.7 whenever validation perplexity does not surpass the previous best in 8 checkpoints.[6] We use minibatches of 4096 words. Training stops when the perplexity on the development set has not improved for 20 checkpoints (1000 updates/batches per checkpoint).

Domain Similarity Scoring Setup To get similarity scores, we build 5-gram language models on the source side[7] with modified Kneser-Ney smoothing using KenLM (Heafield, 2011).

Curriculum Learning Setup The number of batches in each curriculum phase is set to 1000. We split the training data into 40 shards[8], with all the 15k in-domain data in the first shard, and Paracrawl data split into the remaining 39 shards.

3.2 Experimental Comparison

Our goal is to empirically test whether the proposed curriculum learning method improves translation quality in the continued training setup of

---

[2] `https://github.com/kevinduh/sockeye-recipes/tree/master/egs/curriculum`

[3] Appendix A explains our choice of 15k in detail.

[4] `https://www.paracrawl.eu/`

[5] `github.com/awslabs/sockeye`

[6] The Adam optimizer for continued training model is initialized without reloading from the trained generic model.

[7] Appendix D also shows the effect of using language models built from target side and both sides.

[8] After experimenting with various values from 5 to 100 (Appendix B), we found best performance can be achieved at 40 shards.

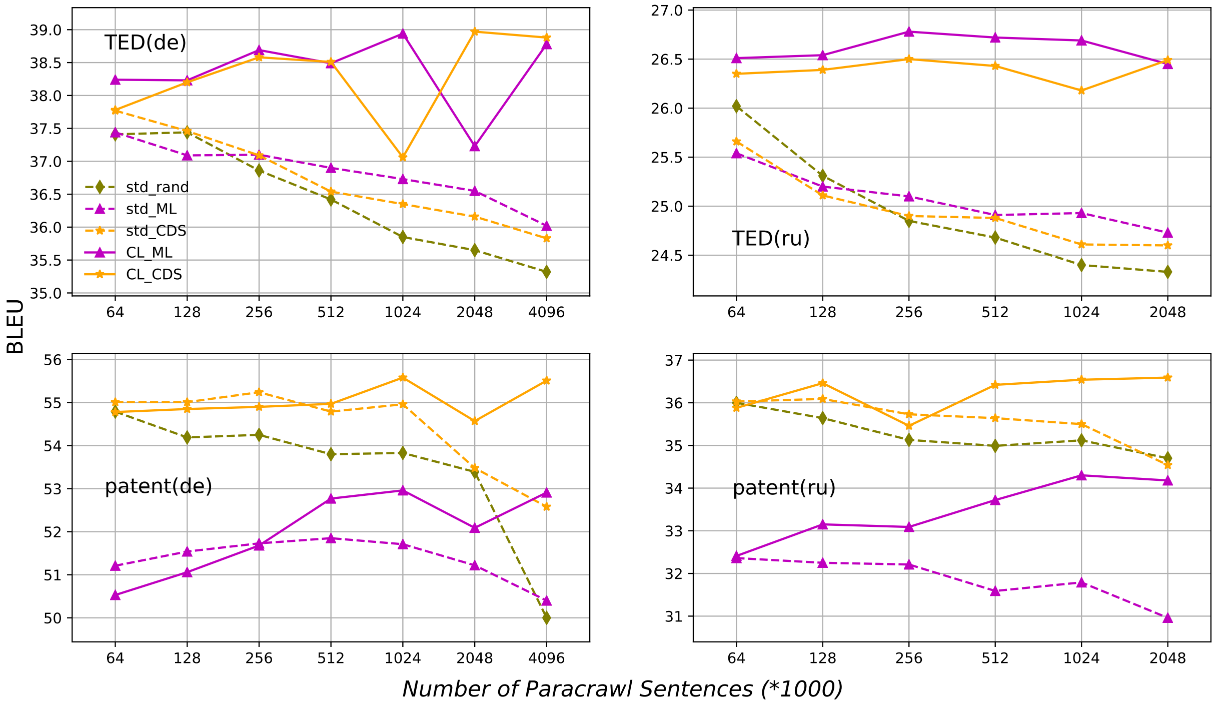

Figure 2: BLEU of adapted models using a concatenation of in-domain and varying amounts of Paracrawl data.

Figure 1. We compare two approaches to continued training: (1) the standard approach reads batches of in-domain and selected Paracrawl in random order; (2) the proposed curriculum learning approach reads these batches according to a schedule. We run the comparison with two data selection methods, leading to four systems:

- **std_ML**: standard continued training with Moore-Lewis scores
- **CL_ML**: curriculum learning approach to continued training with Moore-Lewis scores
- **std_CDS**: standard continued training with scores from Cynical Data Selection
- **CL_CDS**: curriculum learning approach to continued training with scores from Cynical Data Selection

For reference, we show results of the generic model (**GEN**), the model trained from scratch with in-domain data (**IN**), the model continued trained on in-domain data only (**IN_CT**), and a standard continued training model using a random subset (rather than ML or CDS scores) of the concatenated in-domain and Paracrawl data (**std_rand**).

3.3 Results

Table 1 summarizes the key results, where we continue train on 15k in-domain samples and 4096k Paracrawl samples (for de) or 2048k Paracrawl samples (for ru):

	TED(de)	TED(ru)	patent(de)	patent(ru)
GEN	34.59	23.40	35.95	23.41
IN	2.53	1.76	12.09	16.81
IN_CT	36.16	25.04	54.70	35.61
std_rand	35.32	24.33	50.00	34.70
std_ML	36.02	24.73	50.40	30.96
CL_ML	38.78	26.45	52.91	34.18
Δ_ML	2.76	1.72	2.51	3.22
std_CDS	35.83	24.60	52.58	34.54
CL_CDS	**38.88**	**26.49**	**55.51**	**36.59**
Δ_CDS	3.05	1.89	2.93	2.05

Table 1: BLEU of unadapted & adapted models. Δ shows improvement of **CL** over **std**.

- The baseline BLEU scores confirm the need for domain adaptation. Using only the 15k in-domain samples alone (IN) is not sufficient to train a strong domain specific model, yielding BLEU scores as low as 2.53 on TED(de) and 1.76 on TED(ru). The model trained with a large amount of general domain data (GEN) is a stronger baseline, with BLEU scores of 34.59 and 23.40.
- Standard continued training is not robust to samples that are noisy and less similar to in-domain. As expected, continued training on in-domain data (IN_CT) improves BLEU significantly, by up to 18.74 BLEU on patent(de). However, when adding Paracrawl data, the standard continued training strategy (std_rand, std_ML, std_CDS) consistently performs worse than IN_CT.
- Curriculum learning consistently improves BLEU score. Ranking examples using

Moore-Lewis (CL_ML) and Cynical Data Selection (CL_CDS) improve BLEU over their baselines (std_ML and std_CDS) by up to 3.22 BLEU points.

As an additional experiment, we report results on different amounts of Paracrawl data. Figure 2 shows how the curriculum uses increasing amounts of Paracrawl better than standard continued training. Standard continued training model hurts BLEU when too much Paracrawl data is added: for TED(de), there's a 1.94 BLEU drop when increasing CDS data from 64k to 4096k, and for patent(de), the decrease is 2.43 BLEU. By contrast, the curriculum learning models achieve a BLEU score that is as good or better as the initial model, even after being trained on the most dissimilar examples. This trend is clearest on the patent(ru) CL_ML model, where the BLEU score consistently rises from 32.41 to 34.18.

The method used to score domain relevance has a different impact on the TED domain (top plots) and on the patent domain (bottom plots). On the patent domain, which is more distant from Paracrawl, CDS significantly outperforms ML. Replacing ML with CDS improve BLEU from 2.18 to 4.05 BLEU points for standard models and 2.20 to 4.25 BLEU points for curriculum learning models. Interestingly, for patents, the Moore-Lewis method does not beat the random selection, even when curriculum learning is applied. For example, at 64k selected sentences for patent(de), std_rand gets 4.26 higher BLEU scores than CL_ML. By contrast on the TED domain, which is closer to Paracrawl, the Moore-Lewis method slightly outperforms cynical data selection. Due to these differences, we suggest trying different data selection methods with curriculum learning on new tasks; a potential direction for future work may be a curriculum that considers multiple similarity scores jointly.

4 Analysis

4.1 Comparison of Curriculum Strategies

We compare our approach to other curriculum strategies. *CL_reverse* reverses the presenting order of the shards, so that shards containing less similar examples will be visited first, *CL_scrambled* is a model that adopts the same training schedule as *CL*, but no data selection method and ranking is involved here — Paracrawl data are evenly split and randomly assigned to shards; *CL_noshuffle* is another curriculum learning model that does not shuffle shards in each curriculum phase.

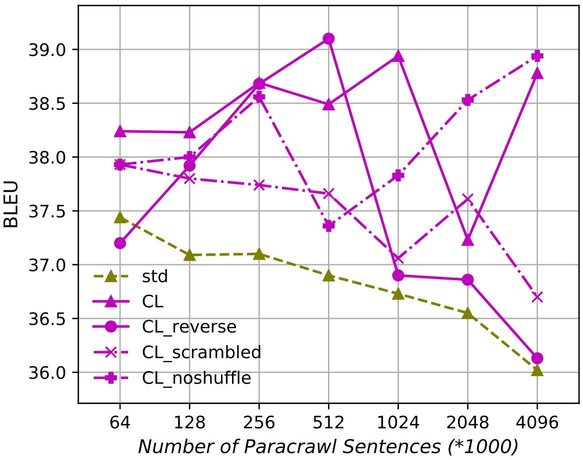

Figure 3: Comparison of various curriculum strategies on German-English TED corpora, where Moore-Lewis method is applied. [9]

Results from Figure 3 show that CL outperforms CL_reverse and CL_noshuffle for 5 out of 7 cases and outperforms CL_scrambled in 6 out of 7 cases. This suggests that it is beneficial to train on examples that are closest to in-domain first and to use a probabilistic curriculum. Analyzing the detailed difference between CL and CL_reverse would be interesting future work. One potential hypothesis why CL might help is that it first trains on a low-entropy subset of the data before moving on to the whole training set, which may have regularization effects.

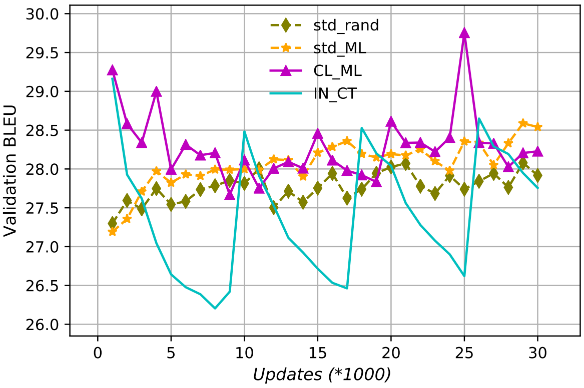

Figure 4: Learning curves for German-English TED NMTs. Except for IN_CT, the other three models all continued trained on the concatenation of in-domain and 1024k Paracrawl data.

---

[9] Each point represents a model trained to convergence on the fixed amount of in-domain and ParaCrawl data whose amount is specified by the x-axis.

4.2 Learning Curves

Learning curves (Figure 4) further illustrate the advantage of our method. Continued training on in-domain data only starts from a strong initialization (thanks to pre-training on large general domain data) but heavily oscillates over training without reaching the initial performance. This behavior may be due to the sparsity of the TED data: the small randomly sampled training set may not represent the development and test data well. Std_ML shows opposite behavior to IN_CT: it starts from a lower initial performance, and then gradually improves to a level comparable to IN_CT. Std_rand behaves similarly to std_ML—in other words, uniformly sampling from Paracrawl drags the initial performance down without helping with the final performance.

Compared to all above, the curriculum learning models start from a high initial performance, suffer much less oscillation than IN_CT, and gradually achieve the highest performance.[10]

4.3 Impact of Curriculum Learning on Lexical Choice: S^4 Analysis

How do translations improve when using curriculum learning? We characterize the impact of curriculum learning on lexical translation errors using the S^4 taxonomy of domain change errors introduced by Irvine et al. (2013) for phrase-based machine translation: (1) SEEN: incorrect translation for a source word that has never been seen in the training corpus; (2) SENSE: incorrect translation for a previously seen source word, whose correct translation (sense) has never been seen in the training corpus; (3) SCORE: a score error is made when the source word and its correct translation are both observed in training data, but the incorrect translation is scored higher than the correct alternative ; and (4) SEARCH: an error caused by pruning in beam search[11].

We extend this taxonomy to neural machine translation. As the unit of S^4 analysis is word alignment between a source word and a reference target word, we first run fast-align (Dyer et al., 2013) to get the source-target word alignments. After this, we follow the algorithm shown in Appendix C to give a summary of S^4 errors on the model's translation of test set.

Figure 5 shows the word translation results for the test set of German-English TED. Most of the errors are SCORE errors, while SEEN and SENSE errors are relatively rare. Curriculum learning significantly improves the adapted NMT systems at the word level — with 4096k Paracrawl data selected by CDS, curriculum continued training model can translate 554 more words correctly than the standard continued training model. This improvement mainly happens in SCORE errors: 1.75% of SCORE errors are corrected. SEEN and SENSE errors are also reduced by 0.02% and 0.026%, respectively. But overall, CL does not help much on SEEN errors.

4.4 Characteristics of Selected Data

We characterize the sentences chosen by different data selection methods, to understand their effect on adaptation as observed in Section 3.3.

Selected Sentences Overlap For each domain in German-English, we compute the overlap between the top n ML and CDS Paracrawl sentences. The overlap is as low as 3.69% for the top 64k sentences in the TED domain, and 8.43% for the patent domain. Even in the top 4096k sentences, there are still 46.25% and 65.40% different ones in TED and patent domain respectively. See Table 2 for examples of selected sentences.

Average Sentence Length The ML score prefers longer sentences and is more correlated with sentence length (See Figure 6) — the curve TED_ML is near linear, which might be a side-effect of sentence-length normalization. CDS produces sentences that better match the average sentence length in the in-domain corpus, which was also observed in Santamaría and Axelrod (2017).

Out-of-Vocabulary Words We count out-of-vocabulary (OOV) tokens in in-domain corpus based on the vocabulary of selected unlabeled-domain data (Figure 7). The CDS subsets cover in-domain vocabulary better than ML subsets as expected, since CDS is based on vocabulary coverage.

Unigram Distribution Distance How do unigram relative frequencies compare in the in-domain and selected Paracrawl data?

---

[10] When converged, IN_CT does not outperform CL_ML.

[11] We will only focus on the first three error categories in this paper for the purpose of model comparison.

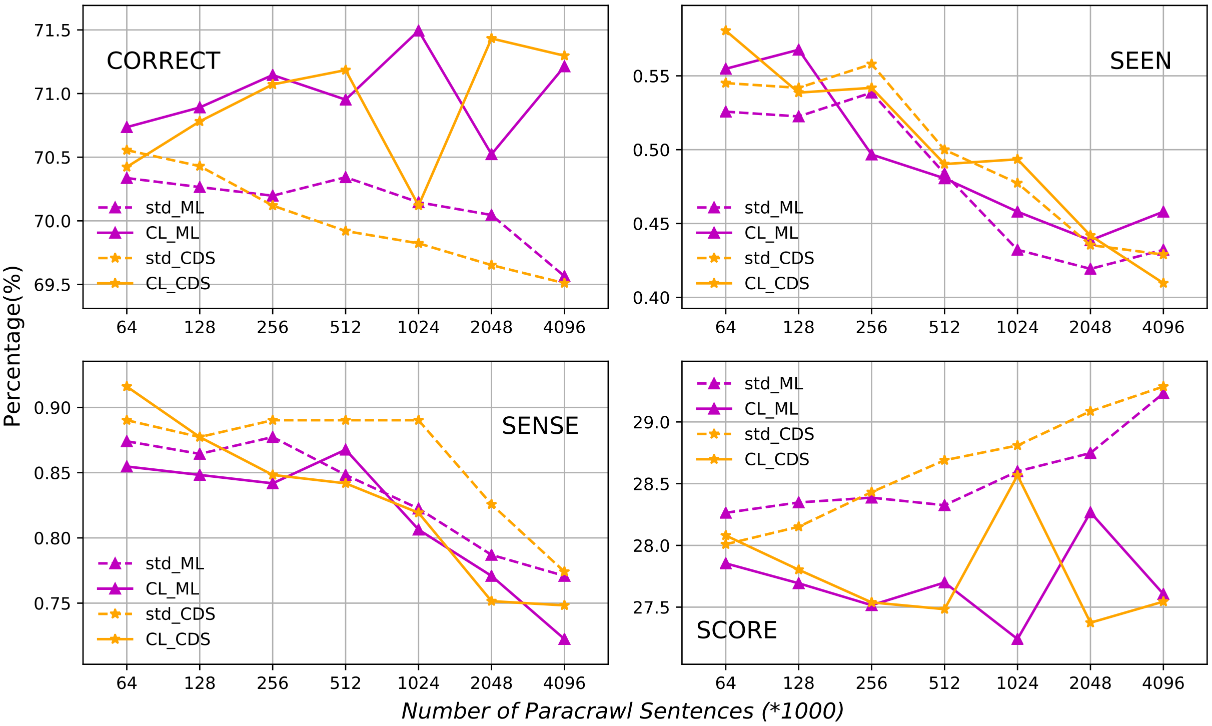

Figure 5: S^4 error analysis on German-English TED.

TED_ML	It changes the way we think; it changes the way we walk in the world; it changes our responses; it changes our attitudes towards our current situations; it changes the way we dress; it changes the way we do things; it changes the way we interact with people.
TED_CDS	But, on the other hand, this signifies that the right of self-determination, as a part of the proletarian peace program, possesses not a "Utopian" but a revolutionary character.
patent_ML	The sites x, y and z can accommodate a large variety of cations with x=na+, k+, ca2+, vacancy; y=mg2+, fe2+, al3+, fe3+, li+, mn2+ and z=al3+, mg2+ , fe3+, v3+, cr3+; while the t site is predominantly occupied by si4+.
patent_CDS	To select alternative viewing methods, such as for 3d-tv.

Table 2: The top ranked sentences selected from German-English Paracrawl corpus.

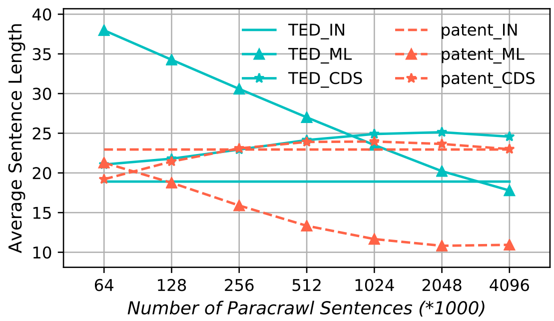

Figure 6: Average sentence length for increasing size of Paracrawl data. This is calculated on the source side of German-English pairs. TED_IN stands for TED corpus. TED_ML and TED_CDS represent the Paracrawl samples selected by ML and CDS methods.

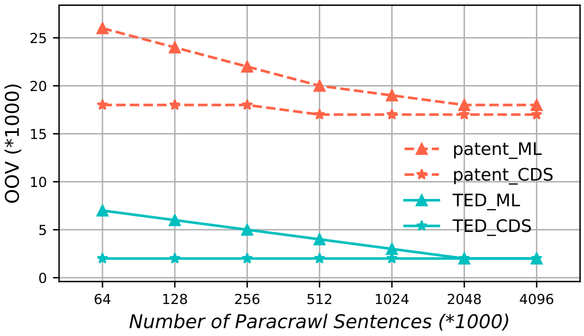

Figure 7: Number of OOV words in the source side of German-English target domain corpora.

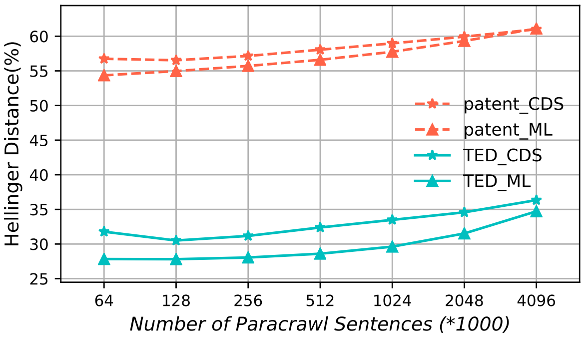

Figure 8: Hellinger distance for source side unigram distributions of German-English corpora between in-domain data and ML/CDS selected data.

We measure the difference of unigram distributions from two corpora by *Hellinger distance*, which is defined as Equation 2 when the probability distribution is discrete, where P and Q are the unigram distributions for the source side of in-domain and Paracrawl. V is the vocabulary size.[12]

$$H_{HD}(P,Q) = \frac{1}{\sqrt{2}}\sqrt{\sum_{i=1}^{V}(\sqrt{p_i} - \sqrt{q_i})^2}. \quad (2)$$

From Figure 8, we can see ML can better match the in-domain vocabulary distribution than CDS.

With respect to the OOV rate and unigram distribution, patent is more distant from the Paracrawl data than TED is. Figure 2 suggests that CDS dominates ML for distant domains such as Patent, while ML can do slightly better than CDS for domains that are not that distant such as TED.

5 Related Work

Curriculum learning has shown its potential to improve sample efficiency for neural models (Graves et al., 2017; Weinshall and Cohen, 2018) by guiding the order of presented samples, usually from easier-to-learn samples to difficult samples. Although there is no single criterion to measure difficulty for general neural machine translation tasks (Kocmi and Bojar, 2017; Wang et al., 2018; Zhang et al., 2018; Kumar et al., 2019; Platanios et al., 2019), for the domain adaptation scenario, we measure difficulty based on the distance from in-domain data. Compared to previous work, our application of curriculum learning mainly focuses on improvements on translation quality without consideration of convergence speed.

Chu and Wang (2018) surveyed recent domain adaptation methods for NMT. In their taxonomy, our workflow in Figure 1 can be considered a hybrid that uses both data-centric and model-centric techniques due to the use of additional unlabeled-domain data, with a modified training procedure based for continued training.

For data-centric domain adaptation methods, our curriculum learning approach has connections to instance weighting. In our work, the presentation of certain examples at specific training phases is equivalent to up-weighting those examples and down-weight the others at that time. Weights of similar samples and less similar ones are adjusted dynamically during the training of NMT models based on the curriculum training strategy. In NMT, instance weighting is usually implemented by modifying the objective function (Chen and Huang, 2016; Wang et al., 2017; Chen et al., 2017). In statistical machine translation, Matsoukas et al. (2009) extract features from sentences to capture their domains and then use a classifier to map features to sentence weights. Foster et al. extend this method by weighting at the level of phrase pairs. Shah et al. (2010) use resampling to weight corpora and alignments. Mansour and Ney (2012) focus on sentence-level weighting for phrase extraction. Zhou et al. (2015) weight examples based on their word distributions.

For model-centric domain adaptation methods, our work is related to van der Wees et al. (2017). They adopt gradual fine-tuning, which does the opposite of our method: training starts from the whole dataset, and the training set gradually decreases by removing less similar sentences. Wang et al. (2018) use a similar approach, where the NMT model is trained on progressively noise-reduced data batches. However, such schedules have the risk of wasting computation on non-relevant data, especially when most of the Paracrawl data is not similar to the target domain.

6 Conclusion

We introduced a curriculum learning approach to adapt neural machine translation models to new domains. Our approach first ranks unlabeled-domain training samples based on their similarity to in-domain data, and then adopts a probabilistic curriculum learning strategy so that more similar samples are used earlier and more frequently during training.

---

[12] In Figure 8, for the purpose of fair comparison, each distribution is defined on the same vocabulary, consisting of the source side vocabulary of TED, patent and Paracrawl data.

We show the effectiveness of our method on four tasks. Results show that curriculum learning models can improve over the standard continued training model by up to 3.22 BLEU points and can take better advantage of distant and noisy data. According to our S^4 analysis of lexical choice errors, this improvement is mainly due to better scoring of words that acquire a new SENSE or have a different SCORE distribution in the new domain. Our extensive empirical analysis suggests that this approach is effective for several reasons: (1) It provides a robust way to augment the training data with samples that have different levels of similarity to the in-domain data. Unlabeled-domain data such as webcrawls naturally have a diverse set of sentences, and the probabilistic curriculum allows us to exploit as much diversity as possible. (2) It implements the intuition that samples more similar to in-domain data are seen earlier and more frequently; when adding a new shard into the training set, the previously visited shards are still used, so the model will not forget what it just learned. (3) It builds on a strong continued training baseline, which continues on in-domain data. (4) The method implements best practices that have shown to be helpful in NMT, e.g. bucketing, mini-batching, and data shuffling.

For future work, it would be interesting to measure how curriculum learning models perform on the general domain test set (rather than the in-domain test set we focus on in this work); do they suffer more or less from catastrophic forgetting (Goodfellow et al., 2014; Kirkpatrick et al., 2017; Khayrallah et al., 2018; Thompson et al., 2019)?

A In-domain Data Details

Dataset	TED(de)	TED(ru)	patent(de)	patent(ru)
#samples	151,627	180,316	821,267	28,536

Table 3: In-domain data statistics.

The total amount of the in-domain data in each domain is summarized in Table 3. In this paper, we uniformly sample 15k in-domain data from each dataset. We choose the amount of 15k, which makes up a relatively small percentage of the original corpora, in order to evaluate the extreme case of low-resource domain adaptation settings. Under this setting, the positive effect of adding more selected unlabeled-domain data into training corpus is more obvious in terms of the performance improvement of NMT models. Our pilot experiments show that curriculum learning can scale with more in-domain data—it consistently outperforms the standard training policy, but with less improvement. This is not surprising, as when there is enough in-domain data, continued training on only the in-domain data can already achieve a pretty good performance, and we do not need to use extra unlabeled-domain data to augment it any more, neither does curriculum learning.

B Data Sharding

We experimented with different number of shards for curriculum learning models as shown in Figure 9. Overall, the performance shows the tendency to first improve and then degrade as the number of shards increases. Consider the extreme case, where the data are all put into one shard, or there are as many shards as samples, then it will actually be the same as the standard continued training.

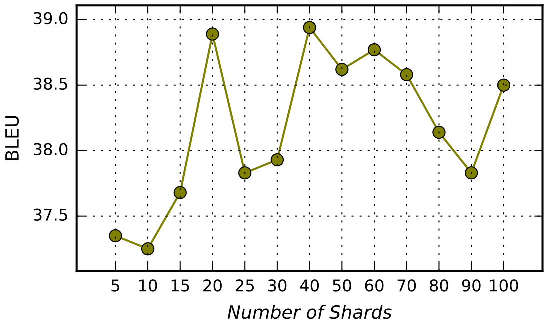

Figure 9: Tuning number of shards on a curriculum learning model trained with German-English corpus augmented by 1024k Paracrawl data.

C S^4 Error Analysis Algorithm

The algorithm for getting S^4 word translation error statistics is shown in 1.

Algorithm 1 S^4 Error Analysis

```
▷$S$: The source-side sentences in test set
▷$f_i$: The $i$th unique word in a sentence
▷$E^r(f_i)$: Words aligned to $f_i$ in the reference translation for test set
▷$E^h(f_i)$: Words aligned to $f_i$ in the output translation for test set
▷$E^t(f_i)$: Words aligned to $f_i$ in the reference translation for training set
procedure S4ErrorCounter($S, E^r, E^h, E^t$)

D Bilingual Criterion

In previous experiments, we only considered the data selection scores obtained from the source side of the corpora. It is very likely that curriculum learning would benefit from also taking into account the features of target side. For Moore-Lewis score, following Axelrod et al. (2011), we sum the scores over each side of the corpus:

$$[H_{I-src}(s)-H_{N-src}(s)]+[H_{I-tr}(s)-H_{N-trg}(s)]. \tag{3}$$

In addition, we also conduct comparison experiments using scores obtained from only the target side for both of the two data selection methods. Results are shown in Figure 10.

For Moore-Lewis method, in terms of the standard models, scores collected from target side can lead to better translation than source side scores, and bilingual criteria is somewhere in between, for all the sizes of Paracrawl data we experimented with. But this does not map to the curriculum learning models perfectly. Although CL_en achieves several impressive BLEU scores (39.35 BLEU at 512k, 39.26 BLEU at 2048k), CL_de can sometimes outperform it. And the performance of their bilingual counterparts are unpredictable: it can be either worse or better than both of them. At 4096k ML selected sentences, CL_bi improves the BLEU score to 39.37 BLEU, which is the best test score among all the results we have for German-English TED. For cynical data selection, it is obvious that curriculum learning models prefer the scores obtained from the source side of the corpus.

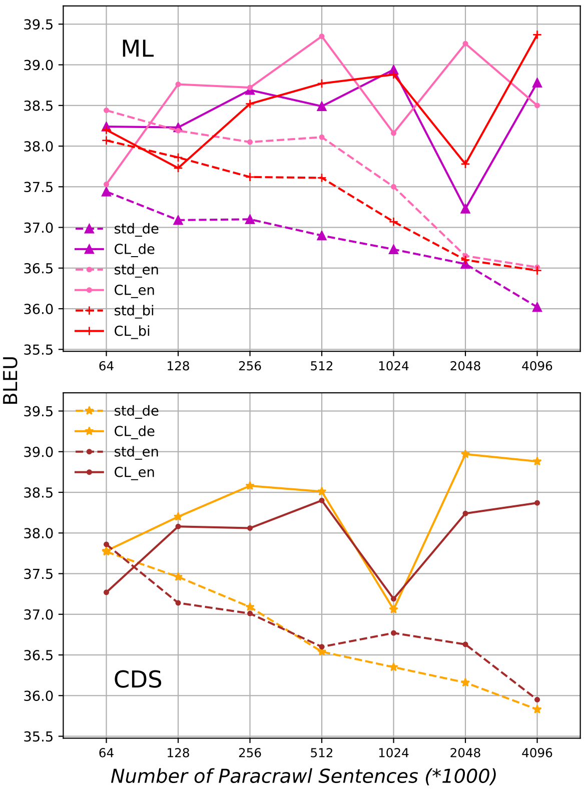

Figure 10: Performance of models continued trained with TED data and Paracrawl data, ranked by their similarity scores collected from the source side (de) or the target side (en) or both sides (bi) of the sentence pairs.

E Perplexity Selection

In Section 3.3, we train models with Paracrawl data of different sizes, only after the training is finished and we get the decoding results of those NMT systems, as shown in Figure 2, can we know which size should be the best choice. Moore and Lewis (2010) proposed a method that can determine the count cut-offs of the selected data beforehand, so that a lot of time and computation will be saved. In their work, the optimal selection threshold is determined by the perplexity of in-domain set evaluated on the language models trained on the different-size selected subsets. We name this method as perplexity selection and we are curious whether it is effective in the NMT settings. Unfortunately, the best thresholds elected by this method (Figure 11) are inconsistent with the cutoffs that achieve high BLEU scores in Figure 2. We can then conclude that perplexity selection may not be an appropriate way to determine the optimal amount of unlabeled-domain data to use for NMT models.

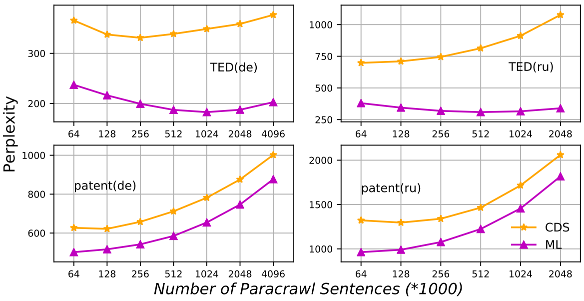

Figure 11: Perplexity of selected data evaluated on the language model learned from in-domain corpus.

However, if computational resources are limited, according to the experiment results (Figure 2) in our work, we recommend 1024k as the first choice for cutoffs on ranked unlabeled-domain data, for NMT domain adaptation models trained with curriculum learning strategy.

Improving Robustness of Machine Translation with Synthetic Noise

Abstract

Modern Machine Translation (MT) systems perform remarkably well on clean, in-domain text. However most human generated text, particularly in the realm of social media, is full of typos, slang, dialect, idiolect and other noise which can have a disastrous impact on the accuracy of MT. In this paper we propose methods to enhance the robustness of MT systems by emulating naturally occurring noise in otherwise clean data. Synthesizing noise in this manner we are ultimately able to make a vanilla MT system more resilient to naturally occurring noise, partially mitigating loss in accuracy resulting therefrom [1].

1 Introduction

Machine Translation (MT) systems have been shown to exhibit severely degraded performance when required to translate of out-of-domain or noisy data (Luong and Manning, 2015; Sakaguchi et al., 2016; Belinkov and Bisk, 2017). This is particularly pronounced when systems trained on clean, formalized parallel data such as Europarl (Koehn, 2005), are tasked with translation of unedited, human generated text such as is common in domains such as social media, where accurate translation is becoming of widespread relevance (Michel and Neubig, 2018).

Improving the robustness of MT systems to naturally occurring noise presents an important and interesting task. Recent work on MT robustness (Belinkov and Bisk, 2017) has demonstrated the need to build or adapt systems that are resilient to such noise. We approach the problem of adapting to noisy data aiming to answer two primary research questions:

1. Can we artificially synthesize the types of noise common to social media text in otherwise clean data?
2. Are we able to improve the performance of vanilla MT systems on noisy data by leveraging artificially generated noise?

In this work we present two primary methods of synthesizing natural noise, in accordance with the types of noise identified in prior work as naturally occurring in internet and social media based text (Eisenstein, 2013; Michel and Neubig, 2018). Specifically, we introduce a **synthetic noise induction** model which heuristically introduces types of noise unique to social media text and **labeled back translation** (Sennrich et al., 2015a), a data-driven method to emulate target noise.

We present a series of experiments based on the Machine Translation of Noisy Text (MTNT) data set (Michel and Neubig, 2018) through which we demonstrate improved resilience of a vanilla MT system by adaptation using artificially noised data.

2 Related Work

Szegedy et al. (2013) demonstrate the fragility of neural networks to noisy input. This fragility has been shown to extend to MT systems (Belinkov and Bisk, 2017; Khayrallah and Koehn, 2018) where both artificial and natural noise are shown to negatively affect performance.

Human generated text on the internet and social media are a particularly rich source of natural noise (Eisenstein, 2013; Baldwin et al., 2015) which causes pronounced problems for MT (Michel and Neubig, 2018).

Robustness to noise in MT can be treated as a domain adaptation problem (Koehn and Knowles, 2017) and several attempts have been made to

handle noise from this perspective. Notable approaches (Li et al., 2010; Axelrod et al., 2011) include training on varying amounts of data from the target domain. Luong and Manning (2015) suggest the use of fine-tuning on varying amounts of target domain data, and Barone et al. (2017) note a logarithmic relationship between the amount of data used in fine-tuning and the relative success of MT models.

Other approaches to domain adaptation include weighting of domains in the system objective function (Wang et al., 2017) and specifically curated datasets for adaptation (Blodgett et al., 2017). Kobus et al. (2016) introduce a method of domain tagging to assist neural models in differentiating domains. Whilst the above approaches have shown success in specifically adapting across domains, we contend that adaptation to noise is a nuanced task and treating the problem as a simple domain adaptation task may fail to fully account for the varied types of noise that can occur in internet and social media text.

Experiments that specifically handle noise include text normalization approaches (Baldwin et al., 2015) and (most relevant to our work) the artificial induction of noise in otherwise clean data (Sperber et al., 2017; Belinkov and Bisk, 2017).

3 Data

To date, work in the adaptation of MT to natural noise has been restricted by a lack of available parallel data. Michel and Neubig (2018) recently introduced a new data set of noisy social media content and demonstrate the success of fine-tuning which we leverage in the current work. The dataset consists of naturally noisy data from social media sources in both English-French and English-Japanese pairs.

In our experimentation we utilize the subset of the data for English to French which contains data scraped from Reddit[2]. The data set contains training, validation and test data. The training data is used in fine-tuning of our model as outlined below. All results are reported on the MTNT test set for French-English. We additionally use other datasets including Europarl (EP) (Koehn, 2005) and TED talks (TED) (Ye et al., 2018) for training our models as described in §5.

Training Data	# Sentences	Pruned Size
Europarl (EP)	2,007,723	1,859,898
Ted talk (TED)	192,304	181,582
Noisy Text (MTNT)	19,161	18,112

Table 1: Statistics about different datasets used in our experiments. We prune each dataset to retain sentences with length ≤ 50.

4 Baseline Model

Our baseline MT model architecture consists of a bidirectional Long Short-Term Memory (LSTM) network encoder-decoder model with two layers. The hidden and embedding sizes are set to 256 and 512, respectively. We also employ weight-tying (Press and Wolf, 2016) between the embedding layer and projection layer of the decoder.

For expediency and convenience of experimentation we have chosen to deploy a smaller, faster variant of the model used in Michel and Neubig (2018), which allows us to provide comparative results across a variety of settings. Other model parameters reflect the implementation outlined in Michel and Neubig (2018).

In all experimental settings we employ Byte-Pair Encoding (BPE) (Sennrich et al., 2015b) using SentencePiece[3].

5 Experimental Approaches

We propose two primary approaches to increasing the resilience of our baseline model to the MTNT data, outlined as follows:

5.1 Synthetic Noise Induction (SNI)

For this method, we inject artificial noise in the clean data according to the distribution of types of noise in MTNT specified in Michel and Neubig (2018). For every token we choose to introduce the different types of noise with some probability on both French and English sides in 100k sentences of EP. Specifically, we fix the probabilities of error types as follows: spelling (0.04), profanity (0.007), grammar (0.015) and emoticons (0.002). To simulate spelling errors, we randomly add or drop a character in a given word. For grammar error and profanity, we randomly select and insert a stop word or an expletive and its translation on either side. Similarly for emoticons, we randomly

select an emoticon and insert it on both sides. Algorithm 1 elaborates on this procedure.

Algorithm 1 Synthetic Noise Induction

```
Inputs:$[(p_1, \eta_1), (p_2, \eta_2) \cdots (p_k, \eta_k)]$   ▷ pairs of noise probabilities and noise functions
procedure ADD_NOISE($fr, en$)
    $o = 1 - \sum_i p_i$   ▷ probability of keeping original
    $D = [o, p_1, p_2, \cdots, p_k]$   ▷ Discrete densities
    $j \leftarrow$ SELECT_INDEX(DRAW($D$))   ▷ noise type
    if $j \neq 0$ then   ▷ not original
        $(fr, en) \leftarrow \eta_j(fr, en)$   ▷ add noise to words
    return $fr, en$
```

5.2 Noise Generation Through Back-Translation

We further propose two experimental methods to inject noise into clean data using the back-translation technique (Sennrich et al., 2015a).

5.2.1 Un-tagged Back-Translation (UBT)

We first train both our baseline model for fr-en and an en-fr model using TED and MTNT. We subsequently take 100k French sentences from EP and generate a noisy version thereof by passing them sequentially through the trained models as shown in Figure 1. The resulting translation will be inherently noisy as a result of imperfect translation of the intervening MT system.

5.2.2 Tagged Back-Translation (TBT)

The intuition behind this method is to generate noise in clean data whilst leveraging the particular style of the intermediate corpus. Both models are trained using TED and MTNT as in the preceding setting, save that we additionally append a tag in front on every sentence while training to indicate the origin data set of each sentence (Kobus et al., 2016). For generating the noisy version of 100k French sentences from EP, we append MTNT tag in front of the sentences before passing them through the pipeline shown in Figure 1.

	Training data	BLEU
	Baselines	
Baseline	Europarl (EP)	14.42
+ FT w/	MTNT-train-10k	22.49
+ FT w/	MTNT-train-20k	23.74
Baseline FT w/	TED-100k	10.92
+ FT w/	MTNT-train-20k	24.10
	Synthetic Noise Induction	
Baseline FT w/	EP-100k-SNI	13.53
+ FT w/	MTNT-train-10k	22.67
+ FT w/	MTNT-train-20k	25.05
	Un-tagged Back Translation	
Baseline FT w/	EP-100k-UBT	18.71
+ FT w/	MTNT-train-10k	22.75
+ FT w/	MTNT-train-20k	24.84
	Tagged Back Translation	
Baseline FT w/	EP-100k-TBT	20.49
+ FT w/	MTNT-train-10k	**23.89**
+ FT w/	MTNT-train-20k	**25.75**

Table 2: BLEU scores are reported on MTNT test set. MTNT valid set is used for fine-tuning in all the experiments. + FT denotes fine-tuning of the Baseline model of that particular sub-table, being continued training for 30 epochs or until convergence.

6 Results

We present quantitative results of our experiments in Table 2. Of specific note is the apparent correlation between the amount of in-domain training data and the resulting BLEU score. The tagged back-translation technique produces the most pronounced increase in BLEU score of +6.07 points ($14.42 \longrightarrow 20.49$). This represents a particularly significant result given that we do not fine-tune the baseline model on in-domain data, attributing this gain to the quality of the noise generated.

The results for all our proposed experimental methods further imply that out-of-domain clean data can be leveraged to make the existing MT models robust on a noisy dataset. However, sim-

Figure 2: The impact of varying the amount of Synthetic Noise Induction on BLEU.

ply using clean data is not that beneficial as can be seen from the experiment involving *FT Baseline w/ TED-100k*.

We further present analysis of both methods introduced above. Figure 2 illustrates the relative effect of varying the level of SNI on the BLEU score as evaluated on the newsdiscuss2015[4] dev set, which is a clean dataset. From this we note that the relationship between the amount of noise and the effect on BLEU score appears to be linear. We also note that the most negative effect is obtained by including profanity. Our current approach involves inserting expletives, spelling and grammatical errors at random positions in a given sentence. However we note that our approach might under-represent the nuanced linguistic usage of expletives in natural text, which may result in its above-mentioned effect on accuracy.

Table 3 shows the decoded output produced by different models. We find that the output produced by our best model is reasonably successful at imitating the language and style of the reference. The output of *Baseline + FT w/ EP-100k-TBT* is far superior than that of *Baseline*, which highlights the quality of obtained back translated noisy EP through our tagging method.

Systems	Output
REFERENCE	Voluntary or not because politicians are *very* friendly with large businesses.
FT w/ EP-100k-TBT	Whether it's voluntarily, or invoiseally because the fonts are *èsn* friends with the big companies.
FT w/ EP-100k-TBT + MTNT-train-10k	Whether it's voluntarily, or invokes because the politics are *rès* friends with big companies.
FT w/ EP-100k-TBT + MTNT-train-20k	Whether it's voluntarily, or invisible because the politics are *very* friends with big companies.

Table 4: Output comparison of decoded sentences for different amounts of supervision.

We also consider the effect of varying the amount of supervision which is added for fine-tuning the model. From Table 4 we note that the *Baseline + FT w/ EP-100k-TBT* model already produces a reasonable translation for the input sentence. However, if we further fine-tune the model using only 10k MTNT data, we note that the model still struggles with generation of *very*. This error dissipates if we use 20k MTNT data for fine-tuning. These represent small nuances which the model learns to capture with increasing supervision.

To better understand the performance difference between UBT and TBT, we evaluate the noised EP data. Figure 1 shows an example where we can clearly see that the style of translation obtained from TBT is very informal as opposed to the output generated by UBT. Both the outputs are noisy and different from the input but since the TBT method enforces the style of MTNT, the resulting output is perceptibly closer in style to the MTNT equivalent. This difference results in a gain of 0.9 BLEU of TBT over UBT.

7 Conclusion

This paper introduced two methods of improving the resilience of vanilla MT systems to noise occurring in internet and social media text: a method of emulating specific types of noise and the use of back-translation to create artificial noise. Both of these methods are shown to increase system accuracy when used in fine-tuning without the need for the training of a new system and for large amounts of naturally noisy parallel data.

Non-Parametric Adaptation for Neural Machine Translation

Abstract

Neural Networks trained with gradient descent are known to be susceptible to catastrophic forgetting caused by parameter shift during the training process. In the context of Neural Machine Translation (NMT) this results in poor performance on heterogeneous datasets and on sub-tasks like rare phrase translation. On the other hand, non-parametric approaches are immune to forgetting, perfectly complementing the generalization ability of NMT. However, attempts to combine non-parametric or retrieval based approaches with NMT have only been successful on narrow domains, possibly due to over-reliance on sentence level retrieval. We propose a novel n-gram level retrieval approach that relies on local phrase level similarities, allowing us to retrieve neighbors that are useful for translation even when overall sentence similarity is low. We complement this with an expressive neural network, allowing our model to extract information from the noisy retrieved context. We evaluate our semi-parametric NMT approach on a heterogeneous dataset composed of WMT, IWSLT, JRC-Acquis and OpenSubtitles, and demonstrate gains on all 4 evaluation sets. The semi-parametric nature of our approach opens the door for non-parametric domain adaptation, demonstrating strong inference-time adaptation performance on new domains without the need for any parameter updates.

1 Introduction

Over the last few years, neural sequence to sequence models (Sutskever et al., 2014; Bahdanau et al., 2015; Cho et al., 2014) have revolutionized the field of machine translation by significantly improving translation quality over their phrase based counterparts (Sennrich et al., 2015; Wu et al., 2016; Zhou et al., 2016). With more gains arising from continued research on new neural network architectures and accompanying training techniques (Vaswani et al., 2017; Gehring et al., 2017; Chen et al., 2018), NMT researchers, both in industry and academia, have doubled down on their ability to train high capacity models on large corpora with gradient based optimization.

However, despite huge improvements in overall translation quality NMT has shown some glaring weaknesses, including idiom processing, and rare word or phrase translation (Koehn and Knowles, 2017; Isabelle et al., 2017; Lee et al., 2018) - tasks that should be easy if the model could retain learned information from individual training examples. NMT has also been shown to perform poorly when dealing with multi-domain data (Farajian et al., 2017a). This 'catastrophic forgetting' problem has been well-studied in traditional neural network literature, caused by parameter shift during the training process (McCloskey and Cohen, 1989; Santoro et al., 2016). Non-parametric methods, on the other hand, are resistant to forgetting but are prone to over-fitting due to their reliance on individual training examples. We focus on a non-parametric extension to NMT, hoping to combine the generalization ability of neural networks with the eidetic memory of non-parametric methods. Given a translation query, we rely on an external retrieval mechanism to find similar source-target instances in the training corpus, which are then utilized by the model.

There has been some work on semi-parametric NMT (Gu et al., 2017; Zhang et al., 2018b; Cao and Xiong, 2018), but its effectiveness has been confined to narrow domain datasets. Existing approaches have relied on sentence level similarity metrics for retrieval, which works well for domains with high train-test overlap, but fails to retrieve useful candidates for broad domains. Even if we could find training instances with overlapping phrases it's likely that the information in most retrieved source-target pairs is noise for the pur-

Proceedings of NAACL-HLT 2019, pages 1921–1931
Minneapolis, Minnesota, June 2 - June 7, 2019.

pose of translating the current query.

To retrieve useful candidates when sentence similarity is low, we use n-gram retrieval instead of sentence retrieval. This results in neighbors which have high local overlap with the source sentence, even if they are significantly different in terms of overall sentence similarity. This is intuitively similar to utilizing information from a phrase table (Koehn et al., 2003) within NMT (Dahlmann et al., 2017), without losing the global context lost when constructing the phrase table. We also propose another simple extension using dense vectors for n-gram retrieval which allows us to exploit similarities beyond lexical overlap.

To effectively extract the signal from the noisy retrieved neighbors, we develop an extension of the approach proposed in (Cao and Xiong, 2018). While (Cao and Xiong, 2018) encode the retrieved targets without any context, we incorporate information from the current and retrieved sources while encoding the retrieved target, in order to distinguish useful information from noise.

We evaluate our semi-parametric NMT approach on two tasks.

- We evaluate our approach on a multi-domain English-French corpus constructed from narrow domain datasets like JRC-Acquis (Steinberger et al., 2006; Tiedemann) and OpenSubtitles (Tiedemann, 2009)[1], and the standard IWSLT and WMT bilingual corpora, as described in Sections 3 and 4. Our results, for the first time, indicate that semi-parametric NMT can be beneficial beyond narrow domain tasks, demonstrating gains of around 0.5 BLEU on WMT, and huge gains ranging from 2-10 BLEU points on IWSLT, JRC-Acquis and OpenSubtitles, when compared to a strong sequence to sequence baseline.

- The semi-parametric nature of our model enables non-parametric inference-time adaptation to new datasets, without the need for any parameter updates. When trained on WMT and evaluated on the other datasets, our model out-performs fine-tuning based adaptation (Luong and Manning, 2015) on JRC-Acquis and OpenSubtitles, and significantly improves performance over the non-adapted model on IWSLT.

2 Semi-parametric NMT

Standard approaches for Neural Machine Translation rely on seq2seq architectures (Sutskever et al., 2014; Bahdanau et al., 2015), where given a source sequence $X = \{x_1, x_2, \dots x_{Tx}\}$ and a target sequence $Y = \{y_1, y_2, \dots y_{Ty}\}$, the goal is to model the probability distribution, $p(y_t|X, y_1, \dots y_{t-1})$.

Semi-parametric NMT (Dahlmann et al., 2017; Gu et al., 2017) approaches this learning problem with a different formulation, by modeling $p(y_t|X, y_1, \dots y_{t-1}, \Phi_X)$ instead, where $\Phi_X = \{(X^1, Y^1) \dots (X^N, Y^N)\}$ is the set of sentence pairs where the source sentence is a neighbor of X, retrieved from the training corpus using some similarity metric. This relies on a two step approach - the retrieval stage finds training instances, (X^i, Y^i), similar to the source sentence X, and the translation stage generates the target sequence Y given X and Φ_X. We follow this setup, proposing improvements to both stages in order to enhance the applicability of semi-parametric NMT to more general translation tasks.

2.1 Retrieval Approaches

Existing approaches have proposed using off the shelf search engines for the retrieval stage. However, our objective differs from traditional information retrieval, since the goal of retrieval in semi-parametric NMT is to find neighbors which might improve translation performance, which might not correlate with maximizing sentence similarity.

Our baseline strategy relies on a sentence level similarity score, similar to those used for standard information retrieval tasks (Robertson, 2004). We compare this against finer-grained n-gram retrieval using the same similarity metric. We also propose a dense vector based n-gram retrieval strategy, using representations extracted from a pre-trained NMT model.

2.1.1 IDF Based Sentence Retrieval

Our baseline approach relies on a simple inverse document frequency (IDF) based similarity score. We define the IDF score of any token, t, as $f_t = \log(\frac{\|C\|}{n_t})$, where $\|C\|$ is the number of sentence pairs in training corpus and n_t is the number of sentences t occurs in. Let any two sentence pairs in the corpus be (X^i, Y^i) and (X^j, Y^j). Then we define the similarity between (X^i, Y^i) and

---

(X^j, Y^j) by,

$$sim(X^i, X^j) = 2 \times \Sigma_{t \in (X^i \cap X^j)} f_t - \Sigma_{t \in (X^i \cup X^j)} f_t \tag{1}$$

For every sentence in the training, dev and test corpora, we find the N most similar training sentence pairs and provide them as context to NMT.

2.1.2 IDF Based N-Gram Retrieval

Motivated by phrase based SMT, we retrieve neighbors which have high local, sub-sentence level overlap with the source sentence. We adapt our approach to retrieve n-grams instead of sentences. We note that the similarity metric defined above for sentences is equally applicable for n-gram retrieval.

Let $X = (t^1, ...t^T)$ be a sentence. Then the set of all possible n-grams of X, for a given n, can be defined as $S_X^n = \{(t_i, ...t_{i+n}) \, \forall \, 1 \le i \le T\}$ (also including padding at the end). To reduce the number of n-grams used to represent every sentence, we define the reduced set of n-grams for X to be $\hat{S_X^n} = \{(t_i, ...t_{i+n}) \, \forall \, 1 \le i \le T, \, i \mod \frac{n}{2} = 1\}$.

We represent every sentence by their reduced n-gram set. For every n-gram in $\hat{S_X^n}$, we find the closest n-gram in the training set using the IDF similarity defined above. For each retrieved n-gram we find the corresponding sentence (In case an n-gram is present in multiple sentences, we choose one randomly). The set of neighbors of X is then the set of all sentences in the training corpus that contain an n-gram that maximizes the n-gram similarity with any n-gram in $\hat{S_X^n}$.

To capture phrases of different lengths we use multiple n-gram widths, n. In case a sentence has already been added to the retrieved set, we find the next most similar sentence to avoid having duplicates. The number of neighbors retrieved for each source sentence is proportional to its length.

2.1.3 Dense Vector Based N-Gram Retrieval

We also extend our n-gram retrieval strategy with dense vector based n-gram representations. The objective behind using a dense vector based approach is to incorporate information relevant to the translation task in the retrieval stage. We use a pre-trained Transformer Base (Vaswani et al., 2017) encoder trained on WMT to generate sub-word level dense representations for the sentence. The representation for each n-gram is now defined to be the mean of the representations of all its constituent sub-words. We use the $L2$ distance of n-gram representations as the retrieval criterion. Note that we use a sub-word level decomposition of sentences for dense retrieval, as compared to word-level for IDF based retrieval (i.e., n-grams are composed of sub-words instead of words).

Following the approach described for IDF based n-gram retrieval, we use multiple values of n, and remove duplicate neighbors while creating the retrieved set.

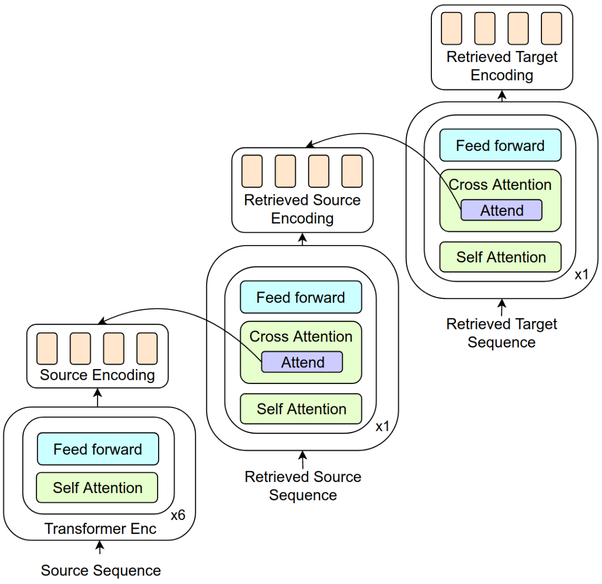

Figure 1: Architecture of the Conditional Source Target Memory. The retrieved targets, Y^i, are encoded in a transformer encoder, incorporating the attention context from the retrieved sources, X^i. In turn, the retrieved sources, X^i, are encoded while incorporating context from the current translation source, X.

2.2 NMT with Context Retrieval

To incorporate the retrieved neighbors, Φ_X, within the NMT model, we first encode them using Transformer layers, as described in subsection 2.2.1. This encoded memory is then used within the decoder via an attention mechanism, as described in subsection 2.2.2.

2.2.1 Conditional Source Target Memory

We now describe how each retrieved translation pair, (X^i, Y^i), is encoded. This architecture is illustrated in Figure 1.

- We first encode the retrieved source, X^i, in a Transformer layer. Apart from self-attention, we incorporate information from the encoder representation of the current source, X, using decoder style cross-attention.

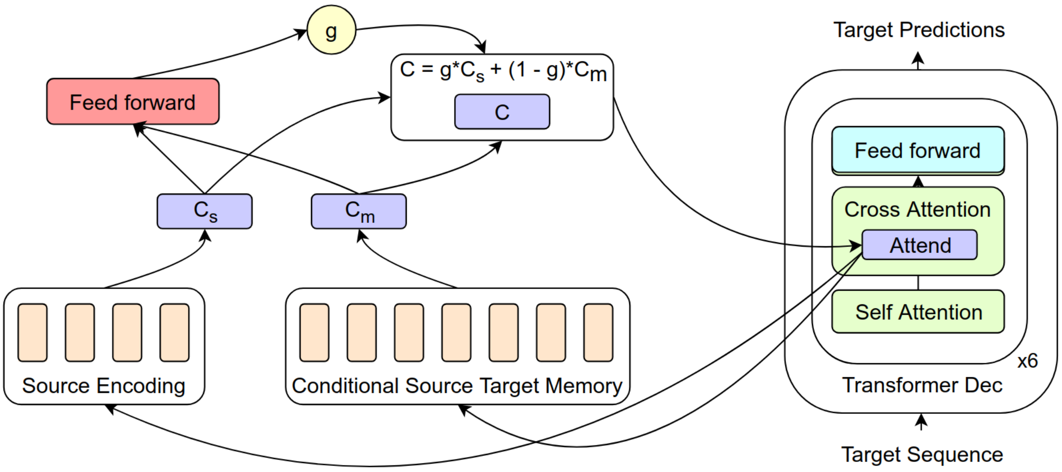

Figure 2: Architecture of the gated attention mechanism used in the multi-source transformer decoder.

- The retrieved target, Y^i, is encoded in a similar manner, attending the encoded representation of X^i generated in the previous step.

The encoded representations for all targets, $\{Y^i, 1 \leq i \leq N\}$, are then concatenated along the time axis to form the Conditional Source Target Memory (CSTM).

2.2.2 Gated Multi-Source Attention

We use gated multi-source attention to combine the context from the source encoder representations and the CSTM. This is similar to the gated attention employed by (Cao and Xiong, 2018). We use a Transformer based decoder that attends to both, the encoder outputs and the CSTM, in every cross-attention layer. The rest of the decoder architecture remains unchanged.

Let the context vectors obtained by applying multi-head attention to the source and memory, with query q_t be c_t^s and c_t^m respectively. Then the gated context vector, c^t, is given by,

$$g_t = \sigma(W_{gs}c_t^s + W_{gm}c_t^m) \tag{2}$$

$$c_t = g_t * c_t^s + (1 - g_t) * c_t^m \tag{3}$$

where g_t is the scalar gating variable at time-step t, and W_{gs} and W_{gm} are learned parameters. These steps are illustrated in Figure 2.

3 Experiments

3.1 Data and Evaluation

We compare the performance of a standard Transformer Base model and our semi-parametric NMT approach on an English-French translation task. We create a new heterogeneous dataset, constructed from a combination of the WMT training set (36M pairs), the IWSLT bilingual corpus (237k pairs), JRC-Acquis (797k pairs)[2] and OpenSubtitles (33M pairs)[3]. For WMT, we use newstest 13 for validation and newstest 14 for test. For IWSLT, we use a combination of the test corpora from 2012-14 for validation and test 2015 for eval. For OpenSubtitles and JRC-Acquis, we create our own splits for validation and test, since no benchmark split is publicly available. After deduping, the JRC-Acquis test and validation set contain 6574 and 5121 sentence pairs respectively. The OpenSubtitles test and validation sets contain 3975 and 3488 pairs. For multi-domain training, the validation set is a concatenation of the four individual validation sets.

All datasets are tokenized with the Moses tokenizer (Koehn et al., 2007) and mixed without any sampling. We use a shared vocabulary SentencePiece Model (Kudo and Richardson, 2018) for sub-word tokenization, with a vocabulary size of 32000 tokens. We train each model for 1M steps, and choose the best checkpoint from the last 5 checkpoints based on validation performance. BLEU scores are computed with tokenized true-cased output and references with *multi-bleu.perl* from Moses.

For IDF based sentence retrieval, for each sentence in the training, dev and test corpus, we use $N = 10$ neighbors per example during both, training and evaluation. For the N-Gram level retrieval strategies, we used $N = 10$ neighbors dur-

+ CSTM	MD + Dense N-Gram	**42.41**	**45.02**	**29.06**	**66.92**

Table 1: Comparison of test translation quality (BLEU) with different retrieval strategies. Multi-domain is a concatenation of all 4 datasets. IDF Sentence, IDF-NGram and Dense N-Gram correspond to multi-domain datasets constructed with the different retrieval strategies.

source	‘The top copy of the passenger waybill *shall be kept on the* bus or coach throughout **the journey to which it refers .**’
neighbor source	‘The top copy of the journey form *shall be kept on the* vehicle during the whole of **the journey to which it refers .**’
baseline translation	‘La copie supérieure de la lettre de transport de voyageurs doit être conservée dans l’ autobus ou l’ autocar tout au long du voyage auquel elle se rapporte .’
neighbor target	‘L’ original de la feuille de route doit se trouver à bord du véhicule *pendant toute la durée du voyage pour lequel elle a été établie .*’
translation	‘L’ original de la feuille de route doit se trouver à bord de l’ autobus ou de l’ autocar *pendant toute la durée du voyage pour lequel elle a été établie .*’
reference	‘L’ original de la feuille de route doit se trouver à bord de l’ autobus ou de l’ autocar *pendant toute la durée du voyage pour lequel elle a été établie .*’

Table 2: A comparison of model outputs on a sample from the JRC-Acquis dataset. This model was trained using IDF based sentence level retrieval with Conditional Source Target Memory. The different colors and text formatting (underlined, italic, bold) represent different overlapping phrases within the model output, the retrieved target and the reference translation.

ing training, and neighbors corresponding to all n-grams during decoding. This was meant to limit memory requirements and enable the model to fit on P100s during training. We used n-gram width, $n = \{6, 10, 18\}$, for both IDF and dense vector based n-gram retrieval approaches. For scalability reasons, we restricted the retrieval set to the in-domain training corpus, i.e. neighbors for all train, dev and test sentences in the JRC-Acquis corpus were retrieved from the JRC-Acquis training split, and similarly for the other datasets.

3.2 Hyper-parameters and Optimization

For our baseline model we use the standard Transformer Base model (Vaswani et al., 2017). For the semi-parametric model, all our hyper-parameters for attention (8 attention heads), model dimensions (512) and hidden dimensions (2048), including those used in the CSTM memory are equivalent to Transformer Base.

The Transformer baselines are trained on 16 GPUs, with the learning rate, warm-up schedule and batching scheme described in (Vaswani et al., 2017). The semi-parametric models were trained on 32 GPUs with each replica split over 2 GPUs, one to train the translation model and the other for computing the CSTM. We used a conservative learning rate schedule (3, 40K) (Chen et al., 2018) to train the semi-parametric models.

We apply a dropout rate(Srivastava et al., 2014) of 0.1 to all inputs, residuals, attentions and ReLU connections in both models. We use Adam (Kingma and Ba, 2014) to train all models, and apply label smoothing with an uncertainty of 0.1 (Szegedy et al., 2015). In addition to the transformer layers, layer normalization (Ba et al., 2016) was applied to the output of the CSTM. All models are implemented in Tensorflow-Lingvo (Shen et al., 2019).

4 Results

We compare the test performance of a multi-domain Transformer Base and our semi-parametric model using dense vector based n-gram retrieval and CSTM in Table 1. Apart from significantly improving performance by

source	‘Consciousness also is **what makes life worth living .**’
neighbor source	‘So in the last 10 years and the hope for the future , we ’ve seen the beginnings of a science of positive psychology , a science of **what makes life worth living .**’
baseline translation	‘La conscience est aussi ce *qui rend la vie valable .*’
neighbor target	‘Donc , depuis 10 ans , et , espérons-le , à l’ avenir nous assistons à l’ émergence d’ une science de la psychologie positive : une science qui fait en sorte **que la vie** vaille **la peine d’ être vécue .**’
translation	‘La conscience est aussi ce qui fait **que la vie** vaut **la peine d’ être vécue .**’
reference	‘La conscience est aussi ce qui fait **que la vie** vaut **la peine d’ être vécue .**’

Table 3: A comparison of model outputs on a sample from IWSLT. This model was trained using IDF based n-gram retrieval with Conditional Source Target Memory. N-Gram level retrieval results in finding neighbors with high local overlap, even when the rest of the sentences are dissimilar.

source	‘I was expecting to see **gnashing of teeth** and a fight breaking out at the gate .’
neighbor source	‘One could almost hear the collective **gnashing of teeth** in the US , especially in the Congress .’
baseline translation	‘J’ espérais voir *des dents brûlantes* et une bataille éclater à la porte .’
neighbor target	‘On a presque entendre **les dents grincer** aux États-Unis , surtout au Congrès .’
translation	‘Je m’ attendais à voir **des grincements de dents** et une bagarre éclater à la porte .’
reference	‘Je m’ attendais à voir **des grincements de dents** et une bagarre éclater à la porte .’

Table 4: A comparison of model outputs on a sample from WMT. This model was trained using IDF based n-gram retrieval with Conditional Source Target Memory. N-Gram level retrieval results in finding neighbors with high local overlap, even when the rest of the sentences are dissimilar.

more than 10 BLEU points on JRC-Acquis, 2-3 BLEU on OpenSubtitles and IWSLT, we notice a moderate gain of 0.5 BLEU points on WMT 14.

4.1 Comparison of retrieval strategies

We compare the performance of all 3 retrieval strategies in Table 1. The semi-parametric model with sentence level retrieval out-performs the seq2seq model by a huge margin on JRC-Acquis and OpenSubtitles. A sample from the JRC-Acquis dataset where the semi-parametric approach improves significantly over the neural approach is included in Table 2. We notice that there is a lot of overlap between the source sentence and the retrieved source, resulting in the semi-parametric model copying large chunks from the retrieved target. However, its performance is noticeably worse on WMT and IWSLT. Based on a manual inspection of the retrieved candidates, we attribute these losses to retrieval failures. For broad domain datasets like WMT and IWSLT sentence retrieval fails to find good candidates.

Switching to n-gram level retrieval brings the WMT performance close to the seq2seq approach, and IWSLT performance to 2 BLEU points above the baseline model. Representative examples from IWSLT and WMT where n-gram retrieval improves over sentence level retrieval can be seen in Tables 3 and 4. Despite the majority of the retrieved neighbor having nothing in common with the source sentence, n-gram retrieval is able to find neighbors that contain local overlaps.

Using dense n-gram retrieval allows us to move beyond lexical overlap and retrieve semantically similar n-grams even when the actual tokens are different. As a result, dense n-gram retrieval improves performance over all our models on all 4 datasets. An illustrative example from WMT is included in Table 5.

source	‘The artist **died** last Sunday at the age of 71 .’
neighbor source	‘A former minister George Thomson **passed away** last week at the age of 87 .’
baseline translation	‘L’ artiste est *mort* dimanche dernier à l’ âge de 71 ans .’
neighbor target	‘George Thomson , ancien ministre , est **décédé** la semaine dernière à l’ âge de 87 ans .’
translation	‘L’ artiste est **décédé** dimanche dernier à l’ âge de 71 ans .’
reference	‘L’ artiste est **décédé** dimanche dernier , à l’ âge de 71 ans . ’

Table 5: A comparison of model outputs on a sample from WMT. This model was trained using dense vector based n-gram retrieval with Conditional Source Target Memory. Dense vector based n-gram retrieval allows us to find semantically similar phrases, even when the lexical context is dissimilar.

Model	newstest 14	IWSLT 2015	OpenSub	JRC-Acquis
No Memory	41.92	43.17	26.67	56.19
TM	41.64	44.32	27.38	64.25
CTM	41.87	44.76	27.74	65.18
CSTM	**42.41**	**45.02**	**29.06**	**66.92**

Table 6: Comparison of test translation quality (BLEU) with different memory architectures. All models are trained on the Dense N-Gram Multi-Domain dataset. CSTM corresponds to the proposed Conditional Source Target Memory. CTM corresponds to Conditional Target Memory, where we ignore the retrieved sources while encoding the retrieved targets, and directly attend the encoding of the current source, X. TM corresponds to encoding the retrieved targets without any context.

4.2 Memory Ablation Experiments

We report the performance of the various memory ablations in Table 6. We first remove the retrieved sources, X^i, from the CSTM, resulting in an architecture where the encoding of a retrieved target, Y^i, only incorporates information from the source X, represented by the row CTM in the table. This results in a clear drop in performance on all datasets. We ablate further by removing the attention to the original source X, resulting in a slightly smaller drop in performance (represented by TM). These experiments indicate that incorporating context from the sources significantly contributes to performance, by allowing the model to distinguish between relevant context and noise.

5 Non-Parametric Adaptation

Using a semi-parametric formulation for MT opens up the possibility of non-parametric adaptation. The biggest advantage of this approach is the possibility of training a single massively customizable model which can be adapted to any new dataset or document at inference time, by just updating the retrieval dataset.

We evaluate our model’s performance on non-parametric adaptation and compare it against a fully fine-tuned model. In this setting, we train a baseline model and a dense n-gram based semi-parametric model on the WMT training corpus. We only retrieve and train on examples from the WMT corpus during training. We use the same hyper-parameters and training approaches used for the multi-domain experiments, as in Section 3.

The baseline model is then fine-tuned independently on JRC-Acquis, OpenSubtitles and IWSLT. The semi-parametric model is adapted non-parametrically to these three datasets, without any parameter updates. Adaptation is achieved via the retrieval mechanism - while evaluating, we retrieve similar examples from their respective training datasets. To quantify headroom, we also fine-tune our semi-parametric model on each of these datasets.

The results for non-parametric adaptation experiments are documented in Table 7. We notice that the non-parametric adaptation strategy significantly out-performs the base model on all 4 datasets. More importantly, the we find that our approach is capable of adapting to both, JRC-Acquis and OpenSubtitles, via just the retrieval apparatus, and out-performs the fully fine-tuned model indicating that non-parametric adaptation might be a reasonable approach when adapting to a lot of narrow domains or documents.

Adaptation Strategy	newstest 14	IWSLT 2015	OpenSub	JRC-Acquis
Base	41.16	39.75	22.92	53.1
Fine-tuning	-	**42.87**	26.55	62.99
Non-Parametric (NP)	**41.57**	40.95	**27.09**	**64.93**
NP + Fine-tuning	-	43.82	29.12	66.72

Table 7: Comparison of test translation quality (BLEU) with different adaptation strategies. The base model (Transformer Base) is trained on the WMT dataset. Fine-tuning corresponds to fine-tuning based adaptation, where we initialize the domain-specific model from the WMT pre-trained Base model, and fine-tune it on the in-domain dataset for a few epochs. Non-parametric corresponds to our semi-parametric NMT model, adapted to in-domain data during inference by retrieving neighbors from the in-domain training corpus.

In-domain fine-tuning on top of non-parametric adaptation further improves by 2 BLEU points on all datasets, increasing the gap even further with the seq2seq adapted models.

6 Related Work

Tools incorporating information from individual translation pairs, or translation memories (Lagoudaki; Reinke, 2013), have been widely utilized by human translators in the industry. There have been a few efforts attempting to combine non-parametric methods with NMT (Gu et al., 2017; Zhang et al., 2018b; Cao and Xiong, 2018), but the key difference of our approach is the introduction of local, sub-sentence level similarity in the retrieval process, via n-gram level retrieval. Combined with our architectural improvements, motivated by the target encoder and gated attention from (Cao and Xiong, 2018) and the extended transformer model from (Zhang et al., 2018a), our semi-parametric NMT model is able to outperform purely neural models in broad multi-domain settings.

Some works have proposed using phrase tables or the outputs of Phrase based MT within NMT (Dahlmann et al., 2017; Zhang et al., 2017; Zhou et al., 2017). While this reduces the noise present within the retrieved translation pairs, it requires training and maintaining a separate SMT system which might introduce errors of its own.

Another class of methods requires fine-tuning the entire NMT model to every instance at inference time, using retrieved examples (Farajian et al., 2017b; Wuebker et al., 2015), but these approaches require running expensive gradient descent steps before every translation.

Beyond NMT, there have been a few other attempts to incorporate non-parametric approaches into neural generative models (Guu et al., 2018; Hayati et al., 2018; Weston et al., 2018). This strong trend towards combining neural generative models with non-parametric methods is an attempt to counter the weaknesses of neural networks, especially their failure to remember information from individual training instances and the diversity problem of seq2seq models (Vijayakumar et al., 2016; Jiang and de Rijke, 2018).

While our approach relies purely on retrieval from the training corpus, there has been quite a lot of work, especially on Question Answering, that attempts to find additional signals to perform the supervised task in the presence of external knowledge sources (Chen et al., 2017; Wang et al., 2018). Retrieving information from unsupervised corpora by utilizing multilingual representations (Guo et al., 2018) might be another interesting extension of this work.

7 Conclusions and Future Work

We make two major technical contributions in this work which enable us to improve the quality of semi-parametric NMT on broad domain datasets. First, we propose using n-gram retrieval, with standard Inverse Document Frequency similarity and with dense vector representations, that takes into account local sentence similarities that are critical to translation. As a result we are able to retrieve useful candidates even for broad domain tasks with little train-test overlap. Second, we propose a novel architecture to encode retrieved source-target pairs, allowing the model to distinguish useful information from noise by encoding the retrieved targets in context of the current translation task.

We demonstrate, for the first time, that semi-parametric methods can beat neural models by significant margins on multi-domain Machine Translation. By successfully training semi-parametric neural models on a broad domain dataset (WMT), we also open the door for non-parametric adaptation, showing huge improvements on new domains without any parameter updates.

While we constrain this work to retrieved context, our architecture can be utilized to incorporate information from other sources of context, including documents, bilingual dictionaries etc. Using dense representations for retrieval also allows extending semi-parametric neural methods to other input modalities, including images and speech.

With this work, we hope to motivate further investigation into semi-parametric neural models for and beyond Neural Machine Translation.

Abstract

Current predominant neural machine translation (NMT) models often have a deep structure with large amounts of parameters, making these models hard to train and easily suffering from over-fitting. A common practice is to utilize a validation set to evaluate the training process and select the best checkpoint. Average and ensemble techniques on checkpoints can lead to further performance improvement. However, as these methods do not affect the training process, the system performance is restricted to the checkpoints generated in the original training procedure. In contrast, we propose an online knowledge distillation method. Our method on-the-fly generates a teacher model from checkpoints, guiding the training process to obtain better performance. Experiments on several datasets and language pairs show steady improvement over a strong self-attention-based baseline system. We also provide analysis on data-limited setting against over-fitting. Furthermore, our method leads to an improvement on a machine reading experiment as well.

1 Introduction

Neural Machine Translation (NMT) (Cho et al., 2014; Sutskever et al., 2014) has been rapidly developed during the past several years. For further performance improvement, deeper and more expressive structures (Johnson et al., 2017; Barone et al., 2017b; Gehring et al., 2017; Vaswani et al., 2017) have been exploited. However, all of these models have more than hundreds of millions of parameters, which makes the training process more challenging. During the training of NMT models, we notice the following two problematic phenomena: First, the training process is unstable. This is evidenced by the decreasing of training loss with fluctuate performance on the validation set. Second, the performance on validation set usually begins to worsen after several epochs, while the training loss keeps decreasing, which suggests the model being at risk of over-fitting.

In order to alleviate these issues, the common practice is to periodically evaluate models on a held-out set (with each evaluated model saved as a *checkpoint*). Training is terminated when m consecutive checkpoints show no improvement and select the checkpoint with best evaluation score as the final model. Further improvement can be achieved by utilizing more checkpoints, by *smoothing*, which averages these checkpoints' parameters to generate more desirable parameters (Sennrich et al., 2016a); or by *ensemble*, which averages these checkpoints' output probabilities at every step during inference (Chen et al., 2017).

However, we notice that all of these methods have a limitation. Once the training process gets parameters with poor performance, selecting, smoothing or ensemble from the checkpoints in this process may have limited generalization performance as well. We impute the limitation to the "offline" property of these methods. In other words, only employing checkpoints after training cannot affect the original training process.

In this paper, we propose to utilize checkpoints to lead the training process. Our method is carried out in a *knowledge distillation* manner. At each training step, because being evaluated on the held-out validation data, the best checkpoint up to the current training step can be seen as a model with the best generalization ability so far. Therefore, we employ this checkpoint as the teacher model, and let the current training model, as the student, learn from the output probability distributions of the teacher model, as well as truth translations in the training data. Such kind of knowledge distillation is performed on-the-fly because the teacher

model could always be updated once any latest better checkpoint is generated. We call our method **O**nline **D**istillation from **C**heckpoints (ODC).

We conduct experiments on four translation tasks (including two low-resource tasks), and one machine reading comprehension task. All the results demonstrate that our ODC method can achieve improvement upon strong baseline systems. ODC also outperforms checkpoint smoothing and ensemble methods, without extra cost during inference. We can achieve further improvement by combining ODC with those methods.

Major contributions of our work include:

1. In contrast to checkpoint smoothing and ensemble which do not affect the training process, we explore the way to distill knowledge from checkpoints to lead the training process in an on-the-fly manner(§3.1, §3.2). We obtain better performance by replacing the best checkpoint with moving average parameters at that step. (§3.3)

2. We conduct experiments on four translation tasks, including two low resource tasks. In all the tasks our method outperforms strong baseline systems (§4.2, §4.3). We also conduct an experiment on machine reading comprehension task and the result shows that our method can be applied to other tasks too (§4.4).

3. We conduct comprehensive analysis and show that our method can significantly alleviate over-fitting issue in low-resource condition (§5.1), and help to find a wider minimum which brings better generation (§5.2).

2 Background

2.1 Neural Machine Translation

Neural Machine Translation (NMT) systems learn a conditional probability $P(Y|X)$ for translating a source sentence $X = (x_1, ..., x_M)$ to a target sentence $Y = (y_1, ..., y_N)$, in which x_i and y_j are the i-th word and j-th word in sentence X and Y, respectively. An NMT model usually consists of an encoder (parameterized by θ_{enc}) and a decoder (parameterized by θ_{dec}). The encoder transforms a sequence of source tokens into a sequence of hidden states:

$$H(X) = (h_1, ..., h_M) = f_{\text{enc}}(X; \theta_{\text{enc}}). \qquad (1)$$

The decoder of NMT is usually a network computing the conditional probability of each target words y_j based on its previous words and the source sentence:

$$p(y_j|y_{<j}, X) \propto \exp(f_{\text{dec}}(y_{<j}, s_j, H(X); \theta_{\text{dec}})), \qquad (2)$$

where s_j is the hidden state of decoder at time step j, p is the distribution of NMT model and θ is all the parameters of NMT model.

The standard way to train an NMT model is to minimize the cross-entropy between the one-hot distribution of the target sentence and the NMT model's output distribution:

$$\begin{aligned} \mathcal{L}(\theta) = &-\sum_{j=1}^{N}\sum_{k=1}^{|\mathcal{V}|} \mathbb{1}\{y_j = k\} \qquad (3) \\ &\cdot \log p(y_j = k|y_{<j}, X; \theta), \\ \theta^* &= \arg\min_{\theta} \mathcal{L}(\theta), \qquad (4) \end{aligned}$$

where $\mathbb{1}(\cdot)$ is the indicator function and $\mathcal{V}$ is the target vocabulary.

2.2 Knowledge Distillation in Neural Machine Translation

Knowledge distillation is a class of methods which transfers knowledge from a pre-trained *teacher* model $\mathcal{T}$, to a *student* model $\mathcal{S}$. The teacher model can be a model with large capacity (Bucila et al., 2006) or an ensemble of several models (Hinton et al., 2015). In knowledge distillation, the student model learns to match the predictions of the teacher model. Concretely, assuming that we learn a classification model (parameterized by θ) on a set of training samples in the form of (x, y) with $|\mathcal{V}|$ classes. Instead of minimizing the cross-entropy loss between one-hot label y and model's output probability $p(y|x;\theta)$, knowledge distillation uses the teacher model's distribution $q(\cdot|x)$ as "soft targets" and optimizes the loss:

$$\begin{aligned} \mathcal{L}_{\text{KD}}(\theta) = -\sum_{k=1}^{|\mathcal{V}|} & q(y = k|x; \theta_{\mathcal{T}}) \qquad (5) \\ & \log p(y = k|x; \theta), \end{aligned}$$

where $\theta_{\mathcal{T}}$ parameterizes the teacher model and $p(\cdot|x)$ is the distribution of the student model.

Kim and Rush (2016) proposed that, as the loss of NMT model (Equation 4) can be factored into minimizing cross-entropy loss between the target

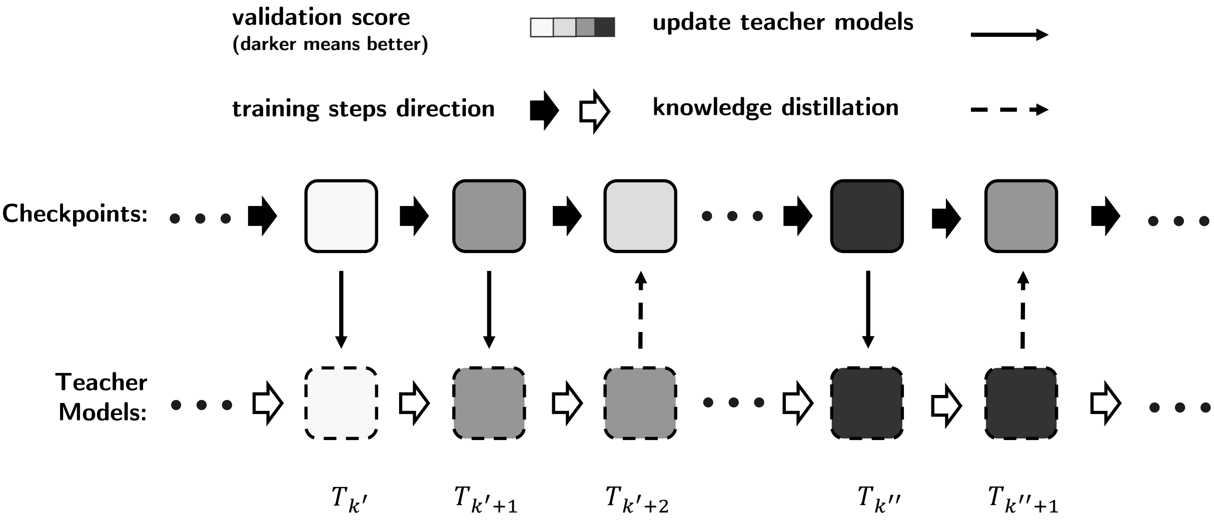

Figure 1: Illustration of online distillation from checkpoints(ODC). Darker color means better performance on validation data. In validation step $T_{k'}$, ODC selects the current best checkpoints as the teacher model; while in the next validation step $T_{k'+1}$, the training generates a better checkpoint, and use it to update the teacher model. In validation step $T_{k'+2}$, training model's performance declines, and the teacher model is used to lead the training of the model. The similar situation happens during the entire training process.

words and word-level probabilities of the NMT model for every position at target side, knowledge distillation on multi-class classification can be naturally applied. They defined word-level knowledge distillation (W-KD) on a sentence as:

$$\mathcal{L}_{\text{W-KD}}(\theta) = -\sum_{i=j}^{N}\sum_{k=1}^{|\mathcal{V}|} q(y_j = k|y_{<j}, H(x); \theta_{\mathcal{T}}) \cdot \log p(y_j = k|y_{<j}, H(x); \theta), \tag{6}$$

where $\mathcal{V}$ is the target vocabulary.

They further proposed sequence-level knowledge distillation (S-KD), which optimizes the student model by matching the predictions of the teacher model in the probability distribution over the space of all possible target sequences:

$$\mathcal{L}_{\text{S-KD}}(\theta) = \sum_{Y \in \tau} q(Y|X; \theta_{\mathcal{T}}) \log p(Y|X; \theta), \tag{7}$$

where τ is the space of target side sentences. As summing over exponential numbers of samples here is intractable, they proposed to train student model on samples generated by teacher model as an approximation.

3 Online Distillation from Checkpoints

3.1 Online Knowledge Distillation

Traditional knowledge distillation maintains a static teacher throughout the training process, which not only requires one pre-training process to obtain the teacher model, but also limits the power of leading the training process.

In contrast, we are aiming at a more integrated process where the teacher model does not come from a separate training process, but from the current training routine itself. More specifically, we update the teacher along with the training process, so the distilled knowledge could be updated when a stronger model comes out. Figure 1 illustrates the paradigm of our method.

In generation tasks, the knowledge distillation could be performed at the word-level or sequence-level. In this paper, we focus on the word-level distillation because this distillation only needs forced teaching, which could be performed efficiently together with the training of the student model compared to generating translations from teacher model. It is more computational-friendly, especially when the NMT models are built with parallelizable convolution (Gehring et al., 2017) or self-attention structures (Vaswani et al., 2017).

3.2 Online Distillation from Best Checkpoint
